Qian (2003) provides examples of these transitional institutions. China implemented a dual-track approach to liberalization, which led to markets in above-plan production, but kept quotas and controlled prices on the levels of production that had existed before reforms. This promoted efficiency at the margin, while endorsing the existing set of informal rights to infra-marginal production, thus protecting the welfare of those who otherwise might have lost heavily from reforms. A highly distinctive ownership form appeared, township and village enterprises (TVEs), which played a significant role in China's growth in the first two decades of reform. TVEs can be interpreted as a mechanism for protecting decentralized property rights when the state is unable to guarantee more formal ones for private owners. Anonymous banking served as a commitment device, limiting government predation by reducing information flows. This arrangement can be understood as a crude substitute for the protection of financial property rights when the independence of the legal system is not a real possibility in the short-run.

Therefore, China constructed mechanisms to address the problems that institutions address in successful countries. However, those mechanisms would not look familiar when matched against best practice in developed countries. As the evolutionary-institutional perspective emphasized, it is fruitless to try to imitate best practices when human capital and institutional capability are not sufficient. In such situations, it might be best to deploy a set of transitional institutions, much more suited to the particular circumstances of a country and its capabilities. This observation resonates with the experience of EE and the FSU reviewed above. Countries with less benign starting points for creating best-practice institutions were doomed to fail in the process, while others could succeed given the right political and human capital preconditions.

Of course, there was a reason why in early transition best-practice institutions were advocated for all countries. It was feared that a country might find it hard to replace transitional institutions once they were set in place, becoming trapped at a low level of development. Whether this fear was ultimately justified will be addressed by Chinese experience in the coming decades.

Transitivity is formally just a property that a binary relation might possess, and thus one could discuss the concept in any context in economics in which an ordering relation is used. Here, however, the discussion of transitivity will be limited to its role in describing an individual agent's choice behaviour. In this context transitivity means roughly that if an agent chooses $A$ over $B$, and $B$ over $C$, that agent ought to choose $A$ over $C$, or at least be indifferent. On the surface this seems reasonable, even 'rational', but this ignores how complicated an agent's decision making process can be. For an excellent discussion of this issue see May (1954). Given a model of agent behaviour, transitivity can be imposed as a direct assumption, or can be an implication of the model for choice behaviour. The standard model of agent behaviour in economics is that the agent orders prospects by means of a utility function, which in effect assumes transitivity. With appropriate continuity and convexity restrictions on utility functions, the model allows one to demonstrate that: (1) Individual demand functions are well defined, continuous, and satisfy the comparative static restriction, the strong axiom of revealed preference (SARP). (In the smooth case, this corresponds to the negative semi-definiteness and symmetry of the Slutsky matrix.) (2) Given a finite collection of such agents with initial endowments of goods, a competitive equilibrium exists. What will be discussed in the remaining part of this article is to what extent one can obtain results analogous to (1) and (2) above while using a model of agent behaviour which does not assume or imply transitive behaviour. To keep the discussion as simple as possible, we will only consider the situation in which the agent's set of feasible commodity vectors is the non-negative orthant of $n$-dimensional Euclidean space, and the agent's problem is to choose a commodity vector $x$ when faced with positive prices and income. A vector $p$ in the positive orthant of Euclidean $n$-space will denote the vector of price-income ratios, or a 'price' system. Two models of agent behaviour which have a long history in economics will now be described. The
first, which will be called the ‘local’ theory, takes as its primitive the assumption that if an agent is currently consuming at a vector \( x \), he is able to determine if an infinitesimal change in \( x \), say \( x \to x + dx \), is a change for better or worse. This idea is represented by a function \( x \to g(x) \), mapping each vector \( x \) into an \( n \)-vector \( g(x) \) such that a small movement from \( x \) in the direction of \( y \) is an improvement if \( g(x)(y - x) > 0 \), and not an improvement otherwise. Given a price system \( p \), an affordable \( x \) is an equilibrium point for the agent if \( g(x)(y - x) \leq 0 \) for all affordable \( y \). That is, no small movement from \( x \) in the direction of an affordable \( y \) is an improvement. A basic question is whether for every \( p \), an equilibrium \( x \) exists. This approach goes back at least to Pareto, and most economists, including Pareto, concerned themselves with the ‘integrability’ problem: when is there a quasi-concave utility function such that \( g(x) \) is a positive scalar multiple of the vector of marginal utilities, for each \( x ? \) Note that if an agent has a differentiable quasi-concave utility function \( u \), and one defines \( g \) by \( g(x) = \lambda(x)Du(x) \) for any \( \lambda(x) > 0 \) then \( g(x)(y - x) > 0 \) is equivalent to \( Du(x)(y-x) > 0 \), and this implies \( u(x + t(y - x)) > u(x) \) for \( t \) positive and sufficiently small. Thus if \( g \) is ‘integrable’, the agent acts as if he maximizes a utility function, and thus results (1) or (2) above will be satisfied. Some economists, however, believed that the local theory could be used to describe agent behaviour without assuming the integrability conditions. Most notable is the work of Allen (1932), Georgescu-Roegen (1936; 1954) and Katzner (1971). Without the integrability conditions and the implied utility function (and thus implied transitivity) the existence of an equilibrium \( x \) given any \( p \) is nontrivial. This problem was solved by Georgescu-Roegen (1954), who showed that if \( g \) is continuous and \( g \) satisfied the ‘principle of persistent nonpreference’ (PPN), that is, \( g(x)(y-x) < 0 \) implies \( g(y)(x-y) > 0 \), then an equilibrium point will exist in any budget set. It should be noted that the integrability problem mentioned above requires PPN (for quasi-concave utility), as well as the Frobenius conditions for mathematical integrability. It is easy to show that Georgescu-Roegen’s assumptions imply that the resulting demand correspondence will be upper-hemicontinuous.

The second basic approach to modelling agent behaviour will be called the ‘global’ theory. In this approach, the primitive of the theory is a binary relation \( R \) on the commodity space with \( xRy \) having the interpretation ‘\( x \) is at least as good as \( y \)’. Define the strict preference relation \( P \) by \( xPy \) equivalent to not \( yRx \). (\( P \) could also be taken as the primitive.) Given a price system \( p \), an affordable \( x \) in an equilibrium point if \( yPx \) implies \( py > 1 \), that is, any vector \( y \) preferred to \( x \) is not affordable. A basic question is whether such an equilibrium point will exist. This approach dates back to Frisch (1926), and the usual approach was to specify conditions on \( R \) which imply \( R \) has a representation by a continuous utility function, that is, \( u(x) \geq u(y) \) equivalent to \( xRy \). This problem was solved by Debreu (1954), who showed that \( R \) must be reflexive, complete, transitive and continuous. With the addition of appropriate convexity conditions, this approach yields the results (1) and (2) above. However, in a remarkable paper, Sonnenschein (1971) showed that one could remove transitivity from the list of standard assumptions and still have a well defined demand correspondence which is upper-hemicontinuous. Specifically, he demonstrated that if \( R \) is continuous, reflexive, and \( P(x) = \{ y : yPx \} \) is convex for all \( x \), then an equilibrium point will exist in any budget set, and the resulting demand correspondence is upper-hemicontinuous. (He also assumed \( R \) is complete, but that assumption was used only to show that an equilibrium point is comparable to every affordable \( y \).) Note that if \( g \) represents local theory, and \( g \) is continuous, then the \( R \) defined by \( xRy \) is equivalent to \( g(x)(y-x) \leq 0 \), satisfies Sonnenschein’s conditions, and an equilibrium \( x \) for \( R \) is an equilibrium point for \( g \), in any budget. Thus Sonnenschein demonstrated that Georgescu-Roegen’s condition PPN is not necessary for the existence of equilibrium
Transitivity: The New Palgrave Dictionary of Economics

In order to resolve question (1) above, a theory must predict a unique equilibrium point in each budget set, in order to get a well defined demand function. In the local theory, if one assumes \( g(x) \neq 0 \) for all \( x \) and strengthens PPN to SPPN: \( g(x)(y - x) \leq 0, x \neq y \) implies \( g(y)(x - y) > 0 \), then the equilibrium point \( x \) will be unique in any budget, and the resulting demand function will be continuous and satisfy the weak axiom of revealed preference (WARP). Thus the local theory, without assuming mathematical integrability (implied transitivity), yields a theory of individual demand functions satisfying WARP. On the other hand, given a continuous demand function \( h \) satisfying WARP, if \( h \) has a continuous inverse, then \( g = h^{-1} \) yields a local theory with \( g \) satisfying SPPN and generating \( h \). Now consider the global theory. If \( R \) is represented by a continuous, strictly quasi-concave nonsatiated utility function, then \( R \) will be reflexive, complete, transitive, strongly convex and nonsatiated. If one simply removes the assumption of transitivity from this list, then Sonnenschein's result implies that an equilibrium point will exist, and the remaining assumptions imply that this point will be unique, and that the resulting demand function will be continuous and satisfy WARP (see Shafer, 1974). Furthermore, Kim and Richter (1986) showed that, with a slight variation in the assumptions on \( R \), any continuous demand function \( h \) satisfying a modified version of WARP can be generated by such an \( R \). Thus, from the point of view of having single valued demand functions, the absence of transitivity, either assumed as in the global theory or implied as in the local theory, is essentially equivalent to Samuelson's theory of observed demand satisfying WARP. Since WARP includes the ‘law of demand’, that is, normal goods have downward sloping demand, in my view little is lost by not assuming transitivity.

Now question (2) above, the problem of existence of competitive equilibrium will be discussed. Again, Sonnenschein observed that if one took the standard assumptions on \( R \) normally used in proofs of existence of a competitive equilibrium, and removed the transitivity assumption, then demand correspondences would be well defined and convex valued, and the standard proof techniques would still work, so equilibrium would exist. Thus transitivity is irrelevant to demonstrating the internal consistency of the competitive model. Note, however, that the assumptions needed by Sonnenschein to demonstrate that individual demand correspondences are well defined and upper-hemicontinuous, namely continuity and convex preferred sets, are too weak to ensure convex valued demand correspondences. Nevertheless, Mas-Colell (1974) demonstrated that with only these assumptions on preferences, competitive equilibria will exist. Thus the only properties of individual preferences which are important to the existence of competitive equilibrium are continuity and convexity.

transversality condition

Robert A. Becker

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The transversality condition for an infinite horizon dynamic optimization problem is the boundary condition determining a solution to the problem's first-order conditions together with the initial condition. The transversality condition requires the present value of the state variables to converge to zero as the planning horizon recedes towards infinity. The first-order and transversality conditions are sufficient to identify an optimum in a concave optimization problem. Given an optimal path, the necessity of the transversality condition reflects the impossibility of finding an alternative feasible path for which each state variable deviates from the optimum at each time and increases discounted utility.

Article

The transversality condition for an infinite horizon dynamic optimization problem acts as the boundary condition determining a solution to the problem's first-order conditions together with the initial condition. Malinvaud (1953) introduced the transversality condition as part of the sufficient conditions for intertemporally efficient capital accumulation programmes. He required the present value of the capital stock to converge to zero as the planning horizon tended towards infinity. An efficient programme is a feasible path of capital stocks starting from a given initial stock, together with a consumption path, having the property that no other feasible programme from the same starting stock provides as much consumption in every period and more consumption in at least one period. He showed that it was possible for a programme to be efficient for any finite planning horizon yet be inefficient when the program was considered over the entire infinite horizon. These inefficient programmes
The New Palgrave Dictionary of Economics

overaccumulated capital and failed to satisfy the transversality condition. Current theories emphasize the transversality condition's necessity. This is illustrated for the discrete time one-sector discounted Ramsey optimal growth model. There is a single all purpose consumption good, $c_t$, produced using capital goods, $k_{t-1}$, carried over from the previous period, and fixed labour. The planner decides how much to consume in the current period and how much to save for next period's production. Capital depreciates entirely within the period. The planner's initial stock of capital produces goods available in the first period. The planner obtains utility, $u(c_t)$, from consumption at time $t$ and maximizes the discounted sum of future utilities. The discount factor, $\delta$, is a given constant.

The planner's problem is:

$$\sup_{\{c_t, k_{t-1}\}_{t=1}^\infty} \sum_{t=1}^\infty \delta^{t-1} u(c_t) \text{ by choice of } \{c_t, k_{t-1}\}_{t=1}^\infty, \text{ subject to:}$$

(1)

$$c_t + k_t \leq f(k_{t-1}) \text{ for } t = 1, 2, \ldots;$$

$$c_t \geq 0, k_{t-1} \geq 0 \text{ all } t, k_0 \leq k, \text{ where } k > 0 \text{ is given.}$$

(2)

Feasible programs are sequences $\{c_t, k_{t-1}\}_{t=1}^\infty$ which satisfy (2). Assume $u: [0, \infty) \to [0, \infty)$ is strictly concave, increasing, twice continuously differentiable, $u(0) = 0$, and satisfies the Inada condition: $\lim_{\varepsilon \to 0^+} u'(\varepsilon) = \infty$. The production function $f: [0, \infty) \to [0, \infty)$ is strictly concave, increasing, twice continuously differentiable, $f(0) = 0$, satisfies $\lim_{k \to 0^+} f'(k) = \infty$, and $\lim_{k \to 0^+} f'(k) < 1$. There is a maximum sustainable stock, $b > 0$, with $f(b) = b$ and $0 < k < b$. The discount factor satisfies $0 < \delta < 1$. There is a unique optimal program, $\{\bar{c}_t, \bar{k}_{t-1}\}_{t=1}^\infty$.

The optimal program satisfies $(\bar{c}_t, \bar{k}_{t-1}) > 0$ for each $t$. The Kuhn–Tucker necessary conditions for an optimum, known as the Euler, or no-arbitrage conditions, are:

$$\delta f'(\bar{k}_t)u'(\bar{c}_{t-1}) = u'(\bar{c}_t), \text{ for each } t.$$
If the planner’s horizon is a finite period, $T$, then (3) and the complementary slackness condition 
\[ \delta^{T-1} u'(t_T) \bar{k}_T = 0 \] 
obtain. The latter condition states capital’s terminal value is zero. For the infinite horizon case of interest, it is natural to conjecture the transversality condition holds as a necessary condition for optimality:

\[ \lim_{T \to \infty} \delta^{T-1} u'(t_T) \bar{k}_T = 0. \]  

(4)

The optimal path of the infinite horizon problem converges monotonically to the stationary optimal programme $(c^*, k^*)$, with $c^* = f(k^*) - k^*$ and $\delta f'(k^*) = 1$. Hence, the transversality condition holds. The economic intuition underlying the necessity of the transversality condition is independent of this convergence result.

Equation (3) expresses the unprofitability of the one-period reversed arbitrages developed below. An arbitrage represents a feasible change in the optimal path. Reversed arbitrages perturb the optimum for finitely many consecutive periods. Unreversed arbitrages change the optimal path permanently from some given time on to infinity. A necessary condition for an optimal path is that no arbitrage increase the discounted sum of future utilities above the optimal discounted utility. The necessity of the transversality condition can be interpreted as a type of no-arbitrage condition for unreversed arbitrages.

Assume \( \{t_t, \bar{k}_{t-1}\}_{t=1}^{\infty} \) is optimal. Suppose the planner decides to increase the first period’s consumption and forgoes one unit of capital to be used in next period’s production. The marginal gain is \( u'(t_1) \) in units of utility at time 1. A T-period reversed arbitrage occurs if at time $T + 1$ the planner reacquires the unit of capital forgone at time one. After time $T + 1$, the arbitrage no longer affects the path.

Two costs are incurred by the acquisition at time $T + 1$. First, there is the direct cost or repurchase cost of forgone consumption, which arises from converting a unit of consumption at time $T + 1$ to a unit of capital to be saved for the next period’s production. This direct cost equals $\delta^T u'(t_{T+1})$ in period 1 utils. The indirect cost arises because the net marginal product of that unit of capital is lost to the planner in every period between $t = 2$ and $t = T + 1$. The indirect cost at time $t$ in utils of time 1 is $\delta^{t-1} u'(t_t) [f'(\bar{k}_{t-1}) - 1]$; adding over $t = 2, \ldots, T + 1$ yields the present value (focal date one) of the indirect cost. The total cost equals the sum of the direct and indirect costs:

\[ \sum_{t=2}^{T+1} \delta^{t-1} u'(t_t) [f'(\bar{k}_{t-1}) - 1] + \delta^T u'(t_{T+1}). \]  

(5)
A necessary condition for the optimality is, for any $T$, the marginal benefit of a $T$-period reversed arbitrage is equal to its marginal (discounted) cost. Thus,

$$u'(\bar{t}_1) = \sum_{t=2}^{T+1} \delta^{t-2} u'(\bar{t}_t) \left[ f'(\bar{k}_{t-1}) - 1 \right] + \delta^T u'(\bar{t}_{T+1}).$$  \hspace{1cm} (6)

Equation (6) applied to a one-period reversed arbitrage reduces to (3), evaluated at $T = 1$. Equation (3) follows from the same reasoning when a reversed arbitrage starts at time $t$.

Equation (6) contains no further information. However, the infinite horizon means the planner can also contemplate the profitability of an unreversed arbitrage in which the unit of capital is permanently sacrificed at time $t = 1$. There is no repurchase cost associated with an unreversed arbitrage, hence the conditions for the unprofitability of an unreversed arbitrage must be

$$u'(\bar{t}_1) = \sum_{t=2}^{\infty} \delta^{t-1} u'(\bar{t}_t) \left[ f'(\bar{k}_{t-1}) - 1 \right].$$ \hspace{1cm} (7)

But (6) and (7) can hold as $T \to \infty$ only if $\lim_{T \to \infty} \delta^T u'(\bar{t}_{T+1}) = 0$, which implies the transversality condition since the capital stocks are bounded. An unreversed arbitrage over-accumulates capital in comparison with the optimal programme. This cannot be optimal. Thus, the transversality condition expresses the zero marginal profit condition for the open-ended arbitrages which are available only in the infinite horizon context. The rate of capital accumulation is thereby limited.

The Euler equations and the transversality conditions are necessary for optimality. For concave optimal growth models – the case where utility and production functions are concave – the Euler equations and transversality conditions are also sufficient to identify an optimal programme. Indeed, transversality conditions are necessary (and sufficient) together with the Euler equations in other dynamic models where the state variables need not be capital stocks.

The transversality condition's necessity is important in connecting dynamic equilibrium paths and optimal growth paths in infinitely lived representative agent economies. The basic idea is to match the Euler and transversality conditions in the equilibrium and optimal growth settings. This results in an equivalence principle: an optimal growth path is a competitive equilibrium, and vice versa.

The necessity of the transversality condition can also be used to exclude bubbles from occurring in asset
Transversality condition: The New Palgrave Dictionary of Economics

Pricing models. The asset's fundamental is the present discounted value of its future dividend payouts. A bubble exists if the asset's price differs from its fundamental value. For example, if the asset is a perpetuity and offers a constant dividend stream, then the no-arbitrage conditions state the capital gain yield plus the dividend yield equals the interest rate at each time. Formally,

\[
\frac{p_{t+1} - p_t}{p_t} + \frac{r}{p_t} = \varpi, \quad t = 1, 2, \ldots
\]

where \( p_t \) is the asset's current price at time \( t \), \( r \) is the asset's return (or dividend) in each period, and \( \varpi \) is the constant interest rate. Equation (8) is a first-order difference equation. Its solution is

\[
p_t = (1 + \varpi)^{t-1} \left[ p_1 - \left( \frac{r}{\varpi} \right) \right] + \left( \frac{r}{\varpi} \right).
\]

For each choice of \( p_1 \), there is a sequence, \( \{ p_t \}_{t=1}^{\infty} \), calculated from (9). Thus, there are an infinite number of price systems satisfying this asset's no-arbitrage equation. Efficient markets would imply the absence of arbitrage opportunities for all time and single out the solution \( p_t = (r / \varpi) \), which occurs if and only if \( p_1 = (r / \varpi) \). Initial prices with \( p_1 > (r / \varpi) \) would create a bubble where \( p_t \) exceeds its fundamental value, \( (r / \varpi) \). Prices continue to rise simply because investors expect them to do so. There is a negative bubble if \( p_1 < (r / \varpi) \). The asset's price becomes negative in finite time, an impossibility as prices must always remain non-negative. Hence, \( p_1 \geq (r / \varpi) \).

The transversality condition takes the form

\[
\lim_{t \to \infty} p_t \left( \frac{1}{1 + \varpi} \right)^{t-1} = 0.
\]

If this is an equilibrium condition, then the initial price must be \( p_1 = (r / \varpi) \) and the asset's market price equals its fundamental at each time. Imposition of the transversality condition picks out the only
The transversality condition: The New Palgrave Dictionary of Economics

The solution of (8) that is not a bubble.

Many deterministic models have stochastic counterparts. For example, technology shocks in the Ramsey problem lead to stochastic Euler equations expressing no-arbitrage opportunities in expectations, or on average, when the planner's objective is the expected discounted sum of future utilities. The corresponding transversality condition also holds in expectations. There can exist particular realizations of the shocks for which a bubble persists. However, on average, there are no unprofitable unreversed arbitragers.

The argument for the necessity of the transversality condition given above is heuristic. Weitzman (2003) presents an analogous intuitive rationale for the transversality condition in continuous time. The terms ‘reversed’ and ‘unreversed’ arbitrage originate in Gray and Salant (1983). Rigorous arguments are found in the references below.

Article

Transversality conditions are optimality conditions often used along with Euler equations to characterize the optimal paths of dynamic economic models. The purpose of this article is to illustrate the role of transversality conditions in characterizing optimal paths as well as in ruling out economic phenomena such as asset bubbles and hyperdeflations in infinite-horizon models. See transversality condition for mathematical foundations.

A geometric example

A simple geometric example best illustrates the mathematical roles of an Euler equation and a transversality condition. What is the shortest path from a point $A$ to a straight line $L$ infinitely long in both directions? The answer is, of course, the straight line from point $A$ to line $L$ that is perpendicular to line $L$. There are two conditions involved here. The first condition is that the shortest path be a straight line: one cannot make the path shorter by deviating from it and eventually returning to it. This is the
implication of the Euler equation for this problem. But there are infinitely many straight lines from point A to line L. In fact, a straight line from point A to line L can be arbitrarily long; even very bad choices satisfy the Euler equation. This is why one needs the second condition, that the shortest path be perpendicular to line L. This additional condition ensures that one cannot make the path shorter by deviating from it and never returning to it.

The condition of perpendicularity in this example and similar conditions on end points in other problems are called transversality conditions in dynamic optimization theory (Hestenes, 1966, p. 87). According to Bolza (1904, p. 106), the term was first introduced by Kneser (1900). Both Euler equations and transversality conditions were initially developed for calculus-of-variations problems. In economics, in particular in macroeconomics, both types of conditions are used mainly for infinite-horizon models in discrete time as well as in continuous time. In what follows, we focus on discrete-time models, which are technically easier to deal with.

**A general discrete-time problem**

Consider the following maximization problem:

\[
\max_{\{x_{t+1}\}_{R=0}^\infty} \sum_{t=0}^{\infty} \beta^t v(x_t, x_{t+1})
\]

(1)

s.t. \( x_{t+1} \geq 0, \quad t = 0, 1, 2, \ldots \),

(2)

\[ x_0 \text{ given}, \]

(3)

where \( \beta \in (0,1) \) is called the discount factor, \( v \) is called the return function, and \( x_t \) is an \( n \)-dimensional vector. There may be other constraints, but we assume that they are never binding at the optimum. We
also assume that the non-negativity constraint is never binding at the optimum, and that the return 
function $v$ is differentiable and concave. Though the return function may depend on $t$, we do not assume 
so here for notational simplicity. To be concrete, we interpret $x_t$ as the stock of wealth (or capital) at the 
beginning of period $t$. In most economic problems, it is costly to accumulate wealth. Hence we assume 
that $v_2(x,y) \leq 0$ for all $x, y$.

The Euler equation for this problem is simply the first-order condition with respect to $x_{t+1}$:

$$v_2(x_t, x_{t+1}) + \beta v_1(x_{t+1}, x_{t+2}) = 0. \tag{4}$$

This condition means that no gain can be achieved by deviating from an optimal path for one period. 
The transversality condition is given by

$$\lim_{T \to \infty} \beta^T [-v_2(x_T, x_{T+1})] x_{T+1} = 0. \tag{5}$$

Though this is the typical transversality condition in economics, other transversality conditions are 
possible depending on the specification of constraints. Condition (5) can be interpreted as saying that the 
present discounted value of wealth at infinity must be zero, or wealth $(x_{T+1})$ should not grow too fast 
compared with its discounted marginal value $(\beta^T [-v_2(x_T, x_{T+1})])$. In other words, the transversality 
condition (5) rules out overaccumulation of wealth. The idea is that, if one saves too much and spends 
too little, then one is not behaving optimally.

It is well known that the Euler equation (4) and the transversality condition (5) are sufficient for 
optimality (Stokey and Lucas, 1989, p. 89). This result is often credited to Mangasarian (1966), who 
showed a finite-horizon version of the result. 

Since the Euler equation is simply the first-order condition with respect to $x_{t+1}$, it is a necessary 
condition for optimality. On the other hand, necessity of the transversality condition is often considered 
to be a difficult issue. But there are two simple ways to prove its necessity if the objective function is 
assumed to be finite for all feasible paths (Kamihigashi, 2002; 2005). If this assumption fails, one can 
try the following test. Shift the entire optimal path downward by a small fixed proportion. Does it reduce 
the value of the objective function by only a finite amount? If so, the transversality condition is 
necessary. See Kamihigashi (2001; 2003) for precise assumptions and statements. See Weitzman (1973), 
Benveniste and Scheinkman (1982), and Michele (1982) for earlier results and arguments.
To see how the transversality condition can be used in practice, consider the basic Ramsey model:

\[
\max \sum_{t=0}^{\infty} \beta^t u(c_t)
\]

subject to
\[
c_t + x_{t+1} = f(x_t), \quad c_t, x_{t+1} \geq 0, \quad t = 0, 1, 2, \ldots, \tag{6}
\]

where \(c_t\) is consumption and \(x_t\) is the stock of capital at the beginning of period \(t\). We assume that the utility function \(u\) and the production function \(f\) are continuously differentiable, strictly increasing, and strictly concave. We also assume that \(f(0)=0, \lim_{x \to 0} f'(x) = \infty\), and \(\lim_{x \to \infty} f'(x) < 1\). The model here is a special case of the general problem described above with \(v(x_t, x_{t+1}) = u(f(x_t) - x_{t+1})\). The Euler equation and the transversality condition are

\[
u'(c_t) = \beta u'(c_{t+1}) f'(x_{t+1}), \tag{9}
\]
Given any initial capital stock $x_0$, there are three types of paths obeying (7) and (9). Specifically, there is a unique level of consumption $\hat{c}_0$ such that a path $\{c_t, x_{t+1}\}$ satisfying (7) and (9) converges to the unique steady state (which is determined by the strictly positive capital stock $x^*$ such that $\beta f'(x^*) = 1$) if and only if $c_0 = \hat{c}_0$. If $c_0 > \hat{c}_0$, then (7) is eventually violated; such paths are ruled out on feasibility grounds. If $c_0 < \hat{c}_0$, then $c_t$ converges to zero and $x_t$ converges to the capital stock $\bar{x}$ given by $f'(\bar{x}) = \bar{x}$.

It can be shown that such paths violate the transversality condition and thus are not optimal. The path converging to the steady state satisfies the transversality condition since $c_t$ and $x_t$ converge to their steady state values; hence this is the optimal path.

The preceding argument shows that when one restricts attention to the dynamical system defined by (7) and (9), most paths do not converge to the steady state. This is an example of the Hahn problem (Hahn, 1987). The Hahn problem disappears here when one takes the transversality condition into account, since only the path converging to the steady state satisfies the transversality condition as well as the feasibility requirements.

Asset bubbles

Transversality conditions are often used to rule out asset bubbles. To be specific, consider a deterministic version of the Lucas (1978) asset pricing model. There are many homogeneous agents, a single good, and a single asset that pays a dividend of $d_t$ units of the good in each period $t$. The population of agents is normalized to one; so is the supply of the asset. Each agent solves

$$\max_{\{c_t, x_{t+1}\}_{t=0}^{\infty}} \sum_{t=0}^{\infty} \beta^t u(c_t)$$

subject to

$$c_t + p_t x_{t+1} = (p_t + d_t) x_t, \quad c_t, x_{t+1} \geq 0, \quad t = 0, 1, 2, ...,$$

where $p_t$ is the price of the good.
where \( c_t \) is consumption, \( p_t \) is the price of the asset, and \( x_t \) is shares in the asset at the beginning of period \( t \). In equilibrium, \( c_t = d_t \) and \( x_t = 1 \). We assume that the utility function \( u \) is concave, differentiable and strictly increasing. The Euler equation and the transversality condition in equilibrium are

\[
u'(d_t) p_t = \beta u'(d_{t+1})(p_{t+1} + d_{t+1}),
\]

\( (14) \)

\[
\lim_{T \to \infty} \beta^T u(d_T) p_T = 0.
\]

\( (15) \)

It is easy to see that the sequence \( \{ p_t^* \} \) given by

\[
p_t^* = \sum_{i=1}^{\infty} \beta^i \frac{u'(d_{t+i})}{u'(d_t)} d_{t+i}
\]

\( (16) \)

satisfies the Euler equation \( (14) \). The right-hand side of \( (16) \) is called the fundamental value of the asset. Let \( \{ b_t \} \) be any nonnegative sequence satisfying

\[
u'(d_t) b_t = \beta u'(d_{t+1}) b_{t+1}.
\]
Then the sequence \( \{ p_t^* + b_t \} \) also satisfies the Euler equation. Hence there are infinitely many paths satisfying the Euler equation. The extra component \( b_t \), which grows at a gross rate of \( \frac{u'(d_t)}{\beta u'(d_{t+1})} \), is interpreted as a bubble. Notice that the bubble component \( b_t \), if strictly positive, violates the transversality condition (15) (with \( p_T=b_T \)). Therefore, if the transversality condition is necessary for optimality, the bubble component must vanish, so that the price must always be equal to the fundamental value. This is indeed the case in this model (Kamihigashi, 2001, p. 1007).

In stochastic models, bubbles can be ruled out by the same argument under standard assumptions, but there are pathological cases in which bubbles are possible (Kamihigashi, 1998; Montrucchio and Privileggi, 2001). Bubbles arise more easily in models with heterogenous agents such as overlapping generations models, where there is no economy-wide transversality condition. See speculative bubbles.

**Hyperdeflations**

Transversality conditions are often used to rule out hyperdeflations in money-in-the-utility-function models of the type studied by Brock (1974) and Obstfeld and Rogoff (1986). In these models, agents derive utility from real money balances in addition to consumption. As in the Lucas asset pricing model, there are many paths satisfying the Euler equation. Along a path satisfying the Euler equation with a positive bubble, the value of real balances grows unboundedly or, equivalently, the nominal price level keeps declining towards zero. Such paths are often interpreted as exhibiting hyperdeflations. Under reasonable assumptions, hyperdeflationary paths are ruled out by the transversality condition, which once again rules out overaccumulation of wealth, or real balances.

However, there are cases in which the transversality condition does not rule out hyperdeflationary paths (Obstfeld and Rogoff, 1986, p. 356). This is because agents, who derive utility from real balances, benefit directly from accumulating wealth.

**No-Ponzi-game conditions**

In formulating a consumer's maximization problem, one must include some constraint on debt, since otherwise the consumer would never pay back his debt, letting it grow unboundedly. One way to rule out this behaviour is to prohibit debt entirely, that is, to require wealth to be always non-negative (as in (12)). A more lenient way is to require only the present discounted value of wealth at infinity to be non-negative. This type of condition is known as a no-Ponzi-game condition (Blanchard and Fischer, 1989, p. 49), but often called a transversality condition as well. A no-Ponzi-game condition is a constraint that prevents overaccumulation of debt, while a typical transversality condition is an optimality condition that rules out overaccumulation of wealth. They place opposite restrictions, and should not be confused.

Bibliography

**How to cite this article**

The term ‘treatment effect’ refers to the causal effect of a binary (0–1) variable on an outcome variable of scientific or policy interest. Economics examples include the effects of government programmes and policies, such as those that subsidize training for disadvantaged workers, and the effects of individual choices like college attendance. The principal econometric problem in the estimation of treatment effects is selection bias, which arises from the fact that treated individuals differ from the non-treated for reasons other than treatment status per se. Treatment effects can be estimated using social experiments, regression models, matching estimators, and instrumental variables.

Article

A ‘treatment effect’ is the average causal effect of a binary (0–1) variable on an outcome variable of scientific or policy interest. The term ‘treatment effect’ originates in a medical literature concerned with the causal effects of binary, yes-or-no ‘treatments’, such as an experimental drug or a new surgical procedure. But the term is now used much more generally. The causal effect of a subsidized training programme is probably the mostly widely analysed treatment effect in economics (see, for example, Ashenfelter, 1978, for one of the first examples, or Heckman and Robb, 1985 for an early survey). Given a data-set describing the labour market circumstances of trainees and a non-trainee comparison group, we can compare the earnings of those who did participate in the programme and those who did not. Any empirical study of treatment effects would typically start with such simple comparisons. We might also use regression methods or matching to control for demographic or background characteristics.

In practice, simple comparisons or even regression-adjusted comparisons may provide misleading estimates of causal effects. For example, participants in subsidized training programmes are often observed to earn less than ostensibly comparable controls, even after adjusting for observed differences (see, for example, Ashenfelter and Card, 1985). This may reflect some sort of omitted variables bias, that is, a bias arising from unobserved and uncontrolled differences in earnings potential between the two groups being compared. In general, omitted variables bias (also known as selection bias) is the most serious econometric concern that arises in the estimation of treatment effects. The link between omitted variables bias, causality, and treatment effects can be seen most clearly using the potential-outcomes framework.
The notion of a causal effect can be made more precise using a conceptual framework that postulates a set of potential outcomes that could be observed in alternative states of the world. Originally introduced by statisticians in the 1920s as a way to discuss treatment effects in randomized experiments, the potential outcomes framework has become the conceptual workhouse for non-experimental as well as experimental studies in many fields (see Holland, 1986, for a survey and Rubin, 1974; 1977, for influential early contributions). Potential outcomes models are essentially the same as the econometric switching regressions model (Quandt, 1958), though the latter is usually tied to a linear regression framework. Heckman (1976; 1979) developed simple two-step estimators for this model.

### Average causal effects

Except in the realm of science fiction, where parallel universes are sometimes imagined to be observable, it is impossible to measure causal effects at the individual level. Researchers therefore focus on average causal effects. To make the idea of an average causal effect concrete, suppose again that we are interested in the effects of a training programme on the post-training earnings of trainees. Let $Y_i$ denote the potential earnings of individual $i$ if he were to receive training and let $Y_{0i}$ denote the potential earnings of individual $i$ if not. Denote training status by a dummy variable, $D_i$. For each individual, we observe $Y_i = Y_{0i} + D_i(Y_{1i} - Y_{0i})$, that is, we observe $Y_{1i}$ for trainees and $Y_{0i}$ for everyone else.

Let $E[\cdot]$ denote the mathematical expectation operator, i.e., the population average of a random variable. For continuous random variables, $E[Y_i] = \int y f_Y(y) \, dy$, where $f_Y(y)$ is the density of $Y_i$. By the law of large numbers, sample averages converge to population averages so we can think of $E[\cdot]$ as giving the sample average in very large samples. The two most widely studied average causal effects in the treatment effects context are the average treatment effect (ATE), $E[Y_{1i} - Y_{0i}]$, and the average treatment effect on the treated (ATET), $E[Y_{1i} - Y_{0i} | D_i = 1]$. Note that the ATET can be rewritten

$$E[Y_{1i} - Y_{0i} | D_i = 1] = E[Y_{1i} | D_i = 1] - E[Y_{0i} | D_i = 1].$$

This expression highlights the counter-factual nature of a causal effect. The first term is the average earnings in the population of trainees, a potentially observable quantity. The second term is the average earnings of trainees had they not been trained. This cannot be observed, though we may have a control group or econometric modelling strategy that provides a consistent estimate.

### Selection bias and social experiments

As noted above, simply comparing those who are and are not treated may provide a misleading estimate of a treatment effect. Since the omitted variables problem is unrelated to sampling variance or statistical inference, but rather concerned with population quantities, it too can be efficiently described by using mathematical expectation notation to denote population averages. The contrast in average outcomes by observed treatment status is

$$E[Y_i | D_i = 1] - E[Y_i | D_i = 0] = E[Y_{1i} | D_i = 1] - E[Y_{0i} | D_i = 0] = E[Y_{1i} - Y_{0i} | D_i = 1] + [E[Y_{0i} | D_i = 1] - E[Y_{0i} | D_i = 0]]$$

Thus, the naive contrast can be written as the sum of two components, ATET, plus selection bias due to the fact that the
average earnings of non-trainees, \( E[Y_0 | D_i = 0] \), need not be a good stand-in for the earnings of trainees had they not been trained, \( E[Y_0 | D_i = 1] \).

The problem of selection bias motivates the use of random assignment to estimate treatment effects in social experiments. Random assignment ensures that the potential earnings of trainees had they not been trained – an unobservable quantity – are well-represented by the randomly selected control group. Formally, when \( D_i \) is randomly assigned, \( E[Y_i | D_i = 1] - E[Y_i | D_i = 0] = E[Y_1 - Y_0 | D_i = 1] = E[Y_1 - Y_0] \). Replacing \( E[Y_i | D_i = 1] \) and \( E[Y_i | D_i = 0] \) with the corresponding sample analogs provides a consistent estimate of ATE.

**Regression and matching**

Although it is increasingly common for randomized trials to be used to estimate treatment effects, most economic research still uses observational data. In the absence of a randomized experiment, researchers rely on a variety of statistical control strategies and/or natural experiments to reduce omitted variables bias. The most commonly used statistical techniques in this context are regression, matching and instrumental variables.

Regression estimates of causal effects can be motivated most easily by postulating a constant-effects model, where \( \gamma_i = \alpha + \beta'X_i + \epsilon_i \) (a constant). The constant-effects assumption is not strictly necessary for regression to estimate an average causal effect, but it simplifies things to postpone a discussion of this point. More importantly, the only source of omitted-variables bias is assumed to come from a vector of observed covariates, \( X_i \), that may be correlated with \( D_i \). The key assumption that facilitates causal inference in regression models (sometimes called an identifying assumption), is that

\[
E[Y_0 | X_i, D_i] = X_i' \beta,
\]

where \( \beta \) is a vector of regression coefficients. This selection-on-observables assumption has two parts. First, \( Y_{0i} \) (and hence \( Y_{1i} \), given the constant-effects assumption) is mean-independent of \( D_i \) conditional on \( X_i \). Second, the conditional mean function for \( Y_{0i} \) given \( X_i \) is linear. Given eq. (1), it is straightforward to show that

\[
E(Y_i(D_i - R(D_i | X_i))) / E(D_i(D_i - R(D_i | X_i))) = \alpha,
\]

where \( R[D_i/X_i] \) are the fitted values from a regression of \( D_i \) on \( X_i \). This is the coefficient on \( D_i \) from the population regression of \( Y_i \) on \( D_i \) and \( X_i \) (that is, the regression coefficient in an infinite sample). Again, the law of large numbers ensures that sample regression coefficients estimate this population regression coefficient consistently.

Matching is similar to regression in that it is motivated by the assumption that the only source of omitted variables or selection bias is the set of observed covariates, \( X_i \). Unlike regression, however, matching estimates of treatment effects are constructed by matching individuals with the same covariates instead of through a linear model for the effect of covariates. Instead of (1), the selection-on-observables assumption becomes

\[
E[Y_j | X_i, D_i] = E[Y_j | X_i], \text{ for } j = 0, 1.
\]
This implies
\[ E(Y_{1i} - Y_{0i} | D_i = 1) = E(E(Y_{1i}X_i | D_i = 1) - [Y_{0i}X_i | D_i = 1] | D_i = 1) = E(E(Y_{1i}X_i | D_i = 1) - [Y_{0i}X_i | D_i = 0] | D_i = 1) \]

(4a)

and, likewise,
\[ E(Y_{1i} - Y_{0i}) = E(E(Y_{1i}X_i | D_i = 1) - [Y_{0i}X_i | D_i = 0]) \]

(4b)

In other words, we can construct ATET or ATE by averaging X-specific treatment-control contrasts, and then reweighting these X-specific contrasts using the distribution of \( X_i \) for the treated (for ATET) or using the marginal distribution of \( X_i \) (for ATE). Since these expressions involve observable quantities, it is straightforward to construct consistent estimators from their sample analogs.

The conditional independence assumption that motivates the use of regression and matching is most plausible when researchers have extensive knowledge of the process determining treatment status. An example in this spirit is the Angrist (1998) study of the effect of voluntary military service on the civilian earnings of soldiers after discharge, discussed further below.

Regression and matching details

In practice, regression can be understood as a type of weighted matching estimator. If, for example, \( E[D_iX_i] \) is a linear function of \( X_i \) (as it might be if the covariates are all discrete), then it is possible to show that eq. (2) is equivalent to a matching estimator that weights cell-by-cell treatment-control contrasts by the conditional variance of treatment in each cell (Angrist, 1998). This equivalence highlights the fact that the most important econometric issue in a study that relies on selection-on-observables assumptions to identify causal effects is the validity of these conditional independence assumptions, not whether regression or matching is used to implement them.

A computational difficulty that sometimes arises in matching models is how to find good matches for each possible value of the covariates when the covariates take on many values. For example, beginning with Ashenfelter (1978), many studies of the effect of training programmes have shown that trainees typically experience a period of declining earnings before they go into training. Because lagged earnings is both continuous and multidimensional (since more than one period's earnings seem to matter), it may be hard to match trainees and controls with exactly the same pattern of lagged earnings. A possible solution in this case is to match trainees and controls on the propensity score, the conditional probability of treatment given covariates. Propensity-score matching relies on the fact that, if conditioning on \( X_i \) eliminates selection bias, then so does conditioning on \( P[D_i = 1 | X_i] \), as first noted by Rosenbaum and Rubin (1983). Use of the propensity score reduces the dimensionality of the matching problem since the propensity score is a scalar, though in practice it must still be estimated. See Dehejia and Wahba (1999) for an illustration.

Regression and matching example

Between 1989 and 1992, the size of the military declined sharply because of increasing enlistment standards.
Policymakers would like to know whether the people—many of them black men—who would have served under the old rules but were unable to enlist under the new rules were hurt by the lost opportunity for service. The Angrist (1998) study attempts to answer this question. The regression and matching assumptions seem plausible in this context because soldiers are selected on the basis of a few well-documented criteria related to age, schooling and test scores and because the control group used in the study also applied to enter the military.

Naive comparisons clearly overestimate the benefit of military service. This can be seen in Table 1, which reports differences-in-means, matching and regression estimates of the effect of voluntary military service on the 1988–91 Social Security-taxable earnings of men who applied to join the military between 1979 and 1982. The matching estimates were constructed from the sample analog of (4a), that is, from covariate-value-specific differences in earnings, weighted to form a single estimate using the distribution of covariates among veterans. The covariates in this case are the age, schooling and test-score variables used to select soldiers from the pool of applicants. Although white veterans earn $1,233 more than non-veterans, this difference becomes negative once the adjustment for differences in covariates is made. Similarly, while non-white veterans earn $2,449 more than non-veterans, controlling for covariates reduces this to $840.

Notes: Figures are in nominal US dollars. The table shows estimates of the effect of voluntary military service on the 1988–91 Social Security-taxable earnings of men who applied to enter the armed forces during 1979–82. The matching and regression estimates control for applicants’ year of birth, education at the time of application, and Armed Forces Qualification Test (AFQT) score. There are 128,968 whites and 175,262 non-whites in the sample. Standard errors are reported in parentheses.

Source: Adapted from Angrist (1998, Tables II and V).

Table 1 also shows regression estimates of the effect of voluntary military service, controlling for the same covariates used for matching. These are estimates of $\alpha_r$ in the equation

$$Y_i = \sum_X d_i \beta_X + \alpha_r D_i + e_i$$

where $\beta_X$ is a regression-effect for $X_1 = X$ and $\alpha_r$ is the regression parameter. This corresponds to a saturated model for discrete $X_i$. The regression estimates are larger than (and significantly different from) the matching estimates. But the regression and matching estimates are not very different economically, both pointing to a small earnings loss for White veterans and a modest gain for Non-whites.

Instrumental variables estimates of treatment effects

The assumptions required for regression or matching to identify a treatment effect are often implausible. Many of the necessary control variables are typically unmeasured or simply unknown. Instrumental variables (IV) methods solve the problem of missing or unknown controls, much as a randomized trial also obviates the need for regression or matching. To see how this is possible, begin again with a constant effects model without covariates, so $Y_{1i} - Y_{0i} = \alpha$. Also, let $Y_{0i} = \beta + \varepsilon_i$, where $\beta \equiv E[Y_{0i}]$. The potential outcomes model can now be written

$$Y_i = \beta + \alpha D_i + \varepsilon_i,$$

(5)

where $\alpha$ is the treatment effect of interest. Because $D_i$ is likely to be correlated with $\varepsilon_i$, regression estimates of eq. (5) do not estimate $\alpha$ consistently.

Now suppose that in addition to $Y_i$ and $D_i$ there is a third variable, $Z_i$, that is correlated with $D_i$, but unrelated to $Y_i$ for any other reason. In a constant-effects world, this is equivalent to saying $Y_{0i}$ and $Z_i$ are independent. It therefore follows that

$$E[\varepsilon_i Z_i] = 0,$$

(6)

a conditional independence restriction on the relation between $Z_i$ and $Y_{0i}$, instead of between $D_i$ and $Y_{0i}$ as required for regression or matching strategies. The variable $Z_i$ is said to be an IV or just ‘an instrument’ for the causal effect of $D_i$ on $Y_i$.

Suppose that $Z_i$ is also a 0–1 variable. Taking expectations of (5) with $Z_i$ switched off and on, we immediately obtain a simple formula for the treatment effect of interest:

$$\frac{E[Y_i Z_i = 1] - E[Y_i Z_i = 0]}{E[D_i Z_i = 1] - E[D_i Z_i = 0]} = \alpha.$$

(7)

The sample analog of this equation is sometimes called the Wald estimator, since it first appear in a paper by Wald (1940) on errors-in-variables problems. There are other more complicated IV estimators involving continuous, multi-valued, or multiple instruments. For example, with a multi-valued instrument, we might use the sample analog of $\text{Cov}(Z_i, Y_i)/\text{Cov}(D_i, Y_i)$. This simplifies to the Wald estimator when $Z_i$ is 0–1. The Wald estimator captures the main idea behind most IV estimation strategies since more complicated estimators can usually be written as a linear combination of Wald estimators (Angrist, 1991).

**IV example**

To see how IV works in practice, it helps to use an example, in this case the effect of Vietnam-era military service on the earnings of veterans later in life (Angrist, 1990). In the 1960s and early 1970s, young men were at risk of being drafted
for military service. Concerns about fairness led to the institution of a draft lottery in 1970 that was used to determine priority for conscription in cohorts of 19-year-olds. A natural instrumental variable for the Vietnam veteran treatment effect is draft-eligibility status, since this was determined by a lottery over birthdays. In particular, in each year from 1970 to 1972, random sequence numbers (RSNs) were randomly assigned to each birth date in cohorts of 19-year-olds. Men with lottery numbers below an eligibility ceiling were eligible for the draft, while men with numbers above the ceiling could not be drafted. In practice, many draft-eligible men were still exempted from service for health or other reasons, while many men who were draft-exempt nevertheless volunteered for service. So veteran status was not completely determined by randomized draft eligibility; eligibility and veteran status are merely correlated.

For white men who were at risk of being drafted in the 1970–71 draft lotteries, draft-eligibility is clearly associated with lower earnings in years after the lottery. This can be seen in Table 2, which reports the effect of randomized draft-eligibility status on average Social Security-taxable earnings in column (2). Column (1) shows average annual earnings for purposes of comparison. For men born in 1950, there are significant negative effects of eligibility status on earnings in 1970, when these men were being drafted, and in 1981, ten years later. For example, the 1981 estimate for whites is $-436$ dollars. In contrast, there is no evidence of an association between eligibility status and earnings in 1969, the year the lottery drawing for men born in 1950 was held but before anyone born in 1950 was actually drafted.

Notes: Figures are in nominal US dollars. There are about 13,500 observations with earnings in each cohort. Standard errors are shown in parentheses.

Sources: Adapted from Angrist (1990, Tables 2 and 3), and unpublished author tabulations. Earnings data are from Social Security administrative records. Veteran status data are from the Survey of Income and Program Participation. Because eligibility status was randomly assigned, the claim that the estimates in column (2) represent the causal effect of draft eligibility on earnings seems uncontroversial. An additional assumption embodied in equation (6) is that the only reason eligibility affects earnings is military service. Given this, the only information required to go from draft-eligibility effects to veteran-status effects is the denominator of the Wald estimator, which is the effect of draft-eligibility on the probability of serving in the military. This information is reported in column (4) of Table 2, which shows that draft-eligible men were 0.16 more likely to have served in the Vietnam era. For earnings in 1981, long after most Vietnam-era servicemen were discharged from the military, the Wald estimates of the effect of military service reported in column (5) amount to about 15 percent of earnings. Effects were even larger in 1970, when affected soldiers were still in the army.

IV with heterogeneous treatment effects

The constant-effects assumption is clearly unrealistic. We'd like to allow for the fact that some men may have benefited from military service while others were undoubtedly hurt by it. In general, however, IV methods fail to capture either ATE or ATET in a model with heterogeneous treatment effects. Intuitively, this is because only a subset of the population is affected by any particular instrumental variable. In the draft lottery example, many men with high lottery numbers volunteered for service anyway (indeed, most Vietnam veterans were volunteers), while many draft-eligible
The draft lottery instrument is not informative about the effects of military service on men who were unaffected by their draft-eligibility status. On the other hand, there is a sub-population who served solely because they were draft-eligible, but would not have served otherwise. Angrist, Imbens and Rubin (1996) call the population of men whose treatment status can be manipulated by an instrumental variable the set of compliers. This term comes from an analogy to a medical trial with imperfect compliance. The set of compliers are those who ‘take their medicine’, that is, they serve in the military when draft-eligible but they do not serve otherwise. Under reasonably general assumptions, IV methods can be relied on to capture the causal effect of treatment on compliers. The average causal effect for this group is called a local average treatment effect (LATE), and was first discussed by Imbens and Angrist (1994). A formal description of LATE requires one more bit of notation. Define potential treatment assignments $D_{0i}$ and $D_{1i}$ to be individual $i$’s treatment status when $Z_i$ equals 0 or 1. One of $D_{0i}$ or $D_{1i}$ is counterfactual since observed treatment status is

$$D_i = D_{0i} + Z_i(D_{1i} - D_{0i}).$$

The key identifying assumptions in this setup are (a) conditional independence, that is, that the joint distribution of $\{Y_{1i}, Y_{0i}, D_{1i}, D_{0i}\}$ is independent of $Z_i$; and (b) monotonicity, which requires that either $D_{1i} \geq D_{0i}$ for all $i$ or vice versa. Monotonicity requires that, while the instrument might have no effect on some individuals, all of those who are affected should be affected in the same way (for example, draft eligibility can only make military service more likely, not less). Assume without loss of generality that monotonicity holds with $D_{1i} \geq D_{0i}$. Given these two assumptions, the Wald estimator consistently estimates LATE, written formally as $\mathbb{E}[Y_{1i} - Y_{0i} | D_{1i} > D_{0i}]$. In the draft lottery example, this is the effect of military service on those veterans who served because they were draft eligible but would not have served otherwise. In general, LATE compliers are a subset of the treated. An important special case where LATE=ATET is when $D_{0i}$ equals zero for everyone. This happens in a social experiment with imperfect compliance in the treated group and no one treated in the control group.

IV Details

Typically, covariates play a role in IV models, either because the IV identification assumptions are more plausible conditional on covariates or because of statistical efficiency gains. Linear IV models with covariates can be estimated most easily by two-stage least squares (2SLS), which can also be used to estimate models with multi-valued, continuous, or multiple instruments. See Angrist and Imbens (1995) or Angrist and Krueger (2001) for details and additional references.

trend/cycle decomposition

Charles R. Nelson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The decomposition of economic time series is motivated by the idea that distinct forces account for long-
term growth, for variation over a time frame associated with the business cycle, and though the seasons. 
While the latter is typically suppressed by ‘seasonal adjustment’, the issue of how to separate trend from 
cycle in series such as GDP has been hotly debated since the 1970s and remains unsettled. Surprisingly 
varied patterns follow from alternative approaches, some placing the bulk of variation into the cycle/
trend following a smooth line, others attributing shifts in level to ‘permanent shocks’ to the trend.

Keywords

ARMA models; business cycles; ergodicity; filtering; identification; Kalman filter; random walks; trend/
cycle decomposition; unobserved components models

Article

Macroeconomists distinguish between the forces that cause long-term growth and those that cause 
temporary fluctuations such as recessions. The former include population growth, capital accumulation, 
and productivity change, and their effect on the economy is permanent. The latter are generally 
monetary shocks such as shifts in central bank policy that affect the real economy through price 
rigidities that cause output to deviate temporarily from its long-run path. This conceptual dichotomy 
motivates the decomposition of aggregate output, real GDP, into two components: the trend which 
accounts for long-term change, and the cycle which is a short-term deviation from trend. While 
economists no longer believe the ‘business cycle’ to be deterministically periodic, that terminology 
remains. Seasonal variation could be a third component, though it has been suppressed in ‘seasonally 
adjusted’ data such as GDP.
This suggests we may express the natural log of GDP (or any other ‘trending’ time series), denoting the 
observation at time $t$ by $y_t$, as follows:
\[ Y_t = \tau_t + c_t. \]

Here \( \tau_t \) denotes the value of the trend and \( c_t \) the cycle at time \( t \), neither of which is observed directly. Since this single equation cannot be solved directly for the unknown trend and cycle, additional assumptions are required for ‘identification’, a procedure which allows estimates of them to be calculated from the GDP data. The fundamental identifying assumption is that the cycle component is temporary, that it dies out after a sufficiently long time. However, this assumption of ‘stationarity’ or ‘ergodicity’, which distinguishes it from trend, which is permanent, does not suffice by itself to achieve identification. More has to be said about the nature of the trend.

The simplest specification of trend is to make \( \tau_t \) a linear function of time where the slope is the long-term growth rate. A second identifying assumption is that trend should account for as much of the variation in the data as possible, minimizing the amplitude of the implied cycle. This is achieved by least squares regression of \( y_t \) on time and the estimated trend is \( \hat{\tau}_t = a + b \text{time} \) where \( a \) and \( b \) are estimates of intercept and slope respectively. The implied cycle component is then \( \hat{c}_t = Y_t - \hat{\tau}_t \). Though successful in accounting for a large fraction of the change in GDP over long periods, this approach implies cycles of extraordinary length, well beyond the roughly seven years between recession dates identified by the National Bureau of Economic Research for the United States, and the pattern is contrary to economic intuition (for the United States the 1970s, a decade of poor economic performance, were well above the trend line while the 1990s, a decade of prosperity, were well below trend). A more flexible trend function is clearly called for, but quadratic or higher-order polynomials in time imply unstable paths when extrapolated into the future. Perron (1989) suggested a segmented trend function allowing for an occasional change level or slope to be captured by dummy variables.

A general approach to estimating a flexible and adaptive trend is filtering, where estimated trend is a weighted average of adjacent observations. Here it is the weighting scheme which identifies the components. For example, \( \hat{\tau}_t = .25 \cdot Y_{t-1} + .50 \cdot Y_t + .25 \cdot Y_{t+1} \) applies symmetric though unequal weights to the current observations and its immediate neighbours. No filter is perfect in the sense of revealing the actual trend, but a desirable filter is one that extracts as much of the trend as possible from the data. A criterion for choosing a filter would be that it produces cycles having characteristics that match our notions of the business cycle, for example that recessions occur on average about every seven years. A widely used filter that does this is the Hodrick and Prescott (1980), filter which penalizes deviations from trend and changes in trend through a loss function.

The distinction between trend and cycle implies that the forecast of GDP far in the future must be the trend, since the cycle will die away. The approach to trend/cycle decomposition proposed by Beveridge and Nelson (1981) turns this conclusion on its head by proposing that the trend at a date in time be defined as the forecast of the distant future (adjusted for average growth). Specifically, they estimate an autoregressive moving average (ARMA) time series model for the growth rate and compute the forecast of the level into the distant future, adjusting for average growth. The resulting measure of trend shows whether actual GDP is above or below its forecast growth path, the difference being the cycle. Since
parameters of the ARMA model are identified, and computation of forecasts is straightforward, the Beveridge–Nelson decomposition is identified. It turns out that the trend component is a random walk with drift regardless of the specific ARMA model, and this accords with the intuition that only unexpected shocks can affect a long horizon forecast.

To obtain the general expressions for the components we rearrange the ARMA model as:

\[ \varphi(L) \Delta y_t = \theta(L) \varepsilon_t \]

\[ \Delta y_t = \psi(L) \varepsilon_t \]

where the average growth rate has been suppressed, the statistical shock \( \varepsilon_t \) is serially random, \( \Delta \) denoted first difference, and \( L \) is the lag operator, and \( \psi(L) = \theta(L)/\phi(L) \). The growth rate of GDP can be thought of as a weighted history of all past shocks where the coefficient of \( \varepsilon_{t-k} \) is \( \psi_k \) plus the expected average growth rate \( \mu \). It may be shown that an algebraically equivalent expression is

\[ y_t = \psi(1) \sum_{k=0}^{\infty} \varepsilon_{t-k} - \tilde{\psi}(L) \varepsilon_t \psi_k = \sum_{j=k+1}^{\infty} \psi_j. \]

Note that the first term is the sum of all past shocks each with weight equal to the total effect of all past shocks. The second term may be shown to be a stationary time series with mean zero. Thus the trend is always a random walk regardless of the ARMA model.

For example, growth in US GDP is roughly an AR(1) process with coefficient .25, so the effect of a shock on the trend is \( \psi(1) = 1/(1-.25) = 1.33 \). This illustrates the surprising implication that the trend component may be highly variable; indeed, the results obtained by Beveridge and Nelson imply that variation in observed GDP is largely the result of variation in the trend component and is therefore permanent.

Unobserved components models identify trend and cycle by specifying a separate and specific stochastic process for each. The trend is generally assumed to be a random walk with drift, allowing it to account for long-term growth while permitting it to be shifted by stochastic shocks. The cycle is assumed to be a process that is stationary in the sense of reverting to a mean over time. (The mean of the cycle is zero for symmetric variation around trend, but evidence exits for asymmetric cycles with a negative mean.) This approach was introduced to economics by Harvey (1985) and Clark (1987). An example would be the
The parameter $\mu$ is the long-term growth rate, the shock $\eta$ is random and may be positive or negative, the parameter $\phi$ measures the persistence of the cycle, and shocks $\epsilon$ drive the cycle. The two shocks are often assumed to be uncorrelated, which reduces the number of parameters to be estimated by one but may also place an unwarranted restriction on the relation between the two components. More generally the cycle process may have a higher-order ARMA specification. Identification of the parameters depends on whether a specific model implies a sufficient number of estimable parameters in the corresponding ARMA reduced form representation of $\Delta y_t$ (corresponding to identification of simultaneous equation models). Given an identified model and parameter estimates, the estimated trend and cycle may be computed using the Kalman filter.

A useful result is that the random walk trend in the unobserved components model is identified even if its parameters are not identified. Morley, Nelson and Zivot (2003) show that the Beveridge–Nelson trend is always the conditional expectation of the trend component given past data. What identifies the trend is the random walk specification for the trend along with the assumption that the cycle process does not persist indefinitely. Thus, the long-horizon forecast reflects only the trend, and such forecasts can always be computed from the reduced form ARMA model.

Triffin, Robert (1911–1993)

Albert Kervyn

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

European Monetary System; European Payment Union; gold-exchange standard; International Monetary Fund; international reserves; Special Drawing Rights; Triffin Plan; Triffin, R.

Article

Triffin was born in 1911 in the pleasant Belgian village of Flobecq. After a brilliant school career, a scholarship enabled him to study law and economics at the university of Louvain. Another scholarship sent him to Harvard, where he got a thorough grounding in theory with Schumpeter and Leontief. His 1938 dissertation, ‘Monopolistic Competition and General Equilibrium Theory’, earned a Wells Prize and was published in 1940.

After a brief return to Belgium, he was appointed instructor at Harvard, and was soon cut off from Europe by the outbreak of the war. In 1942 he joined the Federal Reserve Board to organize a research section on Latin America. This launched him on his parallel career of advising central banks on reform of monetary and exchange arrangements. He rapidly developed what was to remain a main characteristic of his work in this area: a flair for practical suggestions and an imagination that provided alternatives in case of political objections to the first proposals. His success in a number of Latin American countries led to his appointment in 1946 as head of the exchange control division in the newly-created International Monetary Fund (IMF). Moving to Europe as IMF chief representative, he developed a proposal for the European Clearing Union. Having later transferred to the State Department, he succeeded in negotiating his proposal through OEEC, and became the recognized father of the European Payment Union of 1950.

Triffin left the State Department after a policy disagreement, and went to Yale, where he stayed from 1951 to 1977. There he published his two classic works: Europe and the Money Muddle in 1957; Gold and the Dollar Crisis in 1959 and 1960. The first book reviews the European monetary experience, using an integrated analysis of the money supply and the balance of payments. It proclaims the end of the ‘dollar shortage’ and explains the dilemma of the gold-exchange standard in the absence of an adequate supply of gold: either the key-currency country maintains equilibrium in its balance of
payments, and other countries will experience a shortage of the reserves needed to support an expansion of trade and transactions, with an attendant brake on growth; or the desirable growth of world reserves will be preserved only through persistent increases in the liabilities of the key-currency country, raising increasing doubts about its ability to redeem such liabilities, especially when they begin to exceed the country's dwindling gold reserves. The second book, shorter and less analytic, goes further: it contains a bold prophecy of a dollar glut, bound in time to bring down the gold-exchange standard. The fate experienced by sterling in the interwar years was bound to catch up with the dollar as well.

The second part of the book contained the famous ‘Triffin Plan’ to obviate these dangers: on the one hand, the controlled creation of an international reserve instrument by the IMF; on the other hand, regional monetary arrangements, with emphasis on European integration.

The announced dollar glut did indeed develop over the following years with the predicted consequences; the gold parity rate was first abandoned, then the dollar became inconvertible. The first policy prescription was timidly followed with the creation of Special Drawing Rights, but without the essential element of conversion of dollar balances. Indeed the excessive accumulation of such balances was later denounced by Triffin as the main factor in the inflationary development of the 1970s, and as an unwarranted capital inflow into the USA, which on the contrary should be a leading exporter of capital. The other prescription was more successful, and Triffin moved back to Europe (and the University of Louvain) in order to participate more fully in the emergence and development of the European Monetary System.

He was throughout a most active participant in the debate on money and exchanges. In a continuous stream of studies, papers and memoranda, he pressed forward for advances on the two fronts of international monetary reform and European integration.

His reputation as an analyst and skilled deviser of techniques led to his being called in as a consultant all over the world, on domestic as well as regional monetary issues.

Later in life, Triffin remained a much concerned ‘citizen of the world’ and applied his policy-oriented brand of ‘economics of persuasion’ not only to his particular area of expertise, but also to the issues of development and disarmament.

**Selected works**

As a policy-oriented persuader, Triffin has been a prolific writer. In his attempt to reach a wide public for his ideas, he gives the impression of never having refused a contribution. As a result a complete bibliography would include well over 300 items – many in less accessible publications. The following list is therefore highly selective.

1978c. The international role and fate of the dollar. *Foreign Affairs* 57, 269–86.

Trotsky, Lev Davidovich (1879–1940)

Richard B. Day

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Bukharin, N. I.; collectivization; comparative coefficients; industrialization; planning; socialism; Stalin, J. V.; trade monopoly; trade unions; Trotsky, L. D.

Article

Born in 1879, the son of Jewish farmers living near the Black Sea, Trotsky became an important political figure by the time of the Second Congress of the Russian Social Democratic Party in 1903. Disagreeing with Lenin's centralizing view of party organization, Trotsky either favoured the Mensheviks or attempted to mediate between them and the Bolsheviks until making his peace with Lenin in 1917. In the 1905 Revolution he served as chairman of the St Petersburg Soviet, drawing upon that experience to develop the theory of ‘permanent revolution’ in his book Results and Prospects. In the 1917 Revolution Trotsky ranked second only to Lenin among Bolshevik party leaders. He orchestrated the seizure of power and subsequently organized and led the Red Army in the civil war. During the early 1920s Trotsky's political influence waned, and by the middle of the decade he became the political leader and intellectual mentor of the Left Opposition to Stalin. Defeated by Stalin in the intra-party struggle, in 1929 Trotsky was deported from the Soviet Union. In exile he edited Biulleten’ Oppozitsii (Bulletin of the Opposition) and published numerous other writings critical of Stalinist policy, the most important being The Revolution Betrayed. Unable to answer Trotsky's criticisms on intellectual grounds, in August 1940 Stalin replied in the only way he knew: he had Trotsky assassinated in Mexico, his last place of exile.

In Results and Prospects (first published in 1906), Trotsky predicted that Russian backwardness would guarantee the revolution in permanence. Surrounded by stronger enemies, the Russian state had prevented the nobility from becoming politically independent. The nobility were mere tax collectors, extracting revenue from the peasants in order to promote development; and the bourgeoisie, likewise, were weaker than their Western counterparts, for much of the economy was built with foreign loans, serviced by grain exports. The proletariat, in contrast, enjoyed disproportionate strength. Few in number, Russian workers were concentrated in large factories organized around foreign technology. Trotsky
predicted that the proletariat would overthrow the autocracy, by-passing the bourgeois revolution, but would then confront a counter-revolutionary alliance when it implemented its programme. The counter-revolution would be supported by Germany, Austria and France, who would be anxious to prevent the revolution's spread and to safeguard their investments. When these countries mobilized, however, they would drive their own workers to revolt, thereby making the revolution permanent both domestically and internationally.

Aware of Russia's historical dependence on the world economy, Trotsky characteristically viewed economic issues in an international context. Modern industry, he believed, had become so capital intensive that production could only be profitable through specialization in service of the world market. It was in the nature of socialism to emancipate the productive forces from the fetters of the nation state. A victory of the proletariat in the leading countries would mean ‘a radical restructuring of the very economic foundation in correspondence with a more productive international division of labour, which is alone capable of creating a genuine foundation for a socialist order’ (Trotsky Archives No. T-3148). When the international revolution did not come to Soviet Russia's aid as Trotsky had expected, he continued to insist that industrialization must draw upon the resources of the world market. Opposing Stalin's notion of an isolated socialist state (Socialism in One Country), he argued that ‘a properly regulated growth of export and import with the capitalist countries prepares the elements of the future commodity and product exchange [which will prevail] when the European proletariat assumes power and controls production’ (Trotsky Archives No. T-3034). Soviet Russia's relation to the West would involve a dialectic of cooperation and struggle in which the Soviet state would regulate its ‘dependence’ on capitalism through its monopoly of foreign trade. The alternative, the Stalinist vision of autarky, would mean reliance ‘on the curbed and domesticated productive forces, that is … on the technology of backwardness’ (Trotsky, 1941, p. 53).

Uppermost in Trotsky's mind throughout the 1920s was the need not only to preserve access to foreign technology, but also to reduce domestic prices in order to maintain the trade monopoly. In 1923 he warned the party that ‘Contraband is inevitable if the difference between external and internal prices goes beyond a certain limit … contraband, comrades … undermines and washes away the monopoly’ (Dvenadstatyi s'ezd RKP (b) (1923), p. 372; 12th Congress of the Russian Communist Party (Bolsheviks)). Without this protection for new Soviet industries, planned growth would be impossible. For the promotion of new industrial construction, Trotsky proposed to supplement domestic tax revenues by taking advantage of Europe's need for foreign markets and by pursuing all manner of credits:

> What does foreign credit do for our economic development? Capitalism makes advances to us against our savings which do not yet exist … As a result, the foundations of our development are extended … The dialectics of historical development have resulted in capitalism becoming for a time the creditor of socialism. Well, has not capitalism been nourished at the breasts of feudalism? History has honoured the debt. (Pravda, 20 September 1925)

In addition to making use of foreign credits, Trotsky hoped to resume the tsarist pattern of exporting grain in exchange for finished goods. In 1925 he predicted that the Soviet economy would be unable to satisfy more than a fraction of its need for new equipment:
We must not … forget for a moment the great mutual dependence which existed between
the economies of tsarist Russia and world capital. We must just bring to mind the fact that
nearly two-thirds of the technical equipment in our works and factories used to be
imported from abroad. This dependence has hardly decreased in our own time, which
means that it will scarcely be economically profitable for us in the next few years to
produce at home the machinery we require, at any rate, more than two-fifths of the
quantity, or at best more than half of it. (*Pravda*, 20 September 1925)

Trotsky hoped to reconcile a high level of foreign trade with socialist protectionism through strict
determination of priorities. Soviet industries should economize on scarce capital, specialize in those
products in greatest demand, standardize output and reduce costs, while leaving the remaining needs to
be met by low-cost imports. A system of comparative coefficients should be devised by the planners,
comparing the cost and quality of Soviet products with foreign competition. A poor coefficient would
then signal the advisability of imports in the short run and of re-equipment in the long run, as new
resources became available. ‘A comparative coefficient is the same for us as a pressure gauge for a
mechanic on a locomotive. The pressure of foreign production is for us the basic factor of our economic
existence. If our relation to this production is [unsatisfactory], then foreign production will sooner or
later pierce the trade monopoly’ (*Ekonomicheskaia Zhizn’*, 18 August 1925).

In spite of his balanced approach to industrialization, official Soviet historiography insists that Trotsky
was a ‘super-industrializer’, determined to plunder the peasantry. In reality he attempted more
systematically than any of his contemporaries to avert the crisis of forced industrialization by balancing
the needs of the peasantry against those of industry through a policy of ‘commodity intervention’. To the
extent that export-oriented growth clearly depended upon the peasants bringing grain to market, Trotsky
was quite aware that the most urgent consumer needs would also have to be satisfied through imports.
The world market was to function as a ‘reserve’ for both light and heavy industry. The ‘goods famine’,
or the chronic shortage of consumer goods, was ‘obvious and incontestable proof that the distribution of
national economic resources between state industry and the rest of the economy has … acquired the
necessary proportionality’ (Trotsky Archives No. T-2983). The real enemies of the peasantry, in
Trotsky's view, were the authors of Socialism in One Country – Stalin, who saw only the needs of the
machine-building industries, and Bukharin, who urged the peasant to ‘enrich’ himself without seriously
considering the need to provide consumer goods upon which these savings might be spent.

It was Trotsky's concern for the legitimate needs of workers and peasants alike which led him in the
1930s to reconsider the role of market forces, for a time at least, in socialist planning. As early as 1925
he had warned that it was ‘impossible to push industrialization forward with the aid of unreal
credits’ (Trotsky, 1955, p. 186). During the first five-year plan he called for restraints upon the
inflationary financing of heavy industry and ‘strict financial discipline’, even at the expense of closing
down enterprises. A stable currency, in turn, would provide an instrument whereby the masses
themselves could democratically control production decisions from below. ‘The innumerable living
participants in the economy’, Trotsky wrote in 1932,

state and private, collective and individual, must announce their needs and their respective
intensities not only through the statistical calculations of the planning commissions, but
also by the direct pressure of supply and demand. The plan … [must be] verified, and in an important measure must be achieved through the market. (Biulleten’ Oppozitsii 31 (1932), p. 8)

A planned market, free trade unions, and restoration of Soviet democracy: these were the three elements without which any talk of socialism was a mockery.

If there existed the universal mind described in the scientific fantasy of Laplace – a mind which might simultaneously register all the processes of nature and society, measure the dynamic of their movement and forecast the results of their interactions – then, of course, such a mind could a priori draw up a faultless and exhaustive economic plan, beginning with the number of hectares of wheat and ending with buttons on a waistcoat. True, it often appears to the bureaucracy that it possesses just such a mind: and that is why it so easily emancipates itself from control by the market and by soviet democracy. The reality is that the bureaucracy is cruelly mistaken in its appraisal of its own spiritual resources. (Biulleten’ Oppozitsii 31 (1932), p. 8)

In The Revolution Betrayed (1937), his most thorough critique of Stalinist ‘planomania’, Trotsky concluded that the real basis of bureaucratic power had nothing to do with Stalin's pompous claims of industrial triumphs; the horrible truth was that the whole bureaucratic edifice had come to rest upon nothing more profound or despicable than an ability to manufacture poverty. Queues were the foundation of Soviet power and the innermost secret of the police state:

> The basis of bureaucratic rule is the poverty of society in objects of consumption. When there are enough goods in a store, the purchasers can come whenever they want to. When there are few goods, the purchasers are compelled to stand in line. When the lines are very long, it is necessary to appoint a policeman to keep order. Such is the starting point of the Soviet bureaucracy. It ‘knows’ who is to get something and who has to wait. (Trotsky, 1937, p. 112)

Historians will continue to debate whether Trotsky's policies might have avoided forced collectivization and the excesses of Stalin's five-year plans. On one point, however, there can be no dispute: Trotsky was perfectly correct to conclude that Stalin's pursuit of autarky had more in common with the ideals of Hitler than with those of Marx. The Russian revolution, confined to a single backward country, did not lead to the emancipation of the proletariat. Trotsky attempted to reinterpret and apply Marxism to the unexpected conditions of an isolated revolutionary experiment. He did not win the battle against Stalin. He did, however, help to explain and attempt to avert one of the great tragedies of the 20th century.

trust in experiments

Iris Bohnet
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Trust is the willingness to make oneself vulnerable to another person's actions, based on beliefs about that person's trustworthiness. This article focuses on interpersonal trust and trustworthiness between two people, a trustor and a trustee, as measured in laboratory experiments. A trustee behaves trustworthily if he voluntarily refrains from taking advantage of the trustor's vulnerability. Trust applies to all transactions where the outcome is partly under the control of another person and not fully contractible. The article discusses measurement issues, the motives for and influences on trust and trustworthiness (incentives, repetition and demographic variables) and questions of external validity.

Keywords

cooperation; fairness; folk theorem; investment game; public goods games; reciprocity; repeated games; social preferences; trust; trust in experiments; trust games; ultimatum games

Article

Trust is the willingness to make oneself vulnerable to another person's actions, based on beliefs about that person's trustworthiness.

This article focuses on interpersonal trust between two people, a trustor and a trustee. A trustee behaves trustworthily if he voluntarily refrains from taking advantage of the trustor's vulnerability. Trust applies to all transactions where the outcome is partly under the control of another person and not fully contractible, for example, between employers and employees or patients and doctors. Trust and trustworthiness are typically measured in surveys or laboratory experiments. We shortly discuss some survey evidence but focus on behavioural measures of trust.

Measurement

[Further content regarding measurement methods and findings]
Trust attitudes have typically been measured by the following survey question (for example, used in the General Social Survey and the World Values Survey): ‘Generally speaking, would you say that most people can be trusted, or that you can't be too careful in dealing with people?’ Based on this question, trust has declined dramatically across the world since the 1960s. There are noticeable cross-country differences, with Scandinavians most and Latin Americans least likely to trust others. An empirical literature building on Knack and Keefer (1997) shows that trust attitudes are positively correlated with various measures of a country's economic performance.

Around 1990, two seminal papers started a new wave in the economic research on trust. In 1988, Camerer and Weigelt employed a binary-choice trust game, and in 1995 Berg, Dickhaut and McCabe the ‘investment game’ to study trust. In the binary-choice trust game, the trustor decides between a sure outcome and trust. If she chooses the sure thing, she and her trustee both receive (S, S). If she is willing to trust, both either end up with a moderate payoff exceeding S (M, M), or the trustor receives a lower payoff than if she had not trusted, and the trustee the highest possibly payoff, (L, H). Thus, for the trustor, \( T > S > L \), and for the trustee, \( H > M > S \). In the investment game, a trustor and a trustee are endowed with a certain amount of money, A (in some experiments, only trustors are endowed). The trustor can send any amount, \( X \leq A \), to the trustee. \( X \) is multiplied by \( k > 1 \) by the experimenter. In most experiments, \( k=3 \). Trustees receive \( kX \) and then decide how much of it, \( y \leq A + kX \), to return to their trustor. The final payoffs are \( A - X + Y \) for the trustor and \( A + kX - Y \) for the trustee. \( X \) is commonly referred to as trust and \( Y \), or more precisely, \( Y/X \), measures trustworthiness for \( X \geq 0 \). In both games, the equilibrium prediction based on selfish money-maximization and rationality is zero trustworthiness and zero trust.

The relationship between trust attitudes, as measured in surveys, and trust behaviour, as measured in experiments, is not clear. Some have found that they are related (for example, Fehr and Schmidt, 2002), others that they are not (for example, Glaeser et al., 2000). While the investment game and the binary-choice trust game have turned out to be the most widely used games to study trust experimentally, related games include the ‘gift exchange game’, the ‘moonlighting game,’ and standard public goods games (for a review, see Camerer, 2003).

What motivates trust and trustworthiness?

Trust is based on preferences, namely, the willingness to be vulnerable to someone else, and on expectations, namely, the belief about someone else's trustworthiness. A person's willingness to be vulnerable may be related to her attitudes to risk (for example, Eckel and Wilson, 2004), her social preferences (for example, Cox, 2004), and her willingness to accept the risk of betrayal (Bohnet and Zeckhauser, 2004). Bohnet and Zeckhauser introduced an analytical framework to disentangle the various motives, and show that people dislike making themselves vulnerable to the actions of another person more than to natural circumstances. This suggests betrayal aversion: people care not only about outcomes but also about how outcomes come to be. This finding was supported by neuroscientific evidence (Kosfeld et al. 2005).

The relevance of expectations of trustworthiness for trust has typically been measured by including a question about trustors’ beliefs. While this measure is not perfect, generally the relationship between expectations of trustworthiness and trust is very strong. For example, using a within-subject design with
behavioural controls for risk and social preferences, Ashraf, Bohnet and Piankov (2006) found that expectations of trustworthiness explain most of the variance in trust in an investment game but that social preferences also matter.

Trustworthiness is based on trustees’ social preferences, which may be related either to outcomes (for a survey, see Fehr and Schmidt, 2002) or to what the trustors’ actions reveal about their intentions. In a seminal paper, Rabin (1993) introduced a theoretical model of intention-based preferences, reciprocity, into the literature. A large number of empirical studies suggests the importance of reciprocity in trust interactions (for example, Fehr, Gächter and Kirchsteiger, 1997) although outcome-based social preferences also play an important role for trustworthiness (for example, Cox, 2004; Ashraf, Bohnet and Piankov, 2006).

What influences trust and trustworthiness?

Incentives

According to most models, trustors should be more likely to trust the higher the expected returns are from trusting. Bohnet, Herrmann and Zeckhauser (2006) measured the elasticity of trust and found that trust is responsive both to changes in the likelihood and to the cost of betrayal in Western countries. However, this does not necessarily apply in other parts of the world. For example, in Persian Gulf countries people hardly responded to such changes. Instead, many basically demanded a guarantee of trustworthiness before trusting, suggesting substantial aversion to betrayal. In addition, incentives may also not work as predicted by theory if they not only affect behaviour directly but also exhibit an influence on preferences, thus either fostering or undermining people's willingness to accept vulnerability and be trustworthy voluntarily (Bohnet, Frey and Huck, 2001).

Repetition

Generally, people are more likely to trust and be trustworthy in repeated than in one-shot interactions. Theoretically, this result is expected in a traditional model when interactions are indefinitely repeated (folk theorem) but not in finitely repeated games. In support of the theory, experimental evidence suggests that trust and trustworthiness rates are generally higher in indefinitely than in finitely repeated games but they are also higher in the latter than in one-shot interactions. The equilibrium prediction of no trust and trustworthiness is generally refuted, although trust and trustworthiness rates typically drop substantially as the end of the game draws nearer (for example, Gächter and Falk, 2002).

Demographic variables

Generally, the evidence is not as conclusive as we might expect or wish. While in theory variables such as gender, race or country of origin should be easy to control for, experiments produce different results precisely because of the different sets of control variables and the different subject pools used. The most promising approaches include those identifying overarching frameworks able to account for a variety of
Trust in experiments: The New Palgrave Dictionary of Economics

studies. We discuss three such frameworks here: history of discrimination, societal organization and market integration. Groups that historically have been discriminated against, such as women and minorities, are generally less likely to trust. At the same time, often these groups are more trustworthy (for example, Alesina and LaFerrara 2002; Buchan, Croson and Solnick, 2003; Eckel and Wilson, 2003).

Group-based societal organization based on long-standing relationships and repeated interactions within groups can substantially reduce the social uncertainty involved in trust. It is often referred to as ‘collectivist’ in contrast to the Western ‘individualist’ model of organization, which produces trust through more anonymous, institutional arrangements such as contracts and insurance. Trust in strangers has often been found to be higher in individualist (for example, the United States or Switzerland) than in collectivist countries (for example, Japan or the Persian Gulf countries), although the rather small number of studies and sample sizes does not allow any definite conclusions at this point (for example, Bohnet, Herrmann and Zeckhauser, 2006; but see also Croson and Buchan, 1999).

The degree of market integration is related to norms of cooperation and fairness in public goods and ultimatum games. Similarly, the norms of reciprocity typically found in trust experiments in developed countries seem to apply more strongly in societies in which goods and services are exchanged in the market rather than in informal reciprocal-exchange arrangements. Greig and Bohnet's survey of the evidence (2006) suggested that the positive relationship between trust and trustworthiness, normally taken to indicate reciprocity, is more pronounced in developed than in developing countries.

**External validity**

Experiments allow for maximum internal control. Concerns typically arising in field settings such as lack of randomization, selection and endogeneity can easily be addressed by experimental design. To address concerns about the subject pools experimentalists typically use, that is, North American or European students, experiments are now run with representative samples (for example, Fehr et al., 2002 in Germany) and with student and non-student subjects in other parts of the world (for example, Cardenas and Carpenter, 2005, for a survey). To directly test the external validity of trust experiments, Karlan (2005) ran investment games with members of a group lending association in Peru, and compared trustworthiness in the experiment with repayment rates. The more trustworthy subjects indeed were significantly more likely to repay their loans a year later.

Tsuru, Shigeto (1912–2006)

Tsuneo Nakauchi

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

business cycles; Japan, economics in; Marxian methodology; Tsuru, S.

Article

Tsuru was born on 6 March 1912 in Oita and brought up in Nagoya. Political disapproval of his involvement in a socialist study group led to his leaving Japan for the United States in 1913. After receiving a Ph.D. at Harvard in 1940, he taught there briefly as a lecturer. During that period, he married Masako Wada, the niece of Marquis Koichi Kido. They left the United States for Japan in 1942 on board a ship exchanging citizens during wartime.

During the reconstruction of Japan after the Second World War, he served first in the Ministry of Foreign Affairs and later as the vice minister of the Economic Stabilization Board, where he took part in the preparation of the first issue of the Board's Economic White Paper. In 1948, he was appointed Professor of Economics at Hitotsubashi University, where he later served for nine years as the director of the Institute of Economic Research and for three years as president of the university from 1972 until retirement. After retirement, he served as an adviser to the Asahi newspaper. He then assumed a professorship at Meijigakuin University.

Tsuru's analytical works in economics are based on his wide background in the area of both Marxian and modern economics. His principal studies have been incorporated in the Collected Works of Shigeto Tsuru (1976). These constitute 13 volumes, and the last one, in English, is entitled Towards a New Political Economy.

The main areas of the author's interests which developed from his Harvard days encompassed Marxian methodology, business cycle theories and their application to Japan's economic development. A continuing emphasis in the studies was on aspects of the development of capitalism in Japan. His book Has Capitalism Changed? (1961) reflects this particular interest.

Tsuru was one of the first economists in Japan to have drawn the attention of the general public to environmental problems by applying his unusual skills in putting academic concepts into the language of ordinary people.

Tucker, Josiah (1713–1799)

G. Shelton

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
free trade; Hume, D.; self-interest; Tucker, J.

Article

Born in Laugharne, Carmarthenshire, Tucker was Dean of Gloucester from 1758 until his death, and was also a rector in Bristol for over 50 years. Although his career as an ecclesiastic was a long and honourable one, he was best known in his own day for his active part in many contemporary controversies. Whether the subject was the naturalization of foreign Protestants and Jews, the undesirable effect of low-priced liquors, or the cruel custom of cock-throwing on Shrove Tuesday, his pen was always ready. He was responsible for the earliest study of the Methodist movement and the first substantial critique of Locke's political philosophy. The themes which recurred most often were his opposition to monopolies and his hatred of war. His interest in political affairs was not confined to the press: he participated in several Bristol elections as the local Whig agent.

Tucker's period of greatest notoriety came during the American Revolution. In a steady stream of publications he rejected both the conciliation policy of Burke and that of war. Although he had no sympathy for the ideas espoused by the more radical Americans and their supporters in Britain, he saw no economic reason for attempting to retain the colonies by force, since he was convinced that they would willingly trade with her as long as it was in their interest to do so.

In his *Essay on Trade* (1749) Tucker recognized the need for a scientific study of what is now called economics but only the first part of what to be his ‘great work’ on the subject was ever printed, and then only for circulation among friends. However, his other works, which contained the bulk of his ideas, were known to Quesnay and Turgot (who translated one of them) well before the Physiocrats’ first writings appeared, and several of his books were to be found in Adam Smith's library. These ideas included: self-love as a socially useful drive, labour as the true source of wealth, and the importance of machinery as a means of increasing that wealth. His aim was to encourage high productivity which would lead, in turn, to lower prices, increased demand, and more jobs. Anything which obstructed the free circulation of labour and capital, especially regulations supporting vested interests, should be
eliminated. On the other hand, Tucker did not expect that self-interest and the public good would always coincide; some legislation was necessary to encourage that happy outcome by making what was socially desirable also profitable.

Tucker's most significant contribution may have been his argument against the notion put forward by David Hume that rich countries were likely over time to lose their wealth to poorer ones. Tucker eventually convinced Hume that the factors which made a nation rich in the first place tended to give it a practically insurmountable advantage over its less wealthy neighbours. Since Britain enjoyed such an advantage, once Tucker's reasoning was accepted, as it was by Pitt in the 1780s, opposition to free trade could be disarmed and the way cleared for its triumph in the 19th century.

Of mixed Ukrainian-Tartar origin, Tugan-Baranovsky was born in the Kharkov province, and graduated from Kharkov university in 1888. His Magister dissertation for Moscow University was on industrial cycles in Great Britain, and he spent six months of his research time in London in 1892. There could scarcely have been a more masterly master's thesis. It was published in 1894. While criticizing crude underconsumptionist theories, and pointing out that ‘the process of production creates its own market’, especially for producers’ goods, he went on to stress that the simple model derived from J.-B. Say assumes that ‘that entrepreneur, before beginning production, has a wholly correct and accurate knowledge of the requirements of the market and of the output of every branch of industry’. He cited Moffat's phrase ‘the continuous struggle between the requirements of unknown demand and the fluctuations of unknown supply’. He contrasted the ‘propensity to save’ with the output of capital goods of various types, and with the opportunities to invest, which can and do get out of line with one another. He collected much empirical data. In the words of Alvin Hansen, ‘he began a new way of thinking about the problem’ of business cycles.

His doctoral dissertation was another masterpiece, full of original research, The Russian Factory, Past and Present (Russkaya fabrika v proshlom i nastoyashchem) (1898), which has appeared in English translation. This was a major contribution to economic history. In vivid and well-written pages, Tugan-Baranovsky shows the great importance of the state and of serfdom, and the subsequent growth of market-orientated industries based on free labour (though some workers were serfs on quit-rent, a few of whom became serf millionaires). He also made stimulating observations concerning ‘natural’ and ‘artificial’ industrialization, relevant to today's concerns with economic development.

His major contribution to economic theory was Osnovy politicheskoi ekonomii (1917), which went through many editions, and represented an attempt at a synthesis between Marxist political economy (the
labour theory of value) and subjective value theory. He considered that the marginalists ignored ‘the objective conditions of production’, while Marxists failed to recognize that not only objective factors but also subjective valuations were an integral part of a theory of value. He argued that Marx confused value (Wert) with cost (Kosten). He basically supported Marx's theory of exploitation, but defined ‘surplus value’ as equal to the value of the products acquired (consumed) by the capitalists, which earned him criticism from Kondratiev and Struve. He retained from his early Marxism the belief that economists should regard man as not just another factor of production. If horses could write economics, there would be a horse theory of value.

Tugan-Baranovsky to the end of his life retained a particular interest in agriculture and in (voluntary) cooperation. One of his last articles drew attention, prophetically, to the effect of the egalitarian land redistribution of 1917–18 on the marketing of foodstuffs.

His academic career was mainly in the University of St Petersburg, though he was dismissed in 1899 for ‘political unreliability’ and only reinstated in 1905, as a privatdozent. His election to the chair of political economy in 1913 was vetoed by the Minister of Education. Re-elected in 1917, he did not take up his appointment, but returned to his native Ukraine. He became Academician, dean of the Faculty of Law of Kiev, chairman of the Ukrainian cooperatives, president of the Ukrainian economic association, and for a short period Minister of Finance, amid turmoil and civil war. He died in 1919, on his way to Odessa to board a ship for France. He must be seen as the most original of the Russian economists of his generation. Alas, in the Soviet Union he was known chiefly as a ‘legal-marxist’ opponent of Lenin, and few had the opportunity to study his works, though The Russian Factory was reprinted.

tulipmania

Peter Garber
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This curious speculation in tulip bulbs near four centuries ago has become a modern synonym for and warning about the irrational speculation that may break out in any asset market. Nevertheless, a look at the forces that actually drove it provides an alternative, fundamental explanation and a warning to observers of asset markets not to accept so quickly unprovable psychological explanations of asset prices.

Keywords

asset pricing; bubbles; East India Company; forward contracts; multiple equilibria; Mississippi Bubble; South Sea Bubble; speculative bubbles; tulipmania

Article

The Netherlands of 1634–7 was the scene of a curious speculation in tulip bulbs that has come to be known as the Dutch tulipmania. Single bulbs of rare and prized varieties such as Semper Augustus or Viceroy became worth a middle-sized fortune. In its most extreme final phase in January-February 1637, prices of even common varieties such as Switsers or Witte Kroone soared twentyfold within a month and then crashed back to their original values. That these were prices of easily reproducible horticultural products has added to the bemusement of generations of historians and economists.

In the succeeding 370 years, the historical tulipmania became, in itself, an obscure footnote to the conceptual tulipmania of economics and finance, a word warning of the obvious, delusional speculative excess that human behaviour in financial markets can create (see, for example, Kindleberger, 1996). It is interchangeable with words like ‘bubble’ or ‘mania’, which also arose from historically distant events such as the Mississippi or South Sea Bubbles or the more recent ‘irrational exuberance’. These words have been used by economic theorists to emphasize an historical basis for the salience of unstable multiple equilibria in forward-looking financial and macroeconomic theories. They have also been used
to justify ignoring financial market outcomes that contradict favoured asset pricing theories by means of an arbitrary invocation of the existence of a bubble.

The traditional image of tulipmania

Modern references to the tulipmania usually depend on the brief description in Charles Mackay's *Extraordinary Popular Delusions and the Madness of Crowds* (1852). The tulip originated in Turkey and spread into western Europe in the mid-16th century. The tulip was immediately accepted by the wealthy as a beautiful and rare flower, appropriate for the most stylish gardens. The market was for durable bulbs, not flowers. The Dutch dominated the market for tulips, initiating the development of methods to create new flower varieties. The bulbs that commanded high prices produced unique, beautifully patterned flowers; common tulips were sold at much lower prices.

Beginning in 1634, non-professionals entered the tulip trade in large numbers. According to Mackay, individual bulb prices reached astronomic levels. For example, a single Semper Augustus bulb was sold at the height of the speculation for 5,500 guilders, a weight of gold equal to $66,000 evaluated at $600/oz. Mackay provided neither the sources of these bulb prices nor the dates on which they were observed, however.

Finally, and unexplained by Mackay, the frenzy suddenly terminated. According to Mackay, even rare bulbs could find no buyers at ten per cent of their previous prices, creating long-term economic distress. Mackay presented no evidence of immediate post-collapse transaction prices of the rare bulbs. Instead, he cited prices from bulb sales of 60 years, 130 years, or 200 years later as indicators of the magnitude of the collapse and of the obvious misalignment of prices at the peak of the speculation. Moreover, Mackay provided no evidence of the general economic context from which the speculation emerged.

The fundamentals of the tulipmania

Unfortunately, the fundamentals of markets in rare bulbs present a much more prosaic picture. The bulk of the speculation concerned highly prized tulips that were infected with mosaic virus. Mosaic virus had the effect of producing unique feathery patterns in the flower that could be reproduced only through propagation by budding, not by seeds. Hence, the rate of reproduction was much more limited that one might expect. Such bulbs were traded primarily among professionals. Their prices were supported by a strong demand by flower fanciers, not only in the rapidly growing Netherlands of the golden age but also by the wealthy nobility and merchants of surrounding countries. During the period of the tulipmania, 1634–7, the already high prices of such bulbs doubled or tripled. Over the course of decades or centuries, prices for these varieties converged to the low cost of reproduction, and this has been taken as evidence of folly.

However, an examination of the pricing of prized flower varieties throughout history reveals a similar pattern: prices of the prototype are very high, perhaps even representing a medium fortune. Then, as they are reproduced through succeeding generations, they become common. Just as for the value of a prized racehorse put out to stud, the high initial price represents the present discounted value of the valuation above cost of successive, expanding generations, wherein the value of any individual exemplar is bound to fall.
The more frenzied phase of the tulipmania described by Mackay took place from mid-1636 to February 1637, but especially in January, 1637. At this time trading, especially among the non-professionals, took place in newly organized ‘colleges’, which were located in taverns. The trading was not for actual bulbs but for contracts for forward delivery. Since bulbs had to remain in the ground through the winter, none were actually delivered on these contracts before the speculation ended. Contracts were not marked to market, and margin was not posted. A small, fixed amount of ‘wine money’ had to be delivered by the buyer, which provides the flavour of, if not the fuel for, what was happening during the frenzied trading in these taverns.

When this part of the speculation collapsed in February 1637, some city governments proposed winding up outstanding contracts with a ten per cent payment on contracted amounts if the buyer refused to accept delivery. Perhaps this is where Mackay got the notion that bulbs could not be sold at ten per cent of their previous value, even though a buyer might refuse the deal if prices had fallen only to 90 per cent of the contracted amount. There were very few takers even on this offer, but short sales were in any case unenforceable contracts under Dutch law.

When one looks at notarized contracts for actual bulbs, however, the picture is quite different. Some rare bulbs that were auctioned for high prices at the very peak of the speculation in February 1637 still sold for high, albeit much lower, prices in 1642. For example, an Admiraal Liefkens bulb was sold for 1,345 guilders at the peak and for 220 guilders in 1642, an annual percentage decline in value of 36 per cent. This rate of decline is comparable to the typical pattern of price behaviour for valued varieties in successive historical periods and does not indicate anything unusual in the mania. It is the rare bulb price behaviour during the tulipmania that has been emphasized historically. But at the very end common bulbs sold in bulk shot up twentyfold and soon collapsed back to one-twentieth of the peak. It is this usually ignored bit of the episode that remains a puzzle.

An historical background

The tulip market was introduced into the Netherlands during the Eighty Years’ War of independence between the Dutch and the Spanish, and the tulipmania occurred in the middle of the Thirty Years’ War as the two conflicts merged. The Spanish were thwarted in their attempts to subjugate the Netherlands, which consolidated its territory and eventually seized control of most of international shipping. The Thirty Years’ War of 1618–48 was particularly destructive of the populations and economies of central Europe, with many principalities in the Holy Roman Empire losing one-third of their populations. In every year of the war, the Dutch fielded large armies and supported large fleets, though the population of the Netherlands was no more than 1.5 million. The Dutch provided much of the strategic planning and finance for the Protestant effort, along with France, negotiating and financing the successive interventions of Denmark and Sweden on the Protestant side in the 1620s and 1630s.

From 1620 to 1645, the Dutch established near-monopolies on European trade with the East Indies and Japan, conquered most of Brazil, took possession of the Dutch Caribbean islands, and founded New York. In 1635 the Dutch formed a military alliance with Richelieu’s France, which eventually placed the Spanish Netherlands in a precarious position. In 1639 the Dutch completely destroyed a second Spanish Armada of a size comparable to that of 1588. As a result of the war, Spain ceased to be the dominant power in Europe, and the Netherlands, though small in population and resources, temporarily became a major power centre because of its complete control over international trade and international finance.
The Dutch were to 17th-century trade and finance as the British were to 19th-century trade and finance. Sophisticated finance mechanisms evolved with the establishment of its trade and finance dominance. Amsterdam became the leading market for short- and long-term credit; and markets in stocks, commodity futures, and options materialized early in the 17th century. Trading of national loans of many countries centred on Amsterdam, as did a market in the shares of joint stock companies. The East India Company, founded in 1602, gradually gained control over east Asian trade and consistently paid out large dividends. Interest rates on Dutch markets were remarkably low for the times; for example, the East India Company paid no more than five per cent on advances during the 17th century.

There were some dark periods during this golden age, and it should be carefully noted that these occurred during the years of the tulipmania. From 1635 to 1637, bubonic plague ravaged the Netherlands. In July 1634 the Holy Roman Empire completely defeated Swedish forces in the Battle of Nordlingen, forcing a treaty on the German Protestant principalities in the May 1635 Peace of Prague and releasing Spanish resources for the war against the Dutch. Along with the growing war weariness in the Netherlands, these events forced France to enter the Thirty Years’ War militarily with the Dutch alliance in 1635. Initially unprepared, the French suffered major setbacks, culminating in an imperial invasion of northern France in August 1636.

How should we interpret the tulipmania?

The tulipmania is an obscure event from distant history that provides a cornucopia of concepts even now. One can take one's pick from the following views, depending on personal taste:

- It was an outburst of speculative fever that serves to the present day as a warning of the dangers of market speculation.
- It was a curious event limited to the Dutch winter of 1636–7 in the middle of an outbreak of bubonic plague and at the time of the greatest success of the Catholic armies of the Empire in the Thirty Years War against the Protestants.
- It was a drinking game in which people without wealth made the equivalent of million euro bets with each other, with no intention or possibility of paying.
- It was a swing of fashion in the most wealthy society of the era, which caused the most exquisite of tulips to have a higher price than Rembrandt's Night Watch.
- It was a reasonable and well-calculated investment that still causes the most wonderful outburst of colour every Dutch springtime.

**How to cite this article**

Economist, philosopher and administrator, Turgot was born in Paris, in 1727, the third son of a well-established Norman family with a long tradition of public service in the magistrature. Destined originally for a career in the Church, his education was extensive. Because of shyness, his education commenced at home with a private tutor; it continued at the Collèges Duplessis and Bourgogne where, among other things, he studied the philosophical systems of Newton and Locke. In October 1746 he entered the Seminary of Saint-Sulpice in preparation for the priesthood. From June 1749 to early 1751 he was resident student at the Maison de Sorbonne, an annex of the theological faculty of the University of Paris. His already considerable academic distinction led to his election to the office of prior in 1750. This honorary position inspired two of his earliest works, of which the second, *Philosophical Review of the Successive Advances of the Human Mind* (Turgot, 1750a) contained a demonstration of the importance of economic surplus for the development of civilization as part of his four stages theory of human progress:

Tillage … is able to feed more men than are employed in it … Hence towns, trade, the useful arts and accomplishments, the division of occupations, the differences in education, and the increased inequality in the conditions of life. Hence leisure … (and) the cultivation of the arts. (Turgot, 1750a, p. 43)
His father's death in early 1751 possibly saved Turgot from having to take his final vows, since his
inheritance provided sufficient income to commence the administrative career he desired. He gained
appointment to some judicial positions, including that of Master of Requests in early 1753, the stepping
stone to a career as provincial intendant. During the 1750s, Turgot's prolonged residence in Paris
allowed immense intellectual activity but left time for extensive travels through France when
accompanying Gournay on his official tours of inspection of French industry. His contributions to the
*Encyclopédie* (Turgot, 1756; 1757a; 1757b), ranging from articles on Etymology, Existence and
Expansibility to Fairs and Foundations, spread his fame as a philosopher and gained him the friendship
of Voltaire, whom he visited in 1760 during his only journey abroad.

Although Turgot's interest in economics had commenced as early as 1749 when he wrote a critique of
Law's system of paper currency, and such interest was maintained in the Sorbonne orations and other
early writings, it was considerably stimulated by Gournay's friendship. Gournay's death inspired Turgot's
famous eulogy (Turgot, 1759) and earlier he had encouraged Turgot's translation of Tucker (Turgot,
1755), Turgot's comments on Gournay's notes to the translations of Child (Turgot, 1753–4), and most
probably, aspects of the content of Turgot's two economic articles for the *Encyclopédie* (1757a; 1757b).
Gournay's friendship was particularly important because it brought Turgot's economics under more
substantial English influence as compared with Physiocracy (Groenewegen, 1977, p. xiv). Turgot's first
meeting with Quesnay cannot be precisely dated. It may not have occurred till 1756 or 1757 when their
mutual association with the *Encyclopédie* may have brought them together. Turgot (1759, p. 26) cites
Quesnay's contributions with considerable approval, indicating that his generally good relations with the
Physiocrats must by then have been well established. His presence at Quesnay's meeting in the Entresol
at Versailles as a ‘handsome young Master of Requests’ was in any case recorded by Mme de Hausset (n.
d., pp. 117–19). A lifelong friendship with Du Pont de Nemours, which began in 1763, must have
strengthened good relations with the Physiocrats even further. Another enduring friendship was made
with the philosopher and mathematician, Condorcet. Both friends produced memoirs of Turgot's life
after his death (Du Pont, 1782; Condorcet, 1786).

In 1761 Turgot was appointed Intendant of Limoges, a large district containing most of the provinces
of Limousin and Angoumois, and this position he filled with distinction for 13 years. The task of the 18th-
century intendant, a post compared by Morley (1886, p. 112) to that of Chief Commissioner in a large
district of the former British Empire in India, were many:

> He had to collect direct taxation, rectify justice, promote the arts of agriculture, encourage
industry and commerce … Everything came within the scope – sanitation and public
order, morality and poor relief, the recruiting and billeting of soldiers, military equipment,
ration and transport, religious processions and the pairs of churches, colleges and
libraries, parochial and municipal finance. (Dakin, 1939, pp. 27–8, the standard source for
details of Turgot's administrative career as intendant)

Despite this cumbersome and heavy administrative load, Turgot managed to introduce some reforms.
These included changes to the assessment and collection of the taille, transmutation of the *corvée* and
the *milice* into money payments, and establishing public workshops to alleviate hardships suffered by
the population of his province during the long and severe famine of 1769 to 1772. Many of his better
known economic writings date from this period: first of all, his *Reflections on the Production and Distribution of Wealth* (Turgot, 1766a, but not published till 1769–70 in serial form in the *Ephémérides*), a draft for a paper on value and money (Turgot, 1769), observations on two winning entries in a prize competition he had organized on the subject of taxation (Turgot, 1767a; 1767b), and a series of memoranda connected with the ministration of his province in which he pleaded with the central authorities for reforms on the basis of carefully elucidated theoretical principles. The more important of these deal with taxation in general (Turgot, 1763), mines and quarries (Turgot, 1767a), the grain trade (Turgot, 1770a), the rate of interest (Turgot, 1770b) and the trade mark on iron products (Turgot, 1773). His administrative work permitted regular but infrequent visits to Paris to see friends and attend the salons of Mme de Graffigny, Mme de Geoffrin and later, Mlle de Lespinasse. Apart from the French intelligentsia, he there became acquainted with foreign notables like Hume, Adam Smith, Franklin and Gibbon. The exile imposed by his administrative position also inspired a substantial correspondence with Du Pont de Nemours, Condorcet, and his personal secretary, Caillard, making up a large part of the five volume edition of his works as edited by Schelle (1913–23). Schumpeter (1954, p. 248) notes a further significant aspect about Turgot's administrative career: ‘nearly all his creative work must have been done between 18 and 34 because during the 13 years at Limoges, Turgot can have had but scanty leisure, during his nearly 2 years of ministerial office, practically none.’

Louis XVI's succession to the throne in 1774 marks the next stage in Turgot's career; his membership of the Royal Council, first as Minister of the Navy (from 20 July 1774), then as Minister of Finance (from 24 August 1774 to 12 May 1776, the date of his dismissal). While lamenting the fact that so much more could have been done, Du Pont de Nemours (1782) summarized Turgot's career as minister in terms of the reforms accomplished. These included restoration of the domestic free trade in grain, abolition of many small, local duties and other constraints on trade, and the January 1776 measures, of which partial suppression of the guilds and replacing the *corvée* with a more general land tax were the more controversial measures. These last, now generally known as the six Edicts, ultimately caused his downfall even though he did secure royal support for their forcible registration at a famous *Lit de Justice*. As an ‘experience in economic politics, an exception to the general rule that French ministers of finance are financiers rather than economists’, Faure (1961) gives a detailed account of Turgot's ministerial experience and the opposition it encountered almost from the start during the grain riots of early 1775 and the intrigues surrounding the campaign to prevent registration of his 1776 Edicts. The reforms Turgot had accomplished were reversed within six months from his downfall, and ‘leisure and complete freedom as the principal net product from my two years in the ministry’ was how he himself sarcastically summed up his achievements in a letter to Caillard (Schelle, 1913–23, vol. 5, p. 488). The period of retirement in the five years which remained of his life were not years of inactivity.

The sciences which he had formerly cultivated, easily filled up his time; he studied mathematics, he sought to bring the thermometer to greater precision, he searched with l'Abbé Rochon, after various expeditious convenient, and cheap methods of multiplying copies of writing to supply the place of printing, … he preserved all his passion for literature and poetry … (Condorcet, 1786, pp. 255–62)

In 1778 he was elected President of the Académie des Inscriptions et des Belles Lettres. He died in Paris
in March 1781 from gout, a family illness that had steadily wrecked his health, worsening particularly during the last decade of life.

Although Turgot is now largely remembered as a very important 18th-century French economist and a pre-revolutionary reformist finance minister, such an assessment fails to reflect his youthful ambitions and work. Meek (1973, pp. 1–2) indicates that

Turgot set out from the beginning with the conscious intention of becoming a polymath rather than a specialist …. A list of works to be written … begins with ‘The Barcimedes’, a tragedy, and ends with ‘On Luxury, Political Reflections’, and in between these are forty-eight others, including works on universal history, the origin of languages, love and marriage, political geography, natural theology, morality and economics, as well as numerous translations from foreign languages, literary works, and treatises on scientific subjects … What is (especially) remarkable is … that Turgot managed, during his short life of only fifty-four years, to make some contribution to so many of them, or at least to retain an active and intelligent interest in them.

Turgot was therefore considerably more than an economist, and some of the qualities Meek listed needed to be highlighted to underscore that fact. In the first place, he was a superb linguist, ‘reading seven languages – Greek, Latin, Hebrew, Spanish, German, Italian, and English, the last three of which he spoke fluently’ (Dakin, 1939, pp. 10–11) and from some of which he published poetry translations (Turgot, 1760; 1762; 1778). This linguistic skill is reflected in his magnificent library, the catalogue of which (Tsuda, 1974) demonstrates his ability to profit from the economics writings of other countries. Secondly, his wider interests influence the interpretation to be given to his economics. Turgot's contributions cannot be simply assessed in terms of his importance in fashioning certain parts of the marginalists’ toolbox, as done, for example, by Schumpeter (1954). He is far more correctly depicted as ‘an author of transition between the Physiocrats at the end of the eighteenth century and the English classical economists at the start of the nineteenth’ (Bordes, 1981, p. xvi), that is, the true contemporary of those like Smith, Steuart, Condillac, Verri and Beccaria producing economic treatises building on Physiocracy in that quarter century ending in 1776 during which political economy emerged as the science of the reproduction, circulation and distribution of wealth (see Groenewegen, 1983a). Although, apart from the skeleton form of his Reflections (Turgot, 1766a), Turgot never completed such a treatise, this skeleton combined with his youthful views on social progress allows his economics to be depicted as something essential to the understanding of historical stages (see Finzi, 1981). The reduced emphasis on the economics developed by him as a by-product of his administrative career this implies prevents his depiction as a 19th-century liberal (see Morley, 1886; Bourrinet, 1965) or as a general precursor of equilibrium theory (Nogaro, 1944, pp. 26–7; Bordes, 1981, pp. xxvi–xxviii).

Schelle (1913–23, vol. 1, pp. 29–30, 79) draws attention to the fact that the young Turgot was interested above all in sociology, shown by his attempts at analysing causes of progress and decay in taste, science and the arts, and that this analytical interest was enhanced by studying the formation of languages, because etymology provides valuable clues not only to the progression of ideas but to the needs from which ideas originate. Turgot's early work on language formation and social progress appears to have suggested the importance of economic factors in explaining this process, and that the means by which
peoples gain their subsistence, determining as it does their access to economic surplus, is particularly important to explain the manner in which societies, morals, laws, the arts and the sciences gradually develop. Turgot (1750b, p. 172) explicitly relates certain characteristics in the formation of languages to stages of hunters, shepherds and husbandmen with their different requirements for communication. The notion of progress between these stages is implied in his critique (Turgot, 1751a, pp. 242–3) of the alleged virtues of equality in the savage state where he shows that, by preventing the division of labour and the accumulation of capital on which abundance and secure subsistence depend, such equalities also prevent progress in the sciences and arts. The subsequent fragment On Universal History (Turgot, 1751b) combines these elements into ‘a quite advanced statement of the four stages theory – or at any rate a three stages theory, with a distinct hint of the fourth stage’ (Meek, 1977, p. 22).

Although Turgot's On Universal History was not completed, its basic notions stayed with him for the rest of his life and in a number of aspects received further development. The systematic attempt to explain general progress by stages from hunters, shepherds, farmers to a commercial society to a large extent provides the basis on which Turgot constructed his analysis of the production and distribution of wealth in the Reflections, as is explicitly recognized in his discussion of cattle as a form of moveable wealth (Turgot, 1766a, pp. 66–7). Moreover, the whole of the Reflections is imbued with Turgot's sociological concerns with nature of progress and historical development, thereby reinforcing the need to interpret its contents in terms of stadial development. Such a view is also appropriate for its alleged original purpose as providing explanations to accompany an extensive questionnaire on the Chinese economy and society which he had prepared for two young Chinese students in 1766 (see Groenewegen, 1977, pp. xvii–xix). This aspect of the Reflections may be demonstrated from a summary of its contents, a process facilitated by the parts into which Du Pont divided it for publication in Ephémérides.

Under this subdivision (Turgot, 1766a, pp. 43–56); the first part of the Reflections analyses the basic features of the production and distribution of wealth within an agricultural society. Although capital advances are used in such a society, the distributional aspect of such use is ignored at this stage except for its final sections dealing with what for Turgot were contemporary manifestations of agricultural production (1766a, pp. 56–6). Turgot argues at the outset that such an agricultural society presumes a division of labour, a natural consequence of its inequality of property ownership. Hence it presumes a specific set of class relations, that is, division of society between a proprietors’ class owning land and living from its surplus produce without a need to work, and working classes without property earning their living from their labour. Within this working class, the division of labour divides those cultivating the soil to produce food and raw material or products of prime necessity from artisans who transform those primary materials into forms more suitable for people's use. Because artisans depend on those working in agriculture for their livelihood, Turgot calls them a stipendiary class. Because they only transform existing wealth without generating a surplus, Turgot calls them a sterile class to contrast their work with that in agriculture which produces such a surplus and thereby generates new wealth. In this way Turgot demonstrates the appropriateness of Physiocratic class analysis for understanding agricultural society.

At the end of this discussion Turgot suggests that the relationship between proprietors and the working classes in agriculture is itself subject to change with respect to the manner in which proprietors draw the surplus from the land through the organization of production. The method springing first to mind, landlords hiring wage labour for themselves, Turgot views as an unlikely candidate to be first from the perspective of actual historical development. Slavery appears to have been first in this regard. Though
Turgot saw slavery persisting in colonial societies, elsewhere economic circumstances, combined with humanity and landlord's convenience gradually transformed slavery first into bondage of the soil and then vassalage, where former serfs become tenants and surplus product rent and other stipulated dues. One such tenancy, the dominant form in Turgot's France, was sharecropping or métayage in which the landlord made the advances in return for a fixed part of the produce; another, more advanced form existed where a capitalist farmer, or entrepreneur (Turgot, 1766b, pp. 28–9) rented the land from the proprietor for a specified rent and period of time, himself providing the necessary advances for cultivation. Capitalist farming or la grande culture had begun to emerge in France during Turgot's time, and the farmer/entrepreneur class it created ‘has a quite distinct status from that of the ploughman/sharecropper. He does not earn his living by the sweat of his brow like labourers but by employing his capital in a lucrative manner like the shipowners of Nantes and Bordeaux employ theirs in maritime trade’ (Turgot, 1766b, p. 29). As nations become more wealthy, and capital accumulates, a new proprietors’ class is created who live without working from the revenue of money or capital. The section which opens the second part of the Reflections draws attention to this feature by dealing with ‘capitals in general and the revenue of money’.

Explanations of the origin and use of capital, and its impact on ‘the system of distribution of wealth which I have just outlined’ (Turgot, 1766a, p. 56) requires an elementary acquaintance with the theory of money, commerce, exchange and value and hence some retracing of steps. After this digression, which contains little that is new, Turgot presents a fascinating analysis on both the uses of capital and its origins through accumulation and thrift. Turgot discusses accumulation and thrift both historically and analytically. Historically, accumulation is associated with slavery and surplus product from land: analytically, prudence and a desire for self-improvement are seen as major motives for thrift. Turgot argues that the savings process is greatly facilitated by the introduction of money but that this raises new complications such as a need to distinguish saving, hoarding and investment. Turgot's saving–investment analysis denied the possibility that money savings were able to induce substantial leakages from the circular flow because hoarding was seen as irrational and money had only a limited role as a store of value. Turgot argued that savings were immediately transformed into investment (see Groenewegen, 1971).

Turgot's analysis of the productive use of capital and its social implications is presented in the second and third parts of the Reflections. These reveal the degree to which his economics had departed from Physiocracy and anticipated views subsequently developed by Adam Smith. First of all, Turgot's exposition extends the use of capital to all sectors of industry thereby not confining it to agriculture as Quesnay had done. Secondly, Turgot, like Smith, links an increasing need for capital in production with extensions of the division of labour and a consequent lengthening of the time period of production. Thirdly, Turgot associates the provision of capital to industry with a new class of society, the capitalist/entrepreneur as owners of moveable wealth, who invest these resources to reap a return. Hence the working classes of agriculture, manufacturing and trade ‘may be divided into two orders of men, that of the Entrepreneurs of Capitalists, who make all the advances, and that of the mere wage earning workmen’ (Turgot, 1766a, pp. 72–3). Of special significance for analysing distribution, this new class appropriates the resources by which it can live without labour through the creation of interest and profit as a new income type. Profit in this context, is clearly associated by Turgot with a return on productive investment, comprising an interest component, a premium for risk and remuneration for the time and trouble of the entrepreneur in supervising the investment. Part of the Reflections therefore suggests that
the quantitative changes of gradual capital accumulation (perhaps first experienced within agriculture) by a qualitative leap create a new stage of society, the commercial or capitalist stage (see Meek, 1973, pp. 21–6).

However, this view is partially contradicted in some of the Reflections’ later sections. These reveal the new class as mere lenders of money and show Turgot equivocating on whether interest and profit have the same disposable status as the net product of land. Such aspects of Turgot's work show that for him ‘commercial society’ perhaps remained ‘incorporated into the agricultural state [never becoming] a separate stage, characterised and led by an internal logic of its own’ (Finzi, 1982, p. 116), and reinforce the position that Turgot's analytical schema is a transition from the Physiocrats to subsequent classical political economy retaining that ambiguous relationship between capital and land, rent and interest, not really resolved analytically until Ricardo's distribution analysis (see Cartelier, 1981).

Despite this ambivalence in depicting the final stage of social progress, these sections of the Reflections also contain some of Turgot's most analytically significant contributions to economics. Having shown that ‘capitals are the indispensable foundation of all lucrative enterprises’ and that the continual reproduction of these capitals ‘with a steady profit’ constitutes ‘the true idea of the circulation of money’ the disturbance of which may cause economic decline (1766a, pp. 75–6), Turgot analyses the mutual interrelationship of the returns on various types of investment and the rate of interest. Interest itself is shown by Turgot to be determined by the demand for and supply of loanable funds, the demand arising from both consumption and investment needs. These investment needs, or employments of capital as Turgot calls them, are described as: purchasing a landed estate, which yields least; lending a capital at interest the return of which is greater; and investing in agricultural, manufacturing or commercial enterprises, the return of which is greatest. Irrespective of these inequalities in yield to the various employments of capital, Turgot argues that competition combined with capital mobility causes a tendency to equilibrium between them.

As soon as the profits resulting from an employment of money, whatever it may be, increase or diminish, capitals turn in that direction or withdraw from other employments, or withdraw and turn towards other employments, and this necessarily alters in each of these employments, the relation between the capital and the annual product. (1766a, p. 87)

This investment analysis must be seen as a substantial advance on the earlier literature, and hence as a major contribution to economics.

Turgot's other economic writings can be seem as supplementing the analytical framework of the Reflections. This can be particularly illustrated from his theory of value, the outlines of which had been developed by the early 1750s (Schelle, 1913–23, vol. 1, p. 385). Its foundation rested on a relationship between current (market) price and fundamental value dependent on competition and resources mobility. Subsequently (Turgot, 1767b, p. 120 n.) this proposition is elaborated to demonstrate that the market price of a commodity ‘ruled as it is by supply and demand’ and liable to ‘very sudden fluctuations’ though ‘not in any essential proportion to the fundamental value,… has a tendency to approach it continually, and can never move far away from it permanently’. Turgot therefore developed the classical position which saw ‘natural prices’ as the centres of gravitation for market prices. Elaborations on the elementary theory of wages of the Reflections (1766a, pp. 45–6) are made within this value framework.
Turgot did this in a letter to Hume where on the argument that taxes increase ‘the fundamental price of labour’ or ‘the cost of his subsistence’, a tax on wages must be rapidly absorbed in market wage rates (Schelle, 1913–23, vol. 2, pp. 662–3). The Reflections was confined to brief explanations of the current or market price; the unfinished ‘Value and Money’, with its unsuccessful attempts at determining value in various exchange situations, appears as an elaboration of the underlying competitive theory rather than as a new departure towards a more subjective value theory. Turgot's famous analysis of the ‘law of variable proportions’ (Schumpeter, 1954, pp. 260–1) may also be noted here. This arose in criticism of a common Physiocratic assumption that product was invariably proportional to advances. Turgot (1767b, pp. 111–12) argued instead that as ‘advances are gradually increased up to the point where they yield nothing, each increase would be less and less productive’, thereby clearly recognizing the possibility of diminishing returns.

On the basis of these contributions, Schumpeter (1954, pp. 260–1, 307, 332) argued the Turgot was a writer in advance of his time by anticipating much of what became important after the ‘marginal revolution’. Turgot's analysis of the market mechanism is reminiscent of Böhm-Bawerk and Menger; his ‘interest and capital theory … clearly foreshadowed much of the best thought in the last decades of the nineteenth century’. However, it seems more reasonable to conclude ‘that the resemblance between Turgot's economics and that of post-1870 writers is superficial’ and that both in temperament and thrust his economics is part of the classical tradition (Groenewegen, 1982). His development of the Physiocratic notion of reproduction (Turgot, 1763; 1766a, pp. 75–6) and his emphasis on the principle of competition as regulator of the rate of interest, wages and values in general, are firmly within that ‘classical tradition rehabilitated by Sraffa’ (Ravix and Romani, 1984, p. 145).

Turgot's strong laissez-faire position, which turned him into the patron saint of the French liberal economics tradition of the middle of the 19th century, was most systematically expounded in his eulogy of Gournay (1759). This rested on the principle that unrestrained self-interest yields the best results in economic activity, a principle he applied wherever he could during his administrative career. It justified his pleas (1770b) and subsequent imposition of domestic free trade in grain, his criticism of the prevalent regulation of lending at interest (1770a), and the suppression of the guilds in one of his famous 1776 Edicts. More important is his discussion of taxation principles. Turgot's major paper on the subject (Turgot, 1763), after setting out some general principles, defends the concept of the single tax on net product on the basis of Physiocratic theory. However, he identifies difficulties in its implementation. These need detailed examination if the benefits of the policy are to be achieved. More generally, it can be said of his policy implementation that though based on broad principles, these were in practice always modified to cater for actual circumstances.

Turgot's work and its importance in the history of economics have occasionally been vigorously debated, most notably in the controversies over the degree of influence he exerted on Adam Smith and Böhm-Bawerk's interpretation of his capital and interest theory. An assessment of the evidence (Groenewegen, 1969) suggests that Turgot influenced Smith on only a few fairly specific points and that the broad similarities (and differences) in their economic systems are largely explained by their common heritage of British and French predecessors. The quarrel over Böhm-Bawerk's interpretation of Turgot's interest theory (involving Cassel, Wicksell and Marshall) is more instructive for the light it sheds on the participants than for discovering Turgot's views on the subject. For example, it can be suggested that Böhm-Bawerk's position may have been influenced by his considerable youthful debts to Turgot's theory.
while Marshall's involvement may be explained by antipathy to the Austrian economists and some striking similarities between his and Turgot's interest theory (see Groenewegen, 1983b). This debate highlights his analytical contributions to interest and capital theory.

The doctrine of social progress, which played such an important part in establishing Turgot's vision, was also applied by him to his history of ideas. In his fragment On Universal History (1751b, pp. 95–6) a cumulative notion of intellectual progress is presented, in which ideas are seen to develop necessarily from the systems of predecessors; each scientist, as it were, standing on the shoulders of those who came before. Two decades later, Turgot applied this doctrine to the history of economics when defending Melon, the financial economist, against Du Pont's charge that Melon's work was historically unimportant because it was wrong. ‘Someone entering the world after Montesquieu, Hume, Cantillon, Quesnay, M. de Gournay, etc. is less struck by the merit arising from Melon's priority because he does not appreciate it; for him it is no more than a date, and when he reads him, he knew already more than his book’ (Turgot to Caillard, 1 January 1771, in Schelle, 1913–23, vol. 3, p. 500). This line of thought can be applied to Turgot himself. He built on the work of Montesquieu, Hume, Cantillon, Quesnay and Gournay, thereby becoming a major participant in constructing 18th-century classical political economy with noteworthy contributions of his own particularly to the theory of value, capital and interest, production and distribution.

Turgot's works were collected on three occasions: by his friend Du Pont (Turgot, 1808–11), by Daire and Dussard (Turgot, 1844), and by Schelle (1913–23) together with a biography and associated material. Few of his writings were published in his lifetime, but from 1788 to 1792 some of his major economic writings were republished by his friends Condorcet and Du Pont. Comparison of these texts, manuscript versions and the text of the collected works suggests differences attributable to Du Pont, who edited the text for ideological and occasionally political reasons (see Groenewegen, 1977, pp. xxxiv–xxxvi). Schelle first drew attention to, and then removed, many of these corrections, but was not completely successful in this. For this reason, and because of its omissions, particularly of subsequently discovered items from Turgot's voluminous correspondence, Schelle's edition can no longer be described as definitive. Preparing such an edition of Turgot's works awaits both the generous financing required for the task and the services of a devoted editor.

turnpike trusts

Dan Bogart
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Turnpike trusts were private organizations that built and operated toll roads in Britain and the United States during the 18th and 19th centuries. They emerged in 17th century Britain because local governments were unwilling to invest in roads. They issued bonds to finance investment and imposed tolls on road users. In Britain, travel times and freight charges declined by over 40 per cent during 1750–1800; they fell also in the United States. Turnpike trusts also raised land values and promoted urbanization. They show how changes in institutional arrangements can encourage infrastructure investment and promote economic development.

land values; turnpike bonds; turnpike trusts; urbanization

Article

Turnpike trusts were widely employed private organizations that built and operated toll roads in Britain and the United States during the 18th and 19th centuries.

Britain and the United States relied heavily on road transport during their early stages of economic development. They faced a problem, however, because their existing road network was ill-suited for the rising volume of traffic, in particular the growing use of large wagons and carriages. In both economies the demand for road improvements was ultimately satisfied through an institutional innovation known as the ‘turnpike trust’ or the ‘turnpike company.’

Britain had a large network of roads and pathways as early as the 16th century. Although the network was called the ‘Kings Highway’, responsibility for maintenance was placed upon local governments known as parishes. Parishes financed road improvements by forcing their residents to work without pay and by levying property taxes. This method of financing was satisfactory in a pre-industrial economy, in which road improvement costs were low and traffic was largely internal to the parish. Conditions changed during the 17th and 18th centuries, when wages increased and inter-regional trade and travel
began to grow. Each of these factors contributed to a divergence between the road expenditure that parishes were willing to provide and the amount needed for an improved network. Turnpike trusts emerged as a solution to this problem. Trusts were promoted by landowners and merchants, who lobbied for an act of parliament. Each act transferred authority from parishes to a body of trustees composed of the promoters and other local property owners. Trustees were given the right to finance improvements along a particular road by levying tolls and issuing bonds. The tolls were efficacious because they forced road-users to contribute to the costs of improvement, whereas the bonds helped to mobilize funds for initial investment. The act also placed a number of restrictions on trustees. For example, they could not charge tolls above a maximum schedule, and they could not earn direct profits. Instead, it was expected that trustees would benefit indirectly through higher property values (Albert, 1972).

The first turnpike act was passed in 1663, and applied to a short section of the Great North Road connecting London with Leeds, York, and Newcastle. The second turnpike act was not passed until 1695, and it was not until the 1720s that trusts became common along the major highways leading into London. Between 1750 and 1770 turnpike trusts diffused throughout much of the road network, especially in the industrializing areas of the West Midlands and the North. After 1770, the network continued to expand, even as canals were being built. By 1840 there were around 1,000 turnpike trusts managing 20,000 miles (Pawson, 1977).

The British colonies of North America inherited the original system, in which roads were free and local governments – parishes, towns, or counties – were responsible for maintenance and improvement. A similar problem emerged where local governments were unwilling to pay for road improvements, despite an increasing need for investment. Significant institutional changes did not occur until after the American Revolution, when states began passing legislative acts creating turnpike companies (Durrenberger, 1931).

US turnpikes companies were similar to British turnpike trusts, except they were corporations and financed most of their investments by issuing stock. Turnpike companies were widely established in New England and the Middle Atlantic states between 1792 and 1845. The early companies were adopted along roads linking major cities such as Boston, Philadelphia, and New York with smaller cities in their western hinterlands. The later turnpike companies generally built and operated roads that led to other turnpikes and canals. By 1845 there were over 800 turnpike companies managing approximately 15,000 miles (Klein and Majewski, 2004).

In Britain and the US the official rationale for creating turnpikes was that the ‘ordinary’ laws for repairing highways needed to be amended if the roads were to be improved. Did turnpike trusts and turnpike companies meet these expectations? In Britain turnpike trusts were generally successful in increasing road maintenance and investment. On average, they spent between 10 and 20 times more than the parishes they replaced. Most trusts purchased land and materials in order to widen their roads and improve the surface. Many trusts also spent substantial sums on maintenance, as they had to deal with the growing volume of traffic in the 18th century (Bogart, 2005a). US turnpike companies were most successful in raising road investment. The amount of capital raised through stock issues was particular striking given that dividends were rarely paid (Klein, 1990). This contrasts with British turnpike bonds, which usually yielded a return of between four and five per cent (Albert, 1972). American turnpike companies had more difficulties paying for maintenance, in part because traffic volumes were lower, but also because companies had difficulties collecting tolls (Klein, 1990).
How were road-users affected by the rise of turnpike trusts and turnpike companies? The evidence for British transport costs shows that the benefits from improved roads substantially outweighed the burden of the tolls, as travel times and freight charges declined by over 40 per cent between 1750 and 1800 (Pawson, 1977; Bogart, 2005b). The evidence from the United States suggests a similar pattern, in which travel times and freight charges fell after turnpike companies improved the road (Durrenberger, 1931).

The accounts of contemporaries also suggest that turnpike trusts raised land values and contributed to urbanization. These indirect benefits were especially important because they provided added motivation for landowners and merchants to promote turnpikes and purchase their stocks and bonds.

Turnpikes are often viewed alongside the canal companies and railroads that superseded them in the second quarter of the 19th century. Improving a road was far less expensive, and therefore the turnpike movement did not lead to domestic and international capital flows as with canals and railways. The benefits of turnpikes were also smaller given the natural limits of horse-drawn transport. That said, one should recognize that turnpikes generated substantial benefits in their era (Pawson, 1997; Bogart, 2005b). At a time when local and central governments were largely ineffective, these organizations provided a mechanism by which transport investment could be implemented. Their history also provides an illustration of how changes in institutional arrangements can encourage infrastructure investment and promote economic development.

Amos Tversky, a cognitive psychologist, is regarded as a giant in the study of human judgment and decision making, and one of the founders of behavioural economics. Born on 16 March 1937 in Haifa, Israel, his father was a veterinarian and his mother was a social worker and member of the first Israeli Parliament and those following, for some 15 years. Tversky received his BA from the Hebrew University in Jerusalem in 1961, majoring in philosophy and psychology, and a Ph.D. in psychology from the University of Michigan in 1965.

The early work
Tversky's early work in mathematical psychology focused on the study of individual choice behaviour and the analysis of psychological measurement, exploring almost from the beginning the surprising implications of simple and intuitively compelling psychological assumptions. In one early work, Tversky (1969) showed how a series of pair-wise choices could yield intransitive patterns of preference. To do this, he created a set of options such that differences on an important dimension were negligible between adjacent alternatives, but proved to be consequential once compounded across a number of options, yielding a reversal of preference between the first and the last. This pattern not only contradicted a fundamental assumption of utility theory; it also provided a revealing glimpse into the psychological processes involved in decisions of this kind.

For another example, Tversky's (1977) highly influential model of similarity made a number of simple psychological assumptions: items are mentally represented as collections of features, with the similarity between items an increasing function of the features that they have in common, and a decreasing function of their distinct features. Feature weights are task-dependent, such that, for example, the features of the subject of comparison loom larger than the referent's, and common features matter more in judgments of similarity, whereas distinctive features receive greater attention in judgments of dissimilarity. This simple and elegant theory was able to explain observed asymmetries in similarity judgments (A is more similar to B than B is to A), and the fact that item A may be perceived as quite similar to item B and item B quite similar to item C, but items A and C may be perceived as highly dissimilar. Foreshadowing the immensely elegant work to come, these early papers were predicated on the technical mastery of relevant normative theories, and explored simple and compelling psychological principles until their unexpected, and often striking, theoretical implications became apparent.

Another impressive project concerned the mathematical and axiomatic foundations of measurement, in the physical sciences, but especially in the study of behaviour. Although fundamental to modern science, measurement was long considered unproblematic. In fact, it represents non-trivial issues concerning the assignment of numbers to objects in terms of their structural correspondence. Our measurement models, for example, are often are not determined by the data. Tversky's involvement in this project would stretch over two decades and result in three massive volumes (co-authored with Krantz, Luce, and Suppes, 1971; 1989; 1990).

The collaboration with Daniel Kahneman

Tversky's long and extraordinarily influential collaboration with Daniel Kahneman began in 1969 and spanned the fields of judgment and decision making. Having recognized that intuitive predictions and likelihood estimates tend not to follow the principles of statistics or the laws of probability, Tversky and Kahneman (1974) embarked on the study of biases as a method for investigating judgmental heuristics. The beauty of the work was most apparent in the interplay of psychological intuition with normative theory, accompanied by memorable demonstrations. The research showed that judgments often violate basic normative principles despite the fact that people are quite sensitive to these principles' normative appeal. An important theme in this work is a rejection of the claim that people are not able to grasp the relevant normative considerations. Rather, recurrent and systematic errors are attributed to people's reliance on intuitive judgment and heuristic processes in situations where the applicability of normative criteria is not immediately apparent. The experimental demonstrations are noteworthy not only because they violate normative theory, but also because they contradict people's own assumptions about how
Two early examples of judgmental heuristics illustrate this tension:

1. When presented with a description of Linda, a young, single, outspoken and very bright woman, who majored in philosophy, had participated in anti-nuclear demonstrations, and is concerned with issues of discrimination and social justice, most people think Linda is more likely to be a feminist bank teller than a bank teller – even though, of course, the likelihood of the latter must be greater than the former (since all feminist bank tellers are bank tellers).

2. When asked to estimate the number of seven-letter words on a typical page of English text, people are inclined to guess that there are fewer words whose penultimate letter is N than end in ING – even though the latter are necessarily a subset of the former.

In both cases, a heuristic judgment leads to what is known as the conjunction fallacy. In the first, people rely on the fact that Linda is more similar to a feminist bank teller than to a prototypical bank teller; in the second, frequency is judged via the ease with which examples can be brought to mind. In both cases, the reliance on intuitive heuristics leads people to ignore simple normative constraints that, upon reflection, they readily endorse.

In 1979, Kahneman and Tversky published their seminal paper on prospect theory. Although the theory is formally confined to the analysis of individual choice between binary monetary gambles, it incorporates fundamental insights that have revolutionized current theorizing about decision making more generally. Contrary to the notion of utility maximization, which focuses on final assets, the psychological carriers of value in prospect theory are gains and losses relative to some reference point, which is often the status quo. Diminishing sensitivity to greater amounts leads prospect theory's value function to be concave for gains and convex for losses (that is, above and below the reference point, respectively), yielding risk aversion for gains and risk seeking for losses (except for very low probabilities, where these trends can reverse). Because prospects can often be framed as gains or as losses relative to some reference point, this can generate ‘framing effects’, wherein alternative descriptions trigger opposing risk attitudes and elicit discrepant preferences regarding the same final outcomes. For example, imagine being $300 richer than you are and having a choice between $100 for sure and an equal chance at $200 or nothing. Alternatively, imagine being $500 richer and having to choose between a sure $100 loss and an equal chance to lose $200 or nothing. Although the two scenarios offer the same final outcomes ($400 versus an equal chance at $300 or $500), people tend to prefer the certain $100 gain in the first and the chance of a greater loss or nothing in the second, thus expressing opposing preferences.

According to prospect theory, people are loss averse: the loss associated with giving up a good is greater than the pleasure associated with obtaining it. Loss aversion yields ‘endowment effects’ wherein the mere possession of a good can lead to higher valuation of it than if it were not in one's possession (Kaheman, Knetsch and Thaler, 1990), and it can create a general reluctance to negotiate or trade because the disadvantages of departing from the status quo loom larger than the advantages presented by possible alternatives (Samuelson and Zeckhauser, 1988). Furthermore, the impact of probabilities in prospect theory is not linear; rather, it consists of a transformation of the relevant probabilities into ‘decision weights’ which capture the impact on decision makers, exhibited most clearly at the extremes of certainty and impossibility. For example, a reduction in the likelihood of a threatening outcome
from .02 to 0 has a much greater impact on people (as exhibited, say, in their willingness to pay) than a comparable change in likelihoods from .67 to 65.

Later work

Tversky returned to the study of judgment and in his work on support theory (Tversky and Koehler, 1994), a theory of probabilistic judgment that formally distinguishes between events in the world and the manner in which they are mentally represented. Probabilities in support theory are attached not to events, as in standard models, but rather to descriptions of events, called hypotheses. Probability judgments are based on the support (strength of evidence) of the focal hypothesis relative to that of alternative, or residual, hypotheses. The theory distinguishes between explicit disjunctions, which are hypotheses that list their individual components (for example, ‘a car crash due to oil spill, or due to driver fatigue, or due to break failure’), and implicit disjunctions that do not (‘a car crash’). According to the theory, unpacking the description of an event from an implicit to an explicit disjunction generally increases its support and, hence, the perceived likelihood. As a result, alternative descriptions of an event can give rise to substantially different judgments.

A fundamental assumption underlying normative theories is the extensionality principle: options that are extensionally equivalent are assigned the same value, and extensionally equivalent events are assigned the same probability. Normative theories are concerned with options and events in the world: different descriptions of the same states are similarly evaluated. According to Tversky's analyses, on the other hand, judgments and decisions are constructed, not merely revealed, during their elicitation, and their construction depends on the framing of the problem, the method of elicitation, and the valuations and attitudes that these trigger. The extensionality principle is deemed descriptively invalid because alternative decision contexts and alternative descriptions of options or events often produce systematically different judgments and preferences.

Behaviour, Tversky's research made clear, is the outcome of normative ideals that people endorse upon reflection, combined with psychological processes that intrude upon and shape behaviour independently of any deliberative intent. These insights led to dramatic and memorable studies concerning, among others, the hot hand in basketball (Tversky and Gilovich, 1989), the perceived relationship between weather and rheumatism (Redelmeier and Tversky, 1996), money illusion (Shafir, Diamond and Tversky, 1997), self-deception (Quattrone and Tversky, 1984), overconfidence (Griffin and Tversky, 1992), and a variety of other economic, medical and political decisions. Tversky was an intellectual giant whose work had an exceptionally broad appeal, to economists, philosophers, statisticians, physicians, political scientists, sociologists and legal theorists, among others.

Tversky taught at Hebrew University (1966–78) and at Stanford University (1978–96), where he was the inaugural Davis–Brack Professor of Behavioral Sciences and Principal Investigator at the Stanford Center on Conflict and Negotiation. He spent leave periods at Harvard University, the Center for Advanced Studies in the Behavioral Sciences, the Center for Advanced Study at Hebrew University, and the Oregon Research Institute. After 1992 he held an appointment as Senior Visiting Professor of Economics and Psychology and Permanent Fellow of the Sackler Institute of Advanced Studies at Tel Aviv University.

Tversky won many awards for diverse accomplishments. As a young officer in 1956, he earned Israel's highest honour for bravery for rescuing a soldier who had frozen in panic after lighting an explosive
Tversky was in the midst of an enormously productive time when he died of metastatic melanoma on 2 June 1996, at his home in Stanford, California. For a selection of his writings, as well as a complete bibliography, see Shafir (2004); for excellent collections of papers influenced by Tversky's work on judgment and choice, respectively, see Gilovich, Griffin and Kahneman (2001), and Kahneman and Tversky (2000).

When it awarded Daniel Kahneman the 2002 Nobel Memorial Prize in Economic Sciences ‘for having integrated insights from psychological research into economic science, especially concerning human judgment and decision-making under uncertainty’, the Royal Swedish Academy of Sciences, which does not award prizes posthumously, took the unusual step of acknowledging Tversky in its Nobel citation, explaining that his joint work with Kahneman formulated alternative theories that better account for observed behaviour. Two months later, Tversky also posthumously won with Kahneman the prestigious 2003 Grawemeyer Award, which recognizes powerful ideas in the arts and sciences. The citation noted that it was ‘difficult to identify a more influential idea than that of Kahneman and Tversky in the human sciences’.

Twiss, Travers (1809–1897)

Murray Milgate

Edited by John Eatwell, Murray Milgate and Peter Newman

Keywords

Twiss, Travers; political economy

Article

In economics, Twiss's reputation rests primarily upon two contributions: one on the machinery question and the other a View of the Progress of Political Economy in Europe since the Sixteenth Century (1847) of some 300 pages. Both of these works originated in lectures during his tenure as Drummond Professor of Political Economy at Oxford (1942–7). The latter numbers with McCulloch's much shorter Historical Sketch of the Rise and Progress of the Science of Political Economy (1926) as being among the first significant histories of the discipline published in English. The only works of comparable significance in the area which predate it appeared in French: Blanqui's Historie de l'économie politique en Europe (1837–8) and Jean Paul Alban de Villeneuve-Bargemon's Historie de l'économie politique (1836–8 and 1841). Twiss acknowledges his debt to the abovementioned authors, but has been criticized (for example, by Cossa) for a tendency to rely too heavily upon second-hand sources in the construction of his argument.

The published versions of his lectures at Oxford are all that Twiss left to the literature of economics.

Twiss was born in London on 19 March 1809 and died there on 14 January 1897, and was educated at University College, Oxford, taking his BA (in mathematics and classics) in 1830. From 1830 until 1863 he was a fellow of that college. In 1835 he commenced the study of law in Lincoln's Inn and was admitted to the Bar in 1840. Following his term as Drummond Professor (in which he succeeded Merivale), he turned more and more to the study of international law, and in 1852 he was elected to the chair in that field at King's College, London. In 1855 he moved to Oxford as Regius Professor of Civil Law, where he remained until 1870. In 1867 he became the Queen's advocate-general, and was knighted in 1868.

At this point occurred ‘the catastrophe which put an end to his official career’, as the original edition of this Dictionary put it. It seems that in 1872, Twiss instituted an action for malicious libel with intent to extort against a solicitor who had put about statements impugning the moral propriety of Twiss's wife.
As the case proceeded, Lady Twiss was called to testify. However, an arduous cross-examination proved to be too much for her, and she departed London before its conclusion, thus causing Twiss's case to collapse and precipitating his resignation from all offices. Of course, it is not surprising (given the climate of the times) that Lady Twiss's breakdown should have been interpreted as telling evidence against her – but from what we now know of these extraordinary Victorian public rituals over sexual behaviour and preference, and of the pressures placed on the principal actors in such notorious trials, a rather different verdict might just as plausibly be drawn from the episode. From the point of view of individual and social psychology, however, even more interesting is the question of just why these kinds of cases were voluntarily brought before the courts in the first place.

two-sector models

H. Uzawa
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
marginal rate of substitution; Rybczynski theorem; two-sector models

Article
Problems of interest in economic theory, from both the theoretical and policy points of view, occur only when there exists a multitude of goods and services, each of which is either produced by different technologies or utilized for different purposes in consumption. However, it is often the case that an economic system with a multitude of goods and services is too complicated to analyse effectively and to derive conclusions of any practical use. two-sector models enable us to bring forth essential elements of the economic mechanisms in a more complicated real world while still making it possible to analyse graphically the basic structure of equilibrium and to understand the policy implications within the framework of the two-sector analysis. The two-sector analysis plays a particularly important role in trade theory and in growth theory.

A typical two-sector model concerns itself with an economy in which there exist two productive sectors, to be referred to as sector 1 and sector 2, respectively. In the context of growth theory, one sector produces consumption goods and the other investment goods. Both goods are assumed to be composed of homogeneous quantities and to be produced by two factors of production, capital and labour. Both capital and labour are also assumed to be composed of homogeneous quantities.

In each sector, production is assumed to be subject to constant returns to scale and diminishing marginal rates of substitution between capital and labour. Joint products are excluded and external (dis-)economies do not exist. The output in each sector is determined by the quantities of capital and labour allocated to that sector. In sector $j$, let $Y_j$ be the quantity of good $j$ produced by the input of capital and labour by the quantities $K_j$ and $L_j$, respectively, then we may write

$$Y_j = F_j(K_j, L_j), \quad j = 1, 2.$$  (1)

For each $j$, the production function $F_j(K_j, L_j)$ is linear homogeneous and continuously differentiable, so that the marginal rate of substitution between capital and labour is well defined.

Let $K$ and $L$ be the quantities of capital and labour which exist in the economy at a particular moment of time. If both capital and labour are assumed to be freely transferred from one sector to another and both are fully employed, then we have

$$K_1 + K_2 = K, \quad L_1 + L_2 = L.$$  (2)
In a typical two-sector model, it is often assumed that the allocation of two factors of production is perfectly competitive, so that in each sector the wage $w$ is equal to the marginal product of labour and the rentals $r$ of capital goods to the marginal product of capital:

$$w = p_j \frac{\partial F_j}{\partial L_j}, \quad r = p_j \frac{\partial F_j}{\partial K_j},$$  \hspace{1cm} (3)$$

where $p_j$ is the price of good $j$.

In what follows, good 1 is taken as the numéraire, so that $p_1 = 1$ and $p_2 = p$.

Since production is assumed to be subject to constant returns to scale, the model is reduced to one involving per capita quantities only. Let us introduce the following notation:

- $k = K/L$: the capital–labour ratio in the economy as a whole,
- $kJ = K_j/L_j$: the capital–labour ratio in sector $j$,
- $Y_j = Y_j/L$: output of good $j$ per capita,
- $v_j = L_j/L$: the proportion of labour allocation in sector $j$,
- $\omega = w/r$: the wage–rental ratio.

The relations (1)–(3) are then reduced to the following:

$$Y_j = f_j(k_j)v_j,$$  \hspace{1cm} (4)$$

where $f_j(k_j) = F_j(k_j, 1)$.

$$v_1 = \frac{k - k_2}{k_1 - k_2}, \quad v_2 = \frac{k_1 - k}{k_1 - k_2},$$  \hspace{1cm} (5)$$

$$\omega = \frac{f_j(k_j)}{f_j'(k_j)} - k_j,$$  \hspace{1cm} (6)$$
two-sector models: The New Palgrave Dictionary of Economics

The relation (6) means that the wage–rentals ratio $\omega$ is equal to the marginal rate of substitution between capital and labour. The capital–labour ratio $kj$ which satisfies (6) is uniquely determined for given wage–rentals ratio $\omega$; it may be written $kj(kj(\omega))$, which is referred to as the optimum capital–labour ratio corresponding to the wage–rentals ratio $\omega$. It is easily seen that the optimum capital–labour ratio $kj(kj(\omega))$ is an increasing function of the wage–rentals ratio $\omega$. In fact, by differentiating (6) with respect to $\omega$, we get

$$p = \frac{f_1'(k_1)}{f_2'(k_2)},$$

where

$$y_1 = f_1(k_1) \frac{k-k_2}{k_1-k_2}, \quad y_2 = f_2(k_2) \frac{k_1-k}{k_1-k_2}. \tag{8}$$

The relationships between the price ratio $p$ and the wage–rentals ratio $\omega$ may be obtained by differentiating (7) logarithmically, and noting (9):

$$\frac{dk_j}{d\omega} = -\frac{\left[f_j'(k_j)\right]^2}{f_j(k_j)f_j''(k_j)} > 0,$$ \tag{9}

because of the diminishing marginal rate of substitution condition: $f_j'(k_j) > 0$ and $f_j''(k_j) < 0$.

The relationships between the price ratio $p$ and the wage–rentals ratio $\omega$ may be obtained by differentiating (7) logarithmically, and noting (9):

$$\frac{1}{p} \frac{dp}{d\omega} = \frac{1}{\omega + k_2(\omega)} - \frac{1}{\omega + k_1(\omega)}. \tag{10}$$

Hence, we have the following proposition:

*The relative price $p$ of good 2 is an increasing or decreasing function of wage–rentals ratio $\omega$ according to whether good 1 is more or less capital-intensive than good 2.*

In particular, if good 1 is always more capital-intensive than good 2, then the relative price $p$ of good 2 (with respect to the price of good 1) is an increasing function of the wage–
two-sector models: The New Palgrave Dictionary of Economics

rentals ratio $\omega$. The latter is indeed nothing but the essence of the factor–price–equalization theorem. In this case, we can see from (8) that, as the endowment ratio $k$ is increased, the output of good 1 is increased and that of good 2 is decreased, provided that the wage–rentals ratio $\omega$ or relative price $p$ remains constant.

The wage–rentals ratio $\omega$ or price ratio $p$ is determined once the demand conditions are specified. The allocation of capital and labour between two sectors in the perfectly competitive situation, as described above, may be viewed from another point of view. It is easily seen that the allocation of capital and labour which satisfies (1)–(3) is nothing but the solution of the following optimum problem:

Find the allocation $(K_1, K_2, L_1, L_2)$ which maximizes the national product

$$Y = p_1 Y_1 + p_2 Y_2$$

subject to the constraints (1) and

$$K_1 + K_2 \leq K, \quad L_1 + L_2 \leq L.$$  

In fact, wage $w$ and rentals $r$ are the Lagrange multipliers associated with the constraints (2').

The set of all combinations $(Y_1, Y_2)$ of two goods satisfying (1) and (2') then is a convex set, of all possible combinations of the quantities of two goods which can be produced from the given endowments of capital and labour, $K$ and $L$. The competitive allocations of capital and labour then result in those combinations of two goods for which the national product, evaluated at prices $p_1$ and $p_2$, is maximized.

These observations lead us to the following conclusion. Namely, if the demand conditions are those obtained by an optimization of a certain community preference ordering, then the equilibrium prices and outputs are uniquely determined.

The analysis may be carried out in terms of a geometric presentation. For the given techniques of production and the given factors of production, the set of all possible combinations of two goods produced in the two-sector economy is represented by the production possibility set, as shown by the shaded area in Figure 1. In Figure 1, the quantities of good 1 and good 2 are measured along the abscissa and ordinate, respectively, and the boundary curve of the production possibility set is the transformation curve $F_1F_2$, showing the maximum quantity of one good that can be produced, given a specific quantity of the other to be produced. The transformation curve is concave toward the origin and the tangent at each point on the transformation curve has a slope equal to the relative price of two goods, as shown in Figure 1. It is possible to prove these properties by using the contract box, as in Figure 2.

In Figure 2, the endowments of capital and labour are measured along the sides of the box, and the allocations of capital and labour between two sectors are entered in the box from opposite corners. An efficient allocation of factors of production is realized only at a point at which two isoquants are tangent to each other. The efficient locus in the contract box corresponds to the transformation curve in Figure 1. The configuration described in Figure 2 represents the case where good 1 is more capital-intensive than good 2. Let the point A in Figure 1 correspond to the point A in the contract box in Figure 2. Suppose the quantity of good 1 to be produced is reduced by $\Delta Y_1$ and the production of good 2 is increased by $\Delta Y_2$, resulting in a shift from A to A' along the efficiency locus. At point A, the isoquants in two sectors have a common tangent; let $B_1$ and $B_2$ be the points on the labour-side at which the tangent line at A intersects the isoquant passing through A'. Then $\Delta Y_1 / \Delta Y_2 \approx p_2 / p_1$.

These observations lead us to the following conclusion. Namely, if the demand conditions are those obtained by an optimization of a certain community preference ordering, then the equilibrium prices and outputs are uniquely determined.

The analysis may be carried out in terms of a geometric presentation. For the given techniques of production and the given factors of production, the set of all possible combinations of two goods produced in the two-sector economy is represented by the production possibility set, as shown by the shaded area in Figure 1. In Figure 1, the quantities of good 1 and good 2 are measured along the abscissa and ordinate, respectively, and the boundary curve of the production possibility set is the transformation curve $F_1F_2$, showing the maximum quantity of one good that can be produced, given a specific quantity of the other to be produced. The transformation curve is concave toward the origin and the tangent at each point on the transformation curve has a slope equal to the relative price of two goods, as shown in Figure 1. It is possible to prove these properties by using the contract box, as in Figure 2.

In Figure 2, the endowments of capital and labour are measured along the sides of the box, and the allocations of capital and labour between two sectors are entered in the box from opposite corners. An efficient allocation of factors of production is realized only at a point at which two isoquants are tangent to each other. The efficient locus in the contract box corresponds to the transformation curve in Figure 1. The configuration described in Figure 2 represents the case where good 1 is more capital-intensive than good 2. Let the point A in Figure 1 correspond to the point A in the contract box in Figure 2. Suppose the quantity of good 1 to be produced is reduced by $\Delta Y_1$ and the production of good 2 is increased by $\Delta Y_2$, resulting in a shift from A to A' along the efficiency locus. At point A, the isoquants in two sectors have a common tangent; let $B_1$ and $B_2$ be the points on the labour-side at which the tangent line at A intersects. The two distances, $O_1B_1$ and $O_2B_2$, measure the values of the two goods produced, $p_1 Y_1 / w$ and $p_2 Y_2 / w$, respectively. Let C be the point at which $O_1A$ intersects with the isocost passing through A', and let $B'_1$ and $B'_2$ be the points on the labour-side at which the tangent line at C intersects. Then $\Delta Y_1 / \Delta Y_2 \approx p_2 / p_1$.

These observations lead us to the following conclusion. Namely, if the demand conditions are those obtained by an optimization of a certain community preference ordering, then the equilibrium prices and outputs are uniquely determined.

The analysis may be carried out in terms of a geometric presentation. For the given techniques of production and the given factors of production, the set of all possible combinations of two goods produced in the two-sector economy is represented by the production possibility set, as shown by the shaded area in Figure 1. In Figure 1, the quantities of good 1 and good 2 are measured along the abscissa and ordinate, respectively, and the boundary curve of the production possibility set is the transformation curve $F_1F_2$, showing the maximum quantity of one good that can be produced, given a specific quantity of the other to be produced. The transformation curve is concave toward the origin and the tangent at each point on the transformation curve has a slope equal to the relative price of two goods, as shown in Figure 1. It is possible to prove these properties by using the contract box, as in Figure 2.

In Figure 2, the endowments of capital and labour are measured along the sides of the box, and the allocations of capital and labour between two sectors are entered in the box from opposite corners. An efficient allocation of factors of production is realized only at a point at which two isoquants are tangent to each other. The efficient locus in the contract box corresponds to the transformation curve in Figure 1. The configuration described in Figure 2 represents the case where good 1 is more capital-intensive than good 2. Let the point A in Figure 1 correspond to the point A in the contract box in Figure 2. Suppose the quantity of good 1 to be produced is reduced by $\Delta Y_1$ and the production of good 2 is increased by $\Delta Y_2$, resulting in a shift from A to A' along the efficiency locus. At point A, the isoquants in two sectors have a common tangent; let $B_1$ and $B_2$ be the points on the labour-side at which the tangent line at A intersects. The two distances, $O_1B_1$ and $O_2B_2$, measure the values of the two goods produced, $p_1 Y_1 / w$ and $p_2 Y_2 / w$, respectively. Let C be the point at which $O_1A$ intersects with the isocost passing through A', and let $B'_1$ and $B'_2$ be the points on the labour-side at which the tangent line at C intersects. Then $\Delta Y_1 / \Delta Y_2 \approx p_2 / p_1$.

These observations lead us to the following conclusion. Namely, if the demand conditions are those obtained by an optimization of a certain community preference ordering, then the equilibrium prices and outputs are uniquely determined.

The analysis may be carried out in terms of a geometric presentation. For the given techniques of production and the given factors of production, the set of all possible combinations of two goods produced in the two-sector economy is represented by the production possibility set, as shown by the shaded area in Figure 1. In Figure 1, the quantities of good 1 and good 2 are measured along the abscissa and ordinate, respectively, and the boundary curve of the production possibility set is the transformation curve $F_1F_2$, showing the maximum quantity of one good that can be produced, given a specific quantity of the other to be produced. The transformation curve is concave toward the origin and the tangent at each point on the transformation curve has a slope equal to the relative price of two goods, as shown in Figure 1. It is possible to prove these properties by using the contract box, as in Figure 2.
Figure 2
The contract box
As the output of good 1 is reduced, the point $A$ moves towards $O_1$ along the efficiency locus. Then the optimum capital–labour ratio, which is represented by $LAO_1B_1$, is increased, and the tangent line at $A'$ is steeper than that at $A$, indicating an increase in the price ratio $p_2/p_1$. The transformation curve thus is shown to be concave towards the origin and the tangent at each point on it is equal to the price ratio.

The relationships between the price ratio and the wage-rentals ratio may also be discussed in terms of a two-dimensional diagram, as in Figure 3. Suppose good 1 is more capital-intensive than good 2. For the given wage–rentals ratio $\omega$, the unit by which good 2 is measured is so adjusted that $p_2/p_1=1$ and the unit-isoquants for both goods share the same cost line $CC$, as shown in Figure 3. The distance $OC$ along the abscissa measure $p_1/w=p_2/w$. Suppose the wage–rentals ratio is increased from $\omega$ to $\omega'$. Then at the new wage–rentals ratio $\omega'$, the configuration of the cost lines in two sectors must be of the form described in Figure 3. Namely, $OB_1<OB_2$; hence, $p'_2 / w' < p'_2 / w$, implying $p'_2 / p'_1 < 1 = p_2 / p_1$. Thus we have proved that, as the wage–rentals ratio is increased, the price of a good which is more labour-intensive has been increased relative to that of a less labour-intensive good.

Figure 3

The relationships between price ratio $p$ and wage-rentals ratio $\omega$. 

The effect of an increase in the endowment of either capital or labour may also be analysed in terms of the contract box. Suppose the endowment of capital is increased from $K$ to $K'$ so that the new contract box is indicated by $O_1'K'$. If the relative price $p_2/p_1$ remains unchanged, then the factor price ratio $\omega = w/r$ also remains unchanged. Let $A''$ be the point at which the extension of $O_1A$ intersects with the line originating from $O_2'$ which is parallel to $O_2A$. Then at the new configuration, the output of good 1 is increased by $AA''$, while the output of good 2 is decreased from $O_2A$ to $O_2'A'$. Thus we have shown the proposition, known as the Rybczynski theorem: An increase in the endowment of capital increases the output of a good which is more capital-intensive than the other, while decreasing the output of another good which is less capital-intensive, provided the price ratio of the two goods remains constant. The resulting shift in the transformation curve is described in Figure 3, where the efficient point $A$ moves to $A'$ in the new environment.

two-sided markets

M. Armstrong and J. Wright
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A growing number of industries are organized as so-called two-sided markets in which platforms enable interactions between two groups of users, each of which cares about the size and attributes of the other group on the same platform. The literature to date examines how platforms set prices to the two sides and whether the resulting price structure results in market failure. The answers to these questions depend on the nature of cross-group and own-group externalities, the types of fees possible (membership or per-transaction), and whether one or both sides multihome.

Keywords

access pricing; advertising; competitive bottlenecks; complementary goods; cross-group externalities; matching; multihoming; network effects; platforms; price discrimination; shopping malls; singlehoming; two-sided markets; user fees

Article

There are many examples of markets where two or more groups of participants interact via ‘platforms’. Of course, there are countless examples where firms compete to supply two or more groups. However, in a set of interesting cases, cross-group network effects are important, and the benefit enjoyed by a member of one group on a platform depends upon how well that platform does in attracting custom from the other group. For instance, a general purpose credit card scheme cannot offer a valuable service to either side unless it persuades a large number of consumers to carry its card and a large number of retailers to accept its card. The literature on two-sided markets investigates such markets. Many examples of two-sided markets involve platforms that mediate transactions between consumers and retailers (or sellers). Examples include shopping malls, supermarkets, and debit and credit card payment schemes. Another set of examples includes matching agencies, such as real estate agencies that facilitate search and trade between home buyers and home sellers (or landlords and tenants). Advertising
media including Yellow Pages, newspapers, television, and Internet portals also help match potential buyers with sellers, although in a less directed way. Software platforms such as video games, computer operating systems and word processors that connect users and application developers (or readers and writers) provide a further set of examples.

Early theoretical works on two-sided markets tended to focus on specific industries, such as Baxter's (1983) normative analysis of the structure of fees in a credit card network (see credit card industry). More general theoretical frameworks to analyse two-sided markets have been offered by Armstrong (2006), Armstrong and Wright (2007), Caillaud and Jullien (2001; 2003), Hagiu (2005), and Rochet and Tirole (2003), among others. These models extend the earlier literature on network externalities to incorporate heterogeneous agents (the two sides of the market), as well as allowing for price discrimination across the two types of users. A central question is: What determines the structure of prices in two-sided markets? For instance, why is it that shopping malls offer free parking to shoppers and recover the cost from retailers, and why does American Express charge merchants but provide rebates to cardholders? A second question concerns whether the resulting price structure causes any form of market failure. We consider both questions.

Effects of cross-group externalities

Consider a generic two-sided market with buyers and sellers. Positive cross-group externalities have two effects. First, like network effects in one-sided markets, they make demand more sensitive to price. Second, like pricing for complementary goods, they make platforms charge less to one group if this increases the demand from the other group and the other group generates a positive margin. This implies that platforms will charge buyers less and sellers more when sellers value buyers more than vice versa (Armstrong, 2006). By attracting buyers (with a discount), platforms can then attract the more lucrative sellers. Consistent with this idea, Yellow Pages directories are typically given away to readers for free, and profits are made entirely from charging advertisers. This assumes, of course, that the two sides cannot easily internalize the externalities between themselves – a precondition for the structure of prices to be non-neutral in a two-sided market (Rochet and Tirole, 2006). It also assumes that agents make decisions about which of the competing platforms to join. This latter assumption is explored in the following two sections.

Membership fees versus usage charges

Platforms may charge for their services on a ‘lump-sum’ basis: magazines set cover prices and advertisement rates, nightclubs set entry fees for men and women. Alternatively, charges might be levied on a ‘per-transaction’ basis: typically credit card holders receive a percentage rebate on the amount they spend, and retailers pay a percentage of the revenue they collect; real estate agents’ fees are levied only in the event of a sale; charges for telecommunications service are levied on a per-call basis. And sometimes a combination of the two approaches is used: video game platforms charge consumers a fixed charge for their consoles, but game developers pay royalties for their sales.

The analysis of two-sided markets can be quite sensitive to the nature of pricing. With lump-sum charges, profits are the sum of profits obtained from each side, and it is possible to think of one side as
Two-sided markets

The New Palgrave Dictionary of Economics

Subsidizing the other. When cross-group network effects are strong, there are often multiple consistent demand outcomes for a given set of prices, which means that some method (such as specifying consumers’ beliefs about other consumers’ choices) is needed to pin down demand as a function of prices uniquely (Caillaud and Jullien, 2001; 2003).

With per-transaction charges, by contrast, an agent’s decision whether to join a platform is less sensitive to his beliefs about the number of agents from the other side who join the platform. In this case, the equilibrium structure of prices will primarily reflect the need to balance the two sides of the market (Schmalensee, 2002; Wright, 2004). A matching market with lots of potential sellers but few potential buyers will not generate many successful transactions, and this suggests that more buyers need to be attracted to the platform by charging sellers rather than buyers for successful transactions.

A crucial difference between the two forms of tariff is that cross-group externalities are less important with usage charges. Charging on a usage basis is a good strategy for an entrant. If an agent has to pay a new platform only in the event of a successful transaction, then the agent does not have to worry about how well the entrant does in its dealings with the other side of the market. With per-transaction charging, to attract one side a new platform does not have to first get the other side ‘on board’.

**Singlehoming versus multihoming**

When an agent chooses to use only one platform, that agent is said to ‘singlehome’ and when he uses several platforms he ‘multihomes’. For instance, while shoppers may tend to only shop at their nearby shopping mall (singlehome), retailers may locate in several shopping malls (multihome) in order to gain access to the full range of local shoppers. Similarly, people might read a single newspaper each day, while advertisers have to place adverts in several newspapers to reach the whole readership. This pattern, where ‘buyers’ singlehome and ‘sellers’ multihome, characterizes a number of two-sided markets. Armstrong and Wright (2007) show this pattern arises endogenously when only buyers view the platforms as differentiated (as may be true in the two examples just mentioned). This leads to a ‘competitive bottleneck’ – platforms compete aggressively to sign up buyers, charging them less than cost (perhaps nothing), and then make their profits from sellers who want to reach these buyers and do not have a choice of which platform to join in order to reach them. Platforms need to compete to attract the singlehoming buyers but they hold a monopoly position when they deal with sellers. As charges to sellers will be too high, there will be too few sellers from a social welfare point of view. The same logic is also seen for mobile telephony (Armstrong, 2002; Wright, 2002), in which fixed-line callers are charged high fees to call mobile subscribers, who join a single mobile network and receive handset subsidies for doing so. As a result, there may well be too few calls made to each mobile subscriber. To counter this market failure, fixed-to-mobile termination charges are regulated in several countries.

**Negative own-group externalities**

In many examples of two-sided markets, agents not only like more agents from the other side, but they dislike more agents from the same side (for example, firms generally dislike advertising by rival firms in the same directory). Negative own-group externalities will justify higher prices, reflecting the ‘pollution effect’ of attracting additional agents. One case where negative own-group externalities arise
endogenously is when sellers join the platform to better compete for buyers on the other side. Consider, for example, the case of payment schemes that attract cardholders and merchants. To the extent merchants accept cards to attract customers from each other, their private willingness to accept cards includes the surplus their customers get from using cards. As a result, card schemes will charge merchants more and cardholders less (Wright, 2004). In addition, since the surplus of cardholders is over-represented in the profits of the card schemes, merchants will tend to be charged too much and cardholders too little.

Negative own-group externalities can also explain agreements to exclude rival agents from the same platform. For instance, a shopping mall may restrict the number of competing retailers (such as bookstores). If the platform finds it difficult (or costly) to recover revenue from the consumer side, this may be a way to drive up revenue from retailers. If a television channel cannot charge viewers, it may maximize profits by promising one car maker that it will not show an advert from a rival car maker in the same advertising slot. More generally, platforms act somewhat like regulators (Hagiu, 2005; Rochet and Tirole, 2006). They impose rules, conditions and prices for the platform that help solve various inefficiencies, at the cost perhaps of introducing others.

two-stage least squares and the k-class estimator

N.E. Savin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Two-stage least squares has been a widely used method of estimating the parameters of a single structural equation in a system of linear simultaneous equations. This article first considers the estimation of a full system of equations. This provides a context for understanding the place of two-stage least squares in simultaneous-equation estimation. The article concludes with some comments on the lasting contribution of the two-stage least squares approach and more generally the future of the identification and estimation of simultaneous-equations models.

Article

Two-stage least squares (2SLS) was originally proposed as a method of estimating the parameters of a single structural equation in a system of linear simultaneous equations. It was introduced more or less independently by Theil (1953a; 1953b; 1961), Basmann (1957) and Sargan (1958). The early work on simultaneous equations estimation was carried out by a group of econometricians at the Cowles Foundation. This work was based on the method of maximum likelihood. In particular, Anderson and Rubin (1949; 1950) developed the limited information maximum likelihood (LIML) estimator for the parameters of a single structural equation. Anderson (2005) gives the history of 2SLS a revisionist twist
by pointing out that Anderson and Rubin (1950) indirectly includes the 2SLS estimator and its asymptotic distribution. The notation of that paper is difficult and the exposition is somewhat obscure, which may explain why few econometricians are aware of its contents. See Farebrother (1999) for additional insights into the precursors of 2SLS.

2SLS was by far the most widely used method in the 1960s and the early 1970s. The explanation involves both the state of statistical knowledge among applied econometricians and the state of computer technology. The classic treatment of maximum likelihood methods of estimation is presented in two Cowles Commission monographs: Koopmans (1950), *Statistical Inference in Dynamic Economic Models*, and Hood and Koopmans (1953), *Studies in Econometric Method*, which was directed at a wider audience. Among applied econometricians, relatively few had the statistical training to master the papers in these monographs, especially Koopmans (1950). By the end of the 1950s computer programs for ordinary least squares were available. These programs were simpler to use and much less costly to run than the programs for calculating LIML estimates. Owing to advances in computer technology, and, perhaps, also the statistical background of applied econometricians, the popularity of 2SLS started to wane towards the end of the 1970s. In particular, the difficulty of calculating LIML estimates was no longer an important constraint.

This article first considers the estimation of a full system of equations and then focuses on 2SLS. This approach provides a context for understanding the place of 2SLS in simultaneous-equation estimation. The article is organized as follows. A two-equation structural form model with normal errors and no lagged dependent variables is introduced in section 1. Section 2 reviews the properties of the ordinary least squares estimator of the parameters of a structural equation. The indirect least squares estimator is introduced in section 3. In section 4 presents the indirect feasible generalized least squares estimator, and briefly discusses maximum likelihood methods. Section 5 develops two rationales for the 2SLS procedure, and the $k$-class family of estimators is defined in section 6. Finite sample results on the comparisons of estimators are reported in section 7, and the concluding comments are in section 8. (Our exposition of structural-form estimation draws heavily on the treatment by Goldberger, 1991. For the presentation of GMM and more recent methods of simulation-equation estimation, see Mittelhammer, Judge and Miller, 2000.)

1 The model

In the spirit of Goldberger (1991), we consider a two-equation demand and supply model to fix ideas and notation. The endogenous variables are $y_1$ (quantity) and $y_2$ (price), the exogenous variable is $x$ (income), and the disturbances are $u_1$ (demand shock) and $u_2$ (supply shock). For convenience the intercepts are suppressed in both equations. The *structural form* of the model is

$$ Demand \ y_1 = \alpha_1 y_2 + \alpha_2 x + u_1, \quad (1.1) $$
Supply \( y_2 = \alpha_3 y_1 + u_2 \).

(1.2)

With the terms in \( y_1 \) and \( y_2 \) transferred to the left-hand side, the matrix representation of structural form is

\[
(\begin{pmatrix} y_1 \\ y_2 \end{pmatrix}) \begin{pmatrix} 1 & -\alpha_3 \\ -\alpha_1 & 1 \end{pmatrix} = \begin{pmatrix} x(\alpha_2, 0) + (u_1, u_2) \end{pmatrix},
\]

or

\[
y' \Gamma = x' B + u'
\]

In the structural-form coefficient matrices \( \Gamma \) and \( B \), the columns refer to equations, while the rows refer to variables. Each endogenous variable can be solved for in terms of the exogenous variables and structural shocks to get the reduced form of the model:

Quantity. \( y_1 = \pi_{11} x + \nu_1 \).

(1.3)

Price. \( y_2 = \pi_{12} x + \nu_2 \).

(1.4)
In matrix form,

\[(\gamma_1, \gamma_2) = \chi (\pi_{11}, \pi_{12}) + (\nu_1, \nu_2),\]

or

\[y' = x'B\Gamma^{-1} + u'\Gamma^{-1} = x'\Pi + \nu'.\]

The reduced form is derived by post-multiplying the structural form by \(\Gamma^{-1}\), where \(\Pi = B\Gamma^{-1}\) is the reduced-form coefficient matrix and \(\nu' = u'\Gamma^{-1}\) is the reduced-form disturbance vector.

Next we consider the statistical specification of a linear simultaneous-equation model for the general case of a \(m \times 1\) endogenous-variable vector \(y\), the \(k \times 1\) exogenous-variable vector \(x\) and the \(m \times 1\) structural-disturbance vector \(u\). The specification is the following:

\[y'\Gamma = x'B + u',\]

(A1)

\[\Gamma\text{ nonsingular,}\]

(A2)

\[E(u|x) = 0,\]

(A3)
Here $\Gamma$ is $m \times m$, $B$ is $k \times m$, $\Sigma$ is $m \times m$. Assumption (A1) gives the system of $m$ structural equations in $m$ endogenous variables. Assumption (A2) says that the system is complete in the sense that $y$ is uniquely determined by $x$ and $u$. (A3) says that $x$ is exogenous in the sense that the conditional expectation of $u$ given $x$ is zero for all values of $x$. Assumption (A4) is a homoskedasticity requirement, and positive definiteness rules out exact linear dependency among the structural disturbances. The implications of the specification (A1)–(A4) are the following:

\[
\begin{align*}
V(u|x) &= \Sigma \text{positive definite.} \\
(A4)
\end{align*}
\]

\[
E(v|x) = 0, \\
(B2)
\]

\[
V(v|x) = (\Gamma^{-1})\Sigma \Gamma^{-1} = \Omega \text{positive definite.} \\
(B3)
\]

The reduced-form disturbance vector $v$ is mean-independent of, and homoskedastic with respect to, the exogenous variable vector $x$.

Next we turn from the population to the sample. We suppose that a sample of $n$ observations from the multivariate distribution of $x$ and $y$ is obtained by stratified sampling: $n$ values of $x$ are selected, forming the rows of the $n \times k$ observed matrix $X$ with rank $\langle X \rangle = k$. For each observation, a random drawing is made from the relevant conditional distribution of $y$ given $x$, giving the rows of the $n \times m$ observed matrix $Y$, where the successive drawings are independent. The statements about asymptotic properties of the estimators rely on the additional assumption that the matrix $X'X/n$ has a positive definite limit. If
instead sampling is random from the joint distribution of $x$ and $y$, there is no substantial change in the results.

2 Ordinary least squares

In simultaneous equations models, the parameters of interest are the structural parameter, the $\alpha'$s in the demand-supply example and the elements of $\Gamma$ and $B$ and in general case, rather than the reduced form parameters, the $\pi'$s or $\Pi$. Ordinary least squares (OLS) estimation of the structural parameters is not appropriate because the structural parameters are not coefficients of the conditional expectation functions among the observable variables. We now illustrate this point for the supply equation of the demand and supply model.

The reduced form of the demand and supply model expressed explicitly in terms of the structural parameters:

$$y_1 = (\alpha_2 x + \alpha_1 u_2 + u_1) / (1 - \alpha_1 \alpha_3),$$

(2.1)

$$y_2 = (\alpha_2 \alpha_3 x + \alpha_3 u_1 + u_2) / (1 - \alpha_1 \alpha_3).$$

(2.2)

For convenience, suppose that $x$, $u_1$ and $u_2$ are trivariate-normally distributed with zero means, variances $\sigma_x^2$, $\sigma_{u_1}^2$, $\sigma_{u_2}^2$, and zero correlations. Then $y_2$ and $y_1$ are bivariate normal, so the conditional expectation of $y_2$ given $y_1$ is

$$E(y_2|y_1) = \alpha^* y_1$$

with

$$\alpha^* = C(y_1, y_2) / V(y_1).$$
If $\alpha^{*} = \alpha_3$, then the sample least squares regression of $y_2$ on $y_1$ will provide a unbiased minimum variance estimator of $\alpha_3$. If $\alpha^{*} \neq \alpha_3$, then least squares is not appropriate for the estimation of $\alpha_3$. From equations (2.1) and (2.2) we calculate

$$C(y_2, y_3) = (\alpha_2 \alpha_3 \sigma_2^2 + \alpha_3 \sigma_1^2 + \alpha_1 \sigma_2^2) / (1 - \alpha_1 \alpha_3)^2, V(y_1) = (\alpha_2^2 \sigma_X^2 + \sigma_1^2 + \alpha_1^2 \sigma_2^2) / (1 - \alpha_1 \alpha_3)^2.$$ 

Let $\theta = \alpha_2^2 \sigma_X^2 + \sigma_1^2$. Then

$$\alpha^{*} = \alpha_3 \frac{\theta}{(\theta + \alpha_1^2 \sigma_2^2)} + \frac{\alpha_1 \sigma_2^2}{\theta + \alpha_1^2 \sigma_2^2}.$$ 

Clearly the parameter of interest $\alpha_3$ is not the slope of the conditional expectation function of $y_2$ given $y_1$. This result is usually described by saying that OLS gives a biased estimator of the structural parameter $\alpha_3$. Another description is that OLS gives a unbiased estimator of slope of the conditional expectation function, which happens to differ from the slope of the structural equation. Observe that $\alpha^{*} = \alpha_3$ in the special case with $\alpha_1 = 0$; in this case, $y_1$ is a function of $x$ and $u_1$ only so that $E(u_2|y_1) = 0$.

The problem with OLS can be illustrated without relying on normality. From (1.2) we get

$$E(y_2|y_1) = \alpha_3 y_1 + E(u_2|y_1).$$

From eq. (2.2),

$$C(y_1, u_2) = C(\alpha_2 x + \alpha_1 u_2 + u_1, u_2) / (1 - \alpha_1 \alpha_3) = \alpha_1 \sigma_2^2 / (1 - \alpha_1 \alpha_3).$$

Because $y_1$ and $u_2$ are correlated, we see that $E(u_2|y_1) \neq E(u_2) = 0$. 

3 Indirect least squares

The next method we consider uses OLS to estimate the reduced-form parameters, and then converts the OLS reduced-form estimates into estimates of the structural-form parameters. This method, called ‘indirect least squares’ (ILS), produces estimates that are consistent, although not unbiased. Koopmans and Hood (1953) attribute ILS to M.A. Girshick. Again see Farebrother (1999) for precursors.

The key to ILS is the relation that relates the reduced-form coefficients to the structural-form coefficients, namely, \( \Pi = \mathbf{B} \Gamma^{-1} \), which can be rewritten as \( \Pi \Gamma = \mathbf{B} \). Suppose \( \Pi \) is known along with the prior knowledge that certain elements of \( \Gamma \) and \( \mathbf{B} \) are zero. The question is whether we can solve \( \Pi \Gamma = \mathbf{B} \) uniquely for the remaining unknown elements of \( \Gamma \) and \( \mathbf{B} \). When a structural parameter is uniquely determined, we say that the parameter is identified in terms of \( \Pi \) or, more simply, that is identified. This suggests that the identified structural-form parameters may be estimated via OLS estimates of the reduced-form coefficients.

The relation between reduced-form and structural coefficients for the demand and supply model is the following:

\[
\begin{pmatrix}
\pi_{11} & \pi_{12}
\end{pmatrix}
\begin{pmatrix}
1 & -\alpha_3 \\
-\alpha_1 & 1
\end{pmatrix}
= (\alpha_2 \ 0).
\]

There are two equations in three unknowns:

\[
\pi_{11} - \alpha_1 \pi_{12} = \alpha_2 \pi_{12} - \alpha_3 \pi_{11} = 0.
\tag{3.1}
\]

On the right-hand-side of (3.1), solve the equation for \( \alpha_3 = \pi_{12} / \pi_{11} \). We conclude that the slope coefficient of the supply equation is identified. With respect to estimation, the ILS estimate of \( \alpha_3 \) is obtained by replacing \( \pi_{11} \) and \( \pi_{12} \) by their OLS counterparts.

The ILS estimator of \( \alpha_3 \) is consistent since the equation-by-equation OLS estimators of \( \pi_{11} \) and \( \pi_{12} \) are consistent. Moreover, the equation-by-equation OLS estimates are the same as the generalized least squares (GLS) estimates, that is, the OLS and GLS estimates coincide in every sample. This is because the explanatory variables are identical in the two reduced-form equations. A consequence is that the ILS estimator is asymptotically efficient.

4 Indirect feasible generalized least squares
For some simultaneous-equation models, prior knowledge that certain elements of $\Gamma$ and $B$ are zero implies restrictions on $\Pi$. In this situation, equation-by-equation OLS estimates of the $\pi$'s are not optimal, and ILS does not yield a unique estimate of the structural parameters. We now illustrate the case with restrictions on $\Pi$ using a modification of the original structural model.

The modified model has three exogenous variables, $x_1$ (income), $x_2$ (wage rate) and $x_3$ (interest rate). The modification consists of allowing the three exogenous variables to enter the supply equation:

\begin{align*}
\text{Demand:} \quad y_1 &= \alpha_1 y_2 + \alpha_2 x_1 + u_1, \\
&= (4.1) \\
\text{Supply:} \quad y_2 &= \alpha_3 y_1 + \alpha_4 x_1 + \alpha_5 x_2 + \alpha_6 x_3 + u_2. \\
&= (4.2)
\end{align*}

The reduced-form of the modified structural-form system is

\begin{align*}
\text{Quantity:} \quad y_1 &= \pi_{11} x_1 + \pi_{21} x_2 + \pi_{31} x_3 + v_1, \\
&= (4.3) \\
\text{Price:} \quad y_2 &= \pi_{12} x_1 + \pi_{22} x_2 + \pi_{32} x_3 + v_2. \\
&= (4.4)
\end{align*}

In the $\Pi \Gamma = B$ format, the relation between the reduced-form and structural coefficients is:

\[
\begin{pmatrix}
\pi_{11} & \pi_{12} \\
\pi_{21} & \pi_{22} \\
\pi_{31} & \pi_{32}
\end{pmatrix}
\begin{pmatrix}
1 & -\alpha_3 \\
-\alpha_1 & 1
\end{pmatrix}
= 
\begin{pmatrix}
\alpha_2 & \alpha_4 \\
0 & \alpha_5 \\
0 & \alpha_6
\end{pmatrix}.
There are now six equations in six unknowns:

\[
\begin{align*}
\pi_{11} - \alpha_1 \pi_{12} &= \alpha_2 \\
\pi_{12} - \alpha_3 \pi_{11} &= \alpha_4 \\
\pi_{21} - \alpha_1 \pi_{22} &= 0 \\
\pi_{22} - \alpha_3 \pi_{21} &= \alpha_5 \\
\pi_{31} - \alpha_1 \pi_{32} &= 0 \\
\pi_{32} - \alpha_3 \pi_{31} &= \alpha_6.
\end{align*}
\]

(4.5)

The system on the left of (4.5) determines the parameters of the demand equation. Solve either of the equations that has 0 on its right-hand side for \( \alpha_1 = \pi_{31} / \pi_{32} = \pi_{21} / \pi_{22} \), and then get \( \alpha_2 \) from the remaining equation. Clearly, the coefficients of the demand equation are identified in terms of \( \Pi \).

Furthermore, there is a restriction on the \( \pi \)'s, namely \( \pi_{31} / \pi_{32} = \pi_{21} / \pi_{22} \), because on the left of (4.5) there are three equations in two unknowns.

The system on the right-hand side of (4.5), which refers to the supply equation, consists of three equations in four unknowns. Once a value is assigned to \( \alpha_3 \), the equations can be solved for \( \alpha_4, \alpha_5, \alpha_6 \). A different arbitrary value for \( \alpha_3 \) generates different values for \( \alpha_4, \alpha_5, \alpha_6 \). The solution is not unique. Hence, the coefficients of the supply equation are not identified in terms of \( \Pi \).

With respect to estimation, ILS using the equation-by-equation OLS estimates of \( \Pi \) will not give unique estimates of the structural parameters of the supply equation. The result is two different ILS estimates of \( \alpha_4, \alpha_5, \alpha_6 \). This problem can be overcome by estimating the reduced-form subject to the restriction \( \pi_{31} / \pi_{32} = \pi_{21} / \pi_{22} \). The restricted estimates of the \( \pi \)'s can be converted into unique estimates of the \( \alpha \)'s using the sample counterpart of the system (4.5).

Suppose there are restrictions on \( \Pi \). Then the fact that the explanatory variables are identical in every reduced-form equation does not imply that the OLS and GLS estimates of the \( \pi \)'s are the same. In other words, OLS estimation of the reduced form will not be optimal. If the variance matrix of the reduced-form disturbance vector \( \Omega \) is known, then GLS subject to the restrictions on \( \Pi \) is the natural (nonlinear) estimation procedure. The conversion of the GLS estimates of the \( \pi \)'s into estimates of the \( \alpha \)'s can be described as ‘indirect GLS’. Since the GLS estimator is consistent and asymptotically efficient, the indirect-GLS estimators of \( \Gamma \) and \( B \) are also consistent and asymptotically efficient.

When \( \Omega \) is unknown, as is true in practice, feasible GLS is the natural estimation procedure for \( \Pi \).

Feasible GLS is similar to GLS except that an estimator \( \hat{\Omega} \) is used in place of \( \Omega \). The estimator \( \hat{\Omega} \) comes from the residuals of the equation-by-equation OLS reduced-form regressions. The resulting estimates of the \( \alpha \)'s are referred to as ‘indirect-FGLS’ estimates because the FGLS estimates of the \( \pi \)'s are converted into estimates of the \( \alpha \)'s. Because the FGLS estimator of \( \Pi \) is consistent and asymptotically efficient, the indirect-FGLS estimators of \( \Gamma \) and \( B \) are also consistent and asymptotically efficient. Indirect GLS and indirect FGLS are referred to as ‘full-information’ methods because they use all the restrictions on \( \Pi \) at once. Estimation of a single structural equation using only the restrictions on \( \Pi \) for that equation alone is often called ‘limited information’ estimation. If all the restrictions are correctly
specified, then full-information estimators are more efficient than limited-information estimators. In some variants of the simultaneous-equation model it is assumed that \( \mathbf{x} \) is multivariate normal. The addition of the normality assumption enables the estimation of \( \Pi \) by maximum likelihood. The resulting estimator of the structural parameters is known as ‘full-information maximum likelihood’, or FIML. If \( \Omega \) is known, then FIML coincides with indirect-GLS. If \( \Omega \) is unknown, FIML differs from indirect-FGLS, but the estimators have the same asymptotic distribution.

The difference between FIML and indirect FGLS can be clarified by briefly turning from the population to the sample. Let \( \hat{\mathbf{V}} = \mathbf{Y} - \mathbf{X} \hat{\mathbf{P}} \), where \( \hat{\mathbf{P}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y} \) is the estimator of \( \Pi \) obtained by equation-by-equation OLS. The estimator of \( \Omega \) used in FGLS is \( \hat{\Omega} = (1/n)\hat{\mathbf{V}}\hat{\mathbf{V}}' \). The criterion minimized by FGLS is \( \text{tr}(\hat{\Omega}^{-1}\mathbf{V}\mathbf{V}') \), where \( \mathbf{V} = \mathbf{Y} - \mathbf{X}\hat{\mathbf{P}} \). FIML proceeds by inserting \( \hat{\Omega} = (1/n)\hat{\mathbf{V}}\hat{\mathbf{V}}' \) (as a conditional solution) into the log-likelihood function to obtain the log-likelihood concentrated on \( \mathbf{V}'\mathbf{V} \). The consequence is that the criterion minimized by FIML is \( \mathbf{V}'\mathbf{V} \). The difference in the criteria explains the difference in the estimators.

The maximum likelihood estimation of a single structural-form equation that uses only the restrictions on \( \Pi \) for that equation alone is referred to as ‘limited-information maximum likelihood’, or LIML. We next consider another limited-information estimation method.

5 Two-stage least squares

The 2SLS estimator uses the unrestricted reduced-form estimate \( \mathbf{P} \), the equation-by-equation OLS estimates of the \( \mathbf{P} 's \), which accounts for its popularity. The mechanics of the 2SLS method can be described simply. In the first stage, the right-hand-side endogenous variables of the structural equation are regressed on all the exogenous variables in the reduced form, and the fitted values are obtained. In the second stage, the right-hand-side endogenous variables are replaced by their fitted values, and the left-hand-side endogenous variable of the equation is regressed on the right-hand-side fitted values and the exogenous variables included in the equation.

Two rationales for the 2SLS procedure are now developed using the demand equation of the modified structural model. The starting point for the first rationale is the expectation of the demand equation conditional on \( x_1, x_2, \) and \( x_3 \). Taking expectations gives

\[
E(y_1|x_1, x_2, x_3) = \alpha_1E(y_2|x_1, x_2, x_3) + \alpha_2x_1 + E(u_1|x_1, x_2, x_3),
\]

or

\[
E(y_1|x_1, x_2, x_3) = \alpha_1y_2^* + \alpha_2x_1.
\]
From the reduced-form eq. (4.4), $y_2^* = E(y_2| x_1, x_2, x_3) = \pi_{12}x_1 + \pi_{22}x_2 + \pi_{32}x_3$. Because $y_2^*$ is a linear function of the exogenous variables, it is exogenous. If $y_2^*$ were observed, then $y_1$ could be regressed on $y_2^*$ and $x_1$ to get unbiased estimates of $\alpha_1$ and $\alpha_2$. But $y_2^*$ is unobservable because $\pi_{12}, \pi_{22}$ and $\pi_{32}$ are unknown. However, an unbiased and consistent estimate $\hat{y}_2$ can be obtained by replacing the unknown $\pi$'s by their OLS estimates. Then, making the replacement of $\hat{y}_2$ for $y_2^*$ produces consistent estimates of the structural parameters.

The second rationale exploits the fact that in the population the following moment conditions hold:

$$E(u_1) = 0, \ C(x_1, u_1) = C(x_2, u_1) = C(x_3, u_1) = 0.$$ 

These imply two orthogonality conditions:

$$E(y_2^* u_1) = 0, \ E(x_1 u_1) = 0.$$ 

If we let $u_1 = y_1 - (a_1 y_2^* + a_2 x_1)$, then $a_1$ and $a_2$ are the values for $a_1$ and $a_2$ that make $E(y_2^* u_1) = 0$ and $E(x_1 u_1) = 0$. 2SLS chooses the estimates that make the analogous sample quantities zero, that is, $\sum j \hat{y}_2 j u_1 i = 0$ and $\sum j x_1 j u_1 i = 0$, $(i = 1, \ldots, n)$. This illustrates that 2SLS has an instrumental-variable (IV) interpretation.

The IV interpretation can be illustrated more explicitly by writing the demand equation in terms of the observations for a sample size of $n$:

$$y_1 = y_2 \alpha_1 + x_1 \alpha_2 + u_1 = (Y_2 \quad x_1) \begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix} + u_1 = Z_1 \alpha + u_1,$$

where in the context of the demand equation $Y_1$ and $Y_2$ are the columns of $Y$ and $x_1$ is the first column of $X$. As we have shown, regressing $Y_1$ on $Z_1$ will not give a consistent estimator for $\alpha_1$. Instead replace $Z_1$ by
where \( N \) is the idempotent matrix \( X(X'X^{-1})X' \). Regressing \( y_1 \) on \( \hat{Z}_1 \) gives the normal equations,

\[
\hat{Z}_1' \hat{Z}_1 a_1^* = \hat{Z}_1' y_1,
\]

the solution to which is the 2SLS estimator.

The 2SLS normal equations are equivalent to a set of orthogonality conditions: \( \hat{Z}_1' u_1 = 0 \), where \( u_1 = y_1 - Z_1 a_1^* \). The equivalence follows from an algebraic fact:

\[
\hat{Z}_1' Z_1 = Z_1' N Z_1 = Z_1' N N Z_1 = \hat{Z}_1' \hat{Z}_1.
\]

The variables in \( \hat{Z}_1 \) are legitimate instruments because they are, at least asymptotically, uncorrelated with the disturbance. The IV interpretation implies that the 2SLS estimator is consistent. In fact, it is the optimal feasible IV estimator.

We also note that the 2SLS estimator can be interpreted as a general-method-of-moments (GMM) estimator. In the above example, this follows from the fact that \( a_1^* \) minimizes the quadratic form

\[
(y_1 - Z_1 a_1^*)' X(X'X)^{-1} X'(y_1 - Z_1 a_1^*).
\]

It can be shown that 2SLS is the optimal feasible GMM estimator. An advantage of the GMM approach is that heteroskedasticity and autocorrelation can be accommodated by an appropriate redefinition of the optimal weighting matrix in the definition of the GMM estimator (see Ruud, 2000, pp. 718–21).

We conclude this section with some remarks on estimation in the simultaneous-equations model.

1. If all the structural equations are identified, and there are no restrictions on \( \Pi \), then ILS, indirect-FGLS, FIML, LIML and 2SLS all produce the same estimates.
2. If there are restrictions on \( \Pi \), then LIML and 2SLS produce different estimates in the sample.
two-stage least squares and the \(k\)-class estimator: The New Palgrave Dictionary of Economics

but the estimators have the same asymptotic distribution, and similarly for indirect FGLS and FIML.

3. If a parameter is not identified, then there is no method to estimate it consistently.

4. We have confined our attention to the case in which the prior information used for identification consists of normalizations and exclusions (zero restrictions). If other information is available (for example, \(\Sigma\) is diagonal, or a coefficient in one structural equation is equal to a coefficient in another), then some modifications are needed in the description of the estimators and their statistical properties.

6 The \(k\)-class family

The \(k\)-class family of estimators of the coefficients of a single structural equation is illustrated for the demand equation of the modified structural model. For this equation, the estimator is

\[
a_1^* = \left( Z_1' (I - kM) Z_1 \right)^{-1} Z_1' (I - kM) y_1,
\]

where \(M = I - N\). This family was introduced by Theil (1953b; 1961). It includes the OLS estimator \(k = 0\) and the 2SLS estimator \(k = 1\).

A remarkable fact is that the \(k\)-class family includes LIML. The LIML estimator is obtained by setting \(k = \lambda^*\), where \(\lambda^*\) the smallest root of

\[
|W_1 - \lambda W| = 0.
\]

In the determinantal equation, \(W_1\) is the cross-product matrix of residuals from the OLS regression of \((y_1, y_2)\) on \(x_1\) (the included endogenous variables on the included exogenous variable), and \(W\) is the cross-product matrix of the residuals from the OLS regression of \((y_1, y_2)\) on \(X\) (the included endogenous on all the exogenous variables). Moreover, the LIML estimator of \(a_1\) is the value of \(a_1\) that minimizes the variance ratio:

\[
\frac{(1 - a_1) W_1 (1 - a_1)'}{(1 - a_1) W (1 - a_1)'}.
\]
Accordingly, the LIML estimator is also sometimes referred to as the ‘least-variance ratio’ estimator. The $k$-class estimator is consistent if $(k-1)$ converges in probability to 0 and has the same limiting distribution as 2SLS if $n^{1/2}(k-1)$ converges in probability to 0. These conditions are clearly not satisfied when $k = 0$ and hence by OLS. A proof that these conditions are satisfied for LIML is given in Amemiya (1985, pp. 237–8). Zellner (1998) shows that a Bayesian method-of-moments approach justifies certain other members of the $k$-class (and double $k$-class) family of estimators.

7 Finite sample distributions

There has been debate about whether the LIML estimator is better than 2SLS. The reason for this debate is that the finite sample distributions of the estimators differ when there are restrictions on $\Pi$. Hence we now limit our attention to the case where restrictions are present.

A key difference between the estimators is the existence of moments. The 2SLS estimator has moments up to certain order. By contrast, the LIML estimator has no moments. This result holds for an arbitrary number of included endogenous variables. Mariano (2001) reviews the moment existence results.

In addition to the moment existence results, closed form expressions for the moments and probability densities of 2SLS, LIML and $k$-class estimators have been derived. These expressions are complicated; see Phillips (1983) for specific references.

The finite sample results have mostly come from the study of a model with two included endogenous variables. Moreover, it is often assumed that the disturbances are normal. The finite sample results are obtained using analytical and simulation methods. A survey of the results and their practical implications is given in Mariano (2001). One of the results is that the LIML distribution is far more symmetric than 2SLS, though more spread out, and it approaches normality faster. Similarly, Anderson (1982) concludes that for many cases that occur in practice the standard the normal theory is inadequate for 2SLS, but provides a fairly good approximation to the actual distribution of the LIML estimator. The symmetry result is not surprising because the approximate distribution of the LIML estimator (obtained from large sample asymptotic expansions) is median unbiased. Median unbiasedness does not hold in general for 2SLS.

It is helpful to put the debate over the relative merits of LIML and 2SLS in perspective. On the assumption that the model is correctly specified, the presumption is that maximum likelihood will have better properties in some well-defined sense. This is because it uses more information than GMM. See Anderson, Kunitomo and Morimume (1986) and Takeuchi and Morimume (1985) for results on the second-order efficiency of LIML. An advantage of GMM is that it is robust to misspecifications of the disturbance distribution, although this advantage was not the original motivation for introducing 2SLS.

8 Epilogue

Keynesian economics initially played a key role in propelling research into the estimation of simultaneous-equations models. Interest in the estimation of linear simultaneous-equations models began to wane from about the late 1970s. Historically, this decline paralleled the decline of the Keynesian paradigm as a result of the monetarist counter-revolution and later rational expectations.
the same time, there was growing awareness that linear simultaneous-equations models often suffered from potentially serious misspecification. On the one hand, even if one takes for granted the statistical specification of the model (A1–A4), economic theory did not provide a satisfactory basis for deciding what endogenous and exogenous variables should be excluded from individual structural equations. As a consequence, the identification of structural parameters was open to question. On the other hand, the statistical specification of the linear structural-form model was itself questionable, due to either the nature of the data or considerations of economic theory or both. The issue of identification was highlighted by Sims (1980) in a well-known paper aptly titled ‘Macroeconomics and Reality’.

Simultaneous-equations models have been generalized by the introduction of nonlinear structural equations. Amemiya (1974) generalized the 2SLS method to nonlinear models. His nonlinear 2SLS estimator is a GMM estimator. However, unlike in the case of linear models, it cannot be thought of as being obtained in two steps where the first consists of running a least squares regression. The GMM is a two-step estimator, but the first step consists of choosing a weighting matrix. More generally, GMM and IV estimators can be thought of as the descendants of the 2SLS approach. They constitute the contemporary basis for much of the estimation of structural parameters macroeconomics. It is in this sense that 2SLS lives on as a structural estimation method.

Does the identification and estimation of simultaneous-equations models have a future? There are some positive signs. Although indirectly, these issues continue to play a role in the identified vector autoregression literature, for example, Bernanke and Blinder (1992), Gordon and Leeper (1995), Cushman and Zha (1997). More recently, there has been a revival of interest in simultaneous-equations models formulated as nonlinear dynamic stochastic general equilibrium models. This formulation has the advantage that the resulting models are viewed as more firmly anchored in economic theory. Estimation of such models presents serious challenges. Some examples where these challenges are addressed include DeJong, Ingram and Whiteman (2000) and Fernandez-Villaverde and Rubio-Ramirez (2005).

uncertainty and general equilibrium

Mukul Majumdar and Roy Radner
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews alternative approaches to incorporating uncertainty in Walrasian models. It begins with a sketch of the Arrow–Debreu model of complete markets. An extension of this framework allowing for economic agents to have different information about the environment is followed by a critique. When markets are incomplete and trades take place sequentially, several types of equilibrium concept arise according to the hypotheses we make about the way traders form their expectations. We present conditions for the existence of equilibria for two such equilibrium concepts, and discuss the possible failure to attain Paretian welfare optima.

Article

One of the notable intellectual achievements of economic theory during the second half of the 20th century has been the rigorous elaboration of the Walras–Pareto theory of value; that is, the theory of the existence and optimality of competitive equilibrium. Although many economists and mathematicians contributed to this development, the resulting edifice owes so much to the pioneering and influential work of Arrow and Debreu that in this paper we shall refer to it as the ‘Arrow–Debreu theory’. (For comprehensive treatments, together with references to previous work, see Debreu, 1959; Arrow and...
The Arrow–Debreu theory was not originally put forward for the case of uncertainty, but an ingenious device introduced by Arrow (1953), and further elaborated by Debreu (1953), enabled the theory to be reinterpreted to cover the case of uncertainty about the availability of resources and about consumption and production possibilities. (See Debreu, 1959, ch. 7, for a unified treatment of time and uncertainty.) Subsequent research has extended the Arrow–Debreu theory to take account of (a) differences in information available to different economic agents, and the ‘production’ of information, (b) the incompleteness of markets, and (c) the sequential nature of markets. The consideration of these complications has stimulated the developments of new concepts of equilibrium, two of which will be elaborated in this article under the headings: (a) equilibrium of plans, prices, and price expectations (EPPPE) and (b) rational expectations equilibrium (REE). The exploration of these features of real-world markets has also made possible a general-equilibrium analysis of money and securities markets, institutions about which the original Arrow–Debreu theory could provide only limited insights. It has also led to a better understanding of the limits to the ability of the ‘invisible hand’ in attaining a Pareto optimal allocation of resources.

Review of the Arrow–Debreu model of a complete market for present and future contingent delivery

In this section, we review the approach of Arrow (1953) and Debreu (1959) to incorporating uncertainty about the environment into a Walrasian model of competitive equilibrium. The basic idea is that commodities are to be distinguished, not only by their physical characteristics and by the location and dates of their availability and/or use, but also by the environmental event in which they are made available and/or used. For example, ice cream made available (at a particular location on a particular date) if the weather is hot may be considered to be a different commodity from the same kind of ice cream made available (at the same location and date) if the weather is cold. We are thus led to consider a list of ‘commodities’ that is greatly expanded by comparison with the corresponding case of certainty about the environment. The standard arguments of the theory of competitive equilibrium, applied to an economy with this expanded list of commodities, then require that we envisage a ‘price’ for each commodity, the resulting set of price ratios specifying the market rate of exchange between each pair of commodities.

Just what institutions could, or do, effect such exchanges is a matter of interpretation that is, strictly speaking, outside the model. We shall present one straightforward inpt, and then comment briefly on an alternative inpt.

First, however, it will be useful to give a more precise account of concepts of environment and event that we shall be employing. The description of the ‘physical world’ is decomposed into three sets of variables: (a) decision variables, which are controlled (chosen) by economic agents; (b) environmental variables, which are not controlled by any economic agent; and (c) all other variables, which are completely determined (possibly jointly) by decisions and environmental variables. A state of the environment is a complete specification (history) of the environmental variables from the beginning to the end of the economic system in qst. An event is a set of states; for example, the event ‘the weather is hot in New York on 1 July 1970’ is the set of all possible histories of the environment in which the temperature in New York during the day of 1 July 1970 reaches a high of at least (say) 75°F. Granted
that we cannot know the future with certainty, at any given date, there will be a family of *elementary observable* (knowable) *events*, which can be represented by a partition of the set of all possible states (histories) into a family of mutually exclusive subsets. It is natural to assume that the partitions corresponding to successive dates are successively finer, which represents the accumulation of information about the environment.

We shall imagine that a ‘market’ is organized before the beginning of the physical history of the economic system. An elementary contract in this market will consist of the purchase (or sale) of some specified number of units of a specified commodity to be delivered at a specified location and date, if and only if a specified elementary event occurs. Payment for this purchase is to be made now (at the beginning), in ‘units of account’, at a specified price quoted for that commodity–location–date–event combination. Delivery of the commodity in more than one elementary event is obtained by combining a suitable set of elementary contracts. For example, if delivery of one quart of ice cream (at a specified location and date) in hot weather costs $1.50 (now) and delivery of one-quart in non-hot weather costs $1.10, then sure delivery of one quart (that is, whatever the weather) costs $1.50+$1.10=$2.60.

There are two groups of economic agents in the economy: *producers* and *consumers*. A producer chooses a production plan, which determines his input and/or output of each commodity at each date in each elementary event (we shall henceforth suppress explicit reference to location, it being understood that the location is specified in the term ‘commodity’). For a given list of prices, the present value of a production plan is the sum of the values of outputs minus the sum of the values of inputs. Each producer is characterized by a set of production plans that are (given the technological know-how) feasible for him: his production possibility set.

A consumer chooses a consumption plan, which specifies his consumption of each commodity at each date in each elementary event. Each consumer is characterized by: (a) a set of consumption plans that are (physically, psychologically, and so on) feasible for him: his consumption possibility set; (b) preferences among the alternative plans that are feasible for him; (c) his endowment of physical resources, that is, a specification of the quantity of each commodity, for example, labour, at each date in each event, with which he is exogenously endowed; and (d) his shares in each producer, that is, the fraction of the present value of each producer's production plan that will be credited to the consumer's account. (For any one producer, the sum of the consumers’ shares is unity.) For given prices and given production plans of all the producers, the present net worth of a consumer is the total value of his resources plus the total value of his shares of the present values of producers’ production plans.

An equilibrium of the economy is a list of prices, a set of production plans (one for each producer), and a set of consumption plans (one for each consumer), such that (a) each producer's plan has maximum present value in his production possibility set; (b) each consumer's plan maximizes his preferences within his consumption possibility set, subject to the additional (budget) constraint that the present cost of his consumption plan not exceed his present net worth; (c) for each commodity at each date in each elementary event, the total demand equals the total supply: that is, the total planned consumption equals the sum of the total resource endowments and the total planned net output (where inputs are counted as negative outputs).

Notice that (a) producers and consumers are ‘price takers’; (b) for given prices there is no uncertainty about the present value of a production plan or of given resource endowments, nor about the present cost of a consumption plan; (c) therefore, for given prices and given producers’ plans, there is no uncertainty about a given consumer's present net worth; (d) since a consumption plan may specify that, for a given
commodity at a given date, the quantity consumed is to vary according to the event that actually occurs, a consumer's preferences among plans will reflect not only his 'taste' but also his subjective beliefs about the likelihoods of different events and his attitude towards risk (Savage, 1954).

It follows that beliefs and attitudes towards risk play no role in the assumed behaviour of producers. On the other hand, beliefs and attitudes towards risk do play a role in the assumed behaviour of consumers, although for given prices and production plans each consumer knows his (single) budget constraint with certainty.

We shall call the model just described an ‘Arrow–Debreu’ economy. One can demonstrate, under ‘standard conditions’: (a) the existence of an equilibrium, (b) the Pareto optimality of an equilibrium, and (c) that, roughly speaking, every Pareto optimal choice of production and consumption plans is an equilibrium relative to some price system for some distribution of resource endowments and shares (Debreu, 1959). In another direction of research initiated by Debreu (1970), the focus was to identify properties (like local uniqueness, finiteness) of Walrasian equilibria that were generic (typical or robust in a given context or in a class models). In what follows we shall use the term ‘generic’ informally and invite the reader to verify the exact definition from the original reference.

In the above interpretation of the Arrow–Debreu economy, all accounts are settled before the history of the economy begins, and there is no incentive to revise plans, reopen the markets or trade in shares.

There is an alternative inpt, which will be of interest in connection with the rest of this article, but which corresponds to exactly the same formal model. In this second inpt, there is a single commodity at each date – let us call it ‘gold’ – that is taken as a numeraire at that date. A ‘price system’ has two parts: (1) for each date and each elementary event at that date, there is a price, to be paid in gold at the beginning date, for one unit of gold to be delivered at the specified date and event; (2) for each commodity, date, and event at that date, a price, to be paid in gold at that date and event, for one unit of the commodity to be delivered at that same date and event. The first part of the price system can be interpreted as ‘insurance premiums’ and the second part as ‘spot prices’ at the given date and event. The insurance interpretation is to be made with some reservation, however, since there is no real object being insured and no limit to the amount of insurance that an individual may take out against the occurrence of a given event. For this reason, the first part of the price system might be better interpreted as reflecting a combination of betting odds and interest rates.

Although the second part of the price system might be interpreted as spot prices, it would be a mistake to think of the determination of the equilibrium values of these prices as being deferred in real time to the dates to which they refer. The definition of equilibrium requires that the agents have access to the complete system of prices when choosing their plans. In effect, this requires that at the beginning of time all agents have available a (common) forecast of the equilibrium spot prices that will prevail at every future date and event.

**Extension of the Arrow–Debreu model to the case in which different agents have different information**

In an Arrow–Debreu economy, at any one date each agent may have incomplete information about the state of the environment, but all the agents will have the same information. This last assumption is not tenable if we are to take good account of the effects of uncertainty in an economy. We shall now sketch how, by a simple reinput of the concepts of production possibility set and consumption possibility set, we can extend the theory of the Arrow–Debreu economy to allow for differences in information among the
For each date, the information that will be available to a given agent at that date may be characterized by a partition of the set of states of the environment. To be consistent with our previous terminology, we should assume that each such information partition must be at least as coarse as the partition that describes the elementary events at that date; that is, each set in the information partition must contain a set in the elementary event partition for the same date. For example, each set in the elementary event partition at a given date might specify the high temperature at that date, whereas each set in a given agent's information partition might specify only whether this temperature was higher than 75°F, or not. An agent's information restricts his set of feasible plans in the following manner. Suppose that at a given date the agent knows only that the state of the environment lies in a specified set A (one of the sets in his information partition at that date), and suppose (as would be typical) that the set A contains several of the elementary events that are in principle observable at that date. Then any action that the agent takes at that date must necessarily be the same for all elementary events in the set A. In particular, if the agent is a consumer, then his consumption of any specified commodity must be the same in all elementary events contained in the information set A; if the agent is a producer, then his input or output of any specified commodity must be the same for all events in A. (We are assuming that consumers know what they consume and producers what they produce at any given date.)

Let us call the sequence of information partitions for a given agent his information structure and let us say that this structure is fixed if it is given independent of the actions of himself or any other agent. Furthermore, in the case of a fixed information structure, let us say that a given plan (consumption or production) is compatible with that structure if it satisfies the conditions described in the previous paragraph, at each date.

Suppose that consumption and production possibility sets of the Arrow–Debreu economy are interpreted as characterizing, for each agent, those plans that would be feasible if he had 'full information' (that is, if his information partition at each date coincided with the elementary event partition at that date). The set of feasible plans for any agent with a fixed information structure can then be obtained by restricting him to those plans in the full information possibility set that are also compatible with his given information structure.

From this point on, all of the machinery of the Arrow–Debreu economy (with some minor technical modifications) can be brought to bear on the present model. In particular, we get a theory of existence and optimality of competitive equilibrium relative to fixed structures of information for the economic agents. We shall call this the 'extended Arrow–Debreu economy'. *We should add that differences among information structures of the agents may lead to a significant reduction of the number of active markets.* (For a fuller treatment, see Radner, 1968; 1982.)

**Choice of information**

There is no difficulty in principle in incorporating the choice of information structure into the extended Arrow–Debreu economy. We doubt, however, that it is reasonable to assume that the technological conditions for the acquisition and use of information generally satisfy the hypotheses of the standard theorems on the existence and optimality of competitive equilibrium.

The acquisition and use of information about the environment typically require the expenditure of goods and services, that is, of commodities. If one production plan requires more information for its

---

implementation than another (that is, requires a finer information partition at one or more dates), then the list of (commodity) inputs should reflect the increased inputs for information. In this manner a set of feasible production plans can reflect the possibility of choice among alternative information structures. Unfortunately, the acquisition of information often involves a ‘set-up cost’, that is, the resources needed to obtain the information may be independent of the scale of the production process in which the information is used. This set-up cost will introduce a non-convexity in the production possibility set, and thus one of the standard conditions in the theory of the Arrow–Debreu economy will not be satisfied (Radner, 1968).

Even without set-up costs, there is a general tendency for the value of information to exhibit ‘increasing returns’, at least at low levels, provided that the structure of information varies smoothly with its cost. This striking phenomenon leads to discontinuities in the demand for information. (For a precise statement, see Radner and Stiglitz, 1984).

**Critique of the extended Arrow–Debreu economy**

If the Arrow–Debreu model is given a literal input, then it clearly requires that the economic agents possess capabilities of imagination and calculation that exceed reality by many orders of magnitude. Related to this is the observation that the theory requires in principle a complete system of insurance and futures markets, which system appears to be too complex, detailed, and refined to have practical significance. A further obstacle to the achievement of a complete insurance market is the phenomenon of ‘moral hazard’ (Arrow, 1965).

A second line of criticism is that the theory does not take account of at least three important institutional features of modern capitalist economies: money, the stock market, and active markets at every date. These two lines of criticism have an important connection, which suggests how the Arrow–Debreu theory might be improved. If, as in the Arrow–Debreu model, each production plan has a sure unambiguous present value at the beginning of time, then consumers have no interest in trading in shares, and there is no point in a stock market. If all accounts can be settled at the beginning of time, then there is no need for money during the subsequent life of the economy; in any case, the standard motives for holding money are not applicable.

On the other hand, once we recognize explicitly that there is a sequence of markets, one for each date, and not one of them complete (in the Arrow–Debreu sense), then certain phenomena and institutions not accounted for in the Arrow–Debreu model become reasonable.

First, there is uncertainty about the prices that will hold in future markets, as well as uncertainty about the environment.

Second, producers do not have a clear-cut natural way of comparing net revenues at different dates and states. Stockholders have an incentive to establish a stock exchange since it enables them to change the way their future revenues depend on the states of the environment. As an alternative to selling his shares in a particular enterprise, a stockholder may try to influence the management of the enterprise in order to make the production plan conform better to his own subjective probabilities and attitude towards risk.

Third, consumers will typically not be able to discount all of their ‘wealth’ at the beginning of time, because (a) their shares of producers’ future (uncertain) net revenues cannot be so discounted and (b) they cannot discount all of their future resource endowments. Consumers will be subject to a sequence
of budget constraints, one for each date (rather than to a single budget constraint relating present cost of his consumption plan to present net worth, as in the Arrow-Debreu economy).

Fourth, economic agents may have an incentive to speculate on the prices in future markets, by storing goods, hedging, and so on. Instead of storing goods, an agent may be interested in saving part of one date's income, in units of account, for use on a subsequent date, if there is an institution that makes this possible. There will thus be a demand for 'money' in the form of demand deposits.

Fifth, agents will be interested in forecasting the prices in markets at future dates. These prices will be functions of both the state of the environment and the decisions of (in principle, all) economic agents up to the date in quest.

Sixth, if traders have different information at a particular date, then the equilibrium prices at that date will reflect the pooled information of the traders, albeit in a possibly complicated way. Hence, traders who have a good model of the market process will be able to infer something about other traders’ information from the market prices.

Expectations and equilibrium in a sequence of markets

Consider now a sequence of markets at successive dates. Suppose that no market at any one date is complete in the Arrow-Debreu sense: that is, at every date and for every commodity there will be some future dates and some events at those future dates for which it will not be possible to make current contracts for future delivery contingent on those events. In such a model, several types of 'equilibrium' concept suggest themselves, according to the hypotheses we make about the way traders form their expectations.

Let us place ourselves at a particular date–event pair; the excess supply correspondence at that date–event pair reflects the traders’ information about past prices and about the history of the environment up through that date. If a given trader's excess supply correspondence is generated by preference satisfaction, then the relevant preferences will be conditional upon the information available. If, furthermore, the trader's preferences can be scaled in terms of utility and subjective probability, and conform to the expected utility hypothesis, then the relevant probabilities are the conditional probabilities given the available information. These conditional probabilities express the trader's expectations regarding the future. Although a general theoretical treatment of our problem does not necessarily require us to assume that traders’ preferences conform to the expected utility hypothesis, it will be helpful in the following heuristic discussion to keep in mind this particular interpretation of expectations.

A trader's expectations concern both future environmental events and future prices. Regarding expectations about future environmental events, there is no conceptual problem. According to the expected utility hypothesis, each trader is characterized by a subjective probability measure on the set of complete histories of the environment. Since, by definition, the evolution of the environment is exogenous, a trader's conditional subjective probability of a future event, given the information to date, is well defined.

It is not so obvious how to proceed with regard to traders’ expectations about future prices. We shall contrast two possible approaches. In the first, which we shall call the perfect foresight approach, let us assume that the behaviour of traders is such as to determine, for each complete history of the
environment, a unique corresponding sequence of price systems, say \( \varphi^*_t(e) \), where \( e_t \) is the particular event at date \( t \). If the ‘laws’ governing the economic system are known to all, then every trader can calculate the sequence of functions \( \varphi^*_t \). In this case, at any date–event pair a trader's expectations regarding future prices are well defined in terms of the functions \( \varphi^*_t \) and his conditional subjective probability measures on histories of the environment, given his current information. Traders need not agree on the probabilities of future environmental events, and therefore they need not agree on the probability distribution of future prices, but they must agree on which future prices are associated with which events. We shall call this last type of agreement the condition of common price expectation functions.

Thus, the perfect foresight approach implies that, in equilibrium, traders have common price expectation functions. These price expectation functions indicate, for each date–event pair, what the equilibrium price system would be in the corresponding market at that date–event pair. Pursuing this line of thought, it follows that, in equilibrium, the traders would have strategies (plans) such that, if these strategies were carried out, the markets would be cleared at each date–event pair. Call such plans consistent. A set of common price expectations and corresponding consistent plans is called an equilibrium of plans, prices and price expectations (EPPPE).

This model of equilibrium can be extended to cover the case in which different traders have different information, just as the Arrow–Debreu model was so extended. In particular, one could express in this way the hypothesis that a trader cannot observe the individual preferences and resource endowments of other traders. Indeed, one can also introduce into the description of the state of the environment variables that, for each trader, represent his alternative hypotheses about the ‘true laws’ of the economic system. In this way the condition of common price expectation functions can lose much of its apparent restrictiveness.

The situation in which traders enter the market with different nonprice information presents an opportunity for agents to learn about the environment from prices, since current market prices reflect, in a possibly complicated manner, the nonprice information signals received by the various agents. To take an extreme example, the ‘inside information’ of a trader in a securities market may lead him to bid up the price to a level higher than it otherwise would have been. In this case, an astute market observer might be able to infer that an insider has obtained some favourable information, just by careful observation of the price movement. More generally, an economic agent who has a good understanding of the market is in a position to use market prices to make inferences about the (nonprice) information received by other agents.

These inferences are derived, explicitly or implicitly, from an individual’s ‘model’ of the relationship between the nonprice information received by market participants and the market prices. On the other hand, the true relationship is determined by the individual agents’ behaviour, and hence by their individual models. Furthermore, economic agents have the opportunity to revise their individual models in the light of observations and published data. Hence, there is a feedback from the true relationship to the individual models. An equilibrium of this system, in which the individual models are identical with the true model, is called rational expectations equilibrium (REE).

This concept of equilibrium is more subtle, of course, than the ordinary concept of the equilibrium of supply and demand. In a rational expectations equilibrium, not only are prices determined so as to equate supply and demand, but individual economic agents correctly perceive the true relationship.
between the nonprice information received by the market participants and the resulting equilibrium market prices. This contrasts with the ordinary concept of equilibrium in which the agents respond to prices but do not attempt to infer other agents’ nonprice information from the actual market prices. Although it is capable of describing a richer set of institutions and behaviour than is the Arrow–Debreu model, the perfect foresight approach is contrary to the spirit of much of competitive market theory in that it postulates that individual traders must be able to forecast, in some sense, the equilibrium prices that will prevail in the future under all alternative states of the environment. Even if one grants the extenuating circumstances mentioned in previous paragraphs, this approach still seems to require of the traders a capacity for imagination and computation far beyond what is realistic. An equilibrium of plans and price expectations might be appropriate as a conceptualization of the ideal goal of indicative planning, or of a long-run steady state towards which the economy might tend in a stationary environment.

These last considerations lead us in a different direction, which we shall call the *bounded rationality* approach. This approach is much less well defined, but expresses itself in terms of various retreats from the hypothesis of ‘fully rational’ behaviour by traders, for example, by assuming that the trader’s planning horizons are severely limited, or that their expectation formation follows some simple rules-of-thumb. An example of the bounded-rationality approach is the theory of *temporary (or momentary) equilibrium*. In the evolution of a sequence of temporary equilibria, each agent's expectations will be successively revised in the light of new information about the environment and about current prices (see Grandmont, 1987). Therefore, the evolution of the economy will depend upon the rules or processes of expectation formation and revision used by the agents. In particular, there might be interesting conditions under which such a sequence of temporary equilibria would converge, in some sense, to a (stochastic) steady state. This steady state, for example, a stationary probability distribution of prices, would constitute a fourth concept of equilibrium (see Bhattacharya and Majumdar, 2007).

Of the four concepts of equilibrium, the first two are perhaps the closest in the spirit to the Arrow–Debreu theory. How far do some of the conclusions of the Arrow–Debreu theory extend to this new situation? We turn now to this qst. The literature subsequent to the publication of Radner (1967; 1968; 1972) is already voluminous. The interested reader is referred to the reviews by Magill and Shafer (1991), Geanakopolos (1990), Shafer (1998), and the books by Duffie (1988), Magill and Quinzii (1996), LeRoy and Werner (2001).

**Equilibrium of plans, prices and price expectations**

Consider now the model of perfect-foresight equilibrium sketched above, in which the agents have common information at every date–event pair (for a precise description of the model, see Radner, 1972). Three features of the situation are different from the Arrow–Debreu model: (1) there is a sequence of markets (or rather a ‘tree’ of markets), one for each date–event pair, no one of which is complete: (2) for each agent, there is a separate budget constraint corresponding to each date–event pair; (3) even if there is a natural bound on consumption and production, there is no single natural bound on the *positions* that traders can take in the markets for securities, if short sales are permitted, (4) there is no obvious objective for each firm to pursue, since each firm’s profit is defined only for each date–event pair.
To deal with points (3) and (4), consider the following assumptions. Regarding (3), although there is no single natural bound on traders’ positions, some bound is natural; for example, a commitment to deliver a quantity of a commodity vastly greater than the total supply would not be credible to moderately well-informed traders. Regarding (4), assume that the manager of each firm has preferences on the sequence of net revenues that can be represented by a continuous, strictly concave utility function. We elaborate on variations these and other assumptions. In other respects, we make the ‘standard’ assumptions of the Arrow–Debreu model.

A canonical model of sequential trading

For ease of exposition we sketch a matchbox model of sequential trading, variations and extensions of which have provided useful building blocks in the formal development beyond the Arrow–Debreu framework. Our exposition draws upon the excellent introduction to the literature by Shafer (1998). There are two periods, 0 and 1, with $S$ states of nature in period 1. In each period, $\mathcal{E}$ commodities are traded, with the trades in period 1 being contingent on the realized state $s$: thus, there, are $L = \mathcal{E}(S + 1)$ contingent commodities in the model (that is, the commodity space is $\mathbb{R}^L$). We have $I \geq 2$ agents, each characterized by a utility function $u_i$ (representing the preferences) and an endowment vector $w_i$ (in $\mathbb{R}^I_{++}$, the set of all strictly positive vectors in $\mathbb{R}^I$). Denote by $w=(w_1,...,w_I)$ the list of endowment vectors. The utility functions are assumed to have the appropriate smoothness and boundary conditions, strict monotonicity and strict quasiconcavity properties. Each agent is supposed to know his own characteristics and each observes the true state when it occurs in period 1. We write a vector $y$ in $\mathbb{R}^L$ in the form $y=(y(0),y(1),...,y(S))$ with each $y(s)$ in $\mathbb{R}^L$. A spot price system is a vector $p$ in $\mathbb{R}^L_{++}$. See Magill and Shafer (1991) for a more complete description and examples.

We first review the Arrow–Debreu competitive equilibrium in this model in which all trades and prices are decided in period 0. We denote a list of prices by $P=(P(0),P(s))$; $P(0)$ is the vector of prices for goods consumed in period 0, and $P(s)(s \geq 1)$ is the price vector in period 0 for delivery of goods in period 1 contingent on state $s$ being the realized state. The $i$th agent's optimization problem is

$$\max_{x} u_i(x)$$

subject to: $P(0)(x(0) - w_i(0)) + \sum_{s \geq 1} P(s)[x(s) - w_i(s)] = 0.$

Note that the agent faces a single budget constraint. A competitive equilibrium is a collection $((\bar{x}_i)_{i \geq 1}, \bar{p})$ such that

1. (i) $\bar{x}_i$ solves agent $i$’s optimization problem at $\bar{p}$; and
2. (ii) $\sum_{i}[\bar{x}_i(s) - w_i(s)] = 0$ for $s=0,...,S$. 

http://0-www.dictionaryofeconomics.com.library.lemoyne.../article?id=pde2008_U000007&goto=S&result_number=1790] [2009-1-3 20:32:00]
To introduce the model of sequential trading, we suppose there are $J$ assets (or securities) which are traded in period 0 and return dividends in period 1. A unit of asset $j$ will cost $q_j$ units of account payable in 0 ($q=(q_1,\ldots,q_J)$) in $\mathbb{R}^J$ and return $\nu_j(s)$ units of account in period 1 in state $s$. An asset is called \textit{nominal} if the returns are given exogenously; it is called \textit{real} if the return at state $s$ is the market value of a commodity vector, that is, if $\nu_j(s)=p(s)\alpha_j(s)$ for some vector $\alpha_j(s)$ in $\mathbb{R}^J$. Of course, mixtures are possible, but, for our matchbox model, we consider only the pure real asset case or the pure nominal asset case. Denote by $V$ the $S \times J$ matrix of returns that has in row $s$ and column $j$ the dividend, $\nu_j(s)$, of asset $j$ in state $s$, and let $\nu_j(s)$ denote the vector of the returns in state $s$. In the real asset case, the list of vectors $\alpha=(\alpha_j(s))$ parameterizes the asset structure, and the returns matrix $V(p)$ is a function of $p$. In the nominal case the returns matrix $V$ itself parametrizes the asset structure. Denote by $z_j$ the amount purchased of asset $j$, with $z=(z_1,\ldots,z_J)$ being the portfolio of assets. The amount $z_j$ may be positive or negative; the assets are considered to be in zero net supply.

We now apply to this model the concept of an \textit{equilibrium of plans, prices, and price expectations}. At a spot price system $p$ and an asset price system $q$, define an agent's optimization problem as

\[
\begin{align*}
\text{maximize} & \quad u_i(x) \\
\text{subject to:} & \quad p(0)x(0) - w_i(0) = -\varphi, \\
& \quad p(s)(x(s) - w_i(s)) = \sum_j \nu_j(s)z_j, \quad s = 1, \ldots, S.
\end{align*}
\]

We should stress that the agent faces \textit{a multiplicity of budget constraints}. The first constraint listed is that the net expenditure on goods plus the cost of the portfolio of assets must sum to zero. The constraints for $s \geq 1$ indicate that if $s$ is the realized state in period 1, the \textit{net} expenditure on goods must equal the dividends of the asset portfolio. The purchase of the assets in period 0 and their dividends in period 1 provides a means both for transferring income between period 0 and period 1 and for transferring income across the potential states in period 1. Note that these constraints preclude the agent from planning bankruptcy in any state; implicit in the constraints is an infinite penalty for bankruptcy.

An \textit{equilibrium of plans, prices, and price expectations} is a list $(\langle \bar{x}_i, \bar{z}_i \rangle)_{i \geq 1}$, $(\bar{p}, \bar{q})$ such that:

1. (i) $\langle \bar{x}_i, \bar{z}_i \rangle$ solves agent $i$'s optimization problem at $(\bar{p}, \bar{q})$;
2. (ii) $\sum_i \nu_i(s)z_i = 0$, $s=0,\ldots,S$; and
3. (iii) $\sum_i \bar{x}_i = 0$.

The interpretation of the EPPPE concept is as follows. In period 0, each agent $i$ observes the current spot prices $\bar{p}(0)$ and the asset prices $\bar{q}$, the ‘prices’. Then, based on ‘price expectations’ about spot prices in
period 1, say $\bar{s} = 1, \ldots, S$, the agent solves the optimization problem, forming the ‘plans’ $(\bar{x}_i, \bar{z}_i)$. If it turns out that the price expectations of all the agents are the same and the common expectation $\bar{p}(s) (s = 1, \ldots, S)$ is such that, together with the observed prices $\bar{p}(0)$ and $\bar{q}$, all markets clear, then we are in an EPPPE equilibrium.

The information requirements of this model are quite strict. Each agent is fully informed in the sense that he or she will be able to verify the true state once it occurs. In addition, each agent knows exactly the distribution of returns of each asset across the states (that is, each agent knows each $a_j(\cdot)$ in the real asset case and each $\nu_j(\cdot)$ in the nominal case).

We now define completeness of markets in this model. The formal definition is that, for any possible vector of units of account across the $S$ states of nature, an agent can form a portfolio of assets that gives this distribution of returns. That is, for any $S$-vector $y$ of net expenditures on goods in period 1 ($y_S = p(s)(x(s) - w(s))$), there is some portfolio $z$ such that $y = Vz$. In our model, for the nominal case this is equivalent to the returns matrix $V$ having the rank $S$, so that the column vectors of $V$ span all of $R^S$. In particular, there must be $l \geq S$ assets. In the case of real assets the rank of the returns matrix $V(p)$ is a function of $p$, and is thus endogenous to the model. However, since $V(\cdot)$ is linear in $p$, it has a ‘generic’ rank (see Magill and Shafer, 1990, for a precise formulation), and this rank is the maximum rank the returns matrix can take on at any $p$. The real asset structure is defined to be complete if this generic rank is $S$. Again this requires $l \geq S$. We note for later reference that, if one imposes restrictions on the size of trades an agent can make in the asset market, then these markets cannot be complete regardless of the number of assets, since by restricting asset trades $z$ we cannot in general expect to express every vector in $R^S$ in the form $Vz$.

A very useful implication of completeness will now be stated. Suppose the market is complete. Then given a competitive equilibrium $((\bar{x}_i)_{i \geq 1}, \bar{p})$ one can construct a canonical model with an appropriate EPPPE equilibrium $((\bar{x}_i, \bar{z}_i)_{i \geq 1}, \bar{p}, \bar{q})$: it should be stressed that the allocation $(\bar{x}_i)_{i \geq 1}$ is the same. Conversely, given an EPPPE $((\bar{x}_i, \bar{z}_i)_{i \geq 1}, \bar{p}, \bar{q})$, one can construct a competitive equilibrium $((\bar{x}_i)_{i \geq 1}, \bar{p})$. This ‘translation’ of the frameworks has been exploited in the formal analysis, and has clear implications for the optimality of an EPPPE (see Magill and Shafer, 1991; Shafer, 1998).

Radner (1972) demonstrated that an equilibrium exists in a more general model provided we impose bounds on the size of trades in the asset markets.

**Existence Theorem 1:** In the canonical model described above, if each agent’s optimization problem is modified with an additional constraint of the form $z \geq \beta$, then an equilibrium of plans, prices, and price expectations exists.

Reasonable or not, the ‘ad hoc’ constraint in this result posed an intellectual challenge for subsequent researchers. Moreover, as Hart (1975) discovered, without exogenous bounds on the size of trades in the asset markets, equilibria may fail to exist. The main characteristic of Hart’s example is that the returns matrix changes rank with $p$, and one approach has been to restrict attention to asset structures that do not exhibit this behaviour. Cass (2006) and Werner (1985) showed that, if one restricts attention to pure nominal asset structures, then equilibria exist without imposing lower bounds. Similarly, Geanakoplos and Polemarchakis (1986) observed that, in the real asset case, if all assets are denominated in terms of the market value of a single good, then the returns matrix $V(p)$ will have constant rank and – just as in the nominal case – equilibria always exist. In general, then, we have the following theorem.
**Existence Theorem 2:** In the canonical model, if the asset structure is such that the matrix of returns has constant rank, then an equilibrium of plans, prices, and price expectations exists.

To get some insights into the non-existence issue, we provide a simple example. Consider the Radner model with one state in period 1, one asset, two consumers, and two goods, with the following data. Endowments are $w_i(s) = (1, 1)$ for $s=0, 1$. Utility functions are $u_1(x) = v_1(x(0)) + v_1(x(1))$ with $v_1(x) = (1/3)\ln x_1 + (2/3)\ln x_2$ for agent 1 and $u_2(x) = v_2(x(0)) + (1/2)v_2(x(1))$ with $v_2(x) = (2/3)\ln x_1 + (1/3)\ln x_2$ for agent 2. The competitive equilibrium prices can be easily computed in this log-linear economy; they are $p_1(0) = 11/36$, $p_2(0) = 10/36$, $p_1(1) = 7/36$, and $p_2(1) = 8/36$. Now consider a Radner version of the model, with one real asset given by $a_1 = (8, -7)$.

The return on this asset in state 1 is $V = p_1(1)8 - p_2(1)7$, so investing in this asset is essentially a bet that the relative price of good 1 in terms of good 2 is greater than 7/8. Since there is one state and one asset, this is the complete markets case. Note that the 1x1 returns matrix drops rank precisely in the case the relative price is 7/8 in state 1.

We now show that this model does not have an EPPPE equilibrium. First, we try for an equilibrium with the return $V \neq 0$. If such an equilibrium existed, it would have to coincide with the competitive equilibrium since $V$ has rank 1, but in the unique competitive equilibrium the period-1 ratio is 7/8, so $V = 0$, a contradiction. Second, consider the possibility of an equilibrium with $V = 0$. Then there would be no transfers of income between periods 0 and 1, so the period-1 equilibrium would have to coincide with the static competitive equilibrium with the utility functions $u_1$ and $u_2$. But it is easy to see from the symmetry of the functions and the equal endowments that the relative price ratio in this case would be 1, and thus $V \neq 0$, again a contradiction. Thus no equilibrium exists. Note, however, that this example is not robust: alter the asset a small amount so that $V \neq 0$ at the price ratio 7/8 and then the complete markets case will work; or alter endowments or utility parameters a little so that the period-1 price ratio is no longer 7/8, and the complete markets case again works.

This example gives a clue on how to proceed for the existence problem with real assets when markets are complete. One aims at generic results. In this case, remember, $V(p)$ has constant rank $S$ on an open set of full measure in the space of prices. As we have mentioned above, an EPPPE at which $V(p)$ has rank $S$ is equivalent to a competitive equilibrium with a complete set of contingent commodity contracts. That is, the allocations are the same, and there is an easy correspondence between competitive equilibrium prices and the corresponding EPPPE prices. Thus a natural approach is first to obtain a competitive equilibrium, which always exists in our model, and then to construct the corresponding EPPPE prices. If at these prices $V(p)$ has rank $S$, then we have an EPPPE.

Kreps (1982) made the critical observation that, if the rank of the returns matrix is less that $S$, then a perturbation of the returns structure $a$ will restore $V(p)$ to full rank (as in our preceding ex), and thus we will have an EPPPE. That is, generically in $a$, an EPPPE exists. Similarly, Magill and Shafer (1990) observed that a small perturbation of endowment would cause the competitive equilibrium prices to move into the region where $V(p)$ has full rank, and thus an equilibrium exists generically in endowments.

**Generic Existence Theorem 1:** In the canonical model:

1. (1) if $l \geq S$ then, for each $w \in R^L_+$, an equilibrium of plans, prices, and price expectations exists for almost all (asset structure) $a$ in $R^{E+J}_+$.
2. (2) for each asset structure $a$ for which $V(\cdot)$ has generic rank $S$, an equilibrium of plans, prices, and price expectations exists for almost all endowment lists $w$ in $R^{LI}_{++}$.

In the case where both $V(p)$ can change rank with $p$ and markets are not complete (in particular, if $J < S$), the trick of first obtaining a competitive equilibrium and then converting it to an EPPPE equilibrium is no longer available. Nevertheless, by defining a ‘pseudo’ equilibrium concept that replaces the competitive equilibrium in the argument for the complete market case, Duffie and Shafer (1985) were able to show that an EPPPE equilibrium exists generically in both $a$ and $w$.

Generic Existence Theorem 2: In the canonical model with all real assets, an equilibrium of plans, prices, and price expectations exists for almost all $(a,w)$ in $R^{LS} \times R^L_{++}$.

We now look at the issue of local uniqueness. In what follows, in ‘counting’ equilibria we are counting the number of equilibrium allocations, since there may be certain redundancies in equilibrium prices. In the complete market case this is fairly straightforward, requiring only an adaptation of Debreu’s (1970) argument, since competitive equilibria and EPPPE equilibria coincide when the returns matrix has full rank. In the case of incomplete markets and all real assets, an argument similar to Debreu’s applied to the ‘pseudo’ equilibrium also works.

Local Uniqueness Theorem 1: In the canonical model, if the asset structure is such that markets are complete, or if all assets are real, then for almost all $w$ in the space of endowment lists there exist a finite number of EPPPE, and each equilibrium is locally a smooth function of endowment lists $w$ and asset structures $a$ or $V$.

The situation with nominal assets and incomplete markets is, however, completely different. In this case there is ‘serious indeterminacy’ as the following result suggests.

Local Uniqueness Theorem 2: In the canonical model with nominal assets, let the returns matrix $V$ satisfy $J < S$ and $I > J$. Then, for almost all $w$ in the space of endowment lists, the set of allocations of an EPPPE contains a set homeomorphic to $R^{S-1}$. (See Geanakoplos and Mas-Colell, 1989, and a similar result by Balasko and Cass, 1989.)

Next, we turn to Pareto optimality. At an EPPPE equilibrium at which the returns matrix has rank $S$, the resulting equilibrium allocation will also be a competitive equilibrium allocation, and thus fully Pareto efficient. This leads to the following theorem.

Pareto Optimality Theorem 1: For the canonical model:

1. (1) in the nominal asset case, if $V$ has rank $S$ then every EPPPE equilibrium allocation is Pareto efficient;
2. (2) in the real asset case, if the asset structure is such that the generic rank of $V(\cdot)$ is $S$ then, for almost all $w$ in the space of endowment lists, EPPPE equilibrium allocations are Pareto efficient.

In case of incomplete markets, one certainly does not expect full allocative efficiency. The following result (Geanakoplos and Polemarchakis, 1986) emphasizes the failure of the first fundamental theorem.

Non-Optimality Theorem 1: For the canonical model, if $J < S$ then, generically in $(w,a)$ in $R^L_{++}$, EPPPE equilibrium allocations are not Pareto efficient.

One might hope that, in an appropriate sense, EPPPE equilibria are constrained efficient. There is still no generally accepted notion of what the correct definition of ‘constrained efficiency’ might be in this case; some argue that the concept cannot be properly defined unless the reasons for incompleteness of markets are endogenously embedded into the model. Nevertheless, we can discuss certain efficiency properties of the equilibria. First, there are robust examples of the model with multiple equilibria in which two of the EPPPE equilibria have the property that one Pareto dominates the second (Shafer, 1998). As a consequence of such robust examples, any efficiency property that the incomplete market EPPPE equilibria may possess must be ‘weak’. One approach to constrained efficiency is to follow the Lange–Lerner tradition: if a central planner were permitted to choose the asset portfolios for the agents, and then allow agents to trade freely on competitive markets for commodities, could the planner improve upon an EPPPE equilibrium? The answer is, in an appropriate generic sense, ‘yes’ (Geanakopolos and Polemarchakis, 1986). This is, of course, not possible if markets are complete.

Another ‘natural’ question to ask: is there a connection between how inefficient the EPPPE equilibria are and how incomplete the markets may be? One measure of incompleteness is $S-J$, assuming the $J$ assets give the returns matrix a generic rank $J$. By introducing a new asset, which reduces the incompleteness in this sense, does efficiency improve? The answer is ‘no’, again due to an example of Hart (1975), in which a new asset is introduced but the new EPPPE equilibrium allocation is Pareto dominated by the original EPPPE equilibrium allocation. This suggests that perhaps this notion of ‘almost complete’ is at fault.

**Production**

We first discuss the question of existence of equilibrium, but before paraphrasing the existence theorem we must define what we shall call a pseudo-equilibrium.

The definition of pseudo-equilibrium is obtained from the definition of equilibrium by replacing the requirement of consistency of plans by the condition that each date and each event the difference between total saving and total investment (by consumers) is smaller at the pseudo-equilibrium prices than at any other prices.

One can prove (Radner, 1972) that under assumptions about technology and consumer preferences similar to those used in the Arrow–Debreu theory, and with the additional assumptions sketched above: (a) there exists a pseudo-equilibrium; (b) if in a pseudo-equilibrium the current and future prices on the stock market are all strictly positive, then the pseudo-equilibrium is an equilibrium.

The crucial difference between this theorem and the corresponding one in the Arrow–Debreu theory seems to be due to the form taken by Walras's Law, which in this model can be paraphrased by saying that saving must be at least equal to investment at each date in each event. This form derives from the replacement of a single budget constraint (in terms of present value) by a sequence of budget constraints, one for each date–event pair.

In the above model with production, the ‘shareholders’ have unlimited liability, and therefore have a status more like that of partners than of shareholders, as these terms are usually understood. One way to formulate limited liability for shareholders is to impose the constraint on producers that their net revenues be non-negative at each date–event pair. However, in this case producers’ correspondences may not be upper semicontinuous. This is analogous to the problem that arises when, for a given price
system, the consumer's budget constraints force him to be on the boundary of his consumption set. In the case of the consumer, this situation is avoided by some assumption (see Debreu, 1959, notes to ch. 5, pp. 88–9; Debreu, 1962). However, for the case of the producer, it is not considered unusual in the standard theory of the firm that, especially in equilibrium, the maximum profit achievable at the given price system could be zero (for example, in the case of constant returns to scale).

What are conditions on the producers and consumers that would directly guarantee the existence of an equilibrium, not just a pseudo-equilibrium? In other words, under what conditions would the share markets be cleared at every date–event pair? Notice that, if there is an excess supply of shares of a given producer \( j \) at a date–event pair \( (t, e) \), then at date \( (t+1) \) only part of the producer's revenue will be 'distributed'. One would expect this situation to arise only if his revenue is to be negative in at least one event at date \( t+1 \); thus, at such a date–event pair the producer would have a deficit covered neither by 'loans (that is, not offset by forward contracts) nor by shareholders’ contributions. In other words, the producer would be 'bankrupt' at that point.

One approach might be to eliminate from a pseudo-equilibrium all producers for whom the excess supply of shares is not zero at some date–event pair, and then search for an equilibrium with the smaller set of producers, and so on, successively reducing the set of producers until an equilibrium is found. This procedure has the trivial consequence that an equilibrium always exists, since it exists for the case of pure exchange (the set of producers is empty)! This may not be the most satisfactory resolution of the problem, but it does point up the desirability of having some formulation of the possibility of ‘exit’ for producers who are not doing well.

Although the above model with production does not allow for ‘exit’ of producers (except with the modification described in the preceding paragraph), it does allow for ‘entrance’ in the following limited sense. A producer may have zero production up to some date, but plans to produce thereafter; this is not inconsistent with a positive demand for shares at preceding dates.

The creation of new ‘equity’ in an enterprise is also allowed for in a limited sense. A producer may plan for a large investment at a given date–event pair, with a negative revenue. If the total supply of shares at the preceding date–event pair is nevertheless taken up by the market, this investment may be said to have been ‘financed’ by shareholders.

The above assumptions describe a model of producer behaviour that is not influenced by the shareholders or (directly) by the prices of shares. A common alternative hypothesis is that a producer tries to maximize the current market value of this enterprise. There seems to us to be at least two difficulties with this hypothesis. First, there are different market values at different date–event pairs, so it is not clear how these can be maximized simultaneously. Second, the market value of an enterprise at any date–event pair is a price, which is supposed to be determined, along with other prices, by an equilibrium of supply and demand. The ‘market-value-maximizing’ hypothesis would seem to require the producer to predict, in some sense, the effect of a change in his plan on a price equilibrium: in this case, the producers would no longer be price-takers, and one would need some sort of theory of general equilibrium for monopolistic competition.

There is one circumstance in which the value of the firm can be defined unambiguously, given the system of present prices and common expectations about future prices. Call a price system arbitrage-free if it is not possible to make a sure, positive cash flow from trading, without a positive investment. An equilibrium price system is, a fortiori, arbitrage-free. One can show (see Radner, 1967; Harrison and Kreps, 1979; Duffie and Shafer, 1985 that an arbitrage-free price system implicitly determines a system
of ‘insurance premiums’ for a corresponding family of events. This means that by suitable trading one can insure oneself against the occurrence of any of these events. If these events include all of the uncertain events that may affect the (uncertain) revenues of the firm, then they can be used in a natural way to define a present value of the firm at any date–event pair, for any production plan of the firm, and no probability judgements are needed to calculate the value. On the other hand, if the family of ‘insurable events’ is not rich enough, then the value is a random variable, and stockholders may not agree on its probability distribution.

A survey of results on the generic existence of equilibrium with production (and stock markets) is given in Magill and Shafer (1991) (see also Duffie, 1988, ch. 2).

**Rational expectations equilibrium**

The formal study of rational expectations equilibrium was introduced by Radner (1967); it was taken up independently by Lucas (1972) and Green (1973), and further investigated by Grossman, Allen, Jordan, and others. We should emphasize that we are concerned here with the aspect of ‘rational expectations’ in which traders make inferences from market prices about other traders’ information, a phenomenon that is of interest only when traders do not all have the same nonprice information. The term ‘rational expectations equilibrium’ (REE) has also been used to describe a situation in which traders correctly forecast (in some sense or other) the probability distribution of future prices. (See Radner, 1982, for references to the work of Muth and others on this topic.)

The concept of REE has been used to make a number of interesting predictions about the behaviour of markets: see, for example, Futia (1979; 1981) and the references cited there. A sound foundation for such applications requires the investigation of conditions that would ensure the existence and stability of REE.

We adopt the convention that the future utility of the commodities to each trader depends on the state of the environment. With this convention, we can model the inferences that a trader makes from the market prices and his own nonprice information signal by a family of conditional probability distributions of the environment given the market prices and his own nonprice information. We shall call such a family of conditional distributions the trader's market model. Given such a market model, the market prices will influence a trader's demand in two ways: first, through his budget constraint, and second, through his conditional expected utility function. It is this second feature, of course, that distinguished theories of rational expectations equilibrium from earlier models of market equilibrium.

Given the traders’ market models, the equilibrium prices will be determined by the equality of supply and demand in the usual way, and thus will be a deterministic function of the joint nonprice information that the traders bring to the market. In order for the market models of the traders to be ‘rational’, they must be consistent with that function. To make this idea precise, it will be useful to have some formal notation. Let \( p \) denote the vector of market prices, \( e \) denote the (utility-relevant) state of the environment, and \( s_i \) denote traders \( i \)'s nonprice information signal (\( I = 1, \ldots, I \)). The joint nonprice information of all traders together will be denoted by \( s = (s_1, \ldots, s_I) \). We shall call \( s \) the ‘joint signal’. (The term ‘state of information’ is also commonly applied to this array.) Trader \( i \)'s market model, say \( m_i \), is a family of conditional probability distributions of \( e \), given \( s_i \) and \( p \). Given the traders’ market models, the equilibrium price vector will be some (measurable) function of the joint nonprice information, say
To model the required rationality of the traders’ models, suppose that, for each $i$, trader $i$ has (subjective) prior beliefs about the environment and the information signals that are expressed by a joint probability distribution, say $Q_i$, of $e$ and $s$. These prior beliefs need not, of course, be the same for all traders. Given the price function $\phi$, a rational market model for trader $i$ would be the family of conditional probability distributions of $e$, given $s_i$ and $p$, that are derived from the distribution $Q_i$ and the price function $\phi$; thus (supposing $e$ and $s$ to be discrete variables),

$$m_i(e'|s_i, p') = \operatorname{Prob}_{Q_i}(e = e'|s_i \text{ and } \phi(s) = p').$$

(1)

A given price function $\phi$, together with the rationality condition (1), would determine the total market excess supply for each price vector $p$ and each joint information signal $s$, say $Z(p, s, \phi)$. Note that the excess supply for any $p$ and $s$ depends also on the price function $\phi$, since (in principle) the entire price function is used to calculate the conditional distribution in (1). We can now define a rational expectations equilibrium (REE) to be a price function $\phi^*$ such that, for (almost) every $s$, excess supply is zero at the price vector $\phi^*(s)$, that is,

$$Z(\phi^*(s), s, \phi^*) = 0, \text{ for almost every } s.$$

(2)

If markets are incomplete, the existence of REE is not assured by the ‘classical’ conditions of ordinary general equilibrium analysis. Even under such conditions, if traders condition their expected utilities on market prices, then their demands can be discontinuous in the price function. Specific examples of the nonexistence of REE due to such discontinuities were given by Kreps (1977), Green (1977), and others. These examples naturally led theorists to question whether the absence of REE is pervasive or is confirmed to a ‘negligible’ set of such examples. The work of Radner, Allen, and Jordan (see Jordan and Radner, 1982; Allen, 1986, for references) provided – in a certain context – an essentially complete answer, which can be loosely summarized in the statement that \textit{REE exists generically except when the dimension of the space of private information is equal to the dimension of the price space}. (Recall that REE exists generically in a given model if, for any vector of parameters values for which REE does not exist, there are arbitrarily small perturbations of the parameters for which REE does exist.) Furthermore, if the dimension of the space of private information is strictly less than the dimension of the price space, then generically there is a REE that is \textit{fully revealing}, that is, in which the price reveals to each trader all the nonprice information used by all traders (Radner, 1979; Allen, 1981).
Equilibrium and learning with imperfect price models

A more stringent ‘rational expectations’ requirement would concern the opportunities that traders might have for learning from experience. For example, suppose that there is a market at each of a succession of dates $t$, and that the successive exogenous vectors $(e_t, s_t)$ are independent and identically distributed. Suppose further that at the beginning of date $t$ trader $i$ knows the past history of environments, prices, and his own nonprice information. On the basis of this history he updates his initial market model to form a current market model. These current market models, together with the nonprice information signals at date $t$, then determine an equilibrium price at date $t$, say $\hat{P}^*_t$, as above. The updating of models constitutes the learning process of the traders. For a given learning process, one might ask whether the process converges in any useful sense, and if so, whether the models are asymptotically consistent with the (endogenously determined) actual relationship between signals and equilibrium prices, that is whether they converge to a REE. In this case one would say that the REE is stable (relative to the learning process).

Thus far, answers to this question are only fragmentary. Bray (1982) has studied a simpler linear asset-market model in which, at each date, each trader $i$ updates his model by calculating an ordinary least-squares estimate of the regression of $e$ on $p$ and $s$, using all the past values $(e_t, \hat{P}^*_t, s_t)$. For this example, Bray proves stability. On the other hand, Blume and Easley (1982) present a somewhat less optimistic view of the possibility of learning rational expectations. They define a class of learning procedures by which traders use successive observations to form their subjective models, where the term model for trader $i$ means a conditional distribution of $s$, given $s_i$ and $p$. They show that rational expectations equilibria are at least ‘locally stable’ under learning, but that learning possesses may also get stuck at a profile of subjective models that is not an REE. The learning procedures defined by Blume and Easley are applied to a fairly general class of stochastic exchange environments that do not possess the special linear structure of the above example. However, to accommodate this additional generality, Blume and Easley constrain traders to choose their subjective models from a fixed finite set of models and convex combinations thereof. Hence, for some profiles of subjective models, market clearing may result in a ‘true’ model that lies outside the admissible set. It is then intuitively plausible that a natural learning procedure could get stuck at a profile of subjective models that differs from the resulting true model but is in some sense the best admissible approximation to the true model, even if the admissible set contains an REE model. This phenomenon is illustrated in Section 5 of their paper. For a review of a number of themes related to learning, see Blume and Easley (1998).

uncertainty

Peter P. Wakker
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article deals with individual decision making under uncertainty (unknown probabilities). Risk (known probabilities) is not treated as a separate case, but as a sub-case of uncertainty. Many results from risk naturally extend to uncertainty. The Allais paradox, commonly applied to risk, also reveals empirical deficiencies of expected utility for uncertainty. The Ellsberg paradox reveals deviations from expected utility in a relative, not an absolute, sense, giving within-person comparisons: for some events (ambiguous or otherwise) subjects deviate more from expected utility than for other events. Besides aversion, many other attitudes towards ambiguity are empirically relevant.

Article

In most economic decisions where agents face uncertainties, no probabilities are available. This point was first emphasized by Keynes (1921) and Knight (1921). It was recently reiterated by Greenspan (2004, p. 38):

… how … the economy might respond to a monetary policy initiative may need to be drawn from evidence about past behavior during a period only roughly comparable to the current situation. … In pursuing a risk-management approach to policy, we must confront the fact that only a limited number of risks can be quantified with any confidence.

Indeed, we often have no clear statistics available. Knight went so far as to call probabilities unmeasurable in such cases. Soon after Knight's suggestion, Ramsey (1931), de Finetti (1931) and Savage (1954) showed that probabilities can be defined in the absence of statistics after all, by relating them to observable choice. For example, $P(E) = 0.5$ can be derived from an observed indifference between receiving a prize under event $E$ and receiving it under $not-E$ (the complement to $E$). Although widely understood today, the idea that something as intangible as a subjective degree of belief can be made observable through choice behaviour, and can even be quantified precisely, was a major intellectual advance. Ramsey, de Finetti and Savage assumed that the agent, after having determined the probabilities subjectively (as required by some imposed rationality axioms), proceeds as under
expected utility for given objective probabilities. The Allais (1953) paradox (explained later) revealed a descriptive difficulty for known probabilities: people often do not satisfy expected utility. Hence, we need to generalize expected utility. Another, more fundamental, difficulty was revealed by the Ellsberg (1961) paradox (also explained later): for unknown probabilities, people behave in ways that cannot be reconciled with any assignment of subjective probabilities at all, so that further generalizations are needed. (The term ‘subjective probability’ always refers to additive probabilities in this article.) Despite the importance and prevalence of unknown probabilities, understood since 1921, and the impossibility of modelling these through subjective probabilities, understood since Ellsberg (1961), decision theorists continued to confine their attention to decision under risk with given probabilities until the late 1980s. Wald's (1950) multiple priors model did account for unknown probabilities, but attracted little attention outside statistics. As a result of an idea of David Schmeidler (1989, first version 1982), the situation changed in the 1980s. Schmeidler introduced the first theoretically sound decision model for unknown probabilities without subjective probabilities, called rank-dependent utility or Choquet expected utility. At the same time, Wald's multiple priors model was revived when Gilboa and Schmeidler (1989) established its theoretical soundness; a similar result was obtained independently by Chateauneuf (1991, Theorem 2). These discoveries provided the basis for non-expected utility with unknown probabilities that had been sorely missing since 1921. Since the late 1980s, the table has turned in decision theory. Nowadays, most studies concern unknown probabilities. Gilboa (2004) contains recent papers and applications. This article concentrates on conceptual issues of individual decisions in the possible absence of known probabilities.

Theoretical studies of non-expected utility have usually assumed risk aversion for known probabilities (leading to concave utility and convex probability weighting), and ambiguity aversion for unknown probabilities (Camerer and Weber, 1992, section 2.3). These phenomena best fit with the existence of equilibria and can be handled using conventional tools of convex analysis (Mukerji and Tallon, 2001). Empirically, however, a more complex fourfold pattern has been found. For gains with moderate and high likelihoods, and for losses with low likelihoods, risk aversion is prevalent indeed, but for gains with low likelihoods and for losses with high likelihoods the opposite, risk seeking, is prevalent. The fourfold pattern resolves the classical paradox of the coexistence of gambling and insurance, and leads, for instance, to new views on insurance. Whereas all classical studies of insurance explain insurance purchasing through concave utility, empirical measurements of utility have suggested that utility is not very concave for losses, often exhibiting more convexity than concavity (surveyed by Köbberling, Schwieren and Wakker, 2006). This finding is diametrically opposite to what has been assumed throughout the insurance literature. According to modern decision theories, insurance is primarily driven by consumers' overweighting of small probabilities rather than by marginal utility. The fourfold pattern found for risk has similarly been found for unknown probabilities, and usually to a more pronounced degree. Central qts in uncertainty today concern how to analyse not only classical marginal utility but also new concepts such as probabilistic risk attitudes (how people process known probabilities), loss aversion and reference dependence (the framing of outcomes as gains and losses), and, further, states of belief and decision attitudes regarding unknown probabilities (‘ambiguity attitudes’). We end this introduction with some notation and definitions. Decision under uncertainty concerns choices between prospects such as \((E_j^1 : x_1, \ldots, E_j^n : x_n)\), yielding outcome \(x_j\) if event \(E_j\) obtains, \(j = 1, \ldots, n\). Outcomes are monetary. The \(E_j\) are events of which an agent does not know for sure whether they will obtain, such as who of n candidates will win an election. The \(E_j\) are mutually exclusive and exhaustive. No probabilities of the events need to be given. Because the agent is uncertain about which event obtains, he is uncertain about which outcome will result from the prospect, and has to make decisions under uncertainty.

### Decision under risk and non-expected utility through rank dependence

Because risk is a special and simple subcase of uncertainty (as explained later), this chapter on uncertainty begins with a discussion of decision under risk, where the probability \(P_j = P(E_j)\) is given for each event \(E_j\). We can then write a prospect as \((P_1 : x_1, \ldots, P_n : x_n)\), yielding \(x_j\) with probability \(P_j\), \(j = 1, \ldots, n\). Empirical violations of expected-value maximization because of risk aversion (prospects being less preferred than their expected value) led Bernoulli (1738) to propose expected utility, \(\Sigma_{j=1}^n P_j U(x_j)\), to evaluate prospects, where \(U\) is the utility function. Then risk aversion is equivalent to concavity of \(U\). Several authors have argued that it is intuitively unsatisfactory that risk attitude be modelled through the utility of money (Lopes, 1987, p. 283). It would be more satisfactory if risk attitude were also related to the way people feel about probabilities. Economists often react very negatively to such arguments, based as they are on introspection and having no clear link to revealed preference. Arguments against expected utility that are based on revealed preference were put forward by Allais (1953). Figure 1 displays preferences commonly found, with \(K\) denoting $1,000:

\[(0.06:25K, 0.07:25K, 0.87:0) < (0.06:75K, 0.07:0, 0.87:0)\quad \text{and}\quad (0.06:25K, 0.87:25K, 0.07:25K) > (0.06:75K, 0.87:25K, 0.07:0).\]

**Figure 1**

A version of the Allais paradox for risk
Preference symbols $\succ$, $\succsim$, $\sim$ and $\succeq$ are as usual. We denote the outcomes in a rank-ordered manner, from best to worst. In Figure 1a, people usually prefer the ‘risky’ (r) prospect because the high payment of 75K is attractive. In Figure 1b, people usually prefer the ‘safe’ (s) certainty of 25K for sure. These preferences violate expected utility because, after dropping the common (italicized) term $0.87U(0)$ from the expected-utility inequality for Figure 1a and dropping the common term $0.87U(25K)$ from the expected-utility inequality for Figure 1b, the two inequalities become the same. Hence, under expected utility either both preferences should be for the safe prospect or both preferences should be for the risky one, and they cannot switch as in Figure 1. The special preference for safety in the second choice (the\textit{ certainty effect}) cannot be captured in terms of utility. Hence, alternative, non-expected utility models have been developed.

Based on the valuable intuition that risk attitude should have something to do with how people feel about probabilities, Quiggin (1982) introduced rank-dependent utility theory for risk. The same theory was discovered independently for the broader and more subtle context of uncertainty by Schmeidler (1989, first version 1982), a contribution that will be discussed later. A \textit{probability weighting function} $w: [0,1] \rightarrow [0,1]$ satisfies $w(0) = 0, w(1) = 1$, and is strictly increasing and continuous. It reflects the (in)sensitivity of people towards probability. Assume that the outcomes of a prospect $(p_1; x_1, \ldots, p_n; x_n)$ are rank-ordered, $x_1 \succ \ldots \succ x_n$. Then its \textit{rank-dependent utility} (RDU) is $\sum_{j=1}^{n} \pi_j U(x_j)$, where utility $U$ is as before, and $\pi_j$, the \textit{decision weight} of outcome $x_j$ is $w(p_1 + \ldots + p_j) - w(p_1 + \ldots + p_{j-1})$ (which is $w(p_1)$ for $j = 1$).

Tversky and Kahneman (1992) adapted their widely used original prospect theory (Kahneman and Tversky, 1979) by incorporating the rank dependence of Quiggin and Schmeidler. Prospect theory generalizes rank dependence by allowing a different treatment of gains from that of losses, which is desirable for empirical purposes. In this article on uncertainty, I focus on gains, in which case prospect theory in its modern version, sometimes called cumulative prospect theory, coincides with RDU.

With rank dependence, we can capture psychological (mis)perceptions of unfavourable outcomes being more likely to arise, in agreement with Lopes's (1987) intuition. We can also capture decision attitudes of deliberately paying more attention to bad outcomes. An extreme example of the latter pessimism concerns worst-case analysis, where all weight is given to the most unfavourable outcome. Rank dependence can explain the Allais paradox because the weight of the 0.07 branch in Figure 1b may exceed that in Figure 1a:

$$w(1) - w(0.93) \succ w(0.13) - w(0.06).$$

This inequality holds for $w$-functions that are steeper near 1 than in the middle region, a shape that is empirically prevailing indeed.

The following figures depict some probability weighting functions. Figure 2a concerns expected utility, and Figure 2b a \textit{convex $w$}, which means that

$$w(p + r) - w(r) = 0$$

for all $p < 1$, $r > 0$.

http://www.dictionaryofeconomics.com/library/kemoyne.edu/article?id=pde2008_U000005&goto=S&result_number=1789
is increasing in \( r \) for all \( P \approx 0 \). This is equivalent to \( w' \) being increasing, or \( w'' \) being positive. Equation (1) illustrates this property. Equation (2) gives the decision weight of an outcome occurring with probability \( p \) if there is an \( r \) probability of better outcomes. Under convexity, outcomes receive more weight as they are ranked worse (that is, \( r \) is larger), reflecting pessimism. It implies low evaluations of prospects relative to sure outcomes, enhancing risk aversion.

Figure 2
(a) Expected utility: linearity; (b) Aversion to risk: convexity; (c) Insensitivity: inverse-S (d) Prevailing empirical finding; (e) Extreme insensitivity; (f) Extreme aversion and insensitivity.
Empirical studies have found that usually $w(p) > p$ for small $p$, contrary to what convexity would imply, and that $w(p) < p$ only for moderate and high probabilities $p$ (inverse-S; Abdellaoui, 2000; Bleichrodt and Pinto, 2000; Gonzalez and Wu, 1999; Tversky and Kahneman, 1992), as in Figures 2c and 2d. It leads to extremity-oriented behaviour with both best and worst outcomes overweighted. The curves in Figures 2c and 2d also satisfy eq. (1) and also accommodate the Allais paradox. They predict risk seeking for prospects that with a small probability generate a high gain, such as in public lotteries. The inverse-S shape suggests a cognitive insensitivity to probability, generating insufficient response to intermediate variations of probability and then, as a consequence, overreactions to changes from impossible to possible and from possible to certain. These phenomena arise prior to any ‘motivational’ (value-based) preference or dispreference for risk. Extreme cases of such behaviour are in Figure 2e and 2f (where we relaxed the continuity requirement for $w$).

Starmer (2000) surveyed non-expected utility for risk. The main alternatives to the rank-dependent models are the betweenness models (Chew, 1983; Dekel, 1986), with Gul’s (1991) disappointment aversion theory as an appealing special case. Betweenness models are less popular today than the rank-dependent models. An important reason, besides their worse empirical performance (Starmer, 2000), is that models alternative to the rank-dependent ones did not provide concepts as intuitive as the sensitivity to probability/information modelled through the probability weighting $w$ of the rank-dependent models. For example, consider a popular special case of betweenness, called weighted utility. The value of a prospect is

$$
\frac{\sum_{j=1}^{n} p_j f(x_j)U(x_j)}{\sum_{j=1}^{n} p_j f(x_j)}
$$

for a function $f: \mathbb{R} \to \mathbb{R}^+$. This new parameter $f$ can, similar to rank dependence, capture pessimistic attitudes of overweighting bad outcomes by assigning high values to bad outcomes. It, however, applies to outcomes and not to probabilities. Therefore, it captures less extra variance of the data in the presence of utility than $w$, because utility also applies to outcomes. For example, for fixed outcomes, eq. (3) cannot capture the varying sensitivity to small, intermediate and high probabilities found empirically. Both pessimism and marginal utility are entirely specified by the range of outcomes considered without regard to the probabilities involved. It seems more interesting if new concepts, besides marginal utility, concern the probabilities and the state of information of the decision maker rather than outcomes and their valuation. This may explain the success of rank-dependent theories and prospect theory.

Phenomena under uncertainty that naturally extend phenomena under risk

The first approach to deal with uncertainty was the Bayesian approach, based on de Finetti (1931), Ramsey (1931) and Savage (1954). It assumes that people assign, as well as possible, subjective probabilities $P(E_j)$ to uncertain events $E_j$. They then evaluate prospects $(E_1: x_1, \ldots, E_n: x_n)$ through their (subjective) expected utility $\sum_{j=1}^{n} P(E_j)U(x_j)$. This model was the basis of Bayesian statistics and of much of the economics of uncertainty (Greenspan, 2004). The empirical measurement of subjective probabilities has been studied extensively (Fishburn, 1986; Manski, 2004; McClelland and Bolger, 1994). We confine our attention in what follows to models that have been introduced since the mid-1980s, models that deviate from Bayesianism. To Bayesians (including this author) such models are of interest for descriptive purposes.

Machina and Schmeidler (1992) characterized probabilistic sophistication, where a decision maker assigns subjective probabilities to events with unknown probabilities and then proceeds as for known probabilities. The decision maker may, however, deviate from expected utility for known probabilities, contrary to the Bayesian approach, and Allais-type behaviour can be accommodated.

The difference between objective, exogenous probabilities and subjective, endogenous probabilities is important. The former are stable, and readily available for analyses, empirical tests and communication in group decisions. The latter can be volatile and can change at any time by mere further thinking by the agent. For descriptive studies, subjective probabilities may become observable only after complex measurement procedures. Hence, I prefer not to lump objective and subjective probabilities together into one category, as has been done in several economic works (Ellsberg, 1961, p. 645; Epstein, 1999). In this article, the term risk refers exclusively to exogenous objective probabilities. Such probabilities can be considered a limiting case of subjective probabilities, in the same way as decision under risk can be considered a limiting case of decision under uncertainty (Greenspan, 2004, pp. 36–7). Under a differentiability assumption for state spaces, Machina (2004) formalized this inpt. Risk, while not occurring very frequently, is especially suited for applications of decision theory.

The Allais paradox is as relevant to uncertainty as it is to risk (MacCrimmon and Larsson, 1979, pp. 364–5; Wu and Gonzalez, 1999). Figure 3 presents a demonstration by Tversky and Kahneman (1992, section 1.3). The analogy with Figure 1 should be apparent. The authors conducted the following within-subjects experiment. Let \( d \) denote the difference between the closing value of the Dow Jones on the day of the experiment and on the day after, where we consider the events \( H(\text{up}) : d > 35, M(\text{flat}) : 35 \geq d \geq 30, L(\text{down}) : 30 > d \). The total Dow Jones value at the time of the experiment was about 3000. The right prospect in Figure 3b is \((H:75K, L:25K, M:0)\), and the other prospects are denoted similarly. Of 156 money managers during a workshop, 77 per cent preferred the risky prospect \( r \) in Figure 3a, but 68 per cent preferred the safe prospect \( s \) in Figure 3b. The majority preferences violate expected utility, just as they do under risk: after dropping the common terms \( P(L)U(0) \) and \( P(L)U(25K) \) (\( P \) denotes subjective probabilities), the same expected-utility inequality results for Figure 3a as for Figure 3b. Hence, either both preferences should be for the safe prospect, or both preferences should be for the risky one, and they cannot switch as in Figure 3. This reasoning holds irrespective of what the subjective probabilities \( P(H), P(M) \) and \( P(L) \) are. (The condition of expected utility that is falsified here, Savage’s (1954) ‘sure-thing principle’, can be related to the separability preference condition of consumer theory.)

Figure 3
The certainty effect (Allais paradox) for uncertainty

Schmeidler’s (1989) rank-dependent utility (RDU) can accommodate the Allais paradox for uncertainty. We consider a weighting function (or non-additive probability or capacity) \( W \) that assigns value 0 to the vacuous (empty) event \( \emptyset \), value 1 to the universal event, and satisfies monotonicity with respect to set-inclusion (if \( A \supseteq E \) then \( W(A) \geq W(E) \)). Probabilities are special cases of weighting functions that satisfy additivity: \( W(A \cup B) = W(A) + W(B) \) for disjoint events \( A \) and \( B \). General weighting functions need not satisfy additivity. Assume that the outcomes of a prospect \((E_1, x_1; \ldots; E_n, x_n)\) are rank-ordered, \( x_1 \geq \ldots \geq x_n \). Then the prospect’s rank-dependent utility (RDU) is \( \sum_{j=1}^n \pi_j U(x_j) \) where utility \( U \) is as before, and \( \pi_j \), the decision weight of outcome \( x_j \), is \( W(E_1 \cup \ldots \cup E_j - E_{j-1}) (\pi_1 = W(E_1)) \). The decision weight of \( x_j \) is the marginal \( W \) contribution of \( E_j \) to the event of receiving a better outcome.

Quiggin’s RDU for risk is the special case with probabilities \( P_j = P(E_j) \) given for all events, and \( W(E_j) = w(P(E_j)) \) with \( w \) the probability weighting function. Tversky and Kahneman (1992) improved their 1979 prospect theory not only by avoiding violations of stochastic dominance, but also, and more importantly, by extending their theory from risk to uncertainty, by incorporating Schmeidler’s RDU.

Figure 3 can, just as in the case of risk, be explained by a larger decision weight for the M branches in Figure 3b than in Figure 3a:

\[
W(M \cup H \cup L) - W(H \cup L) \geq W(M \cup H) - W(H).
\]

This inequality occurs for \( W \)-functions that are more sensitive to changes of events near the certain universal event \( M \cup H \cup L \) than for events of moderate likelihood such as \( M \cup H \). Although for uncertainty we cannot easily draw graphs of \( W \) functions, their properties are natural analogs of those depicted in Figures 2a–f. \( W \) is convex if the marginal \( W \) contribution of an event \( E \) to a disjoint event \( R \) is increasing in \( R \), that is,
is increasing in $R$ (with respect to set inclusion) for all $E$. This agrees with eq. (4), where increasing $R$ from $H$ to $H \cup L$ leads to a larger decision weight for $E = M$. Our definition of convexity is equivalent to other definitions in the literature such as $W(A \cup B) + W(A \cap B) \geq W(A) + W(B)$. (Take $E = A - B$ and compare $R = A \cap E$ with the larger $R = A$.)

For probabilistic sophistication ($W(\cdot) = W(P(\cdot))$, convexity of $W$ is equivalent to convexity of $w$ under usual richness conditions, illustrating once more the close similarity between risk and uncertainty. Equation (5) gives the decision weight of an outcome occurring under event $E$ if better outcomes occur under event $R$. Under convexity, outcomes receive more weight as they are ranked worse (that is, $R$ is larger), reflecting pessimism. Theoretical economic studies usually assume convex $W$s, implying low evaluations of prospects relative to sure outcomes.

Empirical studies have suggested that weighting functions $W$ for uncertainty exhibit patterns similar to Figure 2d, with unlikely events overweighted rather than, as convexity would have it, underweighted (Einhorn and Hogarth, 1986; Tversky and Fox, 1995; Wu and Gonzalez, 1999). As under risk, we get extremity orientedness, with best and worst outcomes overweighted and lack of sensitivity towards intermediate outcomes (Chateauneuf, Eichberger and Grant, 2005; Tversky and Wakker, 1995).

**Phenomena for uncertainty that do not show up for risk: the Ellsberg paradox**

Empirical studies have suggested that phenomena found for risk hold for uncertainty as well, and do so to a more pronounced degree (Fellner, 1961, p. 684; Kahn and Sarin, 1988, p. 270; Kahneman and Tversky, 1979, p. 281), in particular regarding the empirically prevailing inverse-S shape and its extension to uncertainty (Abdellaouli, Vossman and Weber, 2005; Hogarth and Kunreuther, 1989; Kilka and Weber, 2001; Weber, 1994, pp. 237–8). It is plausible, for example, that the absence of known probabilities adds to the inability of people to sufficiently distinguish between various degrees of likelihood not very close to impossibility and certainty. In such cases, inverse-S shapes will be more pronounced for uncertainty than for risk. This observation entails a within-person comparison of attitudes for different sources of uncertainty, and such comparisons are the main topic of this section. For Ellsberg’s paradox, imagine an urn $K$ with a known composition of 50 red balls and 50 black balls, and an ambiguous urn $A$ with 100 red and black balls in unknown proportion. A ball is drawn at random from each urn, with $R_k$ denoting the event of a red ball from the known urn, and the events $B_k$, $R_a$, and $B_a$ defined similarly. People prefer to bet on the known urn rather than on the ambiguous urn, and common preferences are:

$$(B_k: 100, R_k: 0) > (B_a: 100, R_a: 0) \text{ and } (B_k: 0, R_k: 100) > (B_a: 0, R_a: 100).$$

Such preferences are also found if people can themselves choose the colour to bet on so that there is no reason for suspecting an unfavourable composition of the unknown urn. Under probabilistic sophistication with probability measure $P$, the two preferences would imply $P(B_k) > P(B_a)$ and $P(R_k) > P(R_a)$. However, $P(B_k) + P(R_k) = 1 = P(B_a) + P(R_a)$ yields a contradiction, because two big numbers cannot give the same sum as two small numbers. Ellsberg’s paradox consequently violates probabilistic sophistication and, a fortiori, expected utility. Keynes (1921, p. 75) discussed the difference between the above two urns before Ellsberg did, but did not put forward the choice paradox and deviation from probabilistic sophistication as Ellsberg did. We now analyse the example assuming RDU.

In many studies of uncertainty, such as Schmeidler (1989), expected utility is assumed for risk, primarily for the sake of simplicity. Then, $W(B_k) = W(R_k) = 0.5$ in the above example, with these $W$ values reflecting objective probabilities. Under RDU, the above preferences imply $W(B_a) = W(R_a) < 0.5$, in agreement with convex (or eventwise dominance, or inverse-S; for simplicity of presentation, I focus on convexity hereafter) weighting functions $W$. This finding led to the widespread misunderstanding that it is primarily the Ellsberg paradox that implies convex weighting functions for unknown probabilities, a condition that was sometimes called ‘ambiguity aversion’. I have argued above that it is the Allais paradox, and not the Ellsberg paradox, that implies these conclusions, and I propose another interpretation of the Ellsberg paradox hereafter, following works by Amos Tversky in the early 1990s.

First, it is more realistic not to commit to expected utility under risk when studying uncertainty. Assume, therefore, that $W(B_k) = W(R_k) = w(P(B_k)) = w(P(R_k)) = w(0.5)$ for a
nonlinear probability weighting function. It follows from the Ellsberg paradox that \( W(A) = W(\hat{A}) > W(\hat{A}_1) > W(\hat{A}_2) > W(B) \). This suggests:

**Hypothesis:** In the Ellsberg paradox, the weighting function is more convex for the unknown urn than for the known urn. 

Thus, the Ellsberg paradox itself does not speak to convexity in an absolute sense, and does not claim convexity for known or for unknown probabilities. It speaks to convexity in a relative (within-person) sense, suggesting more convexity for unknown probabilities than for known probabilities. It is, for instance, possible that the weighting function is concave, and not convex, for both known and unknown probabilities, but is less concave (and thus more convex) for the unknown probabilities (Wakker, 2001, section 6; cf. Epstein, 1999, pp. 589–90, or Ghirardato and Marinacci, 2002, example 25).

With information only about observed behaviour, and without additional information about the compositions of the urns or the agent’s knowledge thereof, we cannot conclude which of the urns is ambiguous and which is not. It would then be conceivable that urn K was ambiguous and urn A were unambiguous, and that the agent satisfied expected utility for A and was optimistic or ambiguity seeking (concave weighting function, eq. (5) decreasing in \( R \)) for K, in full agreement with the Ellsberg preferences. Which of the urns is ambiguous and which is not is based on extraneous information, being our knowledge about the composition of the urns and about the agent’s knowledge thereof. This point suggests that no endogenous definition of (un)ambiguity is possible.

The Ellsberg paradox entails a comparison of attitudes of one agent with respect to different sources of uncertainty. It constitutes a within-agent comparison. Whereas the Allais paradox concerns violations of expected utility in an absolute sense, the Ellsberg paradox concerns a relative aspect of such violations, finding more convexity (or eventwise dominance, or inverse-S) for the unknown urn than for the known urn. Such a phenomenon cannot show up if we study only risk, because risk is essentially only one source of uncertainty. Apart from some volatile psychological effects (Kirkpatrick and Epstein, 1992; Piaget and Inhelder, 1975), it seems plausible that people do not distinguish between different ways of generating objective known probabilities.

Uncertainties of particular kinds can be grouped together into sources of uncertainty. Formally, let sources be particular algebras of events, which means that sources are closed under complementation and union, and contain the vacuous and universal events. For example, source \( A \) may concern the performance of the Dow Jones stock index tomorrow, and source \( B \) the performance of the Nikkei stock index tomorrow. Assume that A from source \( A \) designates the event that the Dow Jones index goes up tomorrow, and B from source \( B \) the event that the Nikkei index goes up tomorrow. If we prefer \( (A:100, not-A,0) \) to \( (B:100, not-B:0) \), then this may be caused by a special source preference for \( A \) over \( B \). Say, if \( A \) comprises less ambiguity for us than \( B \). However, it may also occur simply because we think that event A is more likely to occur than event B. To examine ambiguity attitudes we have to find a way to ‘correct’ for differences in perceived levels of likelihood.

One way to detect (strong) source preference for \( A \) over \( B \) is to find an \( A \)-partition \((A_1, \ldots, A_n)\) and a \( B \)-partition \((B_1, \ldots, B_n)\) of the universal event such that for each \( j \), \((A_j:100, not-A_j:0)\) > \((B_j:100, not-B_j:0)\) (Nehring, 2001, definition 4; Tversky and Fox, 1995; Tversky and Wakker, 1995). Because both partitions span the whole universal event, we cannot have stronger belief in every \( A_j \) than \( B_j \) (under some plausible assumptions about beliefs), and hence there must be a preference for dealing with \( A \) events beyond belief. Formally, the condition requires that a similar preference of \( B \) over \( A \) is never detected. The Ellsberg paradox is a special case of this procedure.

Under the above approach to source preference, there is a special role for probabilistic sophistication. For a source \( A \) for which not some of its events are more ambiguous than others, it is plausible that \( A \) exhibits source indifference with respect to itself. This condition can be seen to amount to the additivity axiom of qualitative probability (if \( A_1 \) is as likely as \( A_2 \), and \( A_2 \) is as likely as \( A_3 \), then \( A_1 \cup A_2 \) is as likely as \( A_3 \cup A_4 \) whenever \( A_1 \cap A_2 = A_3 \cap A_4 = \emptyset \)), which, under sufficient richness, implies probabilistic sophistication for \( A \) under RDU, and does so in general (without RDU) under an extra dominance condition (Fishburn, 1986; Sarin and Wakker, 2000). The condition also comprises source sensitivity (Tversky and Wakker, 1995). Probabilistic sophistication, then, entails a uniform degree of ambiguity of a source.

In theoretical economic studies it has usually been assumed that people are averse to ambiguity, corresponding with convex weighting functions. Empirical studies, mostly by psychologists, have suggested a more varied pattern, where different sources of ambiguity can arouse all kinds of emotions. For example, Tversky and Fox (1995) found that basketball fans exhibit source preference for ambiguous uncertain events related to basketball over events with known probabilities, which entails ambiguity seeking. This finding is not surprising in an empirical sense, but its conceptual implication is important: attitudes towards ambiguity depend on many ad hoc emotional aspects, such as a general aversion to deliberate secrecy about compositions of urns, or a general liking of basketball. Uncertainty is a large domain, and fewer regularities can be expected to hold universally for uncertainty than for risk, in the same way as fewer regularities will hold universally for the utility of non-monetary outcomes (hours of listening to music, amounts of milk to be drunk, life duration, and so on) than for the utility of monetary outcomes. It means that there is much yet to be discovered about uncertainty.

Models for uncertainty other than rank-dependence

**Multiple priors**

An interesting model of ambiguity by Jaffray (1989), with a separation of ambiguity beliefs and ambiguity attitudes, unfortunately has received little attention as yet. A surprising case of unknown probabilities can arise when the expected utility model perfectly well describes behaviour, but utility is state-dependent. The (im)possibility of defining probability...
in such cases has been widely discussed (Drèze, 1987; Grant and Karni, 2005; Nau, 2006).

The most popular alternative to Schmeidler's RDU is the multiple priors model introduced by Wald (1950). It assumes a set $\mathcal{P}$ of probability measures plus a utility function $U$, and evaluates each prospect through its minimal expected utility with respect to the probability distributions contained in $\mathcal{P}$. The model has an overlap with RDU: if $W$ is convex, then RDU is the minimal expected utility over $\mathcal{P}$ where $\mathcal{P}$ is the CORE of $W$, that is, the set of probability measures that eventwise dominate $W$. Drèze (1961; 1987) independently developed a remarkable analog of the multiple priors model, where the maximal expected utility is taken over $\mathcal{P}$, and $\mathcal{P}$ reflects moral hazard instead of ambiguity. Drèze also provided a preference foundation. Similar functionals appear in studies of robustness against model misspecification in macroeconomics (Hansen and Sargent, 2001).

Variations of multiple priors, combining pessimism and optimism, employ convex combinations of the expected utility maximized over $\mathcal{P}$ and the expected utility maximized over $W$ (Ghirardato, Maccheroni and Marinacci, 2004, proposition 19). Such models can account for extremity orientedness, as with inverse-$S$ weighting functions and RDU. Arrow and Hurwicz (1972) proposed a similar model where a prospect is evaluated through a convex combination of the minimal and maximal utility of its outcomes (corresponding with $\mathcal{P}$ being the set of all probability measures). This includes maximin and maximax as special cases. Their approach entails a level of ambiguity so extreme that no levels of belief other than 'sure-to-happen', 'sure-not-to-happen' and 'don't know' play a role, similar to Figure 2e and 2f, and suggesting a three-valued logic. Other non-belief-based approaches, including minimax regret, are in Manski (2000) and Savage (1954), with a survey in Barberà, Bossert and Pattanaik (2004).

Other authors proposed models where for each single event a separate interval of probability values is specified (Budescu and Wallsten, 1987; Kyburg, 1983; Manski, 2004). Such interval-probability models are mathematically different from multiple priors because there is no unique relation between sets of probability measures over the whole event space and intervals of probabilities separately for each event. The latter models are more tractable than multiple priors because probability intervals for some relevant event are easier to specify than probability measures over the whole space, but these models did not receive a preference foundation and never became popular in economics. Similar models of imprecise probabilities received attention in the statistics field (Walley, 1991).

Wald's multiple priors model did receive a preference axiomatization (Gilboa and Schmeidler, 1989), and consequently became the most popular alternative to RDU for unknown probabilities. The evaluating formula is easier to understand at first than RDU. The flexibility of not having to specify precisely what 'the' probability measure is, while usually perceived as an advantage at first acquaintance, can turn into a disadvantage when applying the model. We then have to specify exactly what 'the' set of probability distributions is, which is more complex than exactly specifying only one probability measure (cf. Lindley, 1996).

The simple distinction between probability measures that are either possible (contained in $\mathcal{P}$) or impossible (not contained in $\mathcal{P}$), on the one hand adds to the tractability of the model, but on the other hand cannot capture cognitive states where different probability measures are plausible to different degrees. To the best of my knowledge, the multiple priors model cannot yet be used in quantitative empirical measurements today, and there are no empirical assessments of sets of priors available in the literature to date. Multiple priors are, however, well suited for general theoretical analyses where only general properties of the model are needed. Such analyses are considered in many theoretical economic studies, where the multiple priors model is very useful.

The multiple priors model does not allow deviations from expected utility under risk, and a desirable extension would obviously be to combine the model with non-expected utility for risk. Promising directions for resolving the difficulties of the multiple priors model are being explored today (Maccheroni, Marinacci and Rustichini, 2005).

**Model-free approaches to ambiguity**

Dekel, Lipman and Rustichini (2001) considered models where outcomes of prospects are observed but the state space has not been completely specified, as relevant to incomplete contracts. Similar approaches with ambiguity about the underlying states and events appeared in psychology in repeated-choice experiments by Hertwig et al. (2003), and in support theory (Tversky and Koehler, 1994). This section discusses two advanced attempts to define ambiguity in a model-free way that have received much attention in the economic literature.

In a deep paper, Epstein (1999) initiated one such approach, continued in Epstein and Zhang (2001). Epstein sought to avoid any use of known probabilities and tried to endogenize (un)ambiguity and the use of probabilities. (He often used the term uncertainty as equivalent to ambiguity.) For example, he did not define risk neutrality with respect to known probabilities, as we did above, but with respect to subjective probabilities derived from preferences as in probabilistic sophistication (Epstein, 1999, eq. (2)). He qualified probabilistic sophistication as ambiguity neutrality (not uniformity as done above). Ghirardato and Marinacci (2002) used another approach that is similar to Epstein's. They identified absence of ambiguity not with probabilistic sophistication, as did Epstein, but, more restrictively, with expected utility.

The above authors defined an agent as ambiguity averse if there exists another, hypothetical, agent who behaves the same way for unambiguous events, but who is ambiguity neutral for ambiguous events, and such that the real agent has a stronger preference than the hypothetical agent for sure outcomes (or unambiguous prospects, but these can be replaced by their certainty equivalents) over ambiguous prospects. This definition concerns traditional between-agent within-source comparisons as in Yaari (1969). The stronger preferences for certainty are, under rank-dependent models, equivalent to eventwise dominance of weighting functions, leading to non-emptiness of the CORE (Epstein, 1999, lemma 3.4; Ghirardato...
and Marinacci (2002, corollary 3.3). These definitions of ambiguity aversion are not very tractable because of the ‘there exists’ clause. It is difficult to establish which ambiguity neutral agent to take for the comparisons. To mitigate this problem, Epstein (1999, section 4) proposed eventwise derivatives as models of local probabilistic sophistication. Such derivatives exist only for continua of events with a linear structure, and are difficult to elicit. They serve their purpose only under restrictive circumstances (ambiguity aversion throughout plus constancy of the local derivative, called coherence; see Epstein’s Theorem 4.3).

In both above approaches, ambiguity and ambiguity aversion are inextricably linked, making it hard to model attitudes towards ambiguity other than aversion or seeking (such other attitudes include insensitivity), or to distinguish between ambiguity-neutrality or -absence (Epstein, 1999, p. 584, 1st para; Epstein and Zhang, 2001, p. 283; Ghirardato and Marinacci, 2002, p. 256, 2nd para). Both approaches have difficulties distinguishing between the two Ellsberg urns. Each urn in isolation can be taken as probabilistically sophisticated with, in our inpt, a uniform degree of ambiguity, and Epstein’s definition cannot distinguish which of these is ambiguity neutral (cf. Ghirardato and Marinacci, 2002, middle of p. 281). Ghirardato and Marinacci’s definition does so, but only because it selects expected utility (and the urn generating such preferences) as the only ambiguity-neutral version of probabilistic sophistication. Any other form of probabilistic sophistication, that is, any non-expected utility behaviour under risk, is then either mismodeled as ambiguity attitude (Ghirardato and Marinacci, 2002, pp. 256–7), or must be assumed not to exist.

We next discuss in more detail a definition of (un)ambiguity by Epstein and Zhang (2001), whose aim was to make (un)ambiguity endogenously observable by expressing it directly in terms of a preference condition. They called an event \( E \) unambiguous if

\[
\begin{align*}
(E; c, E_2; \gamma, E_3; \beta, E_4; x_4, \ldots, E_n; x_n) \Rightarrow \\
(E; c, E_2; \beta, E_3; \gamma, E_4; x_4, \ldots, E_n; x_n) \Rightarrow \\
(E; c', E_2; \gamma, E_3; \beta, E_4; x_4, \ldots, E_n; x_n) \Rightarrow \\
(E; c', E_2; \beta, E_3; \gamma, E_4; x_4, \ldots, E_n; x_n)
\end{align*}
\]

for all partitions \( E_2, \ldots, E_n \) of not-\( E \), and all outcomes \( c, c', x_4, \ldots, x_n \). \( \gamma \Rightarrow \beta \), with a similar condition imposed on not-\( E \). In words, changing a common outcome \( c \) into another common outcome \( c' \) under \( E \) does not affect preference, but this is imposed only if the preference concerns nothing other than to which event \( (E_2 \text{ or } E_3) \) a good outcome \( \gamma \) is to be allocated instead of a worse outcome \( \beta \). Together with some other axioms, eq. (6) implies that probabilistic sophistication holds on the set of events satisfying this condition, which in the interpretation of the authors designates absence of ambiguity (rather than uniformity). As we will see next, it is not clear why eq. 6 would capture the absence of ambiguity.

**Example.** Assume that events are subsets of \([0,1]\), \( E = [0, 0.5] \), \( \text{not } E = [0.5, 1] \), and \( E \) has unknown probability \( \pi \). Every subset \( A \) of \( E \) has probability \( 2\pi \lambda(A) \) (\( \lambda \) is the usual Lebesgue measure, that is, the uniform distribution over \([0,1])\) and every subset \( B \) of not-\( E \) has probability \( 2(\lambda(B) - \pi) \). Then it seems plausible that event \( E \) and its complement not-\( E \) are ambiguous, but conditional on these events (‘within them’) we have probabilistic sophistication with respect to the conditional Lebesgue measure and without any ambiguity. In Schmeidler (1989), the ambiguous events \( E \) and not-\( E \) are called horse events, and the unambiguous events conditional on them are called roulette events. Yet, according to eq. (6), events \( E \) and not-\( E \) themselves are unambiguous, both preferences in eq. (6) being determined by whether \( \lambda \) (\( E_2 \)) exceeds \( \lambda \) (\( E_3 \)).

In the example, the definition in eq. (6) erroneously ascribes the unambiguity that holds for events conditional on \( E \), so ‘within \( E \)’, to \( E \) as a whole. Similar examples can be devised where \( E \) and not-\( E \) themselves are unambiguous, there is ‘non-uniform’ ambiguity conditional on \( E \), this ambiguity is influenced by outcomes conditional on not-\( E \) through non-separable interactions typical of non-expected utility, and eq. (6) erroneously ascribes the ambiguity that holds within \( E \) to \( E \) as a whole.

A further difficulty with eq. (6) is that it is not violated in the Ellsberg example with urns A and K as above (nor if the uncertainty regarding each urn is extended to a ‘uniform’ continuum as in Example 5.8ii of Abdellaoui and Wakker, 2005), and cannot detect which of the urns is ambiguous. The probabilistic sophistication that is obtained in Epstein and Zhang (2001, Theorem 5.2) for events satisfying eq. (6), and that rules out the two-urn Ellsberg paradox and its continuous extension of Abdellaoui and Wakker (2005), is mostly driven by their Axioms 4 and 6 (the latter is not satisfied by all rank-dependent utility maximizers contrary to the authors’ claim at the end of their Section 4; their footnote 18 is incorrect) and the necessity to consider also intersections of different-urn events (see their Appendix E). This imposes, in my terminology, a uniformity of ambiguity over the events satisfying eq. (6) that, rather than eq. (6) itself, rules out the above counterexamples.
Several authors have considered two-stage approaches with intersections of first-stage events $A_i$, $i = 1, \ldots, \ell$, and second-stage events $K_j$, $j = 1, \ldots, k$, so that $n = \ell k$ events $A_i K_j$ result, and prospects $(A_i^c K_j^c : x_{ij})_{i=1}^{\ell} j=1$ are considered. It can be imagined that in a first stage it is determined which event $A_i$ obtains, and then in a second stage, conditional on $A_i$, which event $K_j$ obtains. Many authors considered such two-stage models with probabilities given for the events in both stages, the probabilities of the first stage interpreted as ambiguity about the probabilities of the second stage, and non-Bayesian evaluations used (Levi, 1980; Segal, 1990; Yates and Zukowski, 1976).

Other authors considered representations

$$\sum_{i=1}^{\ell} Q(A_i) \phi \left( \sum_{j=1}^{k} P(K_j) U(x_{ij}) \right)$$

for probability measures $P$ and $Q$, a utility function $U$, and an increasing transformation $\phi$. For $\phi$ the identity or, equivalently, $\phi$ linear, traditional expected utility with backwards induction results. Nonlinear $\phi$'s give new models. Kreps and Porteus (1979) considered eq. (7) for intertemporal choice, interpreting nonlinear $\phi$'s as non-neutrality towards the timing of the resolution of uncertainty. Ergin and Gul (2004) and Nau (2006) reinterpreted the formula, where now the second-stage events are from a source of different ambiguity than the first-stage events. A concave $\phi$, for instance, suggests stronger preference for certainty, and more ambiguity aversion, for the first-stage uncertainty than for the second.

Klibanoff, Marinacci and Mukerji (2005) considered cases where the decomposition into A- and K-events is endogenous rather than exogenous. This approach greatly enlarges the scope of application, but their second-order acts, that is, prospects with outcomes contingent on aspects of preferences, are hard to implement or observe if those aspects cannot be related to exogenous observables.

Equation (7) has a drawback similar to eq. (3). All extra mileage is to come from the outcomes, to which also utility applies, so that there will not be a great improvement in descriptive performance or new concepts to be developed.

Conclusion

The Allais paradox reveals violations of expected utility in an absolute sense, leading to convex or inverse-S weighting functions for risk and, more generally, for uncertainty. The Ellsberg paradox reveals deviations from expected utility in a relative sense, showing that an agent can deviate more from expected utility for one source of uncertainty (say one with unknown probabilities) than for another (say, one with known probabilities). It demonstrates the importance of within-subject between-source comparisons.

The most popular models for analysing uncertainty today are based on rank dependence, with multiple priors a popular alternative in theoretical studies. The most frequently studied phenomenon is ambiguity aversion. Uncertainty is, however, a rich empirical domain with a wide variety of phenomena, where ambiguity aversion and ambiguity insensitivity (inverse-S) are prevailing but are not universal patterns. The possibility of relating the properties of weighting functions for uncertainty to cognitive inpts such as insensitivity to likelihood-information makes RDU and prospect theory well suited for links with other fields such as psychology, artificial intelligence (Shafer, 1976) and neuroeconomics (Camerer, Loewenstein and Prelec, 2004).

The assumption of uncovered interest parity (UIP) is an important building block for macroeconomic analysis of open economies. It provides a simple relationship between the interest rate on an asset denominated in any one country's currency unit, the interest rate on a similar asset denominated in another country's currency, and the expected rate of change in the spot exchange rate between the two currencies. The theory of interest parity received prominence from expositions by Keynes (for example, 1923, pp. 115–39), whose attention had been captured by the rapid expansion of organized trading in forward exchange following the First World War (Einzig, 1962, pp. 239–41, 275). Although an understanding of
uncovered interest parity: The New Palgrave Dictionary of Economics

the forward exchange market must have developed within various banking circles during the second half of the 19th century, apart from an isolated exposition by a German economist, Walther Lotz (1889), the 19th-century literature on foreign exchange theory apparently dealt only with spot exchange rates (Einzig, 1962, pp. 214–15). Forward exchange trading gave rise to the notion of covered interest parity (CIP), which related the differential between domestic and foreign interest rates to the percentage difference between forward and spot exchange rates. Since it was clear that forward rates also reflected perceptions about future spot rates, it was a short step to the assumption of UIP, which builds on the theory of CIP by essentially postulating that market forces drive the forward exchange rate into equality with the expected future spot exchange rate.

Basic concepts

The concept of interest parity recognizes that portfolio investors at any time $t$ have the choice of holding assets denominated in domestic currency, offering the own rate of interest $r_t$ between times $t$ and $t + 1$, or of holding assets denominated in foreign currency, offering the own rate of interest $r_t^*$. Thus, an investor starting with one unit of domestic currency should compare the option of accumulating $1 + r_t$ units with the option of converting at the spot exchange rate into $s_t$ units of foreign currency, investing in foreign assets to accumulate $s_t(1 + r_t^*)$ units of foreign currency at time $t + 1$, and then reconverting into domestic currency. If the domestic and foreign assets differ only in their currencies of denomination, and if investors have the opportunity to cover against exchange rate uncertainty by arranging at time $t$ to reconvert from foreign to domestic currency one period later at the forward exchange rate $f_t$ (in units of foreign currency per unit of domestic currency), then market equilibrium requires the condition of CIP:

$$1 + r_t = s_t(1 + r_t^*) / f_t. \quad (1)$$

If condition (1) did not hold, profitable market arbitrage opportunities could be exploited without incurring any risks.

Investors also have the opportunity to leave their foreign currency positions uncovered at time $t$ and to wait until time $t + 1$ to make arrangements to reconvert into domestic currency at the spot exchange rate $s_{t+1}$. Unlike $f_t$, the value of $s_{t+1}$ is unknown at time $t$, and so the attractiveness of holding an uncovered position must be assessed in terms of the probabilities of different outcomes for $s_{t+1}$. The assumption of UIP postulates that markets will equilibrate the return on the domestic currency asset with the expected value at time $t$ ($E_t$) of the yield on an uncovered position in foreign currency:
uncovered interest parity: The New Palgrave Dictionary of Economics

This is essentially equivalent to combining the CIP condition with the assumption that exchange rates are driven, at the margin, by risk-neutral market participants who stand ready to take uncovered spot or forward positions whenever the forward rate deviates from the expected future spot rate.

By manipulating condition (1), it is easily seen that CIP implies

\[
1 + r_t = E_t \left[ \frac{s_t(1 + r_t^*)}{s_{t+1}} \right] = s_t(1 + r_t^*)E_t(1/s_{t+1}).
\]

This is essentially equivalent to combining the CIP condition with the assumption that exchange rates are driven, at the margin, by risk-neutral market participants who stand ready to take uncovered spot or forward positions whenever the forward rate deviates from the expected future spot rate.

By manipulating condition (1), it is easily seen that CIP implies

\[
\frac{f_t - s_t}{s_t} = \frac{1 + r_t^*}{1 + r_t} - 1
\]

Hence, as a first approximation (for values of \(1 + r_t\) in the vicinity of 1):

\[
r_t^* - r_t \approx \frac{(f_t - s_t)}{s_t}
\]

In addition, when Jensen's inequality – that is, the difference between \(E_t(1/s_{t+1})\) and \(1/E_t(1/s_{t+1})\) – is ignored, the assumption of UIP can be approximated as

\[
r_t^* - r \approx E_t[(s_{t+1} - s_t)/s_t] = (E_t s_{t+1} - s_t)/s_t.
\]

The assumption of UIP adds an element of dynamics to the CIP condition by hypothesizing a relationship between the observed values of variables at time \(t\) and the value of the spot exchange rate that market participants expect at time \(t\) to prevail at time \(t + 1\). As such, UIP has been embedded in many multi-period models of open economies. The CIP and UIP conditions can be written for any duration of the time period between \(t\) and \(t + 1\). Thus, if the UIP assumption was valid at all horizons, the observed values of the spot exchange rate and the term structures of domestic and foreign interest rates could be used to infer the expected future time path of the spot exchange rate (Porter, 1971).

In addition to playing an important role in the development of multi-period models of open economies,
 uncovered interest parity: The New Palgrave Dictionary of Economics

the UIP condition has been a central focal point in the policy debate over the effectiveness of official intervention in exchange markets (Henderson and Sampson, 1983). To the extent that UIP was valid at short time horizons, official intervention could not succeed in changing the spot exchange rate relative to the expected future spot rate unless the authorities chose to allow interest rates to change. In this sense, exchange market intervention could not be viewed as providing the authorities with an effective policy instrument in addition to interest rates. Thus, the case for intervention has been considered by some to depend on whether the empirical evidence rejects UIP.

Empirical evidence

The theory leading to the CIP condition – and hence also to the UIP assumption – abstracts entirely from any credit risks, capital controls, or explicit taxes on domestic and foreign currency investments. Keynes (1923, pp. 126–7) was well aware that investor choices between foreign and domestic assets do not depend on interest rates and exchange rates alone:

… the various uncertainties of financial and political risk … introduce a further element which sometimes quite transcends the factor of relative interest. The possibility of financial trouble or political disturbance, and the quite appreciable probability of a moratorium in the event of any difficulties arising, or of the sudden introduction of exchange regulations which would interfere with the movement of balances out of the country, and even sometimes the contingency of a drastic demonetization, – all these factors deter … [market participants], even when the exchange risk proper is eliminated, from maintaining large … balances at certain foreign centres.

In those circumstances where it is valid to abstract from the types of considerations cited by Keynes, the CIP condition has been generally confirmed. As one source of evidence, interviews at large banks have established that the CIP condition is used as a formula for determining the exchange rates and interest rates at which trading is actually conducted. Foreign exchange traders use Eurocurrency interest rate differentials to determine the forward exchange rates (in relation to spot rates) that they quote to customers, while traders in Eurocurrency deposits use the spreads between forward and spot exchange rates to set the spreads between the interest rates that their banks offer on domestic and foreign currency deposits (Herring and Marston, 1976; Levich, 1985). As additional evidence, Taylor (1989) has constructed a database of the bid and offer rates quoted contemporaneously for exchange rates and interest rates by foreign exchange and money market brokers, as recorded on the ‘pad’ of the chief dealer at the Bank of England. The data include observations on one- two-, three-, six-, and twelve-month maturities during selected intervals between 1967 and 1987. Taylor's study found no evidence of unexploited profit opportunities during relatively calm periods in foreign exchange and money markets, although potentially exploitable profitable arbitrage opportunities did ‘occasionally occur’ during periods of market turbulence, where the frequency, size and persistence of such opportunities were positively related to length of maturity. Consistently, in circumstances when it is not valid to abstract from capital controls and risks, empirical research has confirmed that deviations from CIP can be related systematically to the effective taxes imposed by capital controls and to non-currency-specific risk
The UIP assumption is more difficult to test than the CIP condition, since market expectations of future exchange rates are not directly observable. Accordingly, UIP has generally been tested jointly with the assumption that exchange market participants form rational expectations, such that future realizations of the exchange rate will equal the value expected at time \( t \) plus an error term that is uncorrelated with all information known at time \( t \). Together the two assumptions imply that

\[
s_{t+1} = f_t + u_{t+1}
\]  
(6)

and hence

\[
s_{t+1} - s_t = r_t - r^*_t + u_{t+1}
\]  
(7)

where \( u \) represents a prediction error. This has led economists to assess the UIP assumption empirically by estimating the values of the \( a \) and \( b \) coefficients in the specification forms

\[
s_{t+1} = a_0 + a_1 f_t + u_{t+1}
\]  
(8)

and

\[
s_{t+1} - s_t = b_0 + b_1 (r_t - r^*_t) + u_{t+1}
\]  
(9)

where it is assumed that the error terms have zero means and are serially uncorrelated.

Empirical assessments of UIP as a framework for predicting the future spot exchange rate have distinguished two issues: the size of the prediction errors, and the question of whether the predictions are systematically biased. On the first issue, it has become widely acknowledged that interest differentials
uncovered interest parity: The New Palgrave Dictionary of Economics

explain only a small proportion of subsequent changes in exchange rates (Isard, 1978; Mussa, 1979; Frenkel, 1981). This finding has been generally interpreted as implying that observed changes in exchange rates are predominantly the result of unexpected information or 'news' about economic developments, policies or other relevant factors.

The issue of whether predictions are systematically biased can be assessed by testing the hypothesis of unbiasedness – namely, that $a_0, a_1 = (0, 1)$ in eq. (8) or $b_0, b_1 = (0, 1)$ in eq. (9). Notably, the test that the slope coefficient is unity receives strong support from studies based on (8) but is soundly rejected by studies based on (9) – at least for prediction horizons of a year or less. However, the apparent conflict between the two sets of regression evidence has been resolved in favour of the latter finding, as it is now accepted that (8) is not a legitimate regression equation (Meese, 1989). The explanation is based on the fact that the sample variances of the spot rate and forward rate are essentially equal. Although the empirical evidence strongly rejects the unbiasedness hypothesis at prediction horizons of up to one year, the evidence is much more favourable to unbiasedness at horizons of 5 to 20 years. In particular, when data for industrial countries are pooled, and when annual exchange rate changes and interest differentials (for each country relative to a numeraire country) are averaged over non-overlapping 5- to 20-year periods, the slope coefficients in eq. (9) become insignificantly different from unity (Flood and Taylor, 1997, who note that the average one-year change over n years is equivalent to the change over n years multiplied by a scale factor; see also Chinn and Meredith, 2004).

Does prediction bias refute the UIP assumption?

Economists have not resolved how to interpret the strong rejection of the unbiasedness hypothesis at short prediction horizons. Several possible explanations have been suggested, with different implications for UIP.

One interpretation rejects the UIP hypothesis but not the rational expectations assumption. According to this view, the finding of systematic prediction bias suggests that market participants are risk averse and require risk premiums to hold uncovered foreign currency positions. The prediction bias is thus perceived as an omitted variable problem that can be addressed, in concept, by extending the right-hand side of eq. (9) to include an expression for the risk premium. A second interpretation of prediction bias abandons the assumption that market participants are fully rational.

Other possible explanations do not require rejection of either UIP or the rational expectations hypothesis. These include explanations based on the 'peso problem', simultaneity bias, incomplete information with rational learning, and self-fulfilling prophecies or rational 'bubbles'. The suggestion that prediction bias reflects a ‘peso problem’ is generally attributed to Rogoff (1980) and Krasker (1980), who drew attention to an episode in which the Mexican peso sold at a forward discount for a prolonged period prior to its widely anticipated devaluation in 1976. Although market expectations eventually proved correct and may well have been rational ex ante, the fact that the devaluation did not occur immediately after it became anticipated made the forward rate a biased predictor over finite data samples that included the pre-devaluation period. The general point is that, even if market participants are risk neutral and form rational expectations, the forward rate can be biased as a predictor of the future spot rate – and the interest rate differential biased as a predictor of the change in the spot rate – whenever market participants repeatedly expect the spot rate to change in response to a policy action or
uncovered interest parity The New Palgrave Dictionary of Economics

...some other event that fails to materialize over a relatively long series of observations. The suggestion that rejection of the unbiasedness hypothesis reflects simultaneity bias was alluded to by Isard (1988) and later emphasized by McCallum (1994). In particular, given that the monetary authorities in most countries rely on a short-term interest rate as a policy instrument that they are prepared to adjust, 
inter alia, in response to undesired exchange rate movements, the estimates of $b_1$ may be biased by the failure to estimate (9) simultaneously with a second relationship between the interest rate differential and the change in the exchange rate.

As suggested by Lewis (1988; 1989), prediction bias can also emerge under UIP and rational expectations if market participants lack complete information but engage in a process of rational learning. This explanation is analogous to the peso problem in so far as it provides an interpretation in which market participants are risk neutral and fully rational but prone to make repeated mistakes. Yet another possibility consistent with UIP is the conjecture that prediction bias arises from the self-fulfilling prophecies of rational, risk-neutral market participants. Such prophecies, which are often referred to as ‘rational bubbles’, have received attention as logical possibilities; but few economists, if any, consider them to have much plausibility as empirical phenomena (Mussa, 1990).

Where things stand

Because the validity of the UIP hypothesis cannot be tested directly and is not resolved by the rejection of the unbiasedness hypothesis, economists have resorted to indirect tests as a means of obtaining suggestive evidence. In particular, survey data on exchange rate expectations have been collected by several different sources since the early 1980s, and a number of studies have shown that exchange rate expectations, as measured by the average forecasts of sample respondents, deviate considerably from prevailing forward exchange rates (Frankel and Froot, 1987; Takagi, 1991; Chinn and Frenkel, 2002). To the extent that survey measures of average expectations are meaningful, this would appear to be strong evidence against UIP.

That said, it also needs to be recognized that intertemporal models of open-economy macroeconomics require equations that link current spot exchange rates to expected future exchange rates. Thus, on pragmatic grounds, the case for abandoning the UIP hypothesis depends on how well economists can model the deviation from UIP – namely, the difference between the forward exchange rate and the expected future spot rate, which is generally referred to as the exchange risk premium.

Behavioural hypotheses about the exchange risk premium can be tested by embedding them in models of observable exchange rates. The first conceptual models of the exchange risk premium were based on a portfolio balance framework in which financial claims were distinguished by currencies of denomination but not by the countries obligated to meet the claims (see, for example, Dooley and Isard, 1983). Empirical tests of this class of portfolio balance model have explained at most a small portion of the variation over time in the exchange risk premium (Tryon, 1983; Boughton, 1987). More sophisticated behavioural hypotheses have recognized – in the spirit of the quotation above from Keynes – that exchange risks and credit risks are interrelated, and that the magnitudes of these risks reflect the relative macroeconomic and political conditions, prospects, and uncertainties of the countries that have issued the portfolio claims (Dooley and Isard, 1983; Isard, 1988). While casual evidence suggests that this type of hypothesis is broadly capable of explaining the empirical behaviour of exchange rates (Dooley and
uncovered interest parity: The New Palgrave Dictionary of Economics

(Isard, 1991), formal empirical tests that capture the many factors contributing to exchange rate risk are difficult to design, and economists have not yet provided a well-specified replacement for the UIP assumption. Accordingly, many intertemporal open-economy macroeconomic models continue to impose the UIP assumption – or the assumption of UIP adjusted by an exogenous exchange risk premium that provides a mechanism for analyzing the effects of ‘exogenous’ changes in risk perceptions or asset preferences. However, consistent with the evidence that rejects the unbiasedness hypothesis, it has proved difficult to mimic the observed behaviour of key macroeconomic variables with models that impose the UIP assumption and also treat exchange rate expectations as fully model-consistent. Thus, models that impose the UIP assumption tend to treat exchange rate expectations as not completely rational. One fairly common practice, for example, is to treat exchange rate expectations (and inflation expectations) as having both forward-looking (model-consistent) and backward-looking components. Quite apart from ongoing debates over the validity of the UIP assumption as an \textit{ex ante} hypothesis, and the usefulness of incorporating the UIP assumption into macroeconomic models, there is abundant evidence, as noted above, that the changes in spot exchange rates that are expected \textit{ex ante} are generally dominated by unexpected changes. Thus, regardless of the usefulness of UIP as an \textit{ex ante} hypothesis for macroeconomic modelling, it is quite clear that UIP by itself provides a very inaccurate framework for predicting the changes in exchange rates that are observed \textit{ex post}.

Article

‘Underconsumption’ is the label given to theories which attribute the failure of the total output of an economy to continue to be sold at its cost of production (including normal profit) to too low a ratio of consumption to output. According to underconsumption theories, such deficient consumption leads either to goods being able to be sold only at below-normal rates of profit, or to goods not being able to be sold at all. These effects are seen as leading in turn to cutbacks in production and increases in unemployment. Underconsumption theories are thus amongst those which seek to explain cyclical or secular declines in the rate of economic growth.

Where underconsumption exists in the sense that the ratio of consumption to output is below the optimum level, it follows that the ratio of ‘unconsumed’ output to total output must be too high. For the period in which underconsumption breaks out, underconsumptionists in general both identify this ‘unconsumed’ output with saving, and equate saving with investment. Thus Haberler, to whose 1937 analysis of underconsumption and related theories the reader should turn for the best extended treatment of the subject, wrote that in ‘its best-reasoned form …, the under-consumption theory uses “under-consumption” to mean “over-saving”’, and that in ‘the under-consumption or over-saving theory … savings are, as a rule, invested …’ (Haberler, 1937, pp. 115 and 117).

While the theories advanced by underconsumptionists overlap with some other macroeconomic theories in certain ways, their basic characteristics make them distinct in other respects. Underconsumption theories share with Keynesian theories, for example, the characteristic that they are ‘demand-side’ (as...
underconsumptionism: The New Palgrave Dictionary of Economics

opposed to ‘supply side’) theories. However, there is a fundamental difference between the two, in that Keynesian theories attribute the failure of total output to reach the full employment level to a deficiency of aggregate demand. The two types of theory consequently have different implications. As Robbins succinctly put it, with reference to the underconsumptionist J.A. Hobson, for ‘Mr Keynes, one way out of the slump would be a revival of investment; for Mr Hobson, this would simply make matters worse’ (Robbins, 1932, p. 420). A further difference between the two lies in the fact that, by contrast with Keynesian theories, hoarding plays no part in underconsumption theories. Underconsumptionists in general confine their analyses to the real sector of the economy, and where monetary factors are discussed at all they are treated as secondary.

There are also some connections between underconsumption theories and the accelerator theory of investment. As Haberler pointed out, the acceleration principle can be used ‘in support of a special type of the under-consumption theory of the business cycle’ (Haberler, 1937, p. 30). More importantly, a variant of the principle can be seen as underlying all underconsumption theories. When first expounded by J.M. Clark, the acceleration principle was used to explain the level of activity in the investment goods sector of an economy by changes in the demand for finished goods. In essence, underconsumptionists base their theories on the idea that changes in the demand for consumption goods determine the future level of activity in the investment goods sector. By this means they draw the conclusion that the level of activity in the economy as a whole is wholly determined by consumption demand.

In a review of Harrod's *Towards a Dynamic Economics*, Joan Robinson suggested that ‘Mr Harrod's analysis provides the missing link between Keynes and Hobson’ (Robinson, 1949, p. 80). The resemblance of underconsumption theories to growth models of the Harrod–Domar type is in fact greater than their resemblance to Keynesian theories. As Domar pointed out in the *American Economic Review* article (1947) expounding his growth model, he shared with Hobson a concern with the capacity-creating effect of investment, a question which Keynes hardly touched on in the *General Theory*. The essential features of underconsumption theories can in fact be captured by a growth model of the Harrod–Domar type, in which however the driving force is provided not by the rate of growth of investment but by the rate of growth of consumption. Such a model is particularly appropriate in the case of those theories which treat underconsumption as a secular rather than a cyclical phenomenon.

There are connections too between underconsumption theories and explanations of ‘economic crises’ in terms of ‘disproportionate production’, to use Marx's terminology. By ‘disproportionate production’ Marx meant an allocation of labour time between sectors or industries other than that required to satisfy social need as reflected in demand. Now underconsumption involves an allocation of too few resources to the consumption goods sector and too many resources to the investment goods sector. But as Haberler pointed out, such ‘vertical disproportion’ should be distinguished from ‘horizontal disproportion’. And unlike cases of horizontal disproportion (if optimal stock levels are ignored), vertical disproportion, involving industries not equidistant from consumption goods industries, cannot be rectified immediately by a return to ‘proportionate’ production. For the excessive production of investment goods consequent upon underconsumption leaves a legacy in the form of excessive productive capacity.

Underconsumption theories thus should be distinguished from the more general category of ‘disproportionality’ theories; the disproportionality element they incorporate is specific and has distinctive consequences.

Over-investment theories provide a different example of vertical disproportion. As they are defined by Haberler, over-investment theories offer an explanation of the excessive aggregate demand characteristic
of an economy during the upswing of a trade cycle. Therefore they also belong to a different category from underconsumption theories, even though the deficiency of consumption characteristic of the latter is accompanied by excessive investment.

Despite their basic similarities, underconsumption theories differ as to the cause of, and hence remedies for, underconsumption. A view to be found in the writings of some underconsumptionists, especially the less well-known ones, is that underconsumption is due to total purchasing power falling short of the value of output. Since all the value of output accrues to the owner of one factor of production or another, this proposition as it stands cannot be sustained. This view as to the cause of underconsumption should not be confused, however, with a superficially similar view relating to its effects, which is at least implicit in all underconsumptionist thinking. This is the idea that income is generated not by production but by purchases of what is produced. In underconsumptionist writings, by contrast for example with Keynesian writings, income may fall short of the value of output.

How this may be so is perhaps best seen in terms of period analysis. An outbreak of underconsumption will lead in the first period to excessive saving accompanied by excessive investment. In the second period the resulting additional capacity will be used, and unless there is an increase in consumption the level of output will exceed the demand for it; hence in this period the income generated by purchases will fall short of the value of output, while at the same time saving, if it is defined as that part of income (as opposed to output) not consumed, will just match investment demand. The deficient demand in the second period will lead in the third period to actual output falling short of potential output, that is to excess capacity, with saving however continuing to equal investment.

One underconsumptionist who clearly did not attribute underconsumption to lack of purchasing power is Malthus. In his correspondence with Ricardo, Malthus instead took the position that ‘a nation must certainly have the power of purchasing all that it produces, but I can easily conceive it not to have the will’ (Sraffa, 1952, p. 132). Like some other underconsumptionists, notably Sismondi and Hobson, Malthus believed that one cause of underconsumption is to be found in the limited capacity of human beings to expand their wants, at least in the short run. It was Malthus's view that men have a tendency towards indolence once their needs for necessaries are satisfied. If in the face of such limited growth in human wants capital accumulation continues apace, the resulting increase in productive capacity will fail to be matched by an equal increase in consumer demand. The remedy for this state of affairs, suggested Malthus, is an increase in commerce, both domestic and foreign, so as to stimulate tastes by exposing the population to new products.

Most commonly, however, underconsumptionists find the cause of underconsumption in a maldistribution of income. The underlying argument is simple. If different economic classes have different propensities to consume, the distribution of an excessive share of income to classes with a relatively low propensity to consume will result in underconsumption. Underconsumptionists agree that a remedy cannot be found by a redistribution of income towards the capitalist class, which they see as having a relatively high propensity to save. They differ, however, on the question of the class to which income should in cases of underconsumption be redistributed. The earliest underconsumptionists ruled out a redistribution of income towards workers, perhaps partly because it was incompatible with their adherence to the wages fund doctrine, according to which total wages are fixed by the capital set aside in advance to pay them. They advocated rather a redistribution of income towards landlords. The first underconsumptionist to advocate a redistribution of income towards workers was Sismondi, whose example was followed by most later underconsumptionists.
Underconsumption theories were first put forward in the 19th century. While some 17th- and 18th-century writers, most notably Mandeville and the Physiocrats, advocated an increase in expenditure on consumption goods, none of them linked this with a corresponding reduction in investment. Therefore although they may be seen as predecessors of Keynes, they should not be classified as underconsumptionists. The first to advance an underconsumption theory in the sense outlined above was Lauderdale, in *An Inquiry into the Nature and Origin of Public Wealth* (1804). Perhaps the best known of the subsequent underconsumptionists are Malthus, Sismondi, Rodbertus, Hobson and Rosa Luxemburg. For a fuller (and sometimes different) account of the theories of these and other underconsumptionists than is possible here, the reader should turn to Bleaney (1976) or Nemmers (1956). Further, additional light has been shed on the overall nature of underconsumptionist theories by the several attempts that have been made to express the theory put forward by Malthus in the form of a model, notably by Eagly (1974), Eltis (1980) and Costabile and Rowthorn (1985).

While some underconsumption theories were largely prompted by current or expected economic events, in other cases the inspiration was mainly intellectual. Both factors seem to have been important in the case of Lauderdale, the earliest underconsumptionist. Lauderdale was in part reacting against the praise of parsimony by Adam Smith, but he was also alarmed at the prospect of the British government using its revenue after the end of the Napoleonic wars for the purpose of capital accumulation in place of wartime consumption. More generally, as a precaution against underconsumption, Lauderdale advocated a lessening of the current inequality of wealth, as Malthus was also to do. By contrast Spence, in *Britain Independent of Commerce* (1807), developed an underconsumption theory on the basis of Physiocratic ideas. His solution for underconsumption was encouragement of consumption by landlords, so as to restore the income of the manufacturing class to its former level.

His correspondence with Ricardo shows that Malthus had developed underconsumptionist views by 1814. This fact is doubly significant. It proves both that Malthus's underconsumptionism preceded the depressed economic conditions which followed the ending of the Napoleonic wars in 1815, rather than being a response to them, and that Marx's charge that Malthus plagiarized Sismondi is unfounded. The underconsumptionist elements in Malthus's thinking are to be found not only in his correspondence with Ricardo, but also in his *Principles of Political Economy Considered with a View to their Practical Application* (1820). The latter had an influence on the underconsumption theory put forward in Chalmers' *Political Economy* (1832). It may also have provided a stimulus for the underconsumption theory advanced in a pamphlet entitled *Considerations on the Accumulation of Capital* (1822). Published anonymously, this pamphlet was written by Cazenove, the friend of Malthus who was later to edit (also anonymously) the second edition of Malthus's *Principles*.

Like Lauderdale, Sismondi reacted against Adam Smith's views on parsimony, and like Malthus he had become an underconsumptionist by the end of the Napoleonic wars, as is evidenced by the material contained in the article entitled ‘Political Economy’ which Sismondi wrote in 1815 for Brewster's *Edinburgh Encyclopaedia*. A complete account of Sismondi’s underconsumption theory is only to be found, however, in his *Nouveaux principes d’économie politique* (1819). Here Sismondi argued that where producers supply a large anonymous market, competition for profits leads each of them on the one hand to overestimate the demand for the commodity he produces and over-accumulate capital accordingly, and on the other hand so to depress wages that they grow at a slower rate than profits. Sismondi’s remedies for underconsumption include organization of industry on a local basis, and a
For a discussion of possible sources of the underconsumptionist elements in the writings of Robert Owen and the Ricardian Socialists the reader is referred to King (1981). A more comprehensive underconsumption theory than in those writings is to be found in Rodbertus's ‘second letter’ to von Kirchmann, published in 1850–51. Rodbertus was reacting against the ideas of Jean-Baptiste Say and his followers. His own view was that in a laissez-faire economy underconsumption must inevitably emerge and worsen, because ‘natural’ laws will ensure that an ever increasing productivity of labour will be accompanied by an ever decreasing share of income going to wages. His remedy was ‘rational’ intervention in the economy to counteract these ‘natural’ laws.

The emphasis in Marx's economic theory on the necessity in a capitalist economy for value not only to be generated in production but also realized by sale makes that theory well adapted to use to the development of an underconsumption theory. Marx himself gave substantial praise to Sismondi for his exposition of such a theory, and there are several passages in Marx's own writings which put forward an underconsumptionist view. On the other hand, there is a well-known passage in Volume 2 of Capital which condemns underconsumption theories in no uncertain terms, and in any case there are other elements in his economic theory which are so much more important to Marx that he is not usually classified as an underconsumptionist. Many, though by no means all, of his followers have in fact condemned underconsumption theories. Examples of such condemnation are to be found in some of Lenin's writings, notably his pamphlet entitled A Characterisation of Economic Romanticism (Sismondi and our Native Sismondists), written in 1897. This pamphlet was particularly directed at the underconsumptionist views of the Russian ‘Populists’, or ‘Narodniks’, who had argued that capitalism could not survive in Russia without the consumer markets provided by its then dwindling peasant economy. It was Lenin's view that for the development of capitalism expansion of the market for investment goods is more important than expansion of the market for consumption goods.

Amongst Marx's earlier followers, those who most strongly supported the underconsumptionist element in Marx's thinking were Kautsky and Rosa Luxemburg. Rosa Luxemburg's main arguments were set out in The Accumulation of Capital (1913). Contrasting the over-growing generation of value in a capitalist economy with the inability of workers and unwillingness of capitalists to realize that value by increasing their consumption, she crossed swords with Tugan Baranovski, who had argued that capitalists ‘see to it that ever more machines are built for the sake of building – with their help – ever more machines’ (Luxemburg, 1913, p. 335). Rosa Luxemburg took the same view as that advanced by J.B. Clark, in his introduction to the English translation of Rodbertus's ‘second letter’ to von Kirchmann, namely that ‘this case presents no glut: but it is an unreal case’ (Rodbertus, 1898, p. 15). She concluded that because it was inevitably faced by increasing underconsumption, a capitalist economy could only survive as long as it was able to dispose of its surplus to non-capitalist consumers, either at home or abroad, the latter accounting in her view for policies of imperialism. Apart from Rosa Luxemburg, others who have both drawn on Marx's ideas and made use of underconsumption theory include Sweezy in The Theory of Capitalist Development (1942), Baran and Sweezy in Monopoly Capital (1966) and Emmanuel in Unequal Exchange (1969).

A causal connection between underconsumption and policies of imperialism was also argued to exist by the non-Marxist writer J.A. Hobson, in Imperialism: A Study (1902). Jointly with A.F. Mummery, Hobson had reacted to the depression in trade in the 1880s by putting forward an underconsumption
theory in *The Physiology of Industry* (1889), which was the first underconsumptionist work actually to use the term ‘underconsumption’. In this book Mummery and Hobson argued that the sole source of demand for investment goods is demand for consumption goods. From this they drew the conclusion, as Malthus had done, that there exists an optimum ratio between saving (investment) and spending (consumption). Like Sismondi, they stressed the role of competition in causing supply to exceed demand. They went beyond the earlier underconsumptionists, however, in specifically arguing that neither a fall in the rate of interest nor a fall in the price level could remedy a state of depression brought about by underconsumption. Hobson's subsequent restatement of this theory, with various amplifications, made him the most influential 20th-century exponent of underconsumption theories. In *The Physiology of Industry* Mummery and Hobson drew the policy conclusion that ‘where Under-consumption exists, Savings should be taxed’ (Mummery and Hobson, 1889, p. 205). In his later works, however, from *The Problem of the Unemployed* (1896) on, Hobson laid most stress on a redistribution of income from what he called ‘unearned income’ (income unrelated to effort) to wages as the main remedy for underconsumption. The most comprehensive expositions of Hobson's underconsumption theory are to be found in *The Industrial System* (1909), which is characterized by a more extensive treatment of underconsumption in a growing economy, *The Economics of Unemployment* (1922), and *Rationalisation and Unemployment* (1930).

Other 20th-century exponents of underconsumption theories include Foster and Catchings, in a number of jointly written books. The theories of Major Douglas, however, with their lack of reference to over-investment and their emphasis on the role of money and credit, do not fit well into the underconsumptionist category.

Underconsumption theories have never been acceptable to orthodox economists, perhaps partly because underconsumptionists in general have lacked rigour in the exposition of their ideas, and partly because underconsumption theories have been seen as a threat to the saving necessary for economic growth in particular, and to capitalism in general. They have also attracted less attention since 1936 than before, because Keynes's *General Theory* satisfied the needs of many of those whose intuitions led them to seek a ‘demand-side’ explanation of economic depression. However, underconsumption theories can be argued still to provide a useful supplement to Keynesian theories, as a reminder that there is a limit to the extent to which employment can be increased by increases in investment alone. There is perhaps some recognition of this in the distinction which is now commonly made as to whether the current need is for an ‘investment-led’ or a ‘consumption-led’ recovery.

underemployment equilibria

Jean-Jacques P. Herings
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The standard model of general equilibrium is extended by allowing for expectations about supply opportunities by households and firms. In this framework there is typically a 1-dimensional continuum of underemployment equilibria that range from equilibria with arbitrarily pessimistic expectations to equilibria with rather optimistic expectations. An example illustrates the model and highlights some features of underemployment equilibria. The multiplicity of equilibria has a natural interpretation as being the result of coordination failures. The results in this framework are compared with those of the fixprice literature. Extensions to a monetary economy are discussed.

Article

Underemployment of resources refers to the situation where an increase in the resource utilization rate could lead to a Pareto improvement. Typical examples are involuntary unemployment and idle production capacities. There are two quite distinct views on the underemployment of resources. In the standard neoclassical world of the Arrow–Debreu model, underemployment of resources cannot occur. In the competitive equilibrium, involuntary unemployment does not exist, and production capacities are
underemployment equilibria: The New Palgrave Dictionary of Economics

left idle when only such is Pareto optimal. The Keynesian tradition, in contrast, builds on wage and price rigidities in its explanation of underemployment of resources. Indeed, Keynes's contribution has been reinterpreted by Clower (1965) and Barro and Grossman (1971) as the economics of general disequilibrium, in which price rigidities lead to quantity constraints for households and firms, which generally have spillover effects in other markets. This lead has been further developed in the fixprice literature, originating in the work of Bénassy (1975), Drèze (1975), and Younès (1975), and in general equilibrium theories on temporary equilibrium (see Grandmont, 1977, for a survey).

Although the fixprice literature stresses wage and price rigidities, Keynes himself postulates that it is possible to encounter self-justifying expectations, beliefs which are individually rational but which may lead to socially irrational outcomes (Keynes, 1936, ch. 12). We therefore would like to address the question whether underemployment of resources is possible when expectations are rational, agents optimize, and trade takes place at competitive prices. The underlying reason for underutilization of resources comes from coordination failures, self-justifying expectations which are individually rational but socially suboptimal.

In the literature, one may distinguish three classes of models with coordination failures. The first class consists of rather abstract game-theoretic models following the seminal work of Bryant (1983); see Cooper, 1999, for a state-of-the art account. An important message coming from this stream of the literature is that coordination failures may occur when there are strategic complementarities and positive externalities. However, these models typically lack a coordinating role for the price mechanism. Strategic models with a coordinating role for prices constitute the second class. Roberts (1987) presents a model that meets these criteria. It is a simple model of a closed economy that allows for coordination failures in a strategic setting. However, outcomes in the second class of models are often not robust to slightly different specifications of the model (Jones and Manuelli, 1992).

The third class of models consists of general equilibrium models of coordination failures. We refer to Citanna et al. (2001) for the most general presentation of these ideas. The third class leads to results that are robust and general. The methodological assumptions are shared with those of the neoclassical model: agent optimization, market clearing, and rational expectations. Underemployment of resources occurs as a consequence of self-confirming, pessimistic expectations about supply opportunities.

**Competitive equilibria**

Consider the classical general equilibrium model with $H$ households, $F$ firms and $L$ commodities as described in Debreu (1959). A household $h$ is characterized by its consumption set, for the sake of simplicity equal to $\mathbb{R}_+^L$, a utility function $u^h: \mathbb{R}_+^L \to \mathbb{R}$, and initial endowments $e^h \in \mathbb{R}_+^L$. The feasible production plans of firm $f$ are described by the production possibility set $Y^f$. If firm $f$ chooses production plan $y^f$ and the prices at which trade takes place are $p \in \mathbb{R}_+^L$, then the firm's profits equal $p \cdot y^f$.

Household $h$ receives a share $\theta \cdot n^h$ of the profits of firm $f$.

We assume both households and firms to be price takers. If trade takes place at prices $p$, then firm $f$ faces the following profit maximization problem:
Under standard assumptions the firm's profit maximization problem is well-defined. For the remainder we assume the profit maximizing production bundle to be unique. This can also be shown to hold under standard assumptions, mainly requiring the strong assumption of decreasing returns to scale.

The utility maximization problem of household $h$ reads as follows:

$$\max_{x^h \in \mathbb{R}^*_+} u^h(x^h) \text{ s.t. } p \cdot x^h \leq w^h,$$

where $w^h$ equals the value of the household $h$'s initial endowments, $p \cdot e^h$, plus the household's share in the firms' profits, $\sum_f \hat{\theta}_f^h \cdot p \cdot y^f$, with $y^f$ the profit maximizing production bundle chosen by firm $f$.

Under standard assumptions, the maximization problem of the household has a unique solution $x^{*h}$. Under the usual microeconomic methodological premises of agent optimization and market clearing, together with rational expectations, one defines a competitive equilibrium as a price system $p^*$ and an allocation $(x^*, y^*) = (x^{*1}, ..., x^{*H}, y^*_1, ..., y^{*F})$ such that at prices $p^*$ households maximize utility by choosing the consumption bundle $x^{*h}$ and firms maximize profits by choosing the production plan $y^{*f}$.

**Rationing**

The puzzle as to how competitive equilibria are achieved in real-world economies remains substantial. First, it is well-known that price adjustment processes need not converge to an equilibrium (Debreu, 1974; Saari and Simon, 1978; Saari, 1985). Blad (1978) stresses that convergence, even if it takes place, can take quite some time. Second, in many situations some agents, or coalitions of agents, set prices at levels not compatible with competitive equilibrium. Drèze (1989) models unions that set wages above competitive levels. Herings (1997) and Tuinstra (2000) show that political interference in the market mechanism can be rational from a partisan point of view and might be responsible for sustained deviations from prices that clear markets. Third, Drèze and Gollier (1993), Drèze (1997), and Herings and Polemarchakis (2005) argue that certain price rigidities are a welfare-improving response to market incompleteness. This argument is particularly valid for the two forms of underemployment most frequently encountered, namely, unemployed labour and excess capacities, two examples of commodities for which future markets are hardly developed.

For the moment we maintain the assumption that trade takes place at given prices $p$. Here, $p$ may or may
not be competitive. We are not focusing on a specific theory of non-market clearing prices, but rather are interested in knowing how agents make decisions given that trade takes place at prices $p$. We deviate from the standard framework and assume that it is not common knowledge whether these prices are competitive or not. Even when all agents know whether prices are competitive or not, it is not necessarily the case that all agents know that all agents know whether prices are competitive or not, and it is even less likely that all agents know that all other agents know that all other agents know whether prices are competitive or not, and so on. Common knowledge of whether prices are competitive requires structural knowledge about the economy, very much at odds with the standard general equilibrium paradigm whereby in a decentralized economy agents only have to maximize utility given the prices that are quoted in the marketplace.

Our price system $p$ may or may not be competitive. Since this fact is not common knowledge, it no longer makes sense for households and firms to express their unconstrained demands and supplies, and they should form expectations about supply and demand opportunities. One possible choice for these expectations is optimistic expectations: all households and firms do not expect to be constrained in either supply or demand. When prices are competitive, we are back in the situation of competitive equilibrium. The question is: are these the only possible expectations compatible with the microeconomic methodological premises of agent optimization and market clearing, together with rational expectations? Motivated by the empirical regularity that constraints on the supply side are more common than those on the demand side, as is suggested by unemployment in labour markets or unused capacities in production processes, we follow van der Laan (1980) and Kurz (1982) and restrict attention to constraints on the supply side. Moreover, for the sake of simplicity, we consider point expectations about supply opportunities.

If trade takes place at prices $p$ and firm $f$ expects supply opportunities of at most $\bar{y}^f \in \mathbb{R}^L_{+}$, then firm $f$'s profit maximization problem becomes:

$$\max_{y^f \in \mathcal{Y}^f} \quad p \cdot y^f \quad \text{s.t.} \quad y^f \leq \bar{y}^f.$$  

At this point it should be noted that, if a firm $f$ does not produce a particular commodity $l$, the value of $\bar{y}^f_l$ is entirely inconsequential. Again, under standard assumptions the firm's profit maximization problem is well-defined. In fact, the constraints related to the expected supply opportunities ensure that the firm's profits are bounded from above, a property that does not hold in general for the competitive model. At prices $p$ and expected supply opportunities of $\bar{y}^f$, the supply of firm $f$, that is, the profit maximizing production plan of firm $f$, is denoted by $s^f(p, \bar{y}^f)$ and the firm's profits by $\pi^f(p, \bar{y}^f)$. The wealth of household $h$ is then equal to $w^h = p \cdot e^h + \sum f \theta^h n^f(p, \bar{y}^f)$. The utility maximization problem of household $h$ that trades at prices $p$, expects supply opportunities equal to $\bar{z}^h$, and has budget $w^h$ equals:
Under standard assumptions, the maximization problem of the household has a unique solution 
\[ d^h(p, z^h, w^h). \]
Since supply may not equal demand, one needs a rule to address discrepancies, called a rationing mechanism. Expected supply opportunities should be related to the rationing mechanism, which determines the allocation in case of excess supplies. For labor markets, one can think of a priority 

system that determines which worker is the first to become unemployed, who is next, and so on and so forth. Another rationing mechanism would share the burden of unemployment equally among workers, for instance by the imposition of an upper bound on the number of hours worked per week.

For notational convenience we assume the latter rationing mechanism in all markets, implying that in 
equilibrium rational agents face the same expected supply opportunities, 
\[ \bar{r} = \cdots = \bar{r} = - \bar{z} = \cdots = - \bar{z}^h. \]
We denote the commonly expected supply opportunities by \( r \in \mathbb{R}^L_+ \).

At expected supply opportunities \( r \), every firm \( f \) faces the constraint \( \bar{y}^f \leq r \) and every household \( h \) optimizes utility subject to \(-r \leq x^h - e^h \). All the results remain true with appropriate modifications for 
general rationing systems; see Herings (1996b) for a survey of rationing systems encountered in the 
literature.

A firm or household is said to be rationed in the market of commodity \( l' \) if the expected supply 

opportunities in this market are binding. More precisely, a firm \( f \) is *rationed* in the market of commodity \( l' \) at prices \( p \) and expected supply opportunities \( r \) if \( s^f(f(p, r)) > \pi^f(p, r) \), where \( \bar{r}^l = +\infty \) and, for \( l \neq l' \), \( \bar{r}^l = r^l \). A household \( h \) is *rationed* in the market of commodity \( l' \) at prices \( p \) and expected supply 

opportunities \( r \) if \( u^h(d^h(p, -r, w^h)) < u^h(d^h(p, -r, w^h)) \), where \( \bar{r} \) is related to \( r \) as before. There is *rationing* on the market of commodity \( l' \) if at least one firm or at least one household is rationed on 
the market of commodity \( l' \).

**Definition:** An *underemployment equilibrium* of the economy \( \mathcal{E} = ((u^h, e^h, \gamma^h), ((\gamma^f, (\theta^h, \bar{r}^h)) f) \) at 

prices \( p \) are expected supply opportunities \( r^* \) and an allocation \( (x^*, y^*) \) such that 

1. (a) for every firm \( f \), \( y^*_f = s^f(p, r^*_f) \), 
2. (b) for every household \( h \), \( x^*_h = d^h(p, -r^*_h, w^*_h) \), where 
   \[ w^*_h = p \cdot e^h + \sum f \theta^h \pi^f(p, r^*_f), \]
3. (c) \( \sum h x^*_h = \sum h e^h + \sum f y^*_f. \)

**An example**
As a simple example, let us consider an economy with one household, one firm, and two commodities. Let us interpret the commodities as leisure and an aggregate consumption good, and suppose that the household owns initially one unit of leisure and nothing of the consumption good, $\varepsilon = (1, 0)$. The household's utility function is Cobb–Douglas, $u(x) = x_1 x_2$. The firm transforms the labour input into output by the production function $v_2 = \frac{2}{3} \sqrt{-3 v_1}$, where $v_1 \leq 0$. When we normalize the price of output to be 1, turning the wage rate into the real wage rate, it is not hard to verify that the competitive equilibrium is given by $p^* = (1, 1)$, $x^* = (\frac{2}{3}, \frac{2}{3})$, and $y^* = (-\frac{1}{3}, \frac{2}{3})$.

Now suppose that it is possible to trade at the competitive equilibrium prices, so $p = (1, 1)$, but it is not common knowledge that these prices are competitive, and as a consequence firms and households form point expectations on supply opportunities $r = (r_1, r_2)$. We want to verify whether such expectations can be self-confirming. It is easily verified that for each $r_1 \in [0, \frac{1}{3})$ there is an underemployment equilibrium with expected supply opportunities $r^*$ given by $r_2^* = \frac{2}{3} \sqrt{3 r_1}$, $x^* = (1 - r_1^*, r_2^*)$, and $y^* = (- r_1^*, r_2^*)$. The household expects a constraint on labor supply equal to $- r_1^*$ yielding labour income $r_1^*$. The firm expects a constraint on the supply of output equal to $r_2^*$. It optimally demands an amount of labour equal to $r_1^*$, leading to profits $\frac{2}{3} \sqrt{3 r_1} - r_1^*$. Notice that the optimal labour demand by the firm equals the constraint on labour supply anticipated by the household. The household's capital income is equal to $\frac{2}{3} \sqrt{3 r_1} - r_1^*$, leading to total income of $\frac{2}{3} \sqrt{3 r_1}$, to be spent on the aggregate consumption good. The optimal demand of the household for the aggregate consumption good equals the supply opportunities expected by the firm, thereby confirming those expectations. There is rationing in both markets. The household is rationed in the labour market and the firm in its output market.

Finally, every $(r_1^*, r_2^*)$ with $r_1^* \geq \frac{1}{3}$ and $r_2^* \geq \frac{2}{3}$ sustains an underemployment equilibrium that coincides with a competitive equilibrium in terms of the allocation reached, $x^* = (\frac{2}{3}, \frac{2}{3})$, $y^* = (-\frac{1}{3}, \frac{2}{3})$. In this case, there is no market with rationing.

In the example, two extreme underemployment equilibria stand out. One is the underemployment equilibrium with completely pessimistic expectations about supply opportunities, $r^* = (0, 0)$, $x^* = (1, 0)$, $y^* = (0, 0)$. The other is the underemployment equilibrium with expectations about supply opportunities that are sufficiently optimistic to obtain the competitive allocation; the minimally optimistic expectations to achieve this are $r^* = (\frac{1}{3}, \frac{2}{3})$. These extreme underemployment equilibria are connected by a set of underemployment equilibria with more moderate expectations on supply opportunities.

In the example, trade was supposed to take place at competitive prices to highlight underemployment caused by mis-coordination of expectations and not by relative prices that are incompatible with competitive equilibrium. One may argue that it is a probability zero event that trade takes place at competitive prices. The crucial features of the example remain unchanged when trade takes place at non-competitive prices. Suppose that trade takes place at a real wage $p_1$ above the competitive wage rate of
1. It can be verified that there is still a no-trade equilibrium sustained by completely pessimistic expectations on expected supply opportunities. Although the competitive allocation is no longer feasible when the real wage is above the competitive level, it can be verified that there is also an underemployment equilibrium where the firm does not face rationing and the household observes rationing of its labour supply; the minimally optimistic expectations on supply opportunities that sustain this equilibrium are given by

\[ r^* = \left( \frac{1}{3(p_1)^2}, \frac{2}{3p_1} \right) \]

leading to consumption and production

\[ x^* = \left( 1 - \frac{1}{3(p_1)^2}, \frac{2}{3p_1} \right), \quad y^* = \left( \frac{-1}{3(p_1)^2}, \frac{2}{3p_1} \right). \]

The same underemployment allocation is sustained by more optimistic expectations

\[ r_1^* = \frac{1}{3(p_1)^2} \text{ and } r_2^* \geq \frac{2}{3p_1}. \]

Again, the two extreme equilibria are connected by a continuum of underemployment equilibria, with expectations ranging from completely pessimistic to expectations that sustain an underemployment equilibrium without rationing of the firm and with rationing of the labour supply of the household. When the real wage \( p_1 \) is below the competitive level, there is still an underemployment equilibrium with completely pessimistic expectations about supply opportunities and no trade. There is also an underemployment equilibrium without rationing of the supply of the household but with rationing of the firm's supply of output. Let \( \bar{r}_2 \) be equal to \( \frac{4(1 + 3(p_1)^2)}{6p_1} \). Notice that \( \bar{r}_2 \) is below 2/3 when the real wage \( p_1 \) is below 1. The minimally optimistic expectations that sustain an equilibrium without rationing of the household are given by \( r^* = (1 - \bar{r}_2 / p_1, \bar{r}_2) \) leading to an allocation \( x^* = (\bar{r}_2 / p_1, \bar{r}_2), \quad y^* = (\bar{r}_2 / p_1 - 1, \bar{r}_2) \). The same underemployment equilibrium allocation is sustained by the more optimistic expectations \( r_1^* \geq 1 - \bar{r}_2 / p_1 \text{ and } r_2^* = \bar{r}_2 \). The two extreme
underemployment equilibria are connected by a continuum of underemployment equilibria with more moderate expectations on supply opportunities.

Animal spirits

The example suggests that in general there is a 1-dimensional continuum of equilibria, ranging from a no-trade equilibrium with completely pessimistic expectations to an equilibrium with rather optimistic expectations and without rationing in at least one market. This result is almost true, except that the case with completely pessimistic supply expectations leads to zero income for the households, a case that is well-known to be problematic for equilibrium existence. Inspired by preliminary results in van der Laan (1982), Herings (1996a; 1998) and Citanna et al. (2001) provide conditions under which the following result holds.

Theorem: Under standard assumptions, the economy ρ = ((u^h, e^h) h, (γ^f, (θ^f) h) f) where trade takes place at prices p possesses a connected set of underemployment equilibria E such that for every ρ ∈ (0, →), there is an equilibrium (r^*, x^*, γ^*) in E with max r^*_l = ρ. (A set is path-connected if any two points in the set can be connected by a path that does not leave the set. Path-connectedness implies connectedness, a slightly weaker topological property of sets, which loosely speaking means that the set consists of one piece.)

The theorem gives general equilibrium underpinnings to the Keynesian ideas that changes in expectations, also referred to as animal spirits, can affect equilibrium economic activity, in particular the level of output and employment. The theorem rules out the case with completely pessimistic expectations, corresponding to max r^*_l = 0. It shows that the set E links equilibria with arbitrarily pessimistic expectations (max r^*_l arbitrarily small, but positive) to equilibria with rather optimistic expectations (max r^*_l arbitrarily large). Notice that the condition max r^*_l arbitrarily large only implies that for one market expectations are sufficiently optimistic to rule out rationing. The expectations on supply opportunities on other markets might still be completely pessimistic.

In the absence of production, the statement of the theorem can be simplified somewhat. It is shown in Herings (1998), under standard assumptions, that the economy ρ = ((u^h, e^h) h) where trade takes place at prices p possesses a connected set of underemployment equilibria E such that for every ρ ∈ [0, →) there is an equilibrium (r^*, x^*, γ^*) in E with max r^*_l = ρ. In exchange economies, the connected set includes an underemployment equilibrium with completely pessimistic expectations.

The theorem demonstrates that the set of equilibria is at least 1-dimensional. In general, one should expect the dimension of the set of equilibria to be exactly equal to 1. The reason is that the model postulates L free variables corresponding to the expected supply opportunities r and L market clearing conditions. Let E be an economy where trade takes place at prices p and let z: \mathbb{R}^L_+ \rightarrow \mathbb{R}^L denote the excess demand function of the economy, a function of expected supply opportunities r. Because of Walras's law, it holds that for every r ∈ \mathbb{R}^L_+, p \cdot z(r) = 0. This implies that there are only L - 1 independent market clearing conditions. Since there are L free variables, this leaves a 1-dimensional
underemployment equilibria: The New Palgrave Dictionary of Economics

At this point it should be observed that the same reasoning also applies to the standard competitive model. And indeed, in general the set of competitive equilibria is 1-dimensional too. Whenever \((p^*, x^*, y^*)\) constitutes a competitive equilibrium, so does \((\lambda p^*, x^*, y^*)\) for \(\lambda\) positive. However, in the standard competitive model, the excess demand function is homogeneous of degree 1, implying that the same allocation is sustained by \(p^*\) and \(\lambda p^*.\) The homogeneity property holds for prices but not for expectations. In general, the excess demand function \(z\) is not homogeneous of any degree, and it is not the case that \(\lambda r^*\) is part of an underemployment equilibrium when \(r^*\) is. Generically, the set \(E\) of the theorem contains a 1-dimensional set of distinct equilibrium allocations.

Coordination failures

The theorem makes clear that a multiplicity of equilibria results even when prices are competitive. The interpretation of the multiplicity of equilibria as coordination failures and the link to the macroeconomic literature on coordination failures were made in Drèze (1997). It would be tempting to conclude that, when trade takes place at competitive prices, then the connected set of underemployment equilibria contains the competitive equilibrium allocation. Although it is true that the competitive equilibrium allocation is an underemployment equilibrium allocation sustained by trade at competitive prices coupled with sufficiently optimistic expectations, it is possible to produce examples where it is outside the connected set of the theorem (Citanna et al., 2001).

Under an additional assumption akin to gross substitutability, the following result holds. If trade takes place at competitive equilibrium prices \(p\), then the economy \(E = \{(u^h, e^h) r, (y^f, (\theta f^h) h) f\}\) possesses a connected set of underemployment equilibria \(E\) such that for every \(\rho \in (0, \rightarrow)\) there is an equilibrium \((r^*, x^*, y^*)\) in \(E\) with \(\max r^*_l = \rho\), and for every \(\rho \in (0, \rightarrow)\) there is an equilibrium \((r^*, x^*, y^*)\) in \(E\) with \(\min r^*_l = \rho\). More precisely, the following assumption on the aggregate excess demand function suffices. If \(r, \bar{r} \in \mathbb{R}_+^l\) with \(r \leq \bar{r}\) and \(r^*_l = \bar{r}^*_l\), then \(Z^*_l(r) \leq Z^*_l(\bar{r})\). The interpretation of the assumption is the following. A weak increase in expected supply opportunities in markets different from \(l'\) should lead to a weak increase in the excess demand for commodity \(l'\).

This assumption, though strong, is not unreasonable. On the household side, a household may lower its supply of commodity \(l'\) in exchange for more supply of another commodity, for instance if the household switches to a more attractive job. A household may also increase its demand for commodity \(l'\) as a consequence of higher income. Indeed, more expected supply opportunities of commodities different from \(l'\) weakly increase the household's income, which will lead to more demand of commodity \(l'\) if it is a normal good. On the producer side, if \(l'\) is an output for some firm, then increased supply opportunities of other goods, lead to a weakly lower supply of commodity \(l'\), when the firm directs more inputs to the production of the other goods. If \(l'\) is an input for a firm, then increased supply opportunities of other goods naturally lead to more production, and thereby an increased input demand, in particular for commodity \(l'\). Notice that the assumption needs to hold only in the aggregate.
Efficiency

It is not hard to argue that underemployment equilibria are not Pareto optimal in general. As soon as there are two commodities, \( l \) and \( l' \), and two households \( h \) and \( h' \), such that household \( h' \) is rationed in the market for commodity \( l' \) but not in the market for commodity \( l \), whereas household \( h \) is not rationed in the market for commodity \( l' \), then it follows almost immediately that the marginal rate of substitution of commodity \( l \) for \( l' \) is not the same for households \( h \) and \( h' \). This contradicts Pareto optimality.

It has been argued before that price rigidities may emerge for efficiency reasons. The argument of the previous paragraph makes clear that such is not the case in a complete markets setting when coordination failures are absent. In an incomplete market setting, however, Drèze and Gollier (1993) and Herings and Polemarchakis (2005) show that price rigidities may lead to equilibria that are Pareto superior to competitive equilibria. In general, it will depend on the magnitude of the coordination failures, whether or not welfare improvements result.

Extensions

For illustrative purposes, we have so far considered the simplest case where trade takes place at predetermined prices for all commodities. It is not hard to generalize this set-up substantially, and allow for general lower bounds \( \underline{P} \) and upper bounds \( \overline{P} \) that define the set of admissible prices at which trade may take place. The notion of underemployment equilibrium should then be extended by the requirement that only when the price of a commodity \( l \) equals its lower bound is rationing of the supply of commodity \( l \) allowed for. In such a more general setting, it may be interesting to also allow for demand rationing when the price of a commodity equals its upper bound. Allowing for demand rationing will enlarge the set of equilibria. By taking all \( \underline{P} \) equal to \(-\infty\) and all \( \overline{P} \) to \(\infty\), we obtain the notion of competitive equilibrium as a special case. The results we mentioned before remain true in this more general set-up.

The existence of a continuum of underemployment equilibria is a robust phenomenon. This seems to be in striking contrast with the conclusion of the fixprice literature, where equilibria are typically locally unique. The reason for this apparent disparity is that the fixprice literature puts one additional constraint on the equilibrium set. It is assumed that there is no rationing in the market of an a priori determined numeraire commodity, called money. Not only is the interpretation of one of the commodities as money controversial, it is also misleading as far as the indeterminacy of equilibrium is concerned.

Suppose we follow Drèze and Polemarchakis (2001) and extend the model by a model of a central bank, which produces money at no cost. Households and firms need money to make transactions, a particular example being a cash-in-advance transactions technology. The central bank sets the nominal interest rate at which it accommodates all money demand. The central bank redistributes the revenues from seigniorage to the households in the form of dividends. Money does not enter into the utility function of the households.

This model fits exactly into the framework discussed so far. Without loss of generality, commodity \( L \) may serve as money. The central bank can be modelled as firm \( F \), which can produce the output money in arbitrary amounts without using inputs. The profits of firm \( F \) are equal to the seigniorage of the
central bank. The price of money is equal to the interest rate. Since the central bank accommodates money demand, the money supply of the central bank is equal to that of a profit-maximizing firm \( F \) that expects a constraint on the supply of commodity \( L \) equal to the aggregate demand for commodity \( L \) (for strictly positive interest rates). Our theorem on the existence of a connected set of underemployment equilibria therefore applies to the case where money is explicitly introduced, thereby contradicting the determinacy results obtained in the fixprice literature.

We have shown how underemployment equilibria result in a general equilibrium model where agents are allowed to form expectations on expected supply opportunities. We analyse whether such expectations can be self-confirming and argue that, even at competitive prices, a continuum of equilibria results, including an equilibrium with approximately no trade and a competitive equilibrium. Such equilibria also arise at other price systems, but are then a consequence of both self-confirming pessimistic expectations and of prices incompatible with competitive equilibrium. Expected supply opportunities in underemployment equilibria bear a close resemblance to the self-justifying expectations of Keynes (1936), beliefs which are individually rational but socially suboptimal. The further study of underemployment equilibria in models with time and uncertainty, incomplete markets, price-setting agents, and a monetary authority features prominently on the research agenda, as it would allow for explicit links with the modern macroeconomic literature on inflation, output and unemployment.

unemployment and hours of work, cross country differences

Richard Rogerson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Since the 1960s labour market outcomes among the world's richest economies have changed dramatically, especially in terms of unemployment rates and time devoted to market work. This article summarizes the evidence regarding these changes and discusses some of the explanations that have been proposed for why these labour market outcomes have evolved so differently across economies.

Keywords

Article

Understanding the forces that determine resource allocations in decentralized economies is one of the fundamental objectives of economics. Because countries often differ greatly in terms of economic policies and institutions, examining how resource allocations differ across countries provides a promising opportunity to learn about these forces. Conversely, when we see large differences in allocations across countries, we are presented with an important opportunity to learn about what factors can generate these large differences. One prominent case in point is the large differences in labour market outcomes – specifically in terms of unemployment rates and hours of work – that exist across rich industrialized economies. A large literature has emerged that documents the nature of these differences and seeks to determine which factors can account for them. This article provides a brief overview of this literature.

Cross-country differences in unemployment

The literature on cross-country differences in unemployment was motivated by a simple real world development: a large and persistent rise in unemployment in several continental European countries relative to the United States, starting in the mid-1970s. Figure 1 displays this fact by showing the evolution of unemployment rates since 1956 for the United States and the average of four economies from Continental Europe: Belgium, France, Germany and Italy.
As the figure reveals, prior to 1970 the unemployment rate in these European countries averaged around three per cent, while since 1990 it has averaged more than ten per cent. This dramatic increase is concentrated in the period 1975–85. In contrast, while the United States also experienced an increase in average unemployment during the 1975–85 period, this
increase is only transitory, the US unemployment rate has averaged close to five per cent in both the early and later time periods. Faced with this dramatic change in relative unemployment rates across countries, economists were naturally led to ask why. Based on the time series plots in Figure 1, an answer to this question had to address two important issues:

1. Why did the increase occur in the 1975–85 period?
2. Why did it occur in some countries and not in others?

At a general level, one can imagine two classes of explanations. One class postulates that something changed in one set of economies during the period 1975–85 but not in the others. A second class postulates that something changed in all economies during the 1975–85 period, but that economies responded in different ways to this change due to differences in their institutions or policies.

Krugman (1994) was the first to suggest that an explanation of the second type seemed promising. His story emphasized that the process of skill-biased technological change became more prominent beginning in the 1970s, thereby creating an economic force tending to increase the dispersion in individual wages. Although all economies were subjected to this underlying change in technological progress, this change was propagated differently across economies. In the United States, wage setting institutions were ‘flexible’ and the result was increased wage dispersion and little change in unemployment. In the economies of Continental Europe, wage setting institutions were ‘rigid’ and did not allow wages to become more dispersed, so the result was instead an increase in unemployment. While subsequent work (see for example, Card, Kramarz and Lemieux, 1999) did not provide support for this story, at least in its simplest form, the contribution was important because it suggested an important class of explanations.

The issue of rigorously distinguishing between the two classes of explanations was subsequently taken up in a paper by Blanchard and Wolfers (2000). Based on statistical analysis, these authors argued that the ‘common shock’ story was most promising. The force of this conclusion is tempered somewhat by two features of the analysis. First, the result that the ‘different shocks’ explanation does not provide a good account of the data is very much dependent on what shocks are explicitly incorporated in the analysis. In particular, Blanchard and Wolfers did not incorporate the fact that taxes changed considerably over this time period, a point we will return to below. Second, their analysis did not attempt to identify what the important common shock(s) were, and did not construct an explicit model to quantify how various institutions affected the propagation of these shocks. However, making use of advances in general equilibrium modelling of unemployment (such as the Diamond–Mortensen–Pissarides matching model or the Lucas–Prescott island model), subsequent work has sought to remedy this limitation by quantitatively evaluating particular candidates from the ‘common shock’ class of explanations in the context of fully specified models.

An early example in this literature was Bertola and Ichino (1995). They argued that the common shock was a permanent increase in the transient nature of production opportunities. The key differences in economic institutions were wage setting institutions that compressed wages and employment protection policies that made layoffs prohibitively costly. Several alternative analyses have since followed. Ljungqvist and Sargent (1998) argue that the common shock was a permanent increase in the amount of ‘turbulence’ for workers, and that the key institutional difference is generosity of income support for displaced workers. Mortensen and Pissarides (1999) and Marimon and Zilibotti (1999) both construct models in which the common shock was skill-biased technological change. While Mortensen and Pissarides stress differences in unemployment insurance (UI) benefits and employment protection as the key institutional differences, Marimon and Zilibotti simply stress differences in UI benefits. Closely related, Hornstein, Krusell and Violante (2007) argue that the common shock is an increase in the rate of capital embodied technological change and that the key institutional differences are taxes, income support programmes, and employment protection.

While explanations of the ‘common shock’ variety have become popular in the literature, some researchers have argued against them. Using purely statistical methods, Nickell, Nunziata and Ochel (2006) challenge the Blanchard and Wolfers finding. In terms of model based analyses, Daveri and Tabellini (2000) argue that differences in the changes in tax rates between Continental Europe and the United States were central to understanding the different evolutions in unemployment rates. They also argue that the impact of higher taxes is very much influenced by wage setting institutions, thereby explaining why some other European countries that also experienced large increases in tax rates did not experience sharp increases in unemployment. This last point – that the effects of individual policies and institutions are not additive – has recently been emphasized by both Blanchard and Giavazzi (2002) and Pries and Rogerson (2005). Another model-based analysis is contained in Pissarides (2007). He argues that a significant part of the relative increase in European unemployment is associated with the slowing of productivity growth that came as European productivity converged to US levels. The literature has made important headway in evaluating specific combinations of driving forces and propagation mechanisms, but there is still much more work to be done. First, much of the work to date has contrasted the behaviour of the United States with an average European country. Given the substantial heterogeneity within Europe, in terms of both policies and outcomes, it is desirable to push these exercises to consider outcomes on a country-by-country basis. Second, as noted above, the literature has focused almost exclusively on accounting for the rise in unemployment in a handful of European economies since 1970. There are also many other interesting episodes in the data. For example, Spain, the United Kingdom and the Netherlands all experienced dramatic increases in unemployment similar to those documented earlier, but each of these countries has subsequently experienced a sharp decrease in unemployment. Understanding the sources of these dynamics should also prove to be very valuable.

While the above discussion has focused on the efforts to understand the sharply different evolutions of unemployment across a small set of countries since the 1970s, the broader
research issue is to understand the quantitative consequences of various policy and institutional features on aggregate unemployment. Alvarez and Veracierto (1999) is one example of work that fits with this more general objective. As motivation for this general question one need only look at the distribution of unemployment rates across countries at any point in time. For example, Table 1 shows the distribution of unemployment rates in 2005.

As the reader can see, the dispersion of unemployment rates across countries is large. Understanding the forces that shape this distribution of outcomes remains an open and challenging research issue.

Other measures of labour market outcomes

If one thinks more carefully about characterizing resource allocations across countries, and specifically as this pertains to the labour market, it becomes clear that differences in unemployment rates may not be the best summary measure of differences in labour market allocations. The benchmark conceptual framework for modern thinking about aggregate resource allocation is the one-sector neoclassical growth model. This model stresses two margins that economists believe to be of first-order importance in thinking about aggregate allocations: the fraction of available time that is devoted to market work, and the fraction of output that is invested rather than consumed. Viewed from this perspective, the unemployment rate is the natural summary statistic to focus on only if it is a good measure of time devoted to market work. Historically, the framework of traditional Keynesian models assumed that this was indeed the case: the simple versions of these models assumed that labour supply is represented as some constant volume of available hours that was unaffected by any aspects of the economic environment. The only reason that observed hours of work would differ from this given value was unemployment. In such a conceptual framework, unemployment and total hours of work provide exactly the same information. But is this conceptual framework adequate to examine labour allocations in modern industrialized economies? Developments such as the rise of female labour force participation, the trend towards early retirement, the changing workweek, and the expansion of part-time work suggest that to view labour supply as a fixed volume of work determined only by the size of the population is to neglect some important economic forces.

To pursue this issue further it is instructive to take a closer look at the data. We look at data for 2005, but the basic messages of the analysis are not affected by the choice of year. Table 2 reports hours of work across countries, organizing the countries into four groups based on their hours worked. For each country, aggregate hours of work are computed as the product of two series from the OECD Labor Market Database: total civilian employment and annual hours of work per person in employment. It is important to note that the measure of annual hours of work per person in employment in this data-set attempts to take into account not only the length of the standard workweek but also the number of statutory holidays, sick days and vacation days. To compare aggregate hours of work across countries one has to make some normalization based on population. One could imagine different normalizations, such as the entire population, the adult population (those aged 15 and over), or the working-age population (those aged 15–64). The resulting patterns are not much affected by this choice, and the numbers reported in Table 2 are based on dividing total hours by the size of the working age population.

Annual hours worked per person aged 15–64 (2005)

Source: OECD Labor Market Database.
The correlation between unemployment rates and hours of work in the 2005 cross section is $-0.58$, indicating a fairly sizable negative correlation. This negative correlation is reflected in the fact that Germany and France are both among the highest unemployment countries as well as the lowest hours-worked countries, while New Zealand is the lowest unemployment country and the highest hours-worked country. However, there are also several counter-examples to this pattern. The Netherlands and Norway, for example, have hours worked and unemployment rates that are both substantially below the average, while Canada has unemployment and hours of work that are both substantially above average. We conclude from this that even at a qualitative level differences in hours of work and differences in unemployment are sometimes quite distinct. But more importantly, even when differences in hours of work and differences in unemployment describe similar situations qualitatively, the quantitative differences are dramatically different. For example, consider the following question. If the unemployment rate in a country such as France were reduced to the same level as the United States by placing some currently unemployed French people into employment, and having them work the same amount as those French people who are currently working, by how much would the gap in hours worked between France and the United States drop? The answer is that the gap would drop from its current value of 378 to 343, a decrease of less than ten per cent. From a pure accounting perspective, differences in unemployment rates are an almost insignificant component of differences in aggregate hours of work. Put somewhat differently, even if we completely understood the factors that give rise to observed differences in unemployment rates, we would understand practically none of the differences in hours of work.

Cross-country differences in hours of work

The previous section suggests that, if one examines cross-country labour market outcomes from the perspective of differences in resource allocations across economies, it will be useful to look at differences in hours of work rather than unemployment rates. An interesting starting point is to look at the evolution of hours worked for the two sets of economies depicted earlier in Figure 1. Figure 2 presents this information, where the reader is reminded that in this figure Continental Europe reflects the simple average for the economies of Belgium, France, Germany and Italy.
Several features are worth noting. Hours of work in Continental Europe decrease at a fairly constant rate from 1956 through to the mid-1980s, at which point they flatten out. The magnitude of this decrease in hours worked in Europe is enormous – a drop of over 35 per cent. In contrast, hours worked in the United States are virtually the same in 2005 as they were in 1956, though there are some low-frequency movements in the series during this time period. In contrast with the unemployment rate evolutions, it is of particular interest to note that there is nothing distinctive about the period 1975–85 from the perspective of the decline of hours in Europe.

Given the dramatic change in relative hours worked across these two sets of economies, it is not surprising that a literature has emerged that seeks to understand this change. Here too, one can imagine two different classes of explanations, one based on changes in some feature of the economic environment in Continental Europe relative to the United States, and the other based on a common change in the economic environments that has been propagated differently in the two sets of economies. There are two key differences relative to the literature on unemployment rates: timing and magnitude. Because we see changes beginning in the mid-1950s, and continuing at a fairly constant rate through to the mid-1980s, we presumably need to identify changes that exhibit this general time series pattern. The second difference is that we are talking about changes that are roughly an order of magnitude larger in terms of implications for hours of work.

Interestingly, whereas the unemployment literature has for the most part pursued the ‘common shocks’ explanation, the hours of work literature has instead focused on differences in policy changes across countries. This view has been heavily influenced by the contribution of Prescott (2004). He argues that, once cross-country differences in taxes are incorporated into the standard growth model, hours of work in the United States and several European economies in both the early 1970s and early 1990s are very close to those predicted by the model that assumes no other differences between the different economies. This general finding is further supported by Davis and Henrekson (2005), Ohanian, Raffo and Rogerson (2006), and Rogerson (2007).

One argument against the tax explanation, as noted by Alesina, Glaeser and Sacerdote (2005), is that it requires an aggregate labour supply elasticity that is larger than the individual labour supply elasticities typically found in estimation exercises using micro data. Recent work suggests that this critique is misplaced. Chang and Kim (2006) and Rogerson and Wallenius (2007) both argue that, when non-convexities are relevant for individual level labour supply decisions, the tight connection between micro and macro elasticities is broken. In particular, both papers argue that reasonable calibrations imply that small micro elasticities are consistent with large macro elasticities. Additional discussion can be found in Prescott (2006) and Rogerson (2006).

While an explanation based on taxes has been the one most developed to date, there are competing explanations. In work that is closely related but distinct from the Prescott analysis,
Ljungqvist and Sargent (2007) argue that it is the nature of benefit programmes in Europe rather than the high tax rates per se that are responsible for the large differences in employment rates between the United States and several European economies. Interestingly, Ljungqvist and Sargent (2007) argue that large aggregate elasticities are inconsistent with the observed cross-country differences once one properly models benefit programmes. On a very different note, Blanchard (2005) has argued that the dominant factor is differences in preferences across countries. In particular, he suggests that the income effect on leisure is larger in European countries than in the United States, and as European productivity has increased to near US levels since the 1960s, Europeans have responded with a larger increase in leisure than that which occurred earlier in the United States. An interesting connection between this explanation and the one based on tax rates is that it is the income effect that is central to generating the tax effects in the analysis of Prescott.

While the discussion has thus far focused on understanding the reasons for the very different evolutions of hours worked between the United States and Continental Europe, the data in Table 2 reveal a host of other differences that are also of interest. Rogerson (2006) describes some additional patterns of interest that are found when one disaggregates the data by age, gender and sector as well as along the employment and hours per worker margins. At a general level, the issue is to understand both qualitatively and quantitatively how various policies or institutions influence hours worked in an economy. Prominent examples of the policies and institutions of interest include such things as labour market regulations (for example, minimum wages, employment protection), product market regulation (for example, entry barriers), tax and transfer policies (for example, unemployment insurance, social security, disability), wage setting practices (for example, importance of unions, centralized versus decentralized wage negotiations). In addition to the papers mentioned earlier, other examples of work that address some of these issues are Bertrand and Kramarz (2002) and Messina (2006) for entry barriers, and Bentolila and Bertola (1990) and Hopenhayn and Rogerson (1993) for firing taxes.

Economists have also recently begun to examine differences in time allocations across countries. If it is the case that individuals in one country spend much more time in market work than individuals in another country, where does this show up in terms of other uses of time? Specifically, to what extent do these differences reflect differences in leisure versus differences in time devoted to home production? In a provocative paper, Freeman and Schettkat (2001) analysed time use data for American and German couples in the 1990s and found that total working time was similar across the two economies, but that there was a systematic difference in the composition of this total working time: couples in the United States devoted more time to market work than German couples, whereas German couples devoted more time to home production than American couples. This finding, coupled with the fact that additional time use surveys have been initiated both in Europe and the United States, has spawned a growing literature on the general issue of time allocations across countries, including Freeman and Schettkat (2005) and Hamermesh, Burda and Weil (2007). Olovsson (2004), Ragan (2005) and Rogerson (2007) all argue that modelling home production is important in understanding the differences in hours of market work across countries.

Conclusions

Labour market outcomes differ dramatically across industrialized countries along several dimensions, including hours of work and unemployment. These differences have changed dramatically over time. Understanding the source of these differences and their evolution over time is a key challenge for economists, and will likely have important consequences for policymakers as well as yield important insights regarding the role of various factors in shaping labour market outcomes. This article has provided a brief introduction to this line of research. While much progress has been made to date, much more work remains to be done.

Abstract

Unemployment insurance (UI) is a social insurance programme in which compensation is paid to unemployed workers. Much of the research on UI has focused on the inherent disincentives. For example, higher benefits have been found to increase unemployment durations, with little clear positive impact on the quality of new jobs. Additionally, financing UI through payroll taxes that are not completely experience-rated provides an incentive for firms to lay off workers. Thus, while UI is an important safety net for unemployed workers, it may also increase unemployment overall.

Article

Unemployment insurance (UI) is a social insurance programme whereby compensation is paid to unemployed workers. The federal–state UI programme in the United States dates from the Social Security Act of 1935, while many European countries began national programmes even earlier. For example, the National Insurance Act of 1911 established UI in the United Kingdom, while Italy and Germany established programmes in 1919 and 1927, respectively.

Institutional aspects of UI

While specific institutional details differ across countries, a typical UI programme is limited to workers who are unemployed through no fault of their own (that is, who have neither quit nor been fired for cause), who are actively looking for work, and who have a demonstrated attachment to the labour force, with the benefits being paid for a limited period of time (see for example, Atkinson and Micklewright,
unemployment insurance: The New Palgrave Dictionary of Economics (1991). Typically, the weekly benefit amount (WBA) is based on previous earnings, using a replacement rate schedule that is subject to a minimum and maximum WBA.

Financing of UI programmes also differs across countries. In some cases it is funded out of general revenues, while in most countries it is funded by a flat tax levied on employers and sometimes on employees (see Storey and Niesner, 1997 for a complete overview of UI programmes in the G-7 nations). Empirical evidence from the United States, though, shows that even when the tax is levied solely on the employer, the incidence is largely on the employee (Anderson and Meyer, 1997; 2000). In the United States, the employer tax is also experience-rated. That is, a firm's tax rate depends on the use of the UI system by its previous employees, with new firms typically charged a rate based on industry experience for the first few years. While each state has its own institutions, a typical system can be characterized by thinking of each firm as having an account with the state UI authority. Taxes are paid into this account, and benefits are paid out of it when the firm lays off employees. A schedule then relates the balance in this account to a tax rate, subject to minimum and maximum rates. A high account balance will merit a lower tax rate, while a lower (possibly even negative) balance will merit a higher tax rate. This characterization is a gross simplification, but captures the basic components of an experience-rated system.

Economic incentives of UI

With experience rating, a firm which lays off a worker today can expect to pay some fraction of that worker's benefits through higher tax payments in the future (for early theoretical work, see Feldstein, 1976; Baily, 1976; Brechling, 1977a; 1977b). For the most common systems used in the United States, one can calculate this marginal tax cost (MTC) of a layoff (see for example, Topel, 1983; this derivation follows Anderson and Meyer, 1993). Let \( \theta \) be the growth of employment (that is, \( N_{t+1} = \theta N_t \)), \( \gamma \) be the growth in the taxable wage base (that is, \( W_{t+1} = \gamma W_t \)), and approximate the tax schedule as a linear relationship with slope \( \eta \). The tax bill can then be expressed in terms of benefits paid, \( N \), \( W \) and the parameters \( \gamma \) and \( \eta \). For interest rate \( i \), when benefits paid increase by a dollar, the present value of the change in this tax bill is

\[
\sum_{t=1}^{\infty} \frac{\theta^2 \gamma^2 \eta}{1 - \theta^2 \gamma^2 \eta} \left(1 - \frac{\theta^2 \gamma^2 \eta}{1 + i}\right)^t.
\]

This sum converges to

\[
\frac{\theta^2 \gamma^2 \eta}{i + \theta^2 \gamma^2 \eta},
\]
which is referred to as the marginal tax cost (MTC) of a layoff. For firms at the maximum (or minimum) tax rate, $\eta = 0$ and this MTC will be zero, implying that benefits to this firm's workers are completely subsidized. Alternatively, the steeper the slope of the tax schedule the closer this marginal tax cost is to 1, and the more perfectly experience-rated is the system.

The subsidy inherent from incomplete experience rating provides an incentive to lay off workers. In fact, Topel (1983) estimates that incomplete experience rating in the United States could be responsible for about one-third of temporary-layoff unemployment spells. More broadly, the MTC can be thought of as a simple adjustment cost, implying that tighter experience rating would not only reduce layoffs in a downturn, but also reduce hiring in a boom, resulting in decreased employment fluctuations (see for example, Anderson, 1993; Card and Levine, 1994; Anderson and Meyer, 1994).

More work exists on the employee disincentives of UI than the firm disincentives. Two simple models imply that higher benefit levels will result in longer unemployment durations. First, as shown in Moffitt and Nicholson (1982), incorporating UI into the budget constraint of a labour supply model results in income and substitution effects which both imply fewer weeks worked. Similarly, a simple job-search model implies that higher UI benefits lower the cost of unemployment, thus increasing the reservation wage and lowering the probability of accepting a new job. The result is again an increase in the duration of unemployment.

The simple job-search model is extended in Mortensen (1977) to incorporate realistic UI programme features such as minimum work requirements for initial qualification, and limited duration of benefits. In this model, for the unemployed who are not currently qualified to receive UI, a new job that could lead to future UI qualification is more valuable the higher the benefit level. In this case, a negative relationship between duration and benefit level would be expected. Allowing benefits to be of limited duration has additional implications as well. First, the level of benefits should have no effect on the reservation wage after they run out. However, search intensity may increase around exhaustion, implying that potential duration of benefits may have a direct effect on unemployment duration.

The economic effects of UI are not all negative. For example, a job-search model also implies that increased duration should result in higher-quality jobs being found. Additionally, UI benefits can allow individuals to smooth consumption during unemployment spells. Finally, this consumption smoothing benefit implies UI can also play an important role as a macroeconomic stabilizer by helping maintain aggregate spending. More broadly, there is a growing literature on optimal UI which takes into account the need to balance costs and benefits (see for example, Baily, 1978; Chetty, 2006, for partial equilibrium and Hopenhayn and Nicolini, 1997; and Acemoglu and Shimer, 1999 for general equilibrium analyses).

**Empirical evidence on the effects of UI**

Most empirical work on UI focuses on the costs, with studies generally confirming a positive relationship between duration and benefit levels. For example, studies of UI recipients in the United Kingdom have found elasticities of around 0.3, while those in the United States have found elasticities in the range of 0.4 to 1. Studies in other OECD countries have typically found relatively low elasticities,
although they tend to be measured without much precision (see Atkinson and Micklewright, 1991 for a review of these studies). Additionally, empirical studies that allow for the exit rate out of unemployment to ‘spike’ around the time of benefit exhaustion have found just such an effect both overall (for example, Meyer, 1990) and for new jobs and recalls separately (for example, Katz and Meyer, 1990).

Additionally, studies in the United States have tended to find that a one-week increase in potential duration results in between a 0.1 and 0.2 week increase in unemployment, with Canadian studies finding slightly larger effects (Atkinson and Micklewright, 1991).

There are fewer empirical studies of the benefits of UI. A notable exception is Gruber (1997), which finds a large consumption smoothing effect of higher benefits. Finally, while a job-search model implies that higher-quality jobs should be found, empirical evidence is largely mixed on this effect (see Decker, 1997 for a review of US studies of benefit effects). In particular, in the United States, several re-employment bonus experiments took place in which UI claimants were offered a cash bonus if they found a new job within a specific amount of time (see Meyer, 1995, for a review). The early experiments found significant reductions in unemployment durations, but no real decline in post-unemployment earnings as would be expected if benefits were significantly subsidizing search. Overall, then, while UI is an important safety net for unemployed workers, it may also increase unemployment.

unemployment measurement

Katharine Bradbury
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Measures of unemployment tally people without a job who are looking for one. For measurement purposes, the critical question is what constitutes ‘looking’. This article summarizes how unemployment is measured in the United States and Europe, and describes recent research investigating the permeability of the dividing line between the unemployed and ‘marginally attached’ subgroups of those out of the labour market. A continuum between unemployed and entirely inactive individuals indicates that additional measures beyond unemployment may be useful in judging the state of the labour market.

Keywords

labour force participation rate; labour market search; non-employment; unemployment; unemployment measurement

Article

Measures of unemployment attempt to count individuals who do not have a job but are looking for one. While the concept is reasonably straightforward, various measurement approaches are used to distinguish those out of work who are looking from those who are not, generally based on the specific methods these individuals use to search for employment, how intensively they search, and how long it has been since they ‘actively’ searched.

Official measure in the United States

In the United States, unemployment is gauged by comparing the number of unemployed individuals with the size of the labour force, as determined by a monthly survey of households. The civilian labour force is defined as individuals aged 16 and older who are either employed or unemployed, but not on active duty in the armed forces. (See U.S. Bureau of Labor Statistics, 2006; Jacobs, 2006, pp. 4–8.)

Individuals are considered unemployed if (a) they lack a job, (b) are available to work, and (c) have actively sought employment in the four weeks preceding the survey or are awaiting call-back to an existing job (even if they did not actively seek employment). Active job search includes contacting employers or employment agencies, sending out résumés, or placing or answering advertisements; simply reading want ads is not considered active job search. Individuals are employed if they worked at least one hour as paid employees during the reference week, or worked in their own business or farm, or worked unpaid for 15 hours or more in a family business, or had a job but were temporarily away from it due to illness, vacation, labour management disputes, parental leave, job training, or other personal or family related reasons.

Anyone in the civilian non-institutional population (ages 16 and older and neither in the military nor in an institution such as a prison or mental hospital) who is not employed and not unemployed is considered to be out of the labour force. The U.S. Bureau of Labor Statistics (BLS) collects information on those out of the labour force to assess the degree to which they may be ‘marginally attached’ to the labour force, by asking about their interest in and availability for work.

Based on these questions, the BLS defines a set of ‘alternative measures of labor underutilization’ that either subtract from the official unemployment rate (for example, by counting only the long-term unemployed) or add to it. The nature of the questions and the alternative measures were revised as of January 1994. Figure 1 plots two of these ‘alternative
measures' and a third concept, along with the official unemployment rate, over the 1994–2006 period. The line marked ‘discouraged’ adds to the official unemployed all discouraged workers, defined as those who have given a job market-related reason for not currently looking for a job, including people who think that no work is available, or who could not find work, or who lack schooling or training, or who say potential employers think they are too young or old, or who believe they have been subject to other types of discrimination. The next measure adds all other marginally attached workers, defined as persons who currently are neither working nor looking for work but indicate that they want, and are available for, a job and have looked for work at some time in the preceding 12 months.

Figure 1
US measures of labour underutilization, 1994–2006. Notes: Not seasonally adjusted, 12-month centred moving averages. Discouraged workers are a subset of the marginally attached; the marginally attached are a subset of those who say they want a job. Each measure adds the noted group to ‘officially’ unemployed individuals and expresses that sum as a per cent of the labour force plus the noted group. Sources: US Bureau of Statistics and author’s calculations.
unemployment measurement: The New Palgrave Dictionary of Economics

In most of the industrialized world, the concept of unemployment is the same and the definition for measurement purposes is quite similar. The dimensions along which measures differ include the type of job search activities that distinguish the unemployed from the marginally attached, the definition of ‘currently available’ for work, and the treatment of individuals on layoff or waiting to start a new job. In addition, age cut-offs may vary. (For more detailed discussion of inter-country definitional differences, see Sorrentino, 2000.) The measurement definition chosen by the Statistical Office of the European Communities (Eurostat) in September 2000 is used to calculate ‘standardized’ unemployment rates for member nations. Eurostat conducts the European Union Labor Force Survey (EU LFS) on a quarterly basis and also releases ‘harmonized’ monthly estimates based on data from member states. The EU LFS divides the population of working age (defined as ages 15 and older) into three groups: employed, unemployed, and inactive. The economically active population (like the labour force in the United States) comprises employed and unemployed persons.

According to Eurostat, the unemployed are those aged 15–74 (or 16–74 in a few nations), who (a) were without work during the reference week, (b) were available to start work within two weeks, and (c) had either actively sought work in the past four weeks or had already found a job to start within the next three months. The specific steps that qualify as actively seeking work include any of the following: being in contact with a public employment office or a private agency to find work, applying to employers directly, asking among friends, relatives, unions, and so on, to find work, placing or answering job advertisements, studying job advertisements, taking a recruitment test or examination or being interviewed, or undertaking various activities to set up a business.

Thus, the EU includes those who only study job advertisements as unemployed (if they pass the other screens) – this is true in Canada as well – while the United States does not consider reading ads as active job search. In addition, persons waiting to start a new job are considered unemployed in Europe, but they are not considered unemployed in the United States unless they have actively searched for work within the previous four weeks. Persons on temporary layoff are considered unemployed in the United States even if they do not seek work, but in Europe they may be counted as employed, unemployed, or inactive, depending on search activity and the strength of their attachment to their job (based on pay and/or a definite recall date within three months).

The dividing line between being unemployed and out of the labour force

Because the distinction is necessarily arbitrary for measurement purposes, a research literature has investigated the dividing line between the unemployed and those out of the labour force. One strand of this literature focuses on transition probabilities among labour market states, investigating the degree to which those out of the labour force (or a marginally attached subset of them) are as likely to move into employment as those labelled unemployed. The issue is that measured unemployment might miss some signals of labour market tightness or slack if those out of the labour force behave similarly to the unemployed. Clark and Summers reported that ‘many of those classified as not in the labor force are functionally indistinguishable from the unemployed’ (1979, p. 31). Flinn and Heckman (1983), by contrast, examined young workers’ transition probabilities into employment and rejected the hypothesis that the distinction between unemployment and being out of the labour force is behaviourally meaningless.

Several recent papers – including Jones and Riddell (1999; 2006) focusing on Canada, Garrido and Toharia (2004) for Spain, Brandolini, Cipollone, and Viviano (2006) for Italy, and Schweitzer (2003) for the UK – describe selected groups of individuals who are officially out of the labour force but might be considered close to the unemployed, as they are attached to the labour force in various ways. These authors test hypotheses regarding behavioral differences – most notably transition probabilities to employment over various time horizons – between the unemployed and subgroups of those out of the labour force. For example, Jones and Riddell consider those who say they want a job; Brandolini, Cipollone and Viviano examine those who searched for employment between five and eight weeks before the survey; Garrido and Toharia examine ‘passive’ job searchers; Schweitzer subdivides those available for or wanting a job according to their primary non-labour market activity. Jones and Riddell also subdivide the unemployed into several categories along similar dimensions, and Schweitzer distinguishes the long-term and short-term unemployed; they examine rates of transition to employment of these unemployed subgroups as well. These researchers find that most of the marginally attached categories lie between the unemployed and the remainder of the ‘inactive’ group; that is, their transitions into employment are higher than the completely inactive, but still generally lower than those of the unemployed. Jones and Riddell and Schweitzer also find heterogeneity within the ranks of the unemployed and note that some marginally attached categories have higher transition rates into employment than selected subcategories of the unemployed.

Measuring labour market slack

These measurement issues are of more than academic interest because unemployment is the most widely used indicator of the degree of tightness or slack in the labour market and, by extension, in the overall economy; as a consequence, it is used by policymakers as a key signal of potential inflationary pressures. The research discussed above points to a continuum of labour market attachment among the non-employed, from those classified as unemployed through various marginally attached groups to people who expressly do not want a job. Some of the research authors argue that unemployment should be defined and measured more inclusively than it is currently. More generally, the arbitrariness of the dividing line between the states of being unemployed and out of the labour force, together with heterogeneity among subgroups within the inactive population, suggest that policymakers might...
gain useful information by looking at a range of measures—along with the official unemployment rate—in judging the state of the labour market. Because the relationship between the measured unemployment rate and ‘true’ economic slack and hence inflation may vary, depending on the specific definitions used in measuring unemployment, potential labour market entrants, the age and gender composition of the population, and labour market institutions, researchers have developed and investigated a variety of alternative indicators of labour market slack. One set of alternative measures sidesteps the difficulty of choosing a dividing line between the unemployed and inactive population by concentrating on the distinction between employment and non-employment. For example, the European Council revised its labour market targets in 2000, replacing the goal of reducing unemployment with the goal of increasing employment rates (employment–population ratios) (European Parliament, 2000). Similarly, Juhn, Murphy, and Topel (1991; 2002), and Murphy and Topel (1997) analyse non-employment and argue that 'the unemployment rate has become progressively less informative about the state of the labor market' (1997, p. 295). Others consider the labour force participation rate an indicator of interest along with the unemployment rate (for example, Anderson, Barrow, and Butcher, 2005; Bradbury, 2005). Complementary approaches consider a variety of direct measures of labour market tightness, either individually (for example, Shimer's 2005 job-finding rate among the unemployed) or in combination (for example, a composite measure of US labour market tightness compiled by Barnes, Chahrour, Olivei and Tang, 2007).

unemployment

Robert Topel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The unemployed are individuals who are without work but who are actively seeking employment. The unemployment rate is the percentage of the labour force – the total number of people either working or seeking work – that is unemployed. The evidence suggests that the ‘natural rate’ of unemployment (or non-employment) is not a constant towards which the labour market converges; rather, it varies with labour market fundamentals.

Article

The unemployed are individuals who are without work but who are actively seeking employment. The unemployment rate is the percentage of the labour force – the total number of people either working or seeking work – that is unemployed. Economists and others are interested in unemployment because it says something – we are not sure exactly what – about the economic conditions generally and the success or failure of economic policy.

Some amount of unemployment is both inevitable and efficient because economic fundamentals are stochastic and information is costly. This point was memorialized in the natural rate hypothesis of Friedman (1968), Phelps (1974) and Alchian (1969). As Friedman put it:

‘The natural rate of unemployment’… is the level that would be ground out by the Walrasian system of general equilibrium equations, provided there is embedded in them the actual structural characteristics of labor and commodity markets, including market imperfections, stochastic variability in demands and supplies, the cost of gathering information about job vacancies and labor availabilities, the costs of mobility, and so on.

This point may seem obvious today, but its origins are fairly modern – the 1960s were not so long ago in the history of economic theory. The contributions of Friedman, Phelps and Alchian were reactions to the place of unemployment in Keynesian models, which posited a stable trade-off between unemployment and inflation – the ‘Phillips curve’. But their broader impact was to establish that unemployment is an equilibrium phenomenon that occurs for the reasons stated above. This view has framed virtually all subsequent research on unemployment, and its formalization is a continuing research endeavour.

Data on unemployment are collected by government statistical agencies, based on household surveys that follow more or less uniform standards and definitions in developed countries. For example, in the United States unemployment statistics are collected monthly as part of the Current Population Survey, administered by the Bureau of Labor Statistics, which is a rotating sample of roughly 60,000 households that records (among other things) respondents’ self-reported labour market activities during the previous week. Jobless persons who have engaged in some effort to find employment in the past four weeks, or who are awaiting recall to a previous job, are recorded as unemployed. Jobless persons who
In a dynamic economy people may be unemployed for many reasons. Young, new entrants to the labour force seek employment, and, as in marriage, it is typically not a good strategy to take the first opportunity that comes along. Other unemployed individuals may have left their previous job to look for something better, or they may have been permanently laid off from a previous job because of changing market conditions. Still others may be on temporary layoff, anticipating recall by their previous employer. These examples demonstrate that unemployment (and other labour force ‘states’) is inherently dynamic: the stock of unemployed is ever-changing, and is determined by labour market flows. New individuals are constantly joining the ranks of the unemployed via quits, layoffs, or entry to the labour force – the inflow to unemployment – while other unemployed job seekers locate and accept new jobs, or choose to stop looking – the outflow from unemployment. Changes in either flow affect the level of unemployment.

No brief overview can do justice to the vast literature on unemployment, nor can it evaluate the myriad social policies – such as unemployment insurance, public employment agencies or ‘active’ labour market programmes – that are meant to reduce unemployment or soften its impact on individuals. (Layard, Nickell and Jackman, 1991, is a slightly dated survey of key issues.) So my aims are more modest. I will summarize key facts about unemployment in the United States, and the factors that have affected the evolution of unemployment, while drawing parallels with other developed economies. Following the arguments in Juhn, Murphy and Topel (JMT) (1991; 2002) and Murphy and Topel (1987; 1997), I provide evidence of a long-term decline in the relative demands for less-skilled workers, so the rewards to employment have declined for marginal workers. This would raise the ‘natural rate’ of unemployment, but the story is complicated by the fact that some of the unemployed eventually leave the labour force. Over the long run, these changes in economic fundamentals increase joblessness – the total of unemployment and non-participation. This means that current unemployment data have a much different interpretation than in the past. For example, the US unemployment rates of 1974, 1997 and 2006 were about equal, at 4.9 per cent of the labour force. Yet non-participation among prime-aged men rose from 5.2 per cent in 1974 to 8.2 per cent in 1987 and 9.4 per cent in 2006. The reason is that many among the least-skilled had given up searching for work – they were no longer counted as unemployed, but changing labour market forces had left them jobless.

**Labour market flows and the evolution of unemployment**

Figures 1 and 2 show the evolution of the male unemployment rate in the United States and several other developed economies since 1965, using comparable definitions. (I present evidence on men because women’s labour force participation is typically more varied.)

Figure 1

Figure 2
Focusing on long-term changes, the key message is that unemployment drifted upward in most industrial countries, but especially in Western Europe. The United States is an exception – in comparison with Western Europe, the United States had relatively high unemployment in the 1960s, but substantially lower relative unemployment after about 1990. Figure 1 also highlights the recent return to ‘low’ unemployment in the United States. By 2000 the US unemployment rate had reached its lowest level in 30 years, and unemployment rates in 1999–2000 were close to the extremely low rates seen during the late 1960s. This is the culmination of a long downward trend in unemployment: the peak unemployment
Equation (1) accords the law of motion for unemployment: The New Palgrave Dictionary of Economics

Then the law of motion for unemployment rise. These newly unemployed individuals may have been employed (E) or they may be previous non-participants (O) who have begun to search for work. Similarly, unemployment will fall if transition rates from unemployment rise. One usually thinks of this in terms of greater ‘job finding’ (λ_{EU}∗(t)), but (2) makes clear that transitions to non-participation – say because of deteriorating labour market opportunities that reduce the return to continued search – will also reduce unemployment.

As above, changes in unemployment are driven by labour-market flows. Other things the same, the fraction of the population that is unemployed increases when transitions to unemployment rise. These newly unemployed individuals may have been employed (E) or they may be previous non-participants (O) who have begun to search for work. Similarly, unemployment will fall if transition rates from unemployment rise. One usually thinks of this in terms of greater ‘job finding’ (λ_{EU}∗(t)), but (2) makes clear that transitions to non-participation – say because of deteriorating labour market opportunities that reduce the return to continued search – will also reduce unemployment.

http://0-www.dictionaryofeconomics.com.library.lemoyne.edu/article?id=pde2008_U000016(第 5/11 页)2009-1-14 17:00:02
JMT (2002) build on (2) to calculate average entry rates and durations of spells for both unemployment ($U$) and non-employment ($N=U+O$) among American men from 1967 through 2000. Figure 3 shows their results for unemployment. Through the late 1980s entry rates and durations of unemployment spells showed a common pattern, rising in recessions and falling in recoveries, with some evidence of a secular increase in both components. But this tight correspondence was broken in the 1990s – increased incidence of spells played a minor role in the recession of 1991–2, while durations soared. The ensuing decline in unemployment during the 1990s expansion was driven almost entirely by a reduction in the incidence of unemployment spells, while durations of unemployment remained high – in fact, flows into unemployment fell below their levels in low-unemployment 1960s, while durations were roughly twice as long. With fewer but longer spells, the population distribution of unemployment became much more concentrated than before.

Figure 3

The dichotomy between incidence and duration is more extreme for non-employment, $N$, which measures total joblessness in the population without regard to whether individuals are searching for a job. The incidence (entry rate) of jobless spells roughly corresponds with the incidence of unemployment – compare Figure 3 – but durations of non-employment show a steady increase, more than doubling (to 15 months) since the 1960s. The sharp increase in average durations in the 1990s is especially noteworthy, reflecting the increased proportion of American men who have simply withdrawn from the labour force. Why did this occur? In an accounting sense it is because a large fraction of labour-force ‘withdrawals’ were temporary in earlier decades, but by the 1990s many men had become ‘full-time’ non-participants. They had left the labour force and made no efforts to find work, so that average transition rates from non-employment to employment plummeted (Figure 4).
Who are the jobless?

To get an idea of why this occurred, it is worth examining the characteristics of those without jobs. The most basic fact is that unemployment and overall joblessness are much more common among the least skilled. Measuring skill by years of completed schooling, unemployment rates are higher among those with fewer years of schooling, and they also increase more during recessions. JMT (2002) examine a broader definition of skill, based on an individual’s position in the overall wage distribution. (JMT impute wages for year-round non-workers from the wage distribution of those who work very few weeks. See JMT, 2002, for a description of their methods.)

Figures 5A and 5B show percentages of the population who are unemployed and out of the labour force (OLF) by percentage intervals of the wage distribution between 1967 and 2000. As with education, both unemployment and non-participation are more common among the less skilled, and in each recession their unemployment rates rise most sharply. Up through the early 1990s, both components of joblessness showed a secular increase that was concentrated among low-wage individuals. For unemployment this trend was reversed in the 1990s but non-participation continued to rise, especially among the least skilled. By 2000 about 20 per cent of men whose skills would put them in the bottom decile of the wage distribution were out of the labour force, which is more than double the fraction of non-participants in the 1960s. Adding the unemployed, by the end of the 1990s nearly 30 per cent of these men were jobless. By comparison, men whose skills put them above the 60th percentile of the wage distribution showed virtually no long-term increase in either unemployment or non-participation. In other words, to understand rising joblessness in the United States, we must focus on changes in economic fundamentals that have affected mainly the lower end of the skill distribution.
The most obvious explanation is that shifts in relative labour demands have reduced labour market opportunities available to the least skilled, so they end up working less. Evidence consistent with this is the well-documented decline in relative wages among low-skilled workers, shown in Figure 6. Between 1970 and 1993, real wages of men in the first decile of the wage distribution declined by over 25 per cent, with smaller though still important declines for all workers below the median of the wage distribution. The post-1993 growth in real wages, which affected the entire skill distribution, corresponds to a convergence of relative fractions of time spent unemployed (Figure 5A), but non-participation remained quite
high among low-wage workers. The continue rise in non-participation while real wage grew in the 1990s suggests a shift in labour supply. Autor and Duggan (2003; 2006) point to Disability Insurance (DI), which became relatively more attractive to low-skill workers who faced a long-term deterioration of labour market opportunities. They document that participation continued to fall because DI subsidized non-work, which was most attractive to low-skilled workers. In earlier times these individuals would have spent transitory periods of unemployment or non-participation, but they would have remained attached to the labour force over the long run. By 2000, many less skilled individuals – faced with declining working opportunities – had simply withdrawn.

Figure 6

Conclusion: US and European unemployment revisited

The broad message of the above evidence is that the ‘natural rate’ of unemployment (or non-employment) is not a constant towards which the labour market converges; rather it varies with labour market fundamentals – as originally suggested by Phelps (1974). But why have unemployment rates evolved so differently in the United States and Europe? A
compelling interpretation is that differences in labour market institutions generate differences in measured unemployment despite similarities in labour market fundamentals. In the United States, the maximum duration of unemployment insurance (UI) is typically six months, and the fraction of earnings replaced by UI is about half. Aside from DI, income support for the long-term jobless is comparatively low. These features may accelerate job-finding among those with marketable skills but weaken labour force attachment among the least skilled, whose opportunities have deteriorated. Then long jobless durations among the least skilled show up in labour force withdrawal. In Europe, UI coverage is much more liberal in terms of both the level and duration of benefits, so those who would leave the labour force in the United States are counted as long-term unemployed. The forces at work and the employment prospects of affected workers are not as different as standard unemployment statistics may suggest.

uneven development

Donald J. Harris
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A striking characteristic of capitalist development is the phenomenon of uneven development, defined as persistent differences in levels and rates of economic development between different sectors of the economy. However, much existing economic theory predicts that many observed features of differentiation would tend to wash out as a result of competitive market forces. This article seeks to bridge this gap. It proposes a strategy for the analysis of uneven development that advances toward a historically and empirically relevant theory. The analysis draws in part on elements of the emerging paradigm of neo-Schumpeterian evolutionary theory and on some documented empirical regularities.

Article

In examining the general character of the process of capitalist development as it has appeared historically across many different countries over a long period of time, it emerges that one of its most striking characteristics is the phenomenon of uneven development. Specifically, the process is marked by persistent differences in levels and rates of economic development between different sectors of the economy.

This differentiation appears at many levels and in terms of a multiplicity of quantitative and qualitative indices (Kuznets, 1966; Maddison, 1982; Mueller, 1990; Pritchett, 1997; Salter, 1966). Relevant measures that sharply identify the phenomenon include the level of labour productivity in different sectors, the level of wages, occupational and skill composition of the labour force, the degree of mechanization and vintage of production techniques, rates of profit, rates of growth, and the size structure of firms. The phenomenon appears regardless of the level of aggregation or disaggregation of the economy, except for the extreme case of complete aggregation – in which case, structural properties of the economy are made to disappear. For example, it appears at the level of comparing the broad aggregates of manufacturing industry and agriculture, at the level of individual industries within the manufacturing sector, and at the level of individual firms in an industry. It appears on a regional level within national economies as well as on a global scale between different national economies. In this latter context, one form taken is the continued differentiation between underdeveloped and advanced economies, usually identified as the problem of underdevelopment.

These disparities appear from observation of the economy as a whole at any given moment and over long periods of time. While the relative position of particular sectors may change from one period to another, there is, nevertheless, always a definite pattern of such differentiation. We may say, therefore, and certainly it is an implication of these observations, that these disparities are continually reproduced by the process of development. Uneven development, in this sense, is an intrinsic or inherent property of the economic process. Far from being merely transitory, it appears to be a pervasive and permanent condition.

Now, it is an equally striking fact that, when we examine the theoretical literature on economic growth, we find the completely opposite picture. In particular, the dominant conception of the growth process that has characterized the post-Second World War literature is constructed in terms of uniform rates of expansion in output, productivity and
employment in all sectors of the economy. In this sense, it is largely a literature of steady-state growth, whether presented in multi-sectoral or aggregative models (Burmeister and Dobell, 1970; Harris, 1978). Some notable and relevant exceptions, including Haavelmo (1954), Leon (1967), Nelson and Winter (1982), Pasinetti (1981), Salter (1965), explicitly examine aspects of the problem of persistent differentiation posed here. The recent flurry of work in endogenous growth theory seeks to incorporate some relevant elements of the problem into the neoclassical conception of the growth process (Aghion and Howitt, 1998). However, much of existing economic theory predicts that, given enough time, many of the features of differentiation which we observe empirically would tend to wash out as a result of the operation of competitive market forces (Harris, 1988). Such differentiation should therefore be viewed only as a transitory feature of the economic process.

Thus, on the one side, we find a historical picture of uneven development as a persistent phenomenon, and on the other, a theory that essentially negates and denies this fact. It is possible to go some of the way towards bridging this gap. Accordingly, I consider here a strategy for analysis of uneven development that breaks through the narrow limits of the existing steady-state theory and advances towards a historically and empirically relevant theory.

The analytics of uneven development

It is necessary to start by recognizing the intrinsic character of the individual firm as an expansionary unit of capital with a complex organization. Various efforts have been made to develop a theory of the firm on this basis. (See, for instance, Penrose, 1959; Baumol, 1967; Marris, 1967; Winter, 2006). In this conception, growth is the strategic objective on the part of the firm. This urge to expand is not a matter of choice. Rather, it is a necessity enforced upon the firm by its market position and by its existence within a world of firms where each must grow in order to survive. It is reinforced also by sociological factors. It is this character of the firm that constitutes the driving force behind the process of expansion of the economy.

In the aggregate, the global economy is conceived to consist of an ordered system of firms (an interlocking network of individual circuits of capital) and its sectors (classified variously as industries, regions, national economies) likewise to be clusters of the firms that are the component units of this system. In this system, it is the firms that compete, not industries or regions, national economies or ‘North’ versus ‘South’. The state sets the rules and jointly determines the external conditions (externalities) within which the firms operate.

This is a crucial starting point because it establishes the idea of growth as the outcome of a process driven by active agents, not by exogenous factors. In particular, in the context of the capitalist economy, growth is the outcome of the self-directed and self-organizing activity of firms, each of which seeks to expand and improve its competitive position in relation to the rest. Once this principle is recognized it becomes possible to move towards an understanding of the problem of uneven development.

The imperative of growth impels the firm constantly to seek new investment opportunities wherever they are to be found. Such opportunities may lie within a wide range – in existing product lines, in new products and processes, in new geographical spaces and natural resource frontiers, or in the take-over of existing firms. However, at the core of this movement, viewed historically over the long term, are the invention, innovation and diffusion of new technologies that give rise to new products and services (Freeman, 1982; Landes, 1969; 1999; Marx, 1906, ch. 15; Mokyr, 1990; 2002).

The emergence of growth centres or leading sectors is a reflection of this underlying process. It is a consequence of the effort on the part of many firms to create or to rush into those spheres where a margin of profitability exists that allows them to capture new profit and growth opportunities. It may be conceived to take the form of a ‘swarm’ (Schumpeter, 1934, p. 223) or ‘contagion’ (Baumol, 1967, p. 101), marked by both entry and exit of firms. Such spheres are opened up, typically through complementary ‘macroinventions’ and ‘microinventions’ (Mokyr, 1990, p. 13) and in a sporadic and discontinuous pattern, as a consequence of the ongoing investment and innovative activity of firms and the competitive interactions among them. It is this constant flux, consisting of the emergence of new growth centres, their rapid expansion relative to existing sectors, and the relative decline of others, that shows up in the economy as a whole as uneven development.

The process of industry evolution

The form of this process, as it appears at the level of particular industries and products, has been identified in terms of certain empirical regularities, though there are also significant variations across industries and products. Studies show that, with some exceptions, the growth of many new industries and products follows a life cycle pattern (Gold, 1964; Gort and Klepper, 1982; Klepper, 1997; Klepper and Graddy, 1990; Mullor-Sebastian, 1983; Wells, 1972). It may be represented schematically by an S-shaped curve of the time-path of output as in Figure 1. (For simplicity, no distinction is made here between products and processes, an industry is assumed to produce a single product, and short-term turbulence in the path of output is ignored.) Accordingly, we may distinguish three phases of expansion: I, the initial phase, where total output is a minute share of aggregate output and grows at a low rate; II, a phase of rapid growth in which output expands rapidly and its share of aggregate output grows; III, the sector reaches a threshold beyond which its growth rate tends to level off and perhaps to decline.

Figure 1
Life cycle of an industry

I  II  III

Industry output
To characterize the associated pattern of technological innovation, Kuznets (1979) identifies a sequence of four distinct phases constituting the life cycle of ‘major’ innovations: (1) the *pre-conception* phase in which necessary scientific and technological preconditions are laid; (2) the phase of *initial application* involving the first successful commercial application of the innovation; (3) the *diffusion* phase marked by spread in adoption and use of the innovation along with continued improvements in quality and cost; (4) the phase of *slowdown* and *obsolescence* in which further potential of the innovation is more or less exhausted and some contraction may occur. This taxonomy is not all-embracing, and there are others that emphasize other features, but it is suggestive in pointing to a certain internal logic of the innovation process.

The process of industry evolution is also typically associated with a changing firm-structure of the industry. In many industries, there is a proliferation of small firms in phase I. As the diffusion of the product occurs and growth speeds up, there is a ‘shaking out’ process by which many of the smaller firms disappear (exit) and the available market is concentrated in the remaining firms. When the industry reaches ‘maturity’, in phase III, there is likely to be a high degree of concentration. This association between industry life cycle and changing firm-structure (commonly called ‘co-evolution’) suggests that the dynamic of expansion through innovation is simultaneously a process of the concentration of capital. This sequence of a single product-cycle, schematically described here, is but a small segment of the time sequence characterizing the historical evolution of the economy. Given that firms are growing, making profits, and seeking to continue to grow, it must be supposed that at least some of them, having entered into phase III, would seek to launch into new investment opportunities. They will therefore actively seek new products that will initiate a corresponding new sequence. Alternatively, the new sequence could come from entry of new start-up firms.

It follows that we can map out the dynamic evolution of the economy as a *sequential process* that is discontinuous, punctuated and stochastic, with varying and overlapping timescales of the different product-cycles, where the overall growth is accountable for on the basis of (1) the individual growth of particular new products coming on stream, (2) the growth of pre-existing products, each of which is growing at a different rate depending on the particular phase reached in its life cycle, and (3) over time the irregular accretion of new products as the innovation process continues.

In this context, the relative position of any firm-cluster (region or national economy) at any time on a relevant index of development may be seen as a matter of the particular products it has managed to capture as a result of the previous pattern of accumulation, the ongoing activity of firms operating within it and the particular timing of their entry into the life cycle of new products.

The causes that produce and sustain the observed patterns of differentiation must then be found within the internal dynamics of this process, leaving aside such historically contingent factors as wars, colonial control, ‘foreign’ intervention, that may also be considered relevant and important.

What role is to be assigned to demand as a factor in this process? At the level of individual consumer products or industries, a common conception is that demand acts as an autonomous factor with a definite influence on the life-cycle pattern of evolution of the product. That influence is exerted in the early phase of introduction of a new product because of an element of resistance due to ‘habit’ formed in a customary pattern of consumption. It is exerted also in the maturity phase because of the operation of ‘saturation effects’ in consumption. But there are reasons to doubt the strength and effectiveness of such factors, as well as their supposed autonomy.

First, in an economy undergoing regular and rapid change, it is not evident what role there is for habit except for the habit of change itself. The experience of, and adaptation to, change may create a high degree of receptivity to change. What then becomes decisive in the evolution of demand (for consumer goods) is the growth of income, and the changing relative price and quality of products. Income and price elasticities of demand are an imperfect, proximate expression of this dynamic effect.

Second, in so far as these latter factors are crucial to the formation of demand, it may be argued that there is a certain self-fulfilling aspect of the expansionary process at the level of industry demand. In particular, investment generates the demand that provides the market for the new products which investment itself creates. This occurs in two ways. First, in so far as these latter factors are crucial to the formation of demand, it may be argued that there is a certain self-fulfilling aspect of the expansionary process at the level of industry demand. Income and price elasticities of demand are an imperfect, proximate expression of this dynamic effect.
Uneven development: The New Palgrave Dictionary of Economics

Each and every individual firm must of course secure a place in the market for its product. Its success in this regard is dependent on its own efforts and capabilities.

Competency, firm capabilities, entry/exit conditions, and the social environment

Analytical treatment (including formal modelling) of the process of industry evolution has flourished since the 1980s in tandem with an outpouring of empirical studies covering different industries, countries and time periods. Much of this work is done within the frame of an emerging paradigm in the Schumpeterian tradition of evolutionary dynamics (Futia, 1980; Iwai, 1984a, 1984b; Nelson and Winter, 1982; Dosi, 1984) and there are other theoretical approaches (Loury, 1979; Dasgupta and Stiglitz, 1980; Durlauf, 1993). For a review of the current state of the art and challenges for research, focusing on the evolutionary approach, see Malerba (2006). Relevant for the present purposes are the significant insights provided so far by this work into the mechanisms and causal factors that govern the process of industry evolution and account for the persistence of differentiation among firms. The neo-Schumpeterian approach develops an explicit formulation of ‘Schumpeterian competition’ in which firms innovate to win super-normal profits, profits are reinvested to provide further growth through innovation and market expansion, and there are winners and losers due to the operation of selection mechanisms and learning mechanisms. Decisions are typically based on bounded rationality. It is shown that such competitive behaviour under specified conditions gives rise to persistent differentiation among firms in terms of size, productivity, costs of production, product characteristics, profitability and growth, and may breed long-term sustainable market concentration among surviving firms, with or without entry. Economies of scale and scope are not a necessary part of the story; a key factor is increasing returns to knowledge and learning. Though there exists a strong tendency to concentration, it is not inevitable, and depends on industry characteristics that vary across industries. There also exist dual tendencies of ‘creative destruction’ and ‘creative accumulation’.

A distinctive feature of this approach is the conception of the firm itself as an organizational unit. The firm is conceived as the embodiment of a set of strategic assets (competences or capabilities), tangible and intangible, consisting of knowledge, skills, and routines, gained through path-dependent experience and learning, that are specific to each firm and non-tradeable. These assets evolve over time (through ‘competence accumulation’) with the ongoing process of evolution of the industry and through interaction with the changing environment. Consequently, diversity among firms is not only a characteristic of the system of firms, it is also reproduced by the evolutionary dynamics of the competitive process. Some key factors determining the evolutionary path of industry structure in terms of firm composition are the following. (1) First- (second-, third-) mover advantages arising from a combination of unique internal attributes of the mover, product characteristics, network effects among users, and random chance events. (2) Non-pecuniary network externalities associated with cues and information gained from interacting with the ‘local’ social environment of firms, users of the product, and institutions involved in knowledge creation and information dissemination (on the national level, the ‘national system of innovation’). (3) Spillover effects among firms and across industries, which may be both positive and negative. (4) Increasing returns to knowledge and learning within the firm. (5) A firm may become ‘locked-in’ to its own trajectory of technology development and reap increasing returns thereafter, but eventually suffer a disadvantage from generating irreversibilities and inertia causing inability to adjust to change (‘success breeds failure’). (6) The very same factors that confer advantages upon early entrants and incumbent firms may create barriers to entry for ‘latecomers’, depending on the stage of industry evolution and timing of entry. Some relatively neglected factors that need to be integrated into a more comprehensive analysis include: (1) the role of market demand, as related to the mutual interaction between producers and users (consumers, other firms, and the state); (2) the role of the financial system (Schumpeter had assigned a crucial role to the granting of credit ‘as an order on the economic system to accommodate itself to the purposes of the entrepreneur’ (1934, p. 107)); (3) workplace and labour market interactions, lightly touched upon by Mansfield (1968, ch. 5) and vividly described in historical detail by Braverman (1974); (4) the system of governance by the state, that sets and enforces the rules and norms, including property rights, governing conduct by firms. Within this extended framework of analysis, it is possible to explain not only how some firms (or firm-clusters) come to capture the position of leaders (and may eventually lose it to others), but equally how some are left behind, others drop out altogether (exit), and still others remain on the ‘periphery’ (so to speak) lacking the internal and external capabilities to enter. In this regard, the explanatory power of this analysis is readily applicable to commonly discussed empirical and historical phenomena such as ‘deindustrialization’, ‘catching up’ (convergence), and ‘falling behind’ (divergence).

What emerges from this analysis also is an understanding of the critical role of public policy and programmes to foster economic development. Because of the pervasiveness of externalities and various forms of coordination problems, market failures are intrinsic to the process, calling thereby for collective intervention to achieve efficiency and socially optimal results.

The aggregation problem

All the preceding analysis concerns the pattern of industrial growth viewed at the level of an individual industry and the firms (or firm-clusters interpreted as, say, regions or countries) that compose it. There is nothing in this analysis to indicate how the pattern of growth of different industries translates into aggregate expansion at the level of the economy as a whole, or how the various industrial patterns fit together to form a complete whole. This is a substantive problem requiring further analytical treatment on its own terms. Its...
uneven development: The New Palgrave Dictionary of Economics

significance derives from recognition that the economy as a whole is not just the sum of its parts. Hence, the motion of the economy cannot simply be deduced from the movement of its parts. The usual methodological device of the ‘representative firm’ necessarily fails in the present context.

A related aspect of the problem is associated with the manifold and complex ways in which growth in one sector (however defined) mutually conditions and is conditioned by growth in other sectors. Such mutual interaction is a necessary consequence of economic interdependence in both production and exchange. (Hence, models of international trade that claim to show uneven development arising uniquely from exchange of products give a one-sided representation of the problem.) The existence of such interaction implies that there is a certain cumulative effect intrinsic in the growth process. Understanding the exact mechanisms through which this effect operates is one of the central analytical problems for the analysis of uneven development.

There is no guarantee that in the aggregate there is always sufficient demand for all products. It is here that the analysis comes full circle, back to the problem of overall effective demand that motivated the early post-war growth theory initiated by Harrod (1948) and Domar (1957). This problem was a central focus of the analysis in the Keynesian and Post Keynesian tradition, less so in the case of the neoclassical tradition (as detailed in Harris, 1985). It appears now that it cannot be escaped in making the transition to the analysis of uneven development.

The analytical framework presented here lays the groundwork for addressing this larger set of problems.

unforeseen contingencies

Barton L. Lipman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

While unforeseen contingencies – possible events that agents do not think of when planning or contracting – are often said to greatly affect the nature of contracting, we lack useful formal models. Most of the existing models boil down to assuming that agents give zero probability to some events that might actually occur, an approach which is not particularly useful for studying the effects of unforeseen contingencies on contracting.

Keywords

control rights; expected utility; incomplete contracts; long-term and short-term contracts; probability; rationality, bounded; short-term contracts; uncertainty; unforeseen contingencies

Article

Many writers have suggested that the nature of contracting, firm structure, and even political constitutions cannot be well understood without taking account of the role of unforeseen contingencies. As I explain in more detail below, many definitions are possible, but I will define unforeseen contingencies to be possibilities that the agent does not ‘think about’ or recognize as possibilities at the time he makes a decision. In virtually any reasonably complex situation, real people do not consider all of the many possible situations that may arise. Because of this, contracts, for example, typically assign broad categories of rights and obligations rather than calling for very specific actions as a function of what might occur. Similarly, firms are designed to figure out what to do rather than simply being programmed to implement some given set of actions. Finally, laws, especially sweeping ones such as constitutions, are intentionally left vague to allow adaptation to circumstances as they arise.

Unfortunately, while it is easy to find eloquent statements in the economics literature regarding the importance of unforeseen contingencies for understanding the nature of economic and political institutions – see, for example, Hayek (1960); Williamson (1975); or Hart (1995) – there is no agreed formal model. I sketch a few known approaches below, but none of them provides a model that can be used to study these
To make this point concretely, I focus on a particular example of an aspect of contracting that we would want a model of unforeseen contingencies to help us understand, namely, the choice between long-term and short-term contracts. It seems obvious that one of the main advantages of a series of short-term contracts is that it is easier to anticipate the relevant contingencies for the near future than for the distant future. Hence in environments with many unforeseen contingencies relative to the value of long-term contracting, we should expect to see more short-term contracting. I will argue below that none of the models of unforeseen contingencies in the literature can be used to illustrate this simple idea.

Before discussing the approaches taken, it is important to clarify what I mean by unforeseen contingencies. First, as I use the term, unforeseen contingencies are not events that the agent has considered but assigned zero probability. This notion is something standard models deal with perfectly well. More importantly, the existence of such events seems to have little to do with the features of economic and political institutions we believe to be related to unforeseen contingencies. To be concrete, consider the trade-off discussed above between long-term contracts and short-term contracts. If the only sense in which some contingencies in the distant future are not foreseen is that they are given zero probability, then the agents will perceive zero costs to excluding them. Hence they will see no 'foreseeability' advantage to short-term contracts, so a model of unforeseen contingencies based on such a definition cannot say anything interesting about the trade-off.

It is also important to note that the use of the term ‘unforeseen’ in law is often closer to the zero probability definition than the definition I use here. In particular, legal usage often seems to suggest that a contingency is ‘unforeseen’ by an agent if it occurred even though the agent gave it ‘low’ probability ex ante. For example, a 1997 US tax law allows a person who sells his home to exclude some of the capital gains from taxation under certain conditions if ‘unforeseen circumstances’ precipitated the move. The Internal Revenue Service (2006, p. 16) recently issued regulations listing events that would ‘count’ as such unforeseen circumstances, including divorce, job loss, or multiple births from a single pregnancy. Surely, most homeowners would not be startled to learn that couples sometimes divorce, that job losses can occur, or that a pregnancy could yield triplets, so these circumstances are not ‘unforeseen’ in the sense used here. Instead, such events are ‘unforeseen’ in the sense that they were very unlikely ex ante, too unlikely to influence the home purchase decision.

While this use of ‘unforeseen’ is evidently valuable for some purposes, it does not seem to be appropriate to the issues of interest here, though it is closer than the zero probability definition. To see this, consider again the trade-off between long-term and short-term contracts. If ‘unforeseen’ contingencies are recognized but given low probability, they can still be incorporated into the contract and, in the absence of costs to doing so, will be. Hence, in the absence of contracting costs, again, short-term contracts will have no foreseeability advantages if this is what we mean by foreseeability. On the other hand, if there are costs of writing ‘long’ contracts, it may be optimal to exclude contingencies with low probability. Hence a sequence of short-term contracts (which delays some of the writing costs) may be better. On the other hand, it is not clear that the advantage of short-term contracts is a gain in foreseeability so much as it is a delay in writing. See Al Najjar, Anderlini and Felli (2006) for a particularly interesting related model.

Turning to models, the idea of how unforeseen contingencies are represented is common to most of the models in the area, though with many variations. (A different approach, which I do not discuss, involves an explicit logic rather than focusing on a state space. See Halpern and Rêgo, 2005 for a good example of this approach and an overview of much of this literature.) In standard models of uncertainty without unforeseen contingencies, there is a set of states of the world, say $\Omega$, which represents the uncertainty.
state $\omega \in \Omega$ should be thought of as a specification of every possible circumstance conceivably relevant to the agent’s situation. For example, for a firm, a state might specify input prices, demand conditions, technological possibilities, what is going on with its rivals, and so on. Part of what is meant by the phrase ‘every relevant circumstance’ is that, if we know the state, then we know the exact consequence (profits or utility) the agent receives as a function of whatever course of action he might choose.

To give a concrete example, suppose there are two relevant sources of uncertainty: whether it rains and whether there is a revolution in country X. This gives us four possible states of the world:

$$\Omega = \{(\text{rain, revolution}), (\text{rain, no revolution}), (\text{no rain, revolution}), (\text{no rain, no revolution})\}.$$ 

Consider an agent who has never considered the possibility of revolution. This agent sees only two possibilities: rain or no rain. That is, the agent has a subjective state space $S$, describing the possibilities as he perceives them, given by

$$S = \{(\text{rain}), (\text{no rain})\}.$$ 

We can think of the ‘state’ (rain) as the event $\{(\text{rain, revolution}), (\text{rain, no revolution})\}$ and think of the ‘state’ (no rain) as analogous. Thus the state space as seen by the agent is actually a partition of the true state space. The variation within an event of this partition is variation that the agent has simply not thought of.

This basic idea appears in numerous forms in the literature. This partition description appears in Ghirardato (2001) and Dekel, Lipman and Rustichini (2001), among others. A more complex form appears in Li (2006a) and in Heifetz, Meier and Schipper (2006a), both of which allow the possibilities recognized by the agent to vary with the true state of the world. For example, it might be that when the true state is (rain, revolution), the agent recognizes the possibility of the revolution, while if it is (rain, no revolution), he does not.

While this idea for representing knowledge is almost uniformly used in the literature, there is greater variation in the way decision-making is represented. Continuing with the rain and revolution example, suppose the agent has a certain amount of money and can either use it to buy an umbrella or invest it in country X or simply save it. Suppose Table 1 gives the true, objective payoff of the agent as a function of his choice and the real state.

<table>
<thead>
<tr>
<th>Objective state</th>
<th>Payoff if buy</th>
<th>Payoff if save</th>
<th>Payoff if invest</th>
</tr>
</thead>
<tbody>
<tr>
<td>(rain, revolution)</td>
<td>5</td>
<td>0</td>
<td>−100</td>
</tr>
<tr>
<td>(rain, no revolution)</td>
<td>5</td>
<td>0</td>
<td>10</td>
</tr>
<tr>
<td>(no rain, revolution)</td>
<td>6</td>
<td>8</td>
<td>−100</td>
</tr>
</tbody>
</table>
Turning to the agent's perceptions, continue to assume that he sees the possibilities only as rain versus no rain. Intuitively, the consequences of buying the umbrella or saving money are unambiguous since they only depend on this. Putting it differently, these acts are measurable with respect to the agent's awareness, so there seems to be no problem. On the other hand, how does the agent perceive the payoffs to investment?

A number of papers in the literature use models that treat the payoffs to investing in ‘states’ (rain) and (no rain) as exogenously given (see, for example, Heifetz, Meier and Schipper, 2006b; Li, 2006b). In a somewhat more restrictive version of the same idea, Modica, Rustichini and Tallon (1998) assume that if the agent does not foresee some possibility, this means he implicitly assumes some particular resolution of this uncertainty. For example, perhaps the agent implicitly assumes there will not be a revolution, so he sees the payoff to investing in each ‘state’ as ten. In other words, these approaches come down to treating the agent's view of the available actions as given by Table 2 for some numbers $x$ and $x'$.  

<table>
<thead>
<tr>
<th>Subjective state</th>
<th>Perceived payoff if buy</th>
<th>Perceived payoff if save</th>
<th>Perceived payoff if invest</th>
</tr>
</thead>
<tbody>
<tr>
<td>(rain)</td>
<td>5</td>
<td>0</td>
<td>$x$</td>
</tr>
<tr>
<td>(no rain)</td>
<td>6</td>
<td>8</td>
<td>$x'$</td>
</tr>
</tbody>
</table>

With more than one agent, these models generally do allow the agents to perceive different possibilities and to assign payoffs differently. For example, if two agents have to jointly agree on what to do with their money in the example above, we could assume that one of them perceives only rain versus no rain, while the other perceives only revolution versus no revolution.

While such a model can be useful for some purposes, it does not appear useful for studying the kinds of issues mentioned in my opening paragraph. To see this, note that the default approach of Modica, Rustichini and Tallon (1998) is identical to a model where the states (rain, revolution) and (no rain, revolution) have zero probability. While other values of $x$ and $x'$ are not as directly interpreted, again, the model is identical to one where the agent believes a revolution is impossible (and may have ‘incorrect’ beliefs about his payoffs). As argued above, if ‘unforeseen’ is taken to mean ‘zero probability’, then short-term contracts do not have foreseeability advantages over long-term contracts. Hence, at least for the purposes of studying the trade-off between short-term and long-term contracts, this model of decision-making does not appear to be useful.

Part of what this approach omits is recognition by an agent that his conception of the world is incomplete. Intuitively, what we need to understand the postulated trade-off between short-term and long-term contracts is a recognition by the agent that his conception of what the world will be like in 2016 will be clearer in 2015 than in 2006.

To state this more concretely in the context of the example, the agent might perceive only the possibility of rain versus no rain, but understand that this omits many currently unforeseen possibilities. How might we represent such a situation? One approach is to separate the agent's uncertainty about what events may occur in the world from his uncertainty about what his payoff will be given a particular action. In the story above, we said that the agent's payoff to investing depends on whether it rains and whether there is revolution. Presumably, the agent does not care about rain or revolution per se but instead cares about what utility or payoff he receives. That is, the ‘states’ as the agent perceives them may be more usefully thought of statements about what payoff the agent gets from each action. In the example, then, any vector...
of three numbers (giving the payoffs to the three actions in some order) could be a ‘state’. Table 3 shows one possible representation along this line.

Perceived payoffs, version 2

<table>
<thead>
<tr>
<th>Subjective state</th>
<th>Perceived payoff if buy</th>

<td>−10</td>
</tr>
</tbody>
</table>

The subjective states (rain, 1) and (rain, 2) represent the agent's uncertainty about the payoffs to investing when the only objective uncertainty he can think of (rain versus no rain) is resolved in favour of rain. This idea also appears in various forms in the literature. Fishburn (1970) includes an early statement of the idea and more involved treatments appear in Ghirardato (2001), Kreps (1979; 1992), Dekel, Lipman and Rustichini (2001), Halpern and Rêgo (2006) (embodied in their ‘virtual moves’), and Epstein, Marinacci, and Seo (2007), among others. Some of these models (for example, Kreps or Dekel, Lipman, and Rustichini) use expected utility over these ‘states’, while others (for example, Ghirardato or Epstein, Marinacci, and Seo) use models of agents who are uncertainty averse with respect to what the ‘right’ payoff is.

At first glance, this approach appears to be capable of generating a model we could use for the purposes of interest. In fact, this model looks very similar to the ‘observable but unverifiable’ uncertainty story used by Grossman and Hart (1986), Hart and Moore (1988), and Hart (1995) to model incomplete contracts. For brevity, I henceforth refer to this as the GHM approach. This approach assumes that some of the variables relevant to the contracting parties are observed by them but cannot be ‘shown’ to a court. As a result, the parties cannot, according to this approach, contract on these variables because a dispute about their realizations cannot be settled by the court. (These papers often also use the assumption that certain actions are indescribable, but this aspect of the GHM approach is not relevant here.) Hence contracts can only allocate control rights – that is, assign the rights to make various decisions ex post. Intuitively, if some variables cannot be contracted on, one has to rely on the parties to choose appropriately in the relevant contingencies.

Similarly, it seems natural to assume that these subjective states cannot be contracted over. If a ‘state’ is simply a specification of a utility function for each agent as a function of the actions, how can such a state be verified? Thus the GHM approach appears to fit naturally with this approach to modelling unforeseen contingencies.

To be more concrete, consider again the trade-off between short-term and long-term contracts. It seems natural to assume that the set of subjective states for a period far in the future is larger than the set for a period closer to the present. In this sense, any contract regarding a distant period cannot be as ‘fine tuned’ as a contract for a close period. This will naturally give a trade-off between the value of contracting far in advance and the value of contracting once the parties know more, and so can contract better.

To be still more explicit, suppose the table above gives the subjective state space. Suppose that if the agents write a long-term contract today, it can only specify an outcome as a function of whether it rains or not. On the other hand, assume that they expect that if they wait and write a contract at a later date, they will learn whether the ‘correct’ state space is \{(rain, 1), \text{(no rain, 1)}\} or \{(rain, 2), \text{(no rain, 2)}\}. Thus a
contract written later will not share risk as well, but can specify the outcomes given rain and no rain more efficiently.

Unfortunately, the work of Maskin and Tirole (1999) calls this conclusion into doubt. They show that observable but unverifiable variables (and indescribable actions) do not justify a departure from standard contract theory. More specifically, even with observable but unverifiable variables, a mechanism can be designed that will induce the parties to reveal to the court what the values of the unverifiable variables are. Thus the fact that they cannot *prove* these facts to the court is not a problem since the court knows they will tell the truth.

Given the similarity to GHM, this suggests that the above model of unforeseen contingencies may not yield results different from standard contract theory either. In terms of the example above, the agents might be able to set up a mechanism that effectively enables them to write a contract specifying different outcomes in the subjective states (rain, 1) and (rain, 2). If so, there cannot be any gain in waiting.

In principle, there are ways one could introduce more realism to the Maskin–Tirole framework and overturn their conclusion. For example, they suggest that bounded rationality may imply that the agents do not understand and so cannot use the complex mechanisms needed to enforce truth telling. On the other hand, it seems surprising that considerations other than unforeseen contingencies would be needed to generate something different from standard contract theory. Maskin and Tirole do not allow the kind of aversion to payoff uncertainty present in Epstein, Marinacci, and Seo, so this is another direction that may be fruitful.

In short, unforeseen contingencies appear to be important to understanding economic and political institutions but, as yet, economic theory lacks a formal model of the phenomenon that can be used to study these issues.

Models with autoregressive unit roots play a major role in modern time series analysis and are especially important in macroeconomics, where questions of shock persistence arise, and in finance, where martingale concepts figure prominently in the study of efficient markets. The literature on unit roots is vast and applications of unit root testing span the social, environmental and natural sciences. The present article overviews the theory and concepts that underpin this large field of research and traces the originating ideas and econometric methods that have become central to empirical practice.
where $\varepsilon_t$ is an orthogonal sequence (that is, $E(\varepsilon_t)=0$, $E(\varepsilon_t\varepsilon_s)=0$ for all $t \neq s$), $L$ is the backshift operator for which $Ly_t = y_{t-1}$ and $a(L)$, $b(L)$ are finite-order lag polynomials

$$a(L) = \sum_{j=0}^{p} a_j L^j, \quad b(L) = \sum_{j=0}^{q} b_j L^j,$$

whose leading coefficients are $a_0 = b_0 = 1$. Parsimonious schemes (often with $p+q \leq 3$) are usually selected in practice either by informal ‘model identification’ processes such as those described in the text by Box and Jenkins (1976) or more formal order-selection criteria which penalize choices of large $p$ and/or $q$. Model (1) is assumed to be irreducible, so that $a(L)$ and $b(L)$ have no common factors. The model (1) and the time series $y_t$ are said to have an autoregressive unit root if $a(L)$ factors as $(1-L)a_1(L)$ and a moving-average unit root if $b(L)$ factors as $(1-L)b_1(L)$.

Since the early 1980s, much attention has been focused on models with autoregressive unit roots. In part, this interest is motivated by theoretical considerations such as the importance of martingale models of efficient markets in finance and the dynamic consumption behaviour of representative economic agents in macroeconomics; and, in part, the attention is driven by empirical applications, which have confirmed the importance of random walk phenomena in practical work in economics, in finance, in marketing and business, in social sciences like political studies and communications, and in certain natural sciences. In mathematics and theoretical probability and statistics, unit roots have also attracted attention because they offer new and important applications of functional limit laws and weak convergence to stochastic integrals. The unit root field has therefore drawn in participants from an excitingly wide range of disciplines.

If (1) has an autoregressive unit root, then we may write the model in difference form as

$$\Delta y_t = u_t = a_1(L)^{-1} b(L) \varepsilon_t,$$

where the polynomial $a_1(L)$ has all its zeros outside the unit circle. This formulation suggests more general nonparametric models where, for instance, $u_t$ may be formulated in linear process (or Wold representation) form as
or as a general stationary process with spectrum \( f_u(\lambda) \). If we solve (2) with an initial state \( y_0 \) at \( t=0 \), we have the important partial sum representation

\[
    y_t = \sum_{j=1}^{t} u_j + y_0 = S_t + y_0,
\]

(4)

showing that \( S_t \) and hence \( y_t \) are ‘accumulated’ or ‘integrated’ processes proceeding from a certain initialization \( y_0 \). A time series \( y_t \) that satisfies (2) or (4) is therefore said to be integrated of order one (or a unit root process or an I(1) process) provided \( f_u(0)>0 \). The latter condition rules out the possibility of a moving-average unit root in the model for \( u_t \) that would cancel the effect of the autoregressive unit root (for example, if \( b(L)=(1-L)b_1(L) \) then model (2) is \( \Delta y_t=\Delta a_1(L)^{-1}b_1(L)\varepsilon_t \), or, after cancellation, just \( y_t=a_1(L)^{-1}b_1(L)\varepsilon_t \), which is not I(1)). Note that this possibility is also explicitly ruled out in the ARMA case by the requirement that \( a(L) \) and \( b(L) \) have no common factors. Alternatively, we may require that \( u_t \neq \Delta v_t \) for some weakly stationary time series \( v_t \), as in Leeb and Pötscher (2001) who provide a systematic discussion of I(1) behaviour. The partial sum process \( S_t \) in (4) is often described as a stochastic trend.

The representation (4) is especially important because it shows that the effect of the random shocks \( u_j \) on \( y_t \) does not die out as the time distance between \( j \) and \( t \) grows large. The shocks \( u_j \) then have a persistent effect on \( y_t \) in this model, in contrast to stationary systems. Whether actual economic time series have this characteristic or not is, of course, an empirical issue. The question can be addressed through statistical tests for the presence of a unit root in the series, a subject which has grown to be of major importance since the mid-1980s and which will be discussed later in this article. From the perspective of economic modelling the issue of persistence is also important because, if macroeconomic variables like real GNP have a unit root, then shocks to real GNP have permanent effects, whereas in traditional business cycle theory the effect of shocks on real GNP is usually considered to be only temporary. In more recent real business cycle theory, variables like real GNP are modelled in such a way that over the long run their paths are determined by supply side shocks that can be ascribed to technological and demographic forces from outside the model. Such economic models are more compatible with the statistical model (4) or close approximations to it in which the roots are local to unity in a sense that is described later in this essay.
Permanent and transitory effects in \( (4) \) can be distinguished by decomposing the process \( u_t \) in \( (3) \) as follows

\[
    u_t = \{C(1) + (L - 1)\hat{C}(L)\}\varepsilon_t = C(1)\varepsilon_t + \hat{\xi}_{t-1} - \hat{\xi}_t,
\]

where \( \hat{\xi}_t = \hat{C}(L)\varepsilon_t, \hat{C}(L) = \sum_0^\infty \gamma_j L^j \) and \( \gamma_j = \sum_{j=1}^\infty \xi_j \). The decomposition \( (5) \) is valid algebraically if

\[
    \sum_{j=0}^\infty j^{1/2}|\gamma_j| < \infty,
\]

as shown in Phillips and Solo (1992), where validity conditions are systematically explored. Equation \( (5) \) is sometimes called the Beveridge–Nelson (1981) or BN decomposition of \( u_t \), although both specialized and more general versions of it were known and used beforehand. The properties of the decomposition were formally investigated and used for the development of laws of large numbers and central limit theory and invariance principles in the paper by Phillips and Solo (1992). When the decomposition is applied to \( (4) \) it yields the representation

\[
    y_t = C(1)\sum_{1}^{t}\varepsilon_j + \hat{\xi}_0 - \hat{\xi}_t + y_0 = C(1)\sum_{1}^{t}\varepsilon_j + \xi_t + y_0, \text{ say,}
\]

where \( \xi_t = \hat{\xi}_0 - \hat{\xi}_t \). The right side of \( (7) \) decomposes \( y_t \) into three components: the first is a martingale component, \( y_t = C(1)\sum_{1}^{t}\varepsilon_j \), where the effects of the shocks \( \varepsilon_j \) are permanent; the second is a stationary component, where the effects of shocks are transitory, viz. \( \xi_t = \hat{\xi}_0 - \hat{\xi}_t \), since the process \( \hat{\xi}_t \) is stationary with valid Wold representation \( \hat{\xi}_t = \hat{C}(L)\varepsilon_t \) under \( (6) \) when \( \varepsilon_j \) is stationary with variance \( \sigma^2 \); and the third being the initial condition \( y_0 \). The relative strength of the martingale component is measured by the magnitude of the (infinite dimensional) coefficient \( C(1) = \sum_{j=0}^\infty \xi_j \), which plays a large role in the measurement of long-run effects in applications. Accordingly, the decomposition \( (7) \) is
sometimes called the martingale decomposition (cf., Hall and Heyde, 1980) where it was used in various forms in the probability literature prior to its use in economics.

The leading martingale term \( Y_t = \mathcal{C}(1) \sum_{s=1}^{t} \varepsilon_s \) in (7) is a partial sum process or stochastic trend and, under weak conditions on \( \varepsilon_t \) (see Phillips and Solo, 1992, for details) this term satisfies a functional central limit theorem whereby the scaled process

\[
n^{-1/2} Y_{[nr]} \Rightarrow B(r),
\]

(8)

a Brownian motion with variance \( \omega^2 = \mathcal{C}(1)^2 \sigma^2 = 2 \pi f \mathcal{u}(0) \), a parameter which is called the long-run variance of \( u_t \), and where \([·]\) signifies the integer part of its argument. Correspondingly,

\[
n^{-1/2} Y_{[nr]} \Rightarrow B(r),
\]

(9)

provided \( V_0 = 0 \rho(\sqrt{n}) \). A related result of great significance is based on the limit

\[
n^{-1} \sum_{t=1}^{[nr]} Y_{t-1} \varepsilon_t \mathcal{C}(1) \Rightarrow \int_0^r BdB
\]

(10)

of the sample covariance of \( Y_{t-1} \) and its forward increment, \( \mathcal{C}(1) \varepsilon_t \). The limit process \( M(r) = \int_0^r BdB \) is represented here as an Ito (stochastic) integral and is a continuous time martingale. The result may be proved directly (Solo, 1984; Phillips, 1987a; Chan and Wei, 1988) or by means of martingale convergence methods (Ibragimov and Phillips, 2004) which take advantage of the fact that \( \sum_{t=1}^{k} Y_{t-1} \varepsilon_t \) is a martingale. The limit theory given (9) and (10) was extended in Phillips (1987b; 1988a) and Chan and Wei (1987) to cases where the model (2) has an autoregressive root in the vicinity of unity ( \( \rho = 1 + \frac{c}{n} \), for some fixed \( c \)) rather than precisely at unity, in which case the limiting process is a linear diffusion (or Ornstein–Uhlenbeck process) with parameter \( c \). This limit theory has proved particularly useful in the analysis of asymptotic local power functions of unit root tests (Phillips, 1987b) and the
unit roots: The New Palgrave Dictionary of Economics

deviations from unity of the form \( \rho = 1 + \frac{c}{k} \), where \( k \to \infty \) but \( \frac{k}{n} \to 0 \), so that the roots are local but
further away from unity, showing that central limit laws rather than functional laws apply in this case
(see also Giraitis and Phillips, 2006). This theory is applicable to mildly explosive processes (where \( c > 0 \)) and therefore assists in bridging the gap between the limit theory for the stationary, unit root and
explosive cases.

Both (8) and (10) have important multivariate generalizations that play a critical role in the study of
spurious regressions (Phillips, 1986) and cointegration limit theory (Phillips and Durlauf, 1986; Engle
and Granger, 1987; Johansen, 1988; Phillips, 1988a; Park and Phillips, 1988; 1989). In particular, if
\( \mathbf{Y}_t = (\mathbf{y}'_t, \mathbf{y}'_t) \), \( \mathbf{u}_t = (\mathbf{u}'_t, \mathbf{u}'_t) \) and \( \mathbf{\epsilon}_t = (\mathbf{\epsilon}'_t, \mathbf{\epsilon}'_t) \) are vector processes and \( E(\mathbf{\epsilon}_t \mathbf{\epsilon}'_t) = \mathbf{\Sigma} \), then: (i) the
decomposition (5) continues to hold under (6), where \( |c_j| \) is interpreted as a matrix norm; (ii) the
functional law (8) holds and the limit process is vector Brownian motion \( \mathbf{B} = (B'_a, B'_b)' \) with covariance
matrix \( \mathbf{\Omega} = \mathbf{C}(1) \mathbf{\Sigma} \mathbf{C}(1)' \); and (iii) sample covariances converge weakly to stochastic processes with
drift, as in

\[
n^{-1} \sum_{t=1}^{n} \mathbf{Y}_t \mathbf{u}'_t = \int_0^t \mathbf{B}_a d\mathbf{B}_b' + \mathbf{\lambda}_{ab}' t,
\]

where \( \lambda_{ab} = \sum_{k=1}^{\infty} E(\mathbf{u}_a t \mathbf{u}_b)' \) is a one sided long-run covariance matrix. The limit process on the right
side of (11) is a semimartingale (incorporating a deterministic drift function \( \lambda_{ab}' t \)) rather than a
martingale when \( \lambda_{ab} \neq 0 \).

The decomposition (7) plays an additional role in the study of cointegration (Engle and Granger, 1987).

When the coefficient matrix \( \mathbf{C}(1) \) is singular and \( \mathbf{\beta}' \) spans the null space of \( \mathbf{C}(1)' \), then \( \mathbf{\beta}' \mathbf{C}(1) = 0 \) and
(7) leads directly to the relationship

\[
\mathbf{\beta}' \mathbf{Y}_t = 0, \text{ a.s.},
\]

which may be interpreted as a long run equilibrium (cointegrating) relationship between the stochastic
trends \( (\mathbf{Y}_t) \) of \( \mathbf{y}_t \). Correspondingly, we have the empirical cointegrating relationship
among the observed series $y_t$ with a residual $\nu_t = \beta' (\xi_t + \nu_0)$ that is stationary. The columns of $\beta$ span what is called the cointegration space.

The above discussion presumes that the initialization $y_0$ has no impact on the limit theory, which will be so if $y_0$ is small relative to the sample size, specifically, if $\nu_0 = O_p(\sqrt{n})$. However, if $\nu_0 = O_p(\sqrt{n})$, for example if $\nu_0 = \nu_0 \theta_n$ is indexed to depend on past shocks $u_{-j}$ (satisfying a process of the form (3)) to some point in the distant past $\theta_n$ which is measured in terms of the sample size $n$, then the results can differ substantially. Thus, if $\theta_n = [\kappa \ n]$, for some fixed parameter $\kappa > 0$, then $\nu_0 \theta_n = \sum_1^{[\kappa n]} u_{-j}$, and

$$n^{-1/2} \nu_0 \theta_n = B_0(\kappa),$$

for some Brownian motion $B_0(\kappa)$ with covariance matrix $\Omega_{00}$ given by the long-run variance matrix of $u_{-j}$. Under such an initialization, (9) and (11) are replaced by

$$n^{-1/2} \nu_r = B(r) + B_0(\kappa) = B(r, \kappa), \quad \text{say}$$

(12)

and

$$n^{-1} \sum_{t=1}^{[nr]} \nu_{at-1} u_{bt}' = \int_0^r B_a(s, \kappa) dB_b(s)' + \lambda_{abr},$$

so that initializations play a role in the limit theory. This role becomes dominant when $\kappa$ becomes very large, as is apparent from (12). The effect of initial conditions on unit root limit theory was examined in simulations by Evans and Savin (1981; 1984), by continuous record asymptotics by Phillips (1987a), in the context of power analysis by Müller and Elliott (2003), for models with moderate deviations from unity by Andrews and Guggenberger (2006), and for cases of large $\kappa$ by Phillips (2006).

Model (4) is of special interest to economists working in finance because its output, $y_t$, behaves as if it has no fixed mean and this is a characteristic of many financial time series. If the components $u_j$ are independent and identically distributed (i.i.d.) then $y_t$ is a random walk. More generally, if $u_j$ is a martingale difference sequence (mds) (that is orthogonal to its own past history so that $E_j-1(u_j) = E(u_j | u_{j-1}, u_{j-2}, \ldots, u_1) = 0$) then $y_t$ is a martingale. Martingales are the essential
mathematical elements in the development of a theory of fair games and they now play a key role in the mathematical theory of finance, exchange rate determination and securities markets. Duffie (1988) provides a modern treatment of finance that makes extensive use of this theory.

In empirical finance much attention has recently been given to models where the conditional variance $E(u_j^2 | u_{j-1}, u_{j-2}, \ldots, u_1) = \sigma_j^2$ is permitted to be time varying. Such models have been found to fit financial data well and many different parametric schemes for $\sigma_j^2$ have been devised, of which the ARCH (autoregressive conditional heteroskedasticity) and GARCH (generalized ARCH) models are the most common in practical work. These models come within the general class of models like (1) with mds errors. Some models of this kind also allow for the possibility of a unit root in the determining mechanism of the conditional variance $\sigma_j^2$ and these are called integrated conditional heteroskedasticity models. The IGARCH (integrated GARCH) model of Engle and Bollerslev (1986) is an example, where for certain parameters $\omega \geq 0$, $\beta \geq 0$, and $\alpha > 0$, we have the specification

$$
\sigma_j^2 = \omega + \beta \sigma_{j-1}^2 + \alpha u_{j-1}^2,
$$

(13)

with $\alpha + \beta = 1$ and $u_j = \sigma_j z_j$, where the $z_j$ are i.i.d. innovations with $E(z_j) = 0$ and $E(z_j^2) = 1$. Under these conditions, the specification (13) has the alternative form

$$
\sigma_j^2 = \omega + \sigma_{j-1}^2 + \alpha \sigma_{j-1}^2 (z_{j-1}^2 - 1),
$$

(14)

from which it is apparent that $\sigma_j^2$ has an autoregressive unit root. Indeed, since

$$
E(\sigma_j^2 | \sigma_{j-1}^2) = \omega + \sigma_{j-1}^2,
$$

$\sigma_j^2$ is a martingale when $\omega = 0$. It is also apparent from (14) that shocks as manifested in the deviation $z_{j-1}^2 - 1$ are persistent in $\sigma_j^2$. Thus, $\sigma_j^2$ shares some of the characteristics of an I(1) integrated process.
But in other ways, \( \sigma_j^2 \) is very different. For instance, when \( \omega = 0 \) then \( \sigma_j^2 \to 0 \) almost surely as \( j \to \infty \) and, when \( \omega > 0 \), \( \sigma_j^2 \) is asymptotically equivalent to a strictly stationary and ergodic process. These and other features of models like (13) for conditional variance processes with a unit root are studied in Nelson (1990).

In macroeconomic theory also, models such as (2) play a central role in modern treatments. In a highly influential paper, R. Hall (1978) showed that under some general conditions consumption is well modelled as a martingale, so that consumption in the current period is the best predictor of future consumption, thereby providing a macroeconomic version of the efficient markets hypothesis. Much attention has been given to this idea in subsequent empirical work.

One generic class of economic model where unit roots play a special role is the 'present value model' of Campbell and Shiller (1988). This model is based on agents’ forecasting behaviour and takes the form of a relationship between one variable \( Y_t \) and the discounted, present value of rational expectations of future realizations of another variable \( X_{t+i} \) (\( i=0,1,2,\ldots \)). More specifically, for some stationary sequence \( c_t \) (possibly a constant) we have

\[
Y_t = \theta (1 - \delta) \sum_{i=0}^{\infty} \delta^i E_t(X_{t+i}) + c_t.
\]

(15)

When \( X_t \) is a martingale, \( E_t(X_{t+i}) = X_t \) and (15) becomes

\[
Y_t = \theta X_t + c_t,
\]

(16)

so that \( Y_t \) and \( X_t \) are co-integrated in the sense of Engle and Granger (1987). More generally, when \( X_t \) is I(1) we have

\[
Y_t = \theta X_t + \bar{c}_t,
\]

(17)

where \( \bar{c}_t = c_t + \theta \sum_{k=1}^{\infty} \delta^k E_t(\Delta X_{t+k}) \), so that \( Y_t \) and \( X_t \) are also co-integrated in this general case.
Models of this type arise naturally in the study of the term structure of interest rates, stock prices and dividends and linear-quadratic intertemporal optimization problems.

An important feature of these models is that they result in parametric linear cointegrating relations such as (16) and (17). This linearity in the relationship between $Y_t$ and $X_t$ accords with the linear nature of the partial sum process that determines $X_t$ itself, as seen in (4), and has been extensively studied since the mid-1980s. However, in more general models, economic variables may be determined in terms of certain nonlinear functions of fundamentals. When these fundamentals are unit root processes like (4), then the resulting model has the form of a nonlinear cointegrating relationship. Such models are relevant, for instance, in studying market interventions by monetary and fiscal authorities (Park and Phillips, 2000; Hu and Phillips, 2004) and some of the asymptotic theory for analysing parametric models of this type and for statistical inference in such models is given in Park and Phillips (1999; 2001), de Jong (2004), Berkes and Horváth (2006) and Pötscher (2004). More complex models of this type are nonparametric and different methods of inference are typically required with very different limit theories and typically slower convergence rates (Karlsten, Myklebust, and Tjøstheim, 2007; Wang and Phillips, 2006). Testing for the presence of such nonlinearities can therefore be important in empirical practice (Hong and Phillips, 2005; Kasparis, 2004).

Statistical tests for the presence of a unit root fall into the general categories of classical and Bayesian, corresponding to the mode of inference that is employed. Classical procedures have been intensively studied and now occupy a vast literature. Most empirical work to date has used classical methods but some attention has been given to Bayesian alternatives and direct model selection methods. These approaches will be outlined in what follows.

Although some tests are known to have certain limited (asymptotic) point optimality properties, there is no known procedure which uniformly dominates others, even asymptotically. Ploberger (2004) provides an analysis of the class of asymptotically admissable tests in problems that include the simplest unit root test, showing that the conventional likelihood ratio (LR) test (or Dickey–Fuller, 1979; 1981, $t$ test) is not within this class, so that the LR test, while it may have certain point optimal properties, is either inadmissible or must be modified so that it belongs to the class. This fundamental difficulty, together with the nonstandard nature of the limit theory and the more complex nature of the asymptotic likelihood in unit root cases partly explains why there is such a proliferation of test procedures and simulation studies analysing performance characteristics in the literature.

Classical tests for a unit root may be classified into parametric, semiparametric and nonparametric categories. Parametric tests usually rely on augmented regressions of the type

$$
\Delta y_t = \Delta y_{t-1} + \sum_{i=1}^{k-1} \phi_i \Delta y_{t-i} + \epsilon_t,
$$

where the lagged variables are included to model the stationary error $u_t$ in (2). Under the null hypothesis
of a unit root, we have $a=0$ in (18) whereas when $y_t$ is stationary we have $a<0$. Thus, a simple test for the presence of a unit root against a stationary alternative in (18) is based on a one-sided $t$-ratio test of $H_0: a = 0$ against $H_1: a < 0$. This test is popularly known as the ADF (or augmented Dickey–Fuller) test (Said and Dickey, 1984) and follows the work of Dickey and Fuller (1979; 1981) for testing Gaussian random walks. It has been extensively used in empirical econometric work since the Nelson and Plosser (1982) study, where it was applied to 14 historical time series for the USA leading to the conclusion that unit roots could not be rejected for 13 of these series (all but the unemployment rate). In that study, the alternative hypothesis was that the series were stationary about a deterministic trend (that is, trend stationary) and therefore model (18) was further augmented to include a linear trend, viz.

$$
\Delta y_t = \mu + \beta t + ay_{t-1} + \sum_{i=1}^{k-1} \phi_i \Delta y_{t-i} + \epsilon_t.
$$

When $y_t$ is trend stationary we have $a<0$ and $\beta \neq 0$ in (19), so the null hypothesis of a difference stationary process is $a=0$ and $\beta = 0$. This null hypothesis allows for the presence of a non-zero drift in the process when the parameter $\mu \neq 0$. In this case a joint test of the null hypothesis $H_0: a = 0, \beta = 0$ can be mounted using a regression $F$-test. ADF tests of $a=0$ can also be mounted directly using the coefficient estimate from (18) or (19), rather than its $t$ ratio (Xiao and Phillips, 1998).

What distinguishes both these and other unit root tests is that critical values for the tests are not the same as those for conventional regression $F$- and $t$-tests, even in large samples. Under the null, the limit theory for these tests is nonstandard and involves functionals of a Wiener process. Typically, the critical values for five or one per cent level tests are much further out than those of the standard normal or chi-squared distributions. Specific forms for the limits of the ADF $t$-test ($ADF_t$) and coefficient ($ADF_a$) test are

$$
ADF_t \Rightarrow \frac{\int_0^1 WdW}{\left(\int_0^1 W^2\right)^{1/2}}, \quad ADF_a \Rightarrow \frac{\int_0^1 WdW}{\int_0^1 W^2},
$$

where $W$ is a standard Wiener process or Brownian motion with variance unity. The limit distributions represented by the functionals (20) are known as unit root distributions. The limit theory was first explored for models with Gaussian errors, although not in the Wiener process form and not using functional limit laws, by Dickey (1976), Fuller (1976) and Dickey and Fuller (1979; 1981), who also provided tabulations. For this reason, the distributions are sometimes known as Dickey–Fuller
unit roots. The New Palgrave Dictionary of Economics
distributions. Later work by Said and Dickey (1984) showed that, if the lag number \( k \) in (18) is allowed to increase as the sample size increases with a condition on the divergence rate that \( k = o(n^{1/3}) \), then the ADF test is asymptotically valid in models of the form (2) where \( u_t \) is not necessarily autoregressive.

Several other parametric procedures have been suggested, including Von Neumann ratio statistics (Sargan and Bhargava, 1983; Bhargava, 1986; Stock, 1994a), instrumental variable methods (Hall, 1989; Phillips and Hansen, 1990) and variable addition methods (Park, 1990). The latter also allow a null hypothesis of trend stationarity to be tested directly, rather than as an alternative to difference stationarity. Another approach that provides a test of a null of trend stationarity is based on the unobserved components representation

\[
y_t = \mu + \beta t + r_t + u_t, \quad r_t = r_{t-1} + v_t,
\]

(21)

which decomposes a time series \( y_t \) into a deterministic trend, an integrated process or random walk \((r_t)\) and a stationary residual \((u_t)\). The presence of the integrated process component in \( y_t \) can then be tested by testing whether the variance \((\sigma^2_v)\) of the innovation \( v_t \) is zero. The null hypothesis is then \( H_0: \sigma^2_v = 0 \), which corresponds to a null of trend stationarity. This hypothesis can be tested in a very simple way using the Lagrange multiplier (LM) principle, as shown in Kwiatkowski et al. (1992), leading to a commonly used test known as the KPSS test. If \( \hat{e}_t \) denotes the residual from a regression of \( y_t \) on a deterministic trend (a simple linear trend in the case of (21) above) and \( \omega^e \) is a HAC (heteroskedastic and autocorrelation consistent) estimate constructed from \( \hat{e}_t \), then the KPSS statistic has the simple form

\[
LM = \frac{n^{-2} \sum_{t=1}^{n} S^2_t}{\omega^e},
\]

where \( S_t \) is the partial sum process of the residuals \( \sum_{j=1}^{t} \hat{e}_j \). Under the null hypothesis of stationarity, this LM statistic converges to \( \int_0^1 V^X_x \), where \( V^X_x \) is a generalized Brownian bridge process whose construction depends on the form \((X)\) of the deterministic trend function. Power analysis indicates that test power depends importantly on the choice of bandwidth parameter in HAC estimation and some recent contributions to this subject are Sul, Phillips and Choi (2006) and Müller (2005) and Harris, Leybourne and McCabe (2007). Other general approaches to testing I(0) versus I(1) have been
By combining $r_t$ and $u_t$ in (21) the components model may also be written as

$$y_t = \mu + \beta t + x_t \Delta x_t = ax_{t-1} + \eta_t.$$  

(22)

In this format it is easy to construct an LM test of the null hypothesis that $y_t$ has a stochastic trend component by testing whether $a=0$ in (22). When $a=0$, (22) reduces to

$$\Delta y_t = \beta + \eta_t,$$

(23)

and so the parameter $\mu$ is irrelevant (or surplus) under the null. However, the parameter $\beta$ retains the same meaning as the deterministic trend term coefficient under both the null and the alternative hypothesis. This approach has formed the basis of several tests for a unit root that have been developed (see Bhargava, 1986; Schmidt and Phillips, 1992) and the parameter economy of this model gives these tests some advantage in terms of power over procedures like the ADF in the neighbourhood of the null. This power advantage may be further exploited by considering point optimal alternatives in the construction of the test and in the process of differencing (or detrending) that leads to (23), as pursued by Elliott, Rothenberg and Stock (1995). In particular, note that (23) involves detrending under the null hypothesis of a unit root, which amounts to first differencing, whereas if the root were local to unity, the appropriate procedure would be to use quasi differencing. However, since the value of the coefficient in the locality of unity is unknown (otherwise, there would be no need for a test), it can only be estimated or guessed. The procedure suggested by Elliott, Rothenberg and Stock (1995) is to use a value of the localizing coefficient in the quasi-differencing process for which asymptotic power is calculated by simulation to be around 50 per cent, a setting which depends on the precise model for estimation that is being used. This procedure, which is commonly known as generalized least squares (GLS) detrending (although the terminology is a misnomer because quasi-differencing not full GLS is used to accomplish trend elimination) is then asymptotically approximately point optimal in the sense that its power function touches the asymptotic power envelope at that value. Simulations show that this method has some advantage in finite samples, but it is rarely used in empirical work in practice, partly because of the inconvenience of using specialized tables for the critical values of the resulting test and partly because settings for the localizing coefficient are arbitrary and depend on the form of the empirical model.

Some unit root tests based on standard limit distribution theory have been developed. Phillips and Han
unit roots: The New Palgrave Dictionary of Economics (2008), for example, give an autoregressive coefficient estimator whose limit distribution is standard normal for all stationary, unit root and local to unity values of the autoregressive coefficient. This estimator may be used to construct tests and valid confidence intervals, but tests suffer power loss because the rate of convergence of the estimator is $\sqrt{n}$ uniformly over these parameter values. So and Shin (1999) and Phillips, Park and Chang (2004) showed that certain nonlinear instrumental variable estimators, such as the Cauchy estimator, also lead to $t$-tests for a unit root which have an asymptotic standard normal distribution. Again, these procedures suffer power loss from reduced convergence rates (in this case, $n^{1/4}$), but have the advantage of uniformity and low bias. Bias is a well known problem in autoregressive estimation and many procedures for addressing the problem have been considered. It seems that bias reduction is particularly advantageous in the case of unit root tests in panel data, where cross-section averaging exacerbates bias effects when the time dimension is small. Some simulation and indirect inference procedures for bias removal have been successfully used both in autoregressions (Andrews, 1993; Gouriéroux, Renault and Touzi, 2000) and in panel dynamic models (Gouriéroux, Phillips and Yu, 2006).

Semiparametric unit root tests are among the most commonly used unit root tests in practical work and are appealing in terms of their generality and ease of use. Tests in this class employ nonparametric methods to model and estimate the contribution from the error process $u_t$ in (2), allowing for both autocorrelation and heterogeneity. These tests and the use of functional limit theory methods in econometrics, leading to the limit formulae (20), were introduced in Phillips (1987a). Direct least squares regression on

$$\Delta y_t = ay_{t-1} + u_t$$

(24)

gives an estimate of the coefficient and its $t$-ratio in this equation. These two statistics are then corrected to deal with serial correlation in $u_t$ by employing an estimate of the variance of $u_t$ and its long-run variance. The latter estimate may be obtained by a variety of kernel-type HAC or other spectral estimates (such as autoregressive spectral estimates) using the residuals $\hat{u}_t$ of the OLS regression on (24). Automated methods of bandwidth selection (or order selection in the case of autoregressive spectral estimates) may be employed in computing these HAC estimates and these methods typically help to reduce size distortion in unit root testing (Lee and Phillips, 1994; Stock, 1994a; Ng and Perron, 1995; 2001). However, care needs to be exercised in the use of automated procedures in the context of stationarity tests such as the KPSS procedure to avoid test inconsistency (see Lee, 1996; Sul, Phillips and Choi, 2006).

This semiparametric approach leads to two test statistics, one based on the coefficient estimate, called the $Z(a)$ test, the other based on its $t$-ratio, called the $Z(t)$ test. The limit distributions of these statistics are the same as those given in (20) for the ADF coefficient and $t$-ratio tests, so the tests are asymptotically equivalent to the corresponding ADF tests. Moreover, the local power functions are also
equivalent to those of the Dickey–Fuller and ADF tests, so that there is no loss in asymptotic power from the use of nonparametric methods to address autocorrelation and heterogeneity (Phillips, 1987b). Similar semiparametric corrections can be applied to the components models (21) and (22) leading to generally applicable LM tests of stationarity ($\sigma^2 = 0$) and stochastic trends ($a=0$). The Z tests were extended in Phillips and Perron (1988) and Ouliaris, Park and Phillips (1989) to models with drift, and by Perron (1989) and Park and Sung (1994) to models with structural breaks in the drift or deterministic component. An important example of the latter is the trend function

$$h_t = \sum_{j=0}^{p} f_j t^j + \sum_{j=0}^{p} f_{m,j} t^j, \text{  where } f_{m,j} = \begin{cases} 0 & t \in \{1, \ldots, m\} \\ (t - m)^j & t \in \{m + 1, \ldots, n\} \end{cases}$$

(25)

which allows for the presence of a break in the polynomial trend at the data point $t=m+1$. Collecting the individual trend regressors in (25) into the vector $x_t$, there exists a continuous function $\chi(\tau) = (1, \tau, \ldots, \tau^p)'$ such that $D_n^{-1/2} x_n \rightarrow \chi(\tau)$ as $n \rightarrow \infty$ uniformly in $\tau \in [0,1]$, where $D_n = \text{diag}(1, n, \ldots, n^p)$. If $\mu = \lim_{n \rightarrow \infty} (m/n) > 0$ is the limit of the fraction of the sample where the structural change occurs, then the limiting trend function $X_\mu(\tau)$ corresponding to (25) has a similar break at the point $\mu$. All the unit root tests discussed above continue to apply as given for such broken trend functions with appropriate modifications to the limit theory to incorporate the limit function $X_\mu(\tau)$. Indeed, (25) may be extended further to allow for multiple break points in the sample and in the limit process. The tests may be interpreted as tests for the presence of a unit root in models where broken trends may be present in the data. The alternative hypothesis in this case is that the data are stationary about a broken deterministic trend of degree $p$.

In order to construct unit root tests that allow for breaking trends like (25) it is necessary to specify the break point $m$. (Correspondingly, the limit theory depends on $X_\mu(\tau)$ and therefore on $\mu$.) In effect, the break point is exogenously determined. Perron (1989) considered linear trends with single break points intended to capture the 1929 stock market crash and the 1974 oil price shock in this way. An alternative perspective is that any break points that occur are endogenous to the data and unit root tests should take account of this fact. In this case, alternative unit root tests have been suggested (for example, Banerjee, Lumsdaine and Stock, 1992; Zivot and Andrews, 1992) that endogenize the break point by choosing the value of $m$ that gives the least favourable view of the unit root hypothesis. Thus, if $ADF(m)$ denotes the ADF statistic given by the $t$-ratio for $\alpha$ in the ADF regression (19) with a broken trend function like (25), then the trend break ADF statistic is

$$ADF(\bar{m}) = \min_{m \leq \bar{m}} ADF(m), \text{ where } \bar{m} = [n\mu], \ m = [n\bar{m}],$$
for some $0 < \underline{\mu} < \bar{\mu} < 1$. The limit theory for this trend break $ADF$ statistic is given by

$$ADF(\hat{m}) = \inf_{\mu \in [\underline{\mu}, \bar{\mu}]} \left[ \int_0^1 W_X(\mu) dW \right] \left[ \int_0^1 W_X^2(\mu) \right]^{-1/2},$$

(27)

where $W_X$ is detrended standard Brownian motion defined by $W_X(r) = W(r) - \left[ \int_0^1 W_X \right] \left[ \int_0^1 W_X^2 \right]^{-1/2} X(r)$.

The limit process $X_\mu(r)$ that appears in the functional $W_X^\mu(r)$ is dependent on the trend break point $\mu$ over which the functional is minimized. Similar extensions to trend breaks are possible for other unit root tests and to multiple breaks (Bai, 1997; Bai and Perron, 1998; 2006; Kapetanios, 2005). Critical values of the limiting test statistic (27) are naturally further out in the tail than those of the exogenous trend break statistic, so it is harder to reject the null hypothesis of a unit root when the break point is considered to be endogenous.

Asymptotic and finite sample critical values for the endogenized trend break $ADF$ unit root test are given in Zivot and Andrews (1992). Simulations studies indicate that the introduction of trend break functions leads to further reductions in the power of unit root tests and to substantial finite sample size distortion in the tests. Sample trajectories of a random walk are often similar to those of a process that is stationary about a broken trend for some particular breakpoint (and even more so when several break points are permitted in the trend). So continuing reductions in the power of unit root tests against competing models of this type is to be expected and discriminatory power between such different time series models is typically low. In fact, the limit Brownian motion process in (9) can itself be represented as an infinite linear random combination of deterministic functions of time, as discussed in Phillips (1998), so there are good theoretical reasons for anticipating this outcome. Carefully chosen trend stationary models can always be expected to provide reasonable representations of given random walk or unit root data, but such models are certain to fail in post-sample projections as the post-sample data drifts away from any given trend or broken trend line. Phillips (1998; 2001) explores the impact of these considerations in a systematic way.

From a practical standpoint, models with structural breaks attach unit weight and hence persistence to the effects of innovations at particular times in the sample period. In effect, break models simply dummy out the effects of certain observations by parameterizing them as persistent effects. To the extent that persistent shocks of this type occur intermittently throughout the entire history of a process, these models are therefore similar to models with a stochastic trend. However, if only one or a small number of such breaks occur then the process does have different characteristics from that of a stochastic trend.
In such cases, it is often of interest to identify the break points endogenously and relate such points to institutional events or particular external shocks that are known to have occurred. More general nonparametric tests for a unit root are also possible. These rely on frequency domain regressions on (24) over all frequency bands (Choi and Phillips, 1993). They may be regarded as fully nonparametric because they test in a general way for coherency between the series \( y_t \) and its first difference \( \Delta y_t \). Other frequency domain procedures involve the estimation of a fractional differencing parameter and the use of tests and confidence intervals based on the estimate. The time series \( y_t \) is fractionally integrated with memory parameter \( d \) if \( (1-L)^d y_t = u_t \) and \( u_t \) is a stationary process with spectrum \( f_u(\lambda) \) that is continuous at the origin with \( f_u(0) > 0 \), or a (possibly mildly heterogeneous) process of the form given in (3). Under some rather weak regularity conditions, it is possible to estimate \( d \) consistently by semiparametric methods irrespective of the value of \( d \). Shimotsu and Phillips (2005) suggest an exact local Whittle estimator \( \hat{d} \) that is consistent for all \( d \) and for which

\[
\sqrt{n} (\hat{d} - d) = N(0, \frac{1}{4}),
\]

extending earlier work by Robinson (1995) on local Whittle estimation in the stationary case where \( |d| < 1 \). These methods are narrow band procedures focusing on frequencies close to the origin, so that long run behaviour is captured. The Shimotsu–Phillips estimator may be used to test the unit root hypothesis \( H_0: d = 1 \) against alternatives such as \( H_1: d < 1 \). The limit theory may also be used to construct valid confidence intervals for \( d \).

The \( Z(a) \), \( Z(t) \) and ADF tests are the most commonly used unit root tests in empirical research. Extensive simulations have been conducted to evaluate the performance of the tests. It is known that the \( Z(a) \), \( Z(t) \) and ADF tests all perform satisfactorily except when the error process \( u_t \) displays strong negative serial correlation. The \( Z(a) \) test generally has greater power than the other two tests but also suffers from more serious size distortion. All of these tests can be used to test for the presence of cointegration by using the residuals from a cointegrating regression. Modification of the critical values used in these tests is then required, for which case the limit theory and tables were provided in Phillips and Ouliaris (1990) and updated in MacKinnon (1994).

While the \( Z \) tests and other semiparametric procedures are designed to cope with mildly heterogeneous processes, some further modifications are required when there is systematic time-varying heterogeneity in the error variances. One form of systematic variation that allows for jumps in the variance has the form

\[
\mathbb{E}(\varepsilon_t^2) = \sigma_t^2 = \sigma^2 g\left(\frac{t}{n}\right),
\]

where the variance evolution function \( g\left(\frac{t}{n}\right) \) may be smooth except for simple jump discontinuities at a finite number of points. Such formulations introduce systematic time variation into the errors, so that we may write \( \varepsilon_t = g\left(\frac{t}{n}\right) \eta_t \), where \( \zeta_t \) is a martingale difference sequence with variance \( \mathbb{E} \varepsilon_t^2 = \sigma^2 \). These evolutionary changes then have persistent effects on partial sums of \( \varepsilon_t \), thereby leading to alternate functional laws of the form

\[
n^{-1/2} \gamma_{[nr]} = \int_0^r g(s) \, dB(s),
\]
in place of (8). Accordingly, the limit theory for unit root tests changes and some nonparametric modification of the usual tests is needed to ensure that existing asymptotic theory applies (Beare, 2006) or to make appropriate corrections in the limit theory (Cavaliere, 2004; Cavaliere and Taylor, 2007) so that there is less size distortion in the tests.

An extension of the theory that is relevant in the case of quarterly data is to the seasonal unit root model

\[(1 - L^4) y_t = u_t. \tag{28}\]

Here, the polynomial \(1-L^4\) can be factored as \((1-L)(1+L)(1+L^2)\), so that the unit roots (or roots on the unit circle) in (28) occur at 1, \(-1\), \(i\), and \(-i\), corresponding to the annual \((L=1)\) frequency, the semi-annual \((L=-1)\) frequency, and the quarter and three quarter annual \((L=i, -i)\) frequency respectively. Quarterly differencing, as in (28), is used as a seasonal adjustment device, and it is of interest to test whether the data supports the implied hypothesis of the presence of unit roots at these seasonal frequencies. Other types of seasonal processes, say monthly data, can be analysed in the same way.

Tests for seasonal unit roots within the particular context of (28) were studied by Hylleberg et al. (1990), who extended the parametric ADF test to the case of seasonal unit roots. In order to accommodate fourth differencing, the autoregressive model is written in the new form

\[\Delta_4 y_t = \alpha_1 y_{1t} - 1 + \alpha_2 y_{2t} - 1 + \alpha_3 y_{3t} - 2 + \alpha_4 y_{3t} - 1 + \sum_{i=1}^{P} \phi_i \Delta_4 y_{t-i} + \varepsilon_t, \tag{29}\]

where \(\Delta_4 \equiv 1-L^4\), \(y_{1t} = (1+L)(1+L^2)y_t\), \(y_{2t} = -(1-L)(1+L^2)y_t\), and \(y_{3t} = -(1-L^2)y_t\). The transformed data \(y_{1t}\), \(y_{2t}\), \(y_{3t}\) retain the unit root at the zero frequency (long run), the semi-annual frequency (two cycles per year), and the annual frequency (one cycle per year). When \(\alpha_1 = \alpha_2 = \alpha_3 = \alpha_4 = 0\), there are unit roots at the zero and seasonal frequencies. To test the hypothesis of a unit root \((L=1)\) in this seasonal model, a \(t\)-ratio test of \(\alpha_1 = 0\) is used. Similarly, the test for a semi-annual root \((L=-1)\) is based on a \(t\)-ratio test of \(\alpha_2 = 0\), and the test for an annual root on the \(t\)-ratios for \(\alpha_3 = 0\) or \(\alpha_4 = 0\). If each of the \(\alpha\)'s is different from zero, then the series has no unit roots at all and is stationary. Details of the implementation of this procedure are given in Hylleberg et al. (1990), the limit theory for the tests is developed in Chan and Wei (1988), and Ghysels and Osborne (2001) provide extensive discussion and applications.

Most empirical work on unit roots has relied on classical tests of the type described above. But Bayesian methods are also available and appear to offer certain advantages like an exact finite sample analysis (under specific distributional assumptions) and mass point posterior probabilities for break point
analysis. In addressing the problem of trend determination, traditional Bayes methods may be employed such as the computation of Bayesian confidence sets and the use of posterior odds tests. In both cases prior distributions on the parameters of the model need to be defined and posteriors can be calculated either by analytical methods or by numerical integration. If (18) is rewritten as

$$y_t = \rho y_{t-1} + \sum_{i=1}^{k-1} \phi_i \Delta y_{t-i} + \epsilon_t$$

then the posterior probability of the nonstationary set \(\{\rho \geq 1\}\) is of special interest in assessing the evidence in support of the presence of a stochastic trend in the data. Posterior odds tests typically proceed with ‘spike and slab’ prior distributions (\(\pi\)) that assign an atom of mass such as \(\pi(\rho = 1) = \theta\) to the unit-root null and a continuous distribution with mass \(1 - \theta\) to the stationary alternative, so that \(\pi(-1 < \rho < 1) = 1 - \theta\). The posterior odds then show how the prior odds ratio \(\theta / (1 - \theta)\) in favour of the unit root is updated by the data.

The input of information via the prior distribution, whether deliberate or unwitting, is a major reason for potential divergence between Bayesian and classical statistical analyses. Methods of setting an objective correlative in Bayesian analysis through the use of model-based, impartial reference priors that accommodate nonstationarity are therefore of substantial interest. These were explored in Phillips (1991a), where many aspects of the subject are discussed. The subject is controversial, as the attendant commentary on that paper and the response (Phillips, 1991b) reveal. The simple example of a Gaussian autoregression with a uniform prior on the autoregressive coefficient \(\rho\) and with an error variance \(\sigma^2\) that is known illustrates one central point of controversy between Bayesian and classical inference procedures. In this case, when the prior on \(\rho\) is uniform, the posterior for \(\rho\) is Gaussian and symmetric about the maximum likelihood estimate \(\hat{\rho}\) (Sims and Uhlig, 1991), whereas the sampling distribution of \(\hat{\rho}\) is biased downwards and skewed with a long left-hand tail. Hence, if the calculated value of \(\hat{\rho}\) were found to be \(\hat{\rho} = 1\), then Bayesian inference effectively assigns a 50 per cent posterior probability to stationarity \(\{|\rho| < 1\}\), whereas classical methods, which take into account the substantial downward bias in the estimate \(\hat{\rho}\), indicate that the true value of \(\rho\) is much more likely to be in the explosive region \(\{|\rho| > 1\}\).

Another major point of difference is that the Bayesian posterior distribution is asymptotically Gaussian under very weak conditions, which include cases where there are unit roots (\(\rho = 1\)), whereas classical asymptotics for \(\hat{\rho}\) are non-standard, as in (20). These differences are explored in Kim (1994), Phillips and Ploberger (1996) and Phillips (1996). The unit root case is one of very few instances where Bayesian and classical asymptotic theory differ. The reason for the difference in the unit root case is that Bayesian asymptotics rely on the local quadratic shape of the likelihood and condition on a given trajectory, whereas classical asymptotics rely on functional laws such as (9), which take into account the persistence in unit root data which manifest in the limiting trajectory.
Empirical illustrations of the use of Bayesian methods of trend determination for various macroeconomic and financial time series are given in DeJong and Whiteman (1991a; 1991b), Schotman and van Dijk (1991) and Phillips (1991a; 1992), the latter implementing an objective model-based approach. Phillips and Ploberger (1994; 1996) develop Bayes tests, including an asymptotic information criterion PIC (posterior information criterion) that extends the Schwarz (1978) criterion BIC (Bayesian information criterion) by allowing for potential nonstationarity in the data (see also Wei, 1992). This approach takes account of the fact that Bayesian time series analysis is conducted conditionally on the realized history of the process. The mathematical effect of such conditioning is to translate models such as (30) to a ‘Bayes model’ with time-varying and data-dependent coefficients, that is,

\[ V_{t+1} = \hat{\rho}_t V_t + \sum_{i=1}^{k-1} \hat{\phi}_{it} \Delta V_{t-i} + e_t, \]

where \( \hat{\rho}_t, \hat{\phi}_{it}, i = 1, \ldots, k - 1 \) are the latest best estimates of the coefficients from the data available to point ‘t’ in the trajectory. The ‘Bayes model’ (31) and its probability measure can be used to construct likelihood ratio tests of hypotheses such as the unit root null \( \rho = 1 \), which relate to the model selection criterion PIC. Empirical illustrations of this approach are given in Phillips (1994; 1995).

Nonstationarity is certainly one of the most dominant and enduring characteristics of macroeconomic and financial time series. It therefore seems appropriate that this feature of the data be seriously addressed both in econometric methodology and in empirical practice. However, until the 1980s this was not the case. Before 1980 it was standard empirical practice in econometrics to treat observed trends as simple deterministic functions of time. Nelson and Plosser (1982) challenged this practice and showed that observed trends can be better modelled if one allows for stochastic trends even when there is some deterministic drift. Since their work there has been a continuing reappraisal of trend behaviour in economic time series and substantial development in the econometric methods of nonstationary time series. But the general conclusion that stochastic trends are present as a component of many economic and financial time series has withstood extensive empirical study.

This article has touched only a part of this large research field and traced only the main ideas involved in unit root modelling and statistical testing. This overview also does not cover the large and growing field of panel unit root testing and panel stationarity tests. The reader may consult the following review articles devoted to various aspects of the field for additional coverage and sources: (a) on unit roots: Phillips (1988b), Diebold and Nerlove (1990), Dolado, Jenkinson and Sosvilla-Rivero (1990), Campbell and Perron (1991), Stock (1994b), Phillips and Xiao (1998), and Byrne and Perman (2006); (b) on panel unit roots: Phillips and Moon (1999), Baltagi and Kao (2000), Choi (2001), Hlouskova and Wagner (2006); and (c) special journal issues of the *Oxford Bulletin of Economics and Statistics* (1986; 1992), *the Journal of Economic Dynamics and Control* (1988), *Advances in Econometrics* (1990), *Econometric Reviews* (1992), and *Econometric Theory* (1994).

Economics in the United States before 1885 was not a discipline of credentialed professionals. Its debates were published in political pamphlets and newspaper editorials as well as college textbooks and scholarly treatises. Its principal project was to set the boundaries of a doctrinal system of economic liberalism and determine the appropriate functions of government. The system was characterized by the sanctity of private property, the celebration of individual labour, and the harmony of the economic and moral orders. Those parts of the system that were imported from abroad were adapted, sometimes ingeniously, to economic and political circumstances at home.

Article
Pre-independence to 1820

Before US independence, the middle Atlantic colonies offered more fertile ground than New England or the South for ideas of political economy from Britain and the European Continent to take root. Eighteenth-century Philadelphia was rivalled only by New York and Boston in its population, which
The religious diversity of Pennsylvania promoted tolerance of notions that, especially from the perspective of the New England theocracy, were tainted by deism or secularism. One consequence was a thriving press. Philadelphia, therefore, was the destination of Benjamin Franklin (1706–1790) when he ran away from his printer's apprenticeship in Boston at the age of 17. The many ideas he published in his new situation included his adaptation of the work of Sir William Petty to American commercial policy. Franklin's *A Modest Enquiry Into the Nature and Necessity of a Paper Currency* (1729), following Petty's *Discourse on Political Arithmetic* (1690), emphasized the importance of the quantity of specie in circulation to commercial prosperity, and a favourable balance of trade to the quantity of specie. Beyond Petty, Franklin argued that issuance of paper money would at once substitute for the specie that was then lacking and, by stimulating production and exports, improve the balance of trade – and thereby garner more specie. Paper money, though commonly disdained, could effect a virtuous circle of commercial vitality and specie accumulation.

In 1757, when Franklin was renowned in America and abroad as a scientist and statesman, he was appointed the Pennsylvania Assembly's emissary to the Crown. The governor of the colony had vetoed the issuance of paper money and other fiscal measures desired by the colonists; Franklin was to convey their complaints. Following the onerous internal taxes established by the Stamp Act of 1765 and the import duties of the Townshend Acts of 1767, they would have more cause to complain. The popular response was 'No taxation without representation' coupled with the colonists' mutual agreement to refuse the importation of British goods. Franklin's own response, more nuanced but to the same effect, drew upon the Physiocratic notion of the pre-eminence of agriculture that had been impressed upon him in France by Anne Robert Jacques Turgot. In his *Positions to be Examined, concerning National Wealth* (1769), Franklin explained that trade is fair when both parties know the value of the traded goods, meaning the value of labour embodied in them; and value is most knowable when the goods consist of agriculture, not manufactures, because agriculture is derived more directly from labour. The implication was that by creating a captive market in America for British manufactured goods, Britain was attempting to hoodwink the colonists. The colonists' eschewal of legal British trade and their substitution of smuggled foreign goods, therefore, were justified. Besides, Franklin added, the frugality necessitated by the boycott would make domestic farmers and tradesmen more productive (Dorfman, 1966, vol. 1, 191–3).

While Franklin engaged the political-economic ideas of the Enlightenment in public argument, he also sought to disseminate them in higher education. His Academy of Philadelphia, later to become the University of Pennsylvania, commenced classes in 1751 with a non-sectarian board of trustees, a progressive Scottish cleric as president, and a curriculum including governance and commerce. The institution's secular orientation and curriculum stood in contrast to those of Harvard (1636), the College of William and Mary (1693), and Yale (1701), which were aligned closely with the Congregational or Anglican churches, directed to the training of ministers and missionaries, and uncongenial to the innovations in moral philosophy and legal and commercial thought from Britain and Europe. Even Princeton (1746), Columbia (1754), and Brown (1764), which were intended to embody a new spirit of religious tolerance, succumbed ultimately to a more constrained orthodoxy. Indeed, so too did Franklin's Academy. But the Revolutionary war shook the orthodoxy. Franklin's curricular plan made inroads at William and Mary in 1779 (O’Connor, 1944, pp. 64–6). Bishop James Madison (1749–1812), the
College's president, cousin of the fourth US president, and a man of radical political views notwithstanding his prominence in the Episcopal Church, became America's first teacher of political economy (O'Connor, 1944, pp. 20–1).

Madison is believed to have relied upon Emer de Vattel's *The Law of Nations, or the Principles of Natural Law Applied to the Conduct and to the Affairs of Nations and of Sovereigns* (1758). The book stood out for its maxims of sovereignty more than commercial policy. To Vattel, the sovereignty of the state is inalienable. While in some times and places the head of state may be a prince, nevertheless, ‘the State is not, and can not be, a patrimony’ (1758, pp. 29, 33). The sovereign is obliged to serve the state's interests, not his own. Although they are peripheral, the book also includes chapters on general commerce, the financing of public roads and canals, money and exchange, and commerce between nations. Vattel makes brief but notable mention of the desirability of defraying the expense of roads and canals from the general revenue of the entire nation, and of the ruler's obligation to encourage trade that is beneficial but to restrict that which is hurtful. In the latter category is that ‘ruinous’ trade which results in a negative balance, entailing more gold and silver leaving the country than entering it (1758, pp. 44, 43).

In Vattel's work, the political thought of the enlightenment is bonded to mercantile economic thought. Neither was particularly avant-garde for the 1770s. Thomas Paine (1737–1809) did not steel the colonists’ patriotic will with 25 editions and 150,000 copies of his *Common Sense* (1776) by arguing merely that King George had not fulfilled adequately a sovereign's obligations to his subjects. Paine remonstrated that monarchy yields tyranny and war; only republican government would serve the cause of liberty. The differences of Paine from Vattel in political economy are equally significant. ‘Our plan is commerce,’ Paine declared. It was no time to ponder which particular avenues and products and circumstances of trade were hurtful and which were not; it was time to throw off the commercial shackles of Britain altogether and trade with all the world. ‘Trade flourishes best when it is free’, he continued a short while later, ‘and it is weak policy to attempt to fetter it’ (Paine, 1778, p. 153).

Paine wrote polemics for the literate multitudes. His work was not the stuff of college curricula; Adam Smith's *Wealth of Nations* was fitter for that purpose. Smith exploded the ‘absurd’ balance-of-trade doctrine (Smith, 1789, p. 456), illuminating in more scholarly fashion than did Paine the virtues of commercial freedom, whether international or domestic, and nudging England towards the ‘natural system of perfect liberty and justice’ in the administration of its colonial trade (1789, p. 572). Regarding roads and canals and other means of facilitating commerce, Smith was disinclined to see them financed with the general revenue of the state. More consistent with his system was their financing by tolls or by local or provincial taxes (1789, pp. 682–3). The *Wealth of Nations* was taken up at William and Mary sometime between the mid-1780s and the 1790s. It was read, debated, and absorbed in America several years earlier, however: an edition was published in Philadelphia within a few years of the Revolution (O'Connor, 1944, pp. 21–2).

Questions of foreign trade policy, and the role of the federal government in undertaking public works and institutions for promoting commerce, dominated the economic debate of the early republic. They were argued passionately because it was believed that upon their answers depended not only the nation's prosperity, but its character and survival. Thomas Jefferson (1743–1826) sought free trade between America and Europe less for the goods that Americans could obtain than for the occupations they would undertake in consequence. In his *Notes on the State of Virginia* (1785), Jefferson observed that, if trade
had not been interrupted and manufactures stimulated by the Revolutionary War, Americans in greater numbers would work the land and buy their textiles from abroad. The advantage of making a living from the land lay in the republican virtues that husbandry instilled in the smallholder. ‘Let our workshops remain in Europe’, Jefferson offered; ‘the loss by the transportation of commodities across the Atlantic will be made up in happiness and permanence of government’ (Spiegel, 1960, pp. 42–3).

Alexander Hamilton (1755–1804), Jefferson's ideological rival, did not repudiate the Virginian's vision of the free trade of American agriculture for European manufactures. He just denied that, under the circumstances, it was realizable. The European powers regularly imposed barriers to the importation of American products, and the several American states had little power to persuade or compel them to do otherwise. Hamilton's answer was to change the circumstances of American government. The unlikelihood of the Jeffersonian ideal became an argument for a strong central authority. In Federalist No. 11 (1788), Hamilton argued that adoption of the Constitution would create a central government with the power to bargain for commercial privileges abroad. If instead disunion persisted, ‘we should then be compelled to content ourselves with the first price of our commodities, and to see the profits of our trade snatched from us to enrich our enemies and persecutors.’

Hamilton envisioned a larger manufacturing sector than did Jefferson, but he did not admit that the growth of manufactures would retard agriculture. In his famous Report on Manufactures (1791), composed during his term as the nation's first Secretary of the Treasury, he offered two reasons. First, even if manufactures slowed the extensive cultivation of land, they would ‘promote a more steady and vigorous cultivation of the lands occupied’. Second, manufactures probably would not slow the extensive cultivation of land, anyway. Immigrants drawn to America by manufacturing jobs would eventually leave them for agriculture, attracted by the promise of independent proprietorship of land (Spiegel, 1960, p. 33).

The question that followed was, ‘Will manufacture develop by itself?’ Hamilton thought not. The scarcity of labour, high wages, and lack of capital conspired against American manufacturers. To survive against European competition would be difficult – but not hopeless. Raw materials were more abundant in the United States and, although wages were indeed higher, the greater expense of labour was counterbalanced by the expenses of transportation and customs duties for those who would import foreign goods. The scarcity of capital could be addressed by fostering a banking system and by the Treasury's issuance of debt, which would serve as a form of money. To Hamilton, as to Paine, the business of America was commerce; but Hamilton was not as squeamish as Paine and his ilk, including Jefferson, about using the powers of the newly constituted federal government to build the institutions and infrastructure of commerce and to encourage industries that might otherwise languish.

Hamilton's name was invoked often in ensuing controversies that exercised Americans and their representatives. Among them were questions of the federal government's role in financing ‘internal improvements’, including the national turnpike stretching from the Potomac to the Ohio River, authorized in 1806; the First Bank of the United States, the charter of which expired in 1811; the Second Bank of the United States, the fate of which was decided in the presidential election of 1832; and the ‘American System’ of tariff protection for domestic manufactures, which sparked debate through most of the 19th century. One of the many whom Hamilton inspired was Daniel Raymond (1786–1849), who became in 1820 the first American author of a systematic treatise on political economy.

From 1820 to the Civil War
Raymond penned his *Thoughts on Political Economy* in his free time as an underemployed Baltimore lawyer (Spiegel, 1960, p. 55). His careful definition of national wealth as ‘a capacity for acquiring the necessaries and comforts of life’, not the value of tangible assets, was intended to combat the idea that the United States was wealthy by virtue mainly of its climate, soil, and nearly limitless territory. Raymond argued that other things mattered too, and more: population density, the distribution of private wealth, the capital and technology applied to agriculture, transport, and other industries, and above all ‘the industrious habits of the people’ (Spiegel, 1960, p. 60). The list corresponded closely to the priorities for government action envisioned by Hamilton.

Raymond's distinction in American economics is that he was first in a class, not that he was influential. More credit for influence is due to Mathew Carey (1760–1839), an Irish publisher and controversialist who emigrated to Philadelphia in 1784 and soon re-established himself in the same vocations. On political economy, he wrote prolifically – but not systematically in the manner of Raymond, whose work he sponsored (Spiegel, 1960, p. 55). Carey was concerned mainly with one issue: the tariff. His *Addresses of the Philadelphia Society for the Promotion of National Industry* (1819) responded to the country's financial crisis of 1819 with a call for further tariff protection for domestic industry. Although the tariff bill of 1820 did not pass, the protectionists’ champion in Congress, Henry Clay, acknowledged Carey's importance to the ferment of the tariff of 1824 (Dorfman, 1966, vol. 1, pp. 384, 389–90). Carey's influence was also exercised importantly, if indirectly, through the writings of Friedrich List (1789–1846), the German thinker who was renowned posthumously in his country and abroad for his protectionist ‘national system’ of political economy. List devised his system during a five-year sojourn in Pennsylvania from 1825 to 1830, in which time he became acquainted with Carey's ideas, lent them his own voice and authority, and propagated them through the protectionist periodical, the *National Gazette* (Dorfman, 1966, vol. 2, p. 577).

The protectionist trend in trade policy that gathered strength in the mid-Atlantic states caused alarm in the South. Jacob Newton Cardozo (1786–1873), publisher of Charleston's *Southern Patriot*, addressed the tariff and other questions in light of David Ricardo's system. An American edition of Ricardo's *Principles of Political Economy and Taxation* was published in 1819; another avenue of his large influence was the *Encyclopædia Britannica* article on ‘Political Economy’ by John Ramsay McCulloch, Ricardo's chief expositor in Britain. The article was republished in 1825 with introduction, summary, and annotations by Columbia College's Reverend John McVickar (O’Connor, 1944, p. 136).

Cardozo's *Notes on Political Economy* appeared in 1826. To Cardozo, the unenlightened social arrangements of Europe – above all, impediments to the alienation of land – had obscured to Ricardo what was evident in the United States. In the absence of unwise customs and legislation, rent was never pernicious. Indeed, some payments that were nominally rent, but were really the returns to the ingenuity of the cultivator, were positively benign. Conversely, where rent was pernicious, it was due to legislation that fomented, in one way or another, ‘monopoly’. In the United States, such legislation was the protective tariff. The genius of Cardozo's argument was that indicted protectionism even more forcefully than did Ricardo's system, thereby serving the interests of the cotton-exporting South and the entrepôt of Charleston, while casting Southern landowners in a productive rather than a parasitic role (Dorfman, 1966, vol. 1, pp. 551–66).

Bank regulation and the sustenance of slavery preoccupied the South as much as the bane of
protectionism. The question of greater urgency varied with the occasion. The 1828 ‘Tariff of Abominations’ and the crisis stemming from South Carolina's 'nullification' of the law in 1832 were occasions of substantive political–economic debate – but so was President Jackson's veto, in 1832, of the proposed re-charter of the Second Bank of the United States. While the Democratic and Whig parties agreed that the currency should be convertible for gold, there were large differences between and even within them regarding the appropriate degrees of competition and regulation of banks, especially those involved in issuing currency. They also differed on the function of the Second Bank of the United States as competitor, usurper, and regulator in the domain of private and state banks. Jackson's objection to the Second Bank of the United States was that its shareholders enjoyed a monopoly of the Federal government's bank transactions. Cardozo shared Jackson's anti-monopoly convictions, but appreciated the Bank's potential as a regulator of the note issuance of other banks, and thus of the recurring cycles of credit expansion, inflation, and contraction. Banks of deposit and discount – ‘banking in its legitimate meaning’ – should be subject to free competition, according to Cardozo, but banks of issue should be subject to severe restriction (Leiman, 1966, p. 112). This exception to perfect freedom served, by means of a stable currency, to protect the value of property and promote trade. Cardozo's justified similarly his support for slavery. Abolitionism was a ‘conspiracy against property’, while slavery heightened the United States' comparative advantage in agriculture and its gains from free trade (Leiman, 1966, p. 176–7).

By the 1820s and 30s, the inviolability of property and free trade were touchstones of economic thought not only in the South. In the North, too, notwithstanding its traditional allegiance to Hamiltonian federalism, the ideas had wide currency. Jefferson's Embargo Act of 1807, which prohibited exports in the (disappointed) expectation of compelling Britain and France to rescind their restraints on American trade, provoked ferocious opposition in the Northeast. Ideas of free trade, and economic liberalism more generally, sank their roots, notwithstanding the irony of their having been planted in opposition to one of their leading advocates. William Cullen Bryant (1794–1878), who began in 1826 his life's work as editor of the New York Evening Post, and concurrently one of the nation's most renowned poets and most prominent spokesmen for unfettered commercial freedom, cut his literary and economic teeth during the embargo. The first poem he published as a boy in rural Massachusetts was a widely circulated satire on the subject. ‘In vain Mechanics ply their curious art, / And bootless mourn the interdicted mart’, complained the 13-year-old Bryant. Jefferson's diplomacy, he mocked, ‘His grand ‘restrictive energies’ employs, / And wisely regulating trade – destroys’ (Bryant, 1808).

To gain acceptance in Northern colleges, however, economic liberalism had to be disassociated from French political radicalism and garbed in religious piety. The first event was already accomplished in the mid-1790s, as the enthusiasm of American partisans of the cause of the French Revolution diminished. The second was the outcome of a longer process that started at the same time and gathered momentum as political economy made its way into college curricula as a subject in its own right. Most colleges introduced political economy as such, and explicitly, in the 1820s: although Harvard, Columbia, and Princeton did so between 1817 and 1819, they were followed by Dickinson, Pittsburgh, Bowdoin, Amherst, Yale, Rutgers, the US Military Academy, Geneva (later renamed Hobart), Williams, Dartmouth, Brown, Union, and Hamilton, all in the years 1822 to 1827 (O’Connor, 1944, p. 100). In most cases the favoured text was Jean Baptiste Say's Treatise on Political Economy. Because Say disapproved of several of the social changes in France since the Revolution, he passed the political test. Because he was a protestant Huguenot, he passed the religious one – although it was a close call
The religious test became more stringent in the 1830s. Religious revivals had recurred with varying intensity since the Great Awakening of the 1730s to 1750s, but none since had swept through the country with as much intensity as those commencing in western New York in 1826 and spreading outward, nationwide, through roughly the decade that followed (Cole, 1954, pp. 75–6). ‘Harvests’ of new souls were most bountiful among the middle class and young in small towns and rural areas (Cole, 1954, p. 80). Colleges were especially fertile ground: the demographics were right, and in most cases so too was the geography. College presidents, besides, saw revivals as a way of boosting their institutions’ visibility and prestige. Students and faculty were particularly amenable to the particular character of the Second Great Awakening. In past eras evangelism sought the salvation of the individual; now it sought that of the nation, even the world. The most popular evangelist of the period, Charles Finney, called upon his listeners to strive for temperance, moral reform in general, and the abolition of slavery (Cole, 1954, p. 77). The last of these causes, even within the flock, was controversial. That the awakened moral sensibilities demanded an end to slavery, there was consensus; that they required the North to impose abolition upon an unwilling South, there was not. As evangelical religion asserted itself in the same citadels where political economy was establishing its foothold, the subject required a text reflecting at least the sensibilities, if not always the objectives, of its teachers and students.

That text was *Elements of Political Economy* (1837) by Reverend Francis Wayland (1796–1865), president of Brown University. Wayland, who had already published his *Elements of Moral Science* in 1835, was the exemplary teacher of political economy for two generations of antebellum men. Political economy partook of moral philosophy; the two subjects were taught proximately, but separately, in the students’ junior or senior year. In the *Moral Science* students learned the nature of their moral constitution, including the power and limits of their unaided conscience to discern right from wrong in their private and public conduct. Inasmuch as conscience was limited, there was recourse first to natural religion and finally to revealed religion. Revealed religion was the study of God's word as manifested in the Bible; natural religion was the study of God's design as manifested in the consequences of human behaviour. Taking intemperance as an example, Wayland illustrated that one could survey the vice and poverty that resulted from the consumption of liquor, consider that God has a design relating all causes to their effects, and thereby infer that God's design forbids intemperance ‘as though He had said so by a voice from heaven’ (Wayland, 1837, p. 120). Of course, one could study other sorts of behaviour and their consequences – production, exchange, distribution, and individual and public consumption – and infer God's design therein, too. To do so required another volume: that was the thrust of Wayland's *Political Economy*.

Wayland taught that the economic role of government is ‘to construct the arrangements of society as to give free scope to the laws of Divine Providence’ (O’Connor, 1944, p. 189). Man must be free to produce what he will and dispose of the product as he pleases. International trade should be unencumbered by protective tariffs. Although the incorporation of banks should be made conditional on arrangements to ensure the convertibility of their notes into specie, nobody who is willing to accept the conditions should be refused a bank charter. Poor laws supporting those capable of work were founded on the premise the rich were obliged to support the poor by law instead of by charity, and as such were a violation of property. Combinations of workers, like combinations of capital owners, were oppressive, even tyrannical. All that man required was the right to sell his labour and invest his capital freely.
Legislation granting one party or the other any additional privileges was ‘impolicy’ (Wayland, 1841, pp. 108–23).

As a treatise in political economy, Wayland's book was rivalled, after 1848, by John Stuart Mill's *Principles of Political Economy*. Mill conveyed the requisite ethical tone, if not a religious one, and allowed sufficient qualifications to the cases for free trade and strict constraints on banknote issuance to appeal to a broader swathe of political opinion than did Wayland. But Mill's book was too lengthy to serve as a college text (Dorfman, 1966, vol. 2, p. 710). In that role, Wayland's was unrivalled. The Elements of Political Economy went through no fewer than 24 printings in Boston and New York between 1837 and 1875, with three more in London and a translation to Hawaiian (O'Connor, 1944, p. 174).

For his large readership and his tightly connected system of economic liberty, Wayland has been designated the ‘Ricardo of evangelists’ (Cole, 1954, p. 178). The designation is not, notably, the ‘evangelist of Ricardo’. The last would not apply, for in one crucial respect Wayland was not the system's most fervent expositor. Those who adhered to the doctrine that man's liberty to reap the fruits of his own industry was sacrosanct, and who followed its implications wherever they might lead, found their way in short order to the question of slavery and determined that it could not be countenanced. ‘Free labor’ was their slogan. Wayland did not travel with them so far: he was silent on the slavery question for the better part of a generation. He believed that the Constitution left slavery a matter for states to decide (Dorfman, 1966, vol. 1, p. 760) – but even as a matter of state law, Wayland was not exercised by the subject.

The Reverend Joshua Leavitt (1794–1873) proselytized a more thoroughgoing interpretation of the free labour doctrine. In the same year that Wayland first published the *Elements of Political Economy*, Leavitt became editor of the *Emancipator*, an organ urging free trade, cheap postage, temperance, and above all, the demise of slavery by political action. The *Emancipator* also advocated the election of James G. Birney of the newly formed Liberty Party as President of the United States in 1840 and 1844 (Cole, 1954, p. 40). Although the Liberty Party was ineffectual and Birney unsuccessful, Leavitt's periodical and the presidential campaigns it championed marked the beginnings of a longer effort. Its objectives were at once to intensify opposition to slavery and to peel the opponents’ support away from the dominant Whig and Democratic parties.

The effort began to show effects once the Liberty Party was eclipsed by the Free Soil Party in 1848 and 1852. Northern ‘Barnburner’ Democrats, who sided with the majority of their party in opposition to the protective tariff, national bank, and internal improvements, but disfavoured its pro-slavery orientation, drifted towards the Free Soilers. So did radical ‘Conscience Whigs’, who could not abide their own party's concessions to the Slave Power. In the run-up to the election of 1852, while Democrats were able temporarily to quell their internal conflict, the cleavage among Whigs widened. The radicals demanded political abolition; the conservative ‘Cotton Whigs’, who represented the party's manufacturing constituency, were loath to disrupt commerce (and the Northern mills’ supply of southern cotton) by fuelling the sectional conflict. The rancour contributed to the Whigs' loss of the presidency. At that moment, the urgency for conservatives to answer the articulation of the free labour doctrine to political abolition was manifest.

The task was delicate: the Whig party cast itself as a friend of labour and opponent of slavery. The tariff, a central plank in its platform, had long been promoted by Whig icons such as Henry Clay and Daniel
Webster as a way of arming workers in ‘an unequal contest with the pauper labor of Europe’ (Eckes, 1995, p. 24). Advocacy of labour did not require compromise of the interests of manufacturers: the party line maintained that in general, as in tariff legislation, the interests of labour and capital were in harmony (Foner, 1970, pp. 20–1). Nor did opposition to slavery require concrete support for its abolition: inheritors of the mantle of Clay and Webster detested slavery but did not see fit to involve the federal government in the fundamental question of its existence, except in new states and territories where prior law did not apply. In order for the conservatives to save the Whig party without sacrificing their convictions, the free labour doctrine and the presumption of harmony of interests had to be retained, but both had to be interpreted to support the protective tariff and to oppose political abolition.

The task was taken up by 19th-century America’s most original economic thinker, Henry Charles Carey (1793–1879), son of Mathew Carey. By 1852 the younger Carey was already an important framer of Whig doctrine. The title of his first major book, *The Harmony of Nature as Exhibited in the Laws which Regulate the Increase of Population and of the Means of Subsistence: and in the Identity of the Interests of the Sovereign and the Subject; the Landlord and the Tenant; the Capitalist and the Workman; the Planter and the Slave* (1836) suffices to describe its contents. His second, a two-volume *Principles of Political Economy* (1840), developed more fully his system: its centrepiece was a law of the progression of civilization that entailed a new refutation of the Ricardian theory of rent. His third, *The Past, the Present, and the Future* (1848), demonstrated that the same law prescribed tariff protection for the United States – an argument that he propounded relentlessly to the end of his life. What remained was to show what the law implied for slavery.

That Carey did in *The Slave Trade, Domestic and Foreign: Why it Exists and How it May be Extinguished* (1853). For the unacquainted reader he reiterated the law of progression. Contrary to Ricardo's teaching, Carey showed that the land that is cultivated first is not the most fertile, which is at the bottom of river valleys where the vegetation is dense. The first settlers to an area do not have the numbers or the technology to clear and till the bottom land: they settle instead at higher altitudes and cultivate less fertile land. As they eke out a living and their numbers grow, they need not confine their work to agriculture. Their employments diversify, and some produce manufactures. Manufacturers devise machines and techniques that are useful in agriculture, allowing the population to inhabit and cultivate more fertile land. They move down the hillside; they produce more food; their numbers grow, and they diversify further their employments; their manufacturers invent better machines and techniques; they move further down the hillside and cultivate better land; and so on. Thus progress requires the development of technology that passes into agricultural use, whether by design or happenstance. Development of technology depends on the diversification of industry – or as Carey put it more vividly, ‘the natural tendency of the loom and the anvil to seek to take their place by the side of the plough and the harrow’ (Carey, 1853, p. 50).

The natural tendency is interrupted at a country’s peril. The United States inflicted upon itself such an interruption, according to Carey, in so far as it relaxed its impediments to foreign trade, impelling settlers to go West and farm more extensively for export rather than planting roots and farming more intensively for the home market. But that was not the only consequence of excessive foreign trade. Amongst a geographically dispersed population with few and small population centres, land tenure was characterized by larger parcels, which were more congenial to the cultivation of crops by slave labour, and correspondingly the demand for free labour was small (Carey, 1853, p. 51).
The extinction of slavery, then, was not to be achieved by political abolition. The sudden reversal of the relationship between master and slave would produce indolence in the latter and cause the ruin of both (Carey, 1853, p. 23–4). It was to be achieved by abolishing the economic conditions that fostered slavery. The conditions were reducible to the small demand for free labour. To increase the demand, it was necessary to ensure that land was cultivated intensively, in small plots, and for sale in a home market that also comprised manufacturers. To ensure that outcome, it was necessary to restrain foreign trade with a protective tariff. Only with the traditional programme of the Whig Party, not the radical one of the Free Soil Party, would both master and slave be set free: the master from his dependence on distant markets, the slave from his shackles.

Carey’s system ultimately failed to be the cement to hold together the Whig Party, but not because it was unpersuasive under the circumstances when he wrote it. Circumstances changed. The Missouri Compromise of 1820 had prohibited the future admission of slave states above latitude 36°30’. Because the compromise rendered the slavery question irrelevant in most of the territory into which the United States would expand, moderate opponents of slavery were willing to leave the question up to state legislatures in the remaining areas. At least one professed opponent of slavery even argued, paradoxically, for its expansion into those areas and beyond. George Tucker (1775–1861), who introduced political economy to curriculum of the University of Virginia in 1825, had earlier served his district in the US House. There, in 1820, he borrowed Malthusian population theory to demonstrate that as the nation expanded westward the means of subsistence would increase, so the number of slaves could be expected to grow. If slaves were confined to the South while only whites migrated to the new areas, the stage would be set for a violent confrontation. The slaves, growing more populous relative to whites in the South if not elsewhere, would rise up against their masters. If slavery were allowed instead to spread westward, then the value of white labour would fall, the value of slave labour would follow, the price of slaves would fall below the cost of their maintenance, and the slaves would eventually be freed voluntarily (Dorfman, 1966, vol. 2, p. 544). Carey’s *The Slave Trade* was but a more comprehensive (and more plausible) justification for maintaining the same inclination manifested for so long by Tucker and many others: to oppose slavery while conciliating slaveholders. At last, just one year after the publication of Carey’s tract, the position was clearly untenable. The Kansas–Nebraska Act, signed into law by President Franklin Pierce in 1854, allowed the slavery question to be put to a vote in the two newly organized territories, both of which were north of 36°30’, and to admit them to the Union as slave states or free according to the voters’ wishes. In effect, the Act repealed the Missouri Compromise; and Tucker’s decades-old notion that such a result would promote, not for ever postpone, slavery’s demise could no longer be believed. Erstwhile conservative Whigs, with Carey in the front ranks, dissolved their party and joined the Conscience Whigs and Barnburner Democrats to organize the Republican Party.

Yet Carey’s free-labour protectionism had become obsolete only in part. Former protectionist Whigs dominated the new Republican Party in financial matters, including tariff policy. After the outbreak of war, they instituted an irredeemable currency and a succession of tariff increases, mainly for war finance. Those who understood the free labour doctrine to have the opposite implications for money and tariffs did not oppose the new legislation: considering the stakes, they acknowledged its expediency. But this marriage of convenience between adherents to otherwise rival political–economic doctrines lasted only as long as the war.
The slavery debate was settled with the war's end, but the money and tariff controversies erupted anew. Popular discontentment was aroused immediately by the myriad internal and external war taxes. The Republican Congress established a revenue commission to study the tax system and recommend an overhaul; its chairman (and after the first year, the sole commissioner) was David A. Wells (1828–1898), known to be a disciple of Henry Carey. From 1865 through 1867, in the first three of his five annual reports, Wells took care not to antagonize his mentor or his patrons. The dominant view in the Republican Party was that tariffs, necessary for revenue in wartime, were opportune for protection in peacetime. Wells recommended accordingly that the internal excises should be dismantled, but the tariffs, which now yielded revenues of over 45 per cent of the value of imports, should be maintained. Wells's report for 1868 marked a change of his thinking, and more. Favourable and unfavourable reviewers alike read it as an insider's repudiation of the American System. By attempting 'indiscriminate or universal protection', Wells determined, the protective tariff rendered 'all protection a nullity' because the iron and steel industries' output was the textile manufactures’ input (Wells, 1869, p. 3). The problem could not be solved simply by raising further the textile tariff: any modification of the tariff law would incite a general scramble for more protection. Given the political reality, Wells reasoned that it was better to determine tariffs by a simple and invariant principle than to attempt ad hoc changes. The principle was a tariff for revenue, not protection. Wells's stand for it, which only hardened in his reports for 1869 and 1870, widened the divide within the Republican coalition. Arthur Latham Perry (1830–1905) of Williams College, an evangelist for free trade in the mould of Leavitt, congratulated Wells for having written ‘our Bible in onslaughts against the monopolists’; Henry Carey published a missive likening Wells to Judas Iscariot.

Although Wells arrived at the revenue tariff position by way of expediency, he occupied it thereafter as a sincere and doctrinaire exponent of free trade. There he joined William Cullen Bryant, who appended in 1866 the presidency of the American Free Trade League (AFTL) to his duties as newspaper editor and publisher; and Perry, who barnstormed for the AFTL after completing in the same year his Elements of Political Economy, the successor to Wayland's work as the principal American textbook on the subject. Bryant, a septuagenarian at the war's end, was of an older generation whose powers were waning; Wells and Perry, in their thirties, were more representative of the spirit of the post-bellum decade. Free trade was the cause that they championed most actively, but they were led to it by attitudes and methods of broader significance.

Both Wells and Perry were schooled in the clerical system of Wayland and were moved by the evangelical impulse of reform, but they were also young enough to partake of the fascination with science that characterized the American mind of the 1840s and 1850s. The fascination was stoked by the appearance of Darwin's On the Origin of Species in 1859, but, like the inquiry into biological adaptation to which Darwin contributed, was present much earlier. The famed Swiss geologist and zoologist Louis Agassiz arrived in the United States in 1846, drew thousands to his public lectures in Boston, and inspired textile magnate Abbott Lawrence to establish a scientific school at Harvard for him to lead. Wells was among the first four graduates of the Lawrence Scientific School. There he learned the talents of empirical observation and statistical argument that he displayed as Commissioner of the Revenue. Perry's scientific inclinations were manifested differently from Wells's but were consonant with them. Perry himself served up few statistics, but he sought to purge political economy of metaphysical
 presumptions that were unanswerable by statistical measurement. The goal could be achieved, he thought, by circumscribing the science, which had been stymied by preoccupation with ‘wealth’. Because the word admitted so many meanings, none of them precise, whatever thing it named was hard to measure. Because the thing was hard to measure, the word was ‘the bog whence most of the mists have arisen which have beclouded the whole subject’ and was ‘totally unfit for any scientific purpose whatever’ (Perry, 1866, p. 29). A better word than ‘wealth’ was ‘value’. Value was no sooner determined than it was measurable; one had only to relinquish any hope of finding an invariant standard of it. The value of a thing was always relative to the other thing for which it was exchanged, and was determined only when the exchange was made. The amount of money exchanged depended on the exchanging parties’ estimates of their desires and the efforts required for their satisfaction. Refashioned thus as the science of exchanges, political economy would concern itself only with things that are measurable in units of money. ‘Catallactics’, or perhaps ‘economics’, was the more accurate name for such a science, Perry allowed – but in this particular question of terminology he was less fastidious.

Regardless of the science’s name, once metaphysics was ostensibly exiled from it, one groped with difficulty within its scope for justification of government constraints of exchange. Therein lay Perry’s enthusiasm for free trade, his unsurpassed appreciation of Frédéric Bastiat, and his more general presumption in opposition to commercial legislation, foreign or domestic.

While Wells’s affinity for statistics and Perry’s redefinition of political economy reflected the scientific aspirations of the post-bellum generation, the American Social Science Association (ASSA) reflected the union of those aspirations with the generation’s reformist impulse. The impulse drew urgency from the tremendous economic transformation that the war had merely paused, not reversed. Fewer than 30 railroad miles were in operation in the United States in 1830; in 1860, the number exceeded 30,000. The railroad hastened migration from the eastern states to the West, but it also changes patterns of life and work within states. Urbanization, which encompassed only nine per cent of the population in 1830, swelled to 20 per cent in 1860 and continued upwards. From its founding in 1865, the ASSA directed itself to inquiry into the attendant problems: sanitary conditions, relief of the poor, prevention of crime, reform of criminal law, prison discipline, treatment of the insane, in addition to other matters in the domain of ‘social science’ (Haskell, 1977, p. 98). Its organization, following that of the British association upon which it was modelled, consisted originally of four departments: Education, Public Health, Jurisprudence, and Economy, Trade, and Finance – the latter of which was concerned with issues ranging from the hours of work to prostitution and intemperance, public libraries, tariffs and other taxes, the national debt, regulation of markets, and the currency (pp. 104–5). Because participants generally shared the classical liberal assumptions of Wells and Perry – indeed, Wells was an early head of the Economy, Trade, and Finance Department and later president of the Association, and Perry was a regular contributor – their inquiries into these subjects tended not to yield proposals for ambitious programmes of government subsidization or regulation. Instead they were aimed (as the Association’s constitution put it) at the diffusion of ‘sound principles’ and at bringing people together ‘for the purpose of obtaining by discussion the real elements of Truth’ (p. 101).

In matters of foreign trade, sound principles implied rejection of protectionism; in the currency, the resumption of specie payments. In the ‘labor question’, which Wells and Perry discussed at a round table in 1866 and again in 1867 (pp. 113–14), sound principles called perhaps for the collection of ample data regarding hours, wages, and conditions of work, but not their regulation on behalf of able-bodied and able-minded adults. Because the interests of workers and employers were in harmony, where poor work
conditions existed they were the result either of a general lack of material progress or lack of knowledge by the actors. The solution to lack of material progress was to clear away any legislative impediments to it. The solution to lack of knowledge was for the ASSA to produce and disseminate it. In neither case was the solution to draw up redistributive ‘class legislation’ or other assaults on the prerogatives of property.

The panic of 1873, the depression in its wake, and the great railroad strike of 1877 undermined confidence in the solutions of the liberal reformers and made room for challengers. The labour question had metastasized into ‘the social question’. The most original and widely read author to address it was Henry George (1839–1897), an autodidact working as a journalist in California when the publication of *Progress and Poverty* made him famous in 1879. George admired David Wells, and corresponded with him as early as 1871. He joined Wells in advocating free trade and denouncing ‘monopoly’ (Dorfman, 1969, p. 142). But George was less deferential to property than was Wells, in whose circles he was viewed less of an ally than a danger.

George attributed the persistent poverty of labour amidst material progress to the unearned rewards of one particular kind of property. Land was the free gift of nature: although improvements on it were the work of man and the returns to improvements were earned, the returns to land were not. Yet the returns to land grew inexorably as population and mechanical invention increased and cultivation was extended. The solution that George proposed was a single tax on land of 100 per cent of its annual value. Under such a system it would matter little if one held title to land, leased it to another, and paid a 100 per cent tax on the rent; or if instead the state held formal title to the land and leased it to (presumably) the same person who would rent it from a private owner. Private property in land could be formally retained, but in effect land would be appropriated by the state for the benefit of all. At the same time, the right to all other property would be respected more scrupulously than before, because the single tax on land would obviate the need for all other taxes.

The political economists associated with liberal reform caught the scent of socialism from George's proposal, and they responded with alarm. Yet Henry George shared most of the values and even some of the legislative prescriptions with which the liberal reformers were most closely identified. He departed from them importantly only in his assumption of the illegitimacy of private ownership of one kind of possession. The challenges that would follow in the middle of the turbulent 1880s, from a new generation of economists including Edmund James (1855–1925), Simon Nelson Patten (1852–1922), and Richard T. Ely (1854–1943), were of another order entirely. The professional credentials of the young economists, which included doctoral studies in Germany and university positions in the United States, were different from Wells's and Perry's (let alone George's); and rather than sharing the values and prescriptions of their elders, they repudiated them thoroughly, defining themselves by opposition to economic liberalism. These economists were the founders in 1885 of the American Economic Association.

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The history of American economics following the founding of the American Economic Association in 1885 is not a simple linear narrative of the triumph of neoclassical economics over historical economics. On the contrary, American economics remained a highly plural enterprise until the 1930s. Although there was strife in the 1880s over the proper method of doing economic research, this strife quickly gave way to a long period of détente. Only following the secularization of economics in the 1920s and the advent of the synthesis of neoclassical and Keynesian economics in the 1940s did this pluralism end.

Article

The 60-year period from the founding of the American Economic Association (AEA) in 1885 to 1945 marks the period when American economics was first professionalized and then came to take its
characteristic, modern form. However, this story is not a simple linear narrative, as the events during this period were influenced by a series of historical contingencies and social forces that meant the outcome remained unpredictable until sometime during the last decade of the period. Historians and economists alike have tended to believe that the story is somewhat more straightforward than it actually was. The historian Dorothy Ross (1991), for instance, has argued that the rise to prominence of John Bates Clark as America's premier (and first native) economic theorist at the turn to the 20th century marks the triumph of neoclassicism in American economics. More recently, Nancy Cohen (2002) has argued that neoclassicism came to dominate even earlier than Ross suggests, by as much as a decade. Both of these arguments are based, in part, on the well worn idea that American economics was characterized by a ‘Methodenstreit’, or ‘war of methods’ in which the Marginalist School defeated the previously strong Historical School by the end of the 19th century. But while it is true that there was a crisis in American economics during the decade after the founding of the AEA, it had a somewhat different nature from that usually understood: it was much more about the purpose of economics than about method.

American economics, circa 1885

The first doctorate in political economy issued by an American university was in 1886 when Henry Carter Adams received his degree from Johns Hopkins University. Before that time, if an American wanted a doctorate in economics, it was necessary to travel to Europe to study. The vast majority who chose this route studied in Germany, to which 9,000 Americans travelled for this purpose between 1820 and 1920 (Herbst, 1965). The most prominent of these young Americans went on to help found the AEA after their return, including Richard T. Ely, J.B. Clark and Simon Nelson Patten.

In Germany, these young economists found a profession that was characterized by scepticism towards Adam Smith's system of ‘perfect liberty’ and his arguments for laissez-faire. It now seems fair to say that the economic ideas that the Germans were most disturbed by were in fact a caricature of Smith: the ‘Manchesterism’ that they found so offensive was more the product of David Ricardo than Adam Smith, but their objection was deep and profound to what they took to be an argument unsuited for all nations at all times. They believed that Smith had made universalizing assumptions about human nature and human behaviour that were not universally correct. In the place of these assumptions, they intended to build a more empirically accurate economics based on careful historical study of how the individual behaviour and economic institutions of different societies had come about. Thus, rather than assuming that all people always weighed their options and made their choices so as to maximize their individual well-being, the leading German economists in the second half of the 19th century believed that it was necessary to study how cultural customs had evolved and how these shaped individual behaviour. Known as the ‘Historical School’, the leading German economists at this time espoused the idea of ‘Nationalökonomie’, or the study of how each nation had come to its current position. These economists taught their students contemporary methods of historical study: careful archival work, the study of laws and customs, the collection of data, and the slow, inductive accumulation of knowledge. However, this did not preclude the study of marginal analysis. Karl Knies, at Heidelberg, who taught marginal techniques to the Austrians Friedrich von Wieser and Eugen Böhm-Bawerk, similarly taught the two most important Americans in Germany, John Bates Clark, the pioneer American marginalist, and
United States economics in (1885–1945) : The New Palgrave Dictionary of Economics

Richard T. Ely, one of the leading representatives of American historical economics. When Clark returned from Germany in 1875 and Ely in 1880 they found the American economics profession unprepared for much of what they had to offer. American economists were anxious about their own lack of theoretical sophistication. Writing on the occasion of the nation's centennial in 1876, Charles Dunbar, Professor of Economics at Harvard, had complained of the unoriginal and derivative character of American economics. Dunbar ‘observed that American scholarship as yet contributed nothing to fundamental economic knowledge. In his reading, American economics to date had been derivative, stagnant, and sterile’ (Barber, 2003, p. 231). This may be have been an exaggeration, but it was the case that American economics texts at this time, mostly written by college presidents for undergraduate moral philosophy classes, lacked theoretical sophistication, and the young economists returning from Europe found an open field for the possibility of producing a new American economics. Another reason for this lack of theoretical sophistication was that texts were written to propagate the virtues of free enterprise, hard work, and republican democracy, a troika of American virtues that posed a problem for the returning young economists. The crux of the problem was that the elders who controlled the newly created academic positions that the young economists hoped to enter expected anyone they hired to espouse the same beliefs regarding laissez-faire. Francis Amasa Walker, who taught at the Massachusetts Institute of Technology (MIT) and who served as the first president of the AEA, would reflect that laissez-faire, ‘was not made the test of economic orthodoxy, merely. It was used to decide whether a man were an economist at all’ (in Coats, 1988, p. 362).

Unfortunately for men like Clark and Ely, this made employment in academe difficult, if not impossible, for on their immediate return from Germany they almost all adhered to Christian socialism. In part, this commitment reflected the enthusiasm they had acquired in Germany for social reform. But it also reflected an effort on their part to build an American ‘Nationalökonomie’. Trained to believe that each country had a unique culture and unique institutions, these young men latched onto evangelical Protestant Christianity, and tried to use it to fashion a native argument for economic reform. Following the Civil War, after an era when the importance of hard work, free enterprise and the rights of capital had been universally preached (Bateman, 2005). American Protestantism had begun to split into two ‘parties’ (cf. Marty, 1986). The ‘private party’ focused on individual salvation and did not view the emerging economic conditions as a matter for Christian concern. The ‘public party’, on the other hand, focused on social reform while de-emphasizing the older evangelical concern with individual piety. In the new economic order of the post-bellum world these two strands of evangelical thought became emblematic of the two most common (and opposing) responses to the growth in industrial production, increasing urbanization, rapid immigration and growing inequality. Each group took the Bible as its primary text, but their purposes and understanding of the world could not have been more different. Whereas the private party Christians focused on individual piety, the public party wanted to build ‘the Kingdom of God on this earth’ through collective action and with the aid of the state.

The progressive era

At the centre of the public party of American Protestantism were the young economists who had returned from Germany. They had learned a new scientific ethic of empirical study and had made initial contact with marginal reasoning. But balanced against this, was the fact, uncomfortable for their elders,
that almost to a person these returning young economists were interested in changing the balance of power between working men and the owners of the new, vertically integrated enterprises that employed them. Thus, the young German-trained economists had some things that the profession craved, such as technical prowess, but they also manifested a political attitude that was unacceptable to much of the profession.

Laissez-faire in 19th-century America was not a technical argument for the efficiency of free markets, but rather a manifestation of a broader Protestant ethos. It meant a limited role for the state in the economy, but it also meant the unfettered right of capitalists to employ workers on the capitalists’ terms; at the time of the Civil War, for instance, virtually throughout the United States it was still illegal to strike or to form a labour union. Thus, when the young, German-trained economists challenged laissez-faire, they were as likely to be arguing for the right of workers to strike as they were to be arguing for the municipal provision of water. In the last decades of the 19th century, then, laissez-faire meant both a limited role for the state and privilege for the prerogatives of capital. Men like Ely and Patten meant to challenge these ideas head-on and they took their warrant to do so as much from Christian scripture as they did from economic theory: they saw their work as economic theorists as an expression of their Christian commitments.

However, they generally met scorn from the older generation. Under the leadership of Ely, Patten, and Clark, the young advocates of labour and the possibility of beneficial state intervention formed the American Economic Association (AEA) in 1885, in part as an effort to provide support for one another and to seek an alternative form of professional recognition. But not all the AEA's members were economists; about a quarter of the members at the first meeting in Saratoga Springs, New York, were Protestant ministers. The young economists with doctorates could perform empirical research showing the extent of poverty, inequality and industrial dislocation in the economy; the ministers could preach the young economists’ findings from their pulpits on Sunday morning to help motivate their parishioners to act to help build the Kingdom.

The formation of the AEA led to one of the most well-known exchanges between the older advocates of laissez-faire and the young economists who hoped to establish a role for the state in the functioning of the economy. William Graham Sumner at Yale University was the most high-profile advocate of laissez-faire at the time of the founding of the AEA, but one of Ely's colleagues at Johns Hopkins, Simon Newcomb, was also widely recognized. Newcomb was an acclaimed astronomer and mathematician who occasionally lectured on economics at Johns Hopkins and he wrote widely on economics in the popular press. Following the establishment of the AEA in 1885, Science magazine asked members of the old and new schools to debate their positions in a series of exchanges (reprinted in Adams, 1886). The exchange was often vitriolic, with Newcomb accusing Ely of being a socialist, no small charge in the immediate aftermath of the Haymarket riots. Often unnoticed in the debate, however, is the fact that both sides called on the authority of Alfred Marshall and William Stanley Jevons to establish their own points. More than anything in the debate, this last fact perhaps illustrates the extent to which the American economics profession at this time was animated by political differences over laissez-faire and the role of the state, rather than primarily by an argument over methods.

Much to the chagrin of Ely, the AEA did not long remain a haven for advocates of the state. With the pressure on the young economists to demonstrate they were not radicals who advocated violence, they felt it necessary to show themselves open to their older colleagues. And since the Association was also billing itself as the national organization for all economists, and because the young economists depended
on the older generation for jobs and support, they hardly felt that they could deny the older economists membership in the new organization when they asked to join. Thus, by 1892, virtually all the older advocates of laissez-faire were members of the organization and the founding statement of principles in favour of a role for the state and amelioration of economic dislocation, which Ely had helped draft in 1885 at the time of the founding, had been abandoned. Ely's response was to boycott the annual meeting that year.

At this point, it is undeniable there was great tension in the profession. It is important to realize, however, that John Bates Clark, the premier marginalist, and Richard T. Ely, the premier historical economist, had worked together to found the AEA. It is true that Clark has dropped his interest in Christian socialism by 1885, but he had not turned completely against historical analysis. Nor, strictly speaking, was Ely an anti-marginalist; Ely had introduced marginal utility into his textbook writing as early as 1893. E.R.A. Seligman, another of the AEA founders, represents a good case study of the way that many economists at this time balanced marginalist and historical techniques in their work. The real conflict within the profession at this time was about the possible role of the state and whether the purpose of economics was to defend laissez-faire, rather than whether marginalism should be used in economic analysis (cf. Yonay, 1998).

The diversity within the profession is also clearly manifest in the leading figures of the old school that emerged during the last two decades of the 19th century: Arthur Hadley, Frank Taussig, and J. Laurence Laughlin. These three men became the leaders respectively at Yale, Harvard and Chicago in the era when departments were emerging as the dominant institutions in the formation of the American economics profession. The work of these men represents three of the main economic problems facing the nation at the end of the 19th century (international trade and tariffs, railroads and monetary policy) and their theoretical eclecticism, while adhering to some form of the older cost-based theories of classical economics, demonstrates the evolving nature of the profession.

J. Laurence Laughlin was the most rigidly classical of these three ‘young traditionalists’ (Dorfman, 1949). Despite writing a dissertation in history under Henry Adams, Laughlin gave no credence to the Historical School and was the last of the major figures in the old school to join the AEA (in 1904). Although not a prolific writer, his History of Bimetallism in the United States (1885) is a landmark study of the history of late 19th-century fights over currency and monetary policy. Ironically, however, after founding the Journal of Political Economy (1892), Laughlin opened the journal to economists of all stripes, and turned the book reviewing over to Thorstein Veblen for several years.

Frank Taussig is probably the most well remembered of the three, not least for his influence on the generation of students who enroled in his ‘EC 11’ graduate seminar at Harvard. Widely respected as a teacher, he was a gregarious person who was the first of the old school economists to join the AEA (in 1886). Although himself an adherent of classical economics, particularly of Ricardo and John Stuart Mill, Taussig was capacious in his analysis of economic problems and was often willing to see the legitimacy of other points of view. There is no better example of this than in his Tariff History of the United States (1888), an adaptation of his dissertation that went through many revisions in its subsequent editions; although he was a dedicated free trader, Taussig had a subtle understanding of the use of tariffs for revenue collection and appreciated, for instance, the arguments for sometimes protecting infant industries. Like Laughlin, Taussig was also an eclectic and important early journal editor. Charles Dunbar had founded the Quarterly Journal of Economics at Harvard (1886), but when Taussig became its editor, he opened his pages to economists of all views.
Arthur Hadley tackled one of the major economic issues in late 19th-century American capitalism, the railroads. His early reputation was based on his *Railroad Transportation* (1885), in which he argued that businesses with large fixed costs would not necessarily shut down when prices fell below the cost of production. Instead, he pointed out that as long as the firm could cover what are now known as variable costs and still make some contribution towards paying fixed costs such as interest payments, that they would stay in business. Hadley represents an intriguing figure for he acknowledged that his results on the role of fixed cost contradicted some of Ricardo's arguments and he also accepted the basic validity of marginal utility reasoning. Thus, he seemed to have transcended classical economics in many regards. Yet his outlook was unmistakably laissez-faire, and he believed that there was no reason for further work in marginal utility theory, since its validity had been shown and that more work represented an unnecessary foray into psychology. In the end, his economics was driven largely by the study of costs, as in classical economics, and his conclusions did not stray far from the classic dogmas.

Members of the older generation were not alone in forming strong departments during the last decade of the 19th century. Johns Hopkins, which was founded in 1876 to establish higher education, especially graduate education, in the German style in the United States, was the first notable American graduate course in economics, producing the first Ph.D. granted in economics in the United States. The department's two notables were Simon Newcomb and Richard T. Ely. However, after his falling out with Newcomb, Ely left Johns Hopkins in 1892 for the University of Wisconsin, where he quickly assembled one of the top economics departments in the nation. Initially, Ely's move to Wisconsin was seen to be a possible precursor for regional factionalism in American economics. After Ely failed to attend the annual meeting of the AEA in 1892, there was concern among many Eastern economists that he would lead a movement from the Midwest to create a new professional organization that would promote his original challenge to laissez-faire.

However, following Ely's academic trial in Wisconsin in 1894 on charges of entertaining a union organizer in his home and of advocating socialism in his lectures, people from both camps began to look for common ground. Ely self-consciously chose to lower his profile after he was acquitted in his trial, and the advocates of laissez-faire began to realize that it was not good for the profession's credibility to have high-profile public disagreement. What followed at the turn of the century was the emergence of a kind of détente in American economics: leading figures in the profession continued to build strong departments around the country, but economists were granted a wide berth to examine social and economic conditions and to use the tools they saw best suited for the specific question at hand. Support for laissez-faire and government intervention were both accepted; what was expected was a rigorous approach to one's position.

One basis for this détente was undoubtedly the common Protestant background of most American economists at this time. Although Ely, Patten, John R. Commons, and Henry Carter Adams were asking American Protestants to turn away from their traditional position in favour of the prerogatives of the owners of capital, they were making the appeal on biblical grounds and were self-consciously appealing to the emerging public party of Protestantism. Since prominent members of the group of younger economists (for example, Ely and Adams) made it clear in their academic trials that they were not advocating the overthrow of the state, but rather the empirical study of the conditions of labourers, it became harder to demonize them for their impulse to seek what were clearly Christian ends. For their part, the older advocates on laissez-faire were willing to begin the difficult work of absorbing new theoretical techniques and accepted the call of the younger economists to undertake more empirical...
work and to let its results inform their understanding of the true effects of relatively untrammelled markets.

This détente between the younger and older economists, and between advocates of laissez-faire and advocates of more rights for labourers, created a fertile ground for American economics. During this period, there was not a single orthodoxy in American economics; one could work with marginalist ideas, historical ideas, or with both. New School economists such as Ely, Clark, and Seligman, as well as Old School economists such as Taussig and Hadley, all employed both techniques in their work. All that was required to be taken seriously in this world of plural methods was a dedication to the examination of the contemporary economic issues that were arising as America became an industrialized, urbanized nation. That the *American Economic Review*, which was founded in 1911, showed no marked tendency towards any school in its published articles is strong evidence that there was no single dominant school at this time.

Perhaps the most notable dissent from this détente was the *sui generis* Thorstein Veblen. Like the young economists returning from Germany, Veblen was interested in a more ‘scientific’ economics. But he was never much interested in large-scale empirical work such as the social survey movement fostered by Ely and Commons at the turn of the century. Instead, Veblen wanted economics to be rebuilt as an evolutionary science based on Darwinian principles of natural selection (Hodgson, 2004). Veblen's greatest theoretical advances would come during the first decade of the 20th century, but they were offered as part of a sardonic and biting criticism of Clark's work and so not only alienated Clark and his followers but also the bulk of the profession who saw their toolbox as containing many different techniques, one of which might sometimes be marginal reasoning. Veblen agreed that American economists should examine the newly emerging American capitalism, but he was not interested in pluralism of techniques.

Perhaps the most visible sign of the emerging détente among most American economists at this time was Ely's election to the presidency of the AEA in 1900. Not only had his feared defection been averted, but he had been successfully pulled back into the centre of the organization. Ely and Veblen never shared a close personal or professional relationship and Veblen would later harbour a bitter resentment that his brilliance and originality had been ignored by the AEA in the pivotal years when it would have helped his professional stature. Despite the fact that Ely and Veblen shared an interest in historical analysis, Veblen's style and his self-certainty in the Darwinian method kept him apart from the mainstream.

The year 1900 also marked the beginning of the Progressive Era, a profound shift in American society that would propel economists like Ely, Adams and Commons into the mainstream of American thought. With the emergence of progressivism during the first two decades of the 20th century, the cultural, political, and religious centre of American society would move away from 19th-century ideals of laissez-faire and towards an ethos of active civic engagement in trying to ameliorate the many social dislocations of the new industrialism, emerging urban poverty and concentrations of power in large corporations. The public party of Protestantism was the central force of progressivism in the first decade of the new century and economists like Ely and Adams, who had been subjected to political pressure to mitigate their views in the late 19th century, now found themselves in great demand and at the head of progressive projects such as regulatory commissions and social survey projects (Furner, 1975; Bateman 2001). Just as the laissez-faire economists in the 19th century had benefited from the dominant Protestant ethos, so too would the young, so-called ‘ethical economists’ benefit from the rise of public party Protestantism early in the 20th century. This public recognition, and the university positions that
often came with it, undoubtedly made it easier for the ethical economists to ignore Veblen's criticisms. This is not to say that the economics profession as a whole was receiving the attention it believed it deserved. On the contrary, for a significant part of the 20th century, the AEA was actively concerned with measures that would secure it an appropriate public profile (see Bernstein, 2001).

The First World War and the end of the idyll

At the same time that the young economists who had founded the AEA were rising to popular prominence, another generation of marginalist economists was also beginning to emerge. One of the most distinguished of the new generation of marginalists was trained by Ely. Allyn Young received his doctorate working under Ely at Wisconsin and became the first of many to become revisers and co-authors of Ely's best-selling *Principles* text. Some of the new generation of marginalists, such as Frank Fetter, examined the psychological dimensions of utility and sought to more clearly articulate the welfare implications of marginal utility reasoning. Perhaps the most innovative marginalist thinker to emerge after Clark was Irving Fisher. Fisher's mentors at Yale were William Graham Sumner and Willard Gibbs. Gibbs was one of the most prominent mathematicians of his generation and he influenced Fisher to develop marginal economics in a more technical, mathematical form that would later come to characterize American neoclassical economics.

While Fisher's work was recognized and lauded, it was not, however, representative of the mainstream in the first two decades of the 20th century. Progressivism defined the centre of American political and intellectual life from roughly the turn of the century to the end of the First World War; but during the second decade of the century it shed some of its public rhetoric of Protestant reform as it began to pull in Jewish writers like Walter Lippman and Herbert Croly. Progressivism also became more focused on industrial efficiency as many embraced Frederick Taylor's time and motion studies as a means to achieve greater productivity and raise the standard of living. But the moralism of Protestant reform still suffused much of progressive thinking and would lead to the movement's quick demise after the war.

The problem for progressivism after 1918 was that one of its greatest proponents, Woodrow Wilson, had led the nation into war using the rhetoric of reform and democracy. He had been supported by the Protestant clergy, many of whom had used their pulpits to preach the justness and necessity of the war when America had entered the conflict in 1917. Thus, when the war was over, and the atrocity of the trench fighting was driven home to people, there was a quick and sudden turn against progressivism and especially against the moralism and rhetoric of moral improvement that had underpinned it (Danbom, 1987). The hope that had supported the progressive movement was now widely seen to have been based on an unrealistic understanding of human nature.

This shift away from progressive moralism had a quick and deep effect upon all the American social sciences that had been pioneered by public party Protestants; sociology, political science, and economics all made a sudden turn to a more ‘scientific’ and less ‘moralistic’ basis. Dorothy Ross (1991) has called this ‘the advent of scientism’. Of course, all three social sciences had considered themselves scientific before the war (Furner, 1975), and all had been interested in empirical survey work of urban and rural populations; but they had all operated on an implicit belief that if this survey work revealed social pathologies such as poverty and child labour, that good Christian women and men would surely act to alleviate them when faced with the evidence. After the war, such a reliance on an idea that people were
well motivated and altruistic was abandoned. So, too, was the idea that people who lived in squalid social conditions would experience moral improvement if the conditions were changed. Thus, in the years immediately before 1920, progressive social science quickly unravelled. Realizing that they had lost the sympathy of the larger populace, and faced with the need for serious soul-searching on their own part, all three social sciences made an explicit effort to eschew the optimistic, moralistic rhetoric of progressivism and embraced a new kind of ‘scientific’ endeavour. Entwined in their decisions to embrace a more value-neutral approach to social enquiry was a clear understanding that both public and private funding hinged on catching the tone of the times.

The name of this movement in economics was ‘institutionalism’ (see institutionalism, old; Rutherford, 2000; Bateman, 2004). The term was coined in 1918, at exactly the moment when the break from liberal Protestantism was happening in all three of these social sciences. The men who formed the nucleus of this emerging group, men like Walton Hamilton and Wesley Mitchell, self-consciously endeavoured to set up an empirical, data-generated research project that would be appealing to funding agencies such as the Carnegie and Rockefeller Foundations. The founding of the National Bureau of Economic Research (NBER), with Mitchell as the director, was one of the signal achievements of the early institutionalists. One effect of the effort towards a more empirical basis for economic research was that subjects that had been at the centre of American economics for at least four decades, such as poverty and philanthropy, were dropped from the research agenda of almost all institutionalists. Instead, intense attention was paid to the cost structure of American industry, the business cycle, and the working of the financial system; these seemed to be the proper objects of serious economic scientists. Ultimately, the object of the institutionalists was to find a more scientific basis for ‘social control’, thus eradicating the need for the moralism of the progressives.

The most notable break with the past, however, was that for the first time since the founding of the AEA, there was now a group of American economists who were attempting to establish an institutional and historical approach to economics and who did not want a détente with marginal analysis. The Methodenstreit that many people now project back on to the late 19th century was actually beginning to emerge. The institutionalists were interested in developing a behaviouralist basis for individual behaviour and they eschewed the idea that marginal decision-making was the driving force behind most economic activity.

The institutionalists were also the first group of American economists to work to establish an explicitly secular economics. This reflected their desire to distance themselves from the moralizing rhetoric of the Christian economists who had founded the AEA and drew from the work of one of the institutionalists’ main influences in pragmatic philosophy, John Dewey. While not every individual American economist had been a Protestant before the First World War, the ethos of Protestantism had suffused and stabilized the détente that held for most of the three decades after Ely had been exonerated in his academic trial. Liberal Protestant economists had believed that a kind of moral Darwinism was at work in American society and their common purpose in exploring social questions to determine where and when state intervention might (or might not) be appropriate had been made possible by their shared ethos. Now, however, the men who stepped forward to found institutionalism were making an explicit argument that science alone should inform their work; they staked their future on the idea that they could do better, more empirical science than the a priori marginalists who they believed depended on untested and incorrect assumptions about human behaviour.

The marginalists were fully up to the fight, however, and engaged the institutionalists after 1930 in an
increasingly pointed dispute. In the first decade of institutionalism's rise, the détente held reasonably well. And during the 1920s, institutionalism was at least as well represented in the top graduate schools as marginalism. While marginalist thinkers such as Irving Fisher went about their work, the institutionalists controlled two of the top four graduate courses (Columbia and Wisconsin) and produced a large plurality of American Ph.D.s (Bowen, 1953; Backhouse, 1998; Biddle, 1998).

The Great Depression and the New Deal

Contrary to the idea that American economics in the 1920s and 1930s was characterized by a final struggle between some latter-day historicists (that is, institutionalists) against the dominant neoclassicists, the pluralism of this period was much richer and represented a wide range of possibilities regarding the future direction of the profession. It might more correctly be said that no school of thought in American economics was completely dominant at this time. A nice example of this diversity would be to consider Harvard in the 1930s. Frank Taussig was still on the faculty and remained one of the leading authorities on international trade. Joseph Schumpeter would join the department in 1932, bringing a Continental influence, if not exactly an Austrian one. Edward Chamberlin would finish his work on imperfect competition at Harvard during the 1920s, under the twin influences of Marshall and Allyn Young. Young, who died in 1929, had been one of America's top theorists, but as noted above, he was a student of Ely's who had later tacked hard to the marginalist tradition. One could not define this department as simply neoclassical, but neither was it simply institutionalist. The full secularization of American economics, however, had prepared the ground for a more strident return to laissez-faire arguments, much like the ones that had existed before 1885.

For by the 1930s, leading marginalist thinkers such as Frank Knight were prepared to engage in what Yuval Yonay (1998) has termed ‘the fight for the soul of economics’. Despite their control of many of the top graduate courses (Backhouse, 1998), and their initial success at fundraising, the institutionalists were hit hard by the kind of criticism that Knight levelled against Sumner Slichter in his 1932 review of Slichter's new institutionalist textbook. Knight did not like Slichter's methods of analysis, but his real bête noire was Slichter's focus on intervention to improve the performance of the economy. By this time, the institutionalists had clearly staked out their position of advocacy for ‘controlling’ the economy, and the advocates of marginalism, such as Knight and Jacob Viner, strongly disagreed. However, though some took clear sides, there were others who straddled both camps: John Maurice Clark (J.B. Clark's son) drew on many neoclassical tools, such as externalities, but his work on the control of business went further in directions favoured by institutionalists, turned away from the cause in the 1930s, arguing that many of the institutionalists’ concerns were best handled by treating them as externalities within the neoclassical model; before his untimely death in 1929, Allyn Young had done his pioneering work in the economies of scale and supervised Chamberlin's doctoral thesis. The divide between institutionalism and neoclassicism was thus still blurred in this period.

Equally destructive of the myth that American economics was essentially a linear narrative of the development of neoclassical economics after 1890 is the rich American tradition of work on money, banking and the business cycle during the inter-war years (Laidler, 1999). The work in these areas drew from the pre-First World War work of major figures such as Laughlin, Fisher, and Mitchell, and represented a wide range of theoretical development, as well as a full range of policy options.

Perhaps the most well remembered work from this period is Irving Fisher's work on the quantity theory and the relationships between money growth, the price level, and economic activity. Fisher (1911; 1923; 1925) was not alone in positing a close relationship between money and prices. Carl Snyder (1924) of the Federal Reserve Bank of New York drew on Fisher's work to suggest that the close relationship between money and prices supported a ‘money growth guideline’ (Laidler, 1999).

There was no orthodoxy in monetary and cycle theory, however. For instance, Irving Fisher (1925) came to believe that there was no business cycle, simply fluctuations around the mean values of prices. This outlook contrasted sharply with Mitchell's careful empirical search for the factors that underlie what he believed were the regular oscillations of the economy. Both Mitchell and Alvin Hansen worked in the 1920s to develop versions of the accelerator principle, a concept previously developed by J.M. Clark in 1917, trying to uncover the ways that a growing economy could pick up momentum and how that same pattern of growth could ultimately lead to a downturn.

Likewise, just as some economists did not agree with Fisher's conclusions about the nature of the cycle, there were many who did not agree with his conclusions regarding the relationship between money and prices. In the inter-war years, there developed what David Laidler has termed an American version of the British Banking School. H. Parker Willis, who worked for the Federal Reserve in the second decade of the 20th century and later taught at Columbia's School of Business, and Benjamin Anderson, who had a position at Harvard before becoming the chief economist at Chase Bank, both argued against Fisher's use of the quantity theory. Willis had studied under Laughlin at Chicago and he followed in Laughlin footsteps in denying the necessary connection between money and prices.

In this rich mix of work regarding money and the business cycle, there was, not surprisingly, widespread disagreement about the possibilities for stabilization policy. Economists as diverse as Fisher, Mitchell, and Allyn Young supported different kinds of stabilization policy. Others, like Willis, adhered to a version of the real-bills doctrine, arguing that stability would come only through a prudent effort on the part of the Federal Reserve to limit its lending to those with high-quality, short-term commercial paper. Although they did not have academic appointments, William Trufant Foster and Waddill Catchings (1923; 1925; 1928) used the Pollak Foundation for Economic Research as an effective platform to publicize a version of underconsumptionist theory. They argued that there was a need for monetary and fiscal expansion to sustain consumption and avoid recession. Paul Douglas (1927) at Chicago, who became a US senator from Illinois, made these ideas popular with his call for large-scale public works.

While there were, thus, many forms of arguments for fiscal and monetary efforts to sustain prosperity, it might seem that the institutionalists’ predisposition for controlling the economy would have been popular after 1929, but neither the popular nor the professional tide turned toward the institutionalists after 1929. In retrospect, it was, perhaps, their unique bad luck to have played a role in developing parts of Franklin Delano Roosevelt's initial response to the Great Depression, his first New Deal. Many institutionalists joined Rexford Tugwell from Columbia University in Roosevelt's first term of administration, but they failed to provide a recognizably successful policy for combating the depression. Although the marginalist economists were not offering a popular plan for recovery, the institutionalists’ efforts in the New Deal did not provide them with a set of successes upon which to build their legacy (Barber, 1996).

It was also the bad luck of the institutionalists that by the end of the 1930s, when John Maynard Keynes's *General Theory of Employment, Money, and Interest* (1936) came to be widely seen as
providing a theoretical underpinning for recovery, that the emerging neoclassical theorists like Paul Samuelson were already working to give his theory a neoclassical underpinning. The efforts to cast the *General Theory* in a general equilibrium model effected a remarkable and unexpected transformation in the future prospects for American economics, overshadowing the fact that the foundations of what came to be thought of as Keynesian fiscal policy were laid by institutionalists (Barber, 1996; Rutherford and DesRoches, 2008). Before the Great Depression, economists of all stripes had argued about possible monetary and fiscal interventions (see Barber, 1985; Laidler, 1999). Although the pure idea of ‘social control’ was an institutionalist construction, the potential for using fiscal and monetary policy came from almost every corner of the profession. Keynes's work provided a common analytical framework for examining such macroeconomic interventions, and Samuelson's work linked that analytical framework to marginalist, neoclassical ideas. Likewise, Alvin Hansen's embrace of Keynes's theoretical framework after his initial resistance lent important impetus to an alternative form for analysis of the business cycle, even though he turned to Keynesian economics only when he saw that it could be used to defend ideas he already held. Hansen built his graduate seminar on fiscal policy at Harvard around his reinterpretation of Keynes's *General Theory*, and in the 1940s and early 1950s wrote a series of texts that embodied much of the institutionalist concern with the business cycle and economic stabilization (see Mehrling, 1997, chs 7–8). The project that institutionalists had undertaken in the 1920s to provide a new psychological basis for economic behaviour had never led to any substantive advances, which helped to make the mathematical elegance of Samuelson's work all the more attractive. It did not hurt that the tools of neoclassicism, in their Keynesian guise, were now seen to be as amenable to intervention as they were to laissez-faire. Edward Chamberlin's (1933) work analysing imperfect competition in the 1930s also started to lend a new sense of realism and possibility to the emerging neoclassical framework. In the 1930s, much empirical work had been undertaken by institutionalists, but it was Edward Mason and Joe Bain, who, drawing on Chamberlin’s theory, developed the framework that was to dominate empirical work on industrial economics in the 1950s. Harold Hotelling's theoretical breakthroughs in formulating mathematical models of resource depletion in the 1930s added even more lustre to neoclassicism. A new, sharp sense of what it meant to be an economic theorist was emerging, and institutionalism did not appear to have a ready response.

**The econometric movement and the Second World War**

The event that symbolized this confidence in more formal theorizing than the institutionalists had generally favoured was the foundation of the Econometric Society in 1930. It was an international society, but Fisher, Schumpeter and other American economists were influential in its formation. Its importance lay in providing a focus for mathematical theories, covering both the cycle and microeconomics, and statistical research. An influential figure was Alfred Cowles, who not only supported the Econometric Society and its new journal, but also established the Cowles Commission. This was an economic research organization, set up in 1932, the heyday of which was from 1939 to 1955 when it was based in Chicago. Located outside the economics department, it provided a focus for the development and propagation of neoclassical theory (with particular emphasis on Walrasian general equilibrium theory) and statistical methods for testing and applying the theory. It was here, in the early 1940s, that Tjalling Koopmans and Trygve Haavelmo developed the methods that led to what has been
Two further developments were important in the transformation of American economics that took place in this period. One was the influx of a large number of émigrés from Europe. The United States had always been a home for such people, and in the 1920s many economists arrived from Russia and Eastern Europe, but this increased dramatically in the 1930s and 1940s. By the mid-1940s, almost half the authors of articles in the American Economic Review had been born outside the United States, most of these being affiliated to American universities (Backhouse, 1998).

The other influence was the Second World War itself. This was, like no previous war, an economists’ war (Bernstein, 2001). Economists were recruited en masse into government. Many were employed to tackle what were clearly economic problems relating to domestic economic activity or to the estimation of enemy economic capacity. The most notable outcome of such work was national income analysis. Official estimates of US national income had first been calculated in 1933, in response to the onset of the depression, when Simon Kuznets was seconded to the Bureau of Foreign and Domestic Commerce from the NBER, where he had been working on the problem (elsewhere Clark Warburton, at the Brookings Institution, and Laughlin Currie had been working on similar lines). Under Robert Nathan this work was developed, and monthly figures were produced by 1938. But it was only during the war that these estimates were developed, under Martin Gilbert, into a system of accounts. One reason for this was that national income proved indispensable to the war effort, its main achievement being to calculate what Roosevelt could promise in his Victory Program.

However, the significance of the war went further than this, for economists also became involved in activities not traditionally associated with their subject. Operations Research, initiated in Britain in the 1930s, was taken up by the American armed forces, through the Office of Strategic Services (a forerunner of the Central Intelligence Agency) where economists were employed alongside mathematicians, statisticians and physicists to solve problems related to military strategy and tactics. Out of this arose techniques that later proved influential, such as linear programming, with which members of the Cowles Commission (Koopmans and George Dantzig) were heavily involved. Economists achieved a high reputation as general problem-solvers. Most important, however, was the effect on the way economics was conceived. Much of this work was focused on optimization and was highly technical. Economics came to be seen as akin to engineering. In the 1920s and for much of the 1930s it had been institutionalism that was associated with quantitative work; statistical work related to neoclassical theory did exist (for example work on measuring demand functions) but there was no parallel with the work being done at the NBER and by the institutionalists. In contrast, by the 1940s, there was in place a serious research programme, with techniques that were perceived to rival those of the hard sciences, in which theory and data interacted in a way that was different from that found in inter-war institutionalism. The transition was a very slow process: for instance, when Kenneth Arrow entered Columbia as an undergraduate in the 1940s, he was still not taught modern price theory (Colander, Holt and Rosser, 2004, ch. 10), but rather the institutional economics of the 1920s and 1930s. The scene was set for the disputes that were, in the late 1940s and early 1950s, to determine the way economics was to evolve after the Second World War.

Conclusions
At the beginning of the 20th century, America's economic heritage was still tied up with the cultural influence of Protestantism. By the 1930s, that legacy had disappeared. The significance of institutionalism was not that it continued the earlier historical economics acquired by Ely, J.B. Clark and their contemporaries in Germany but that it was an organized movement for a purely secular and scientific economics (Rutherford, 1999). Some 50 years after the founding of the AEA, the profession was still split deeply on the proper role of the state in the economy, but everyone in the discussion now believed that the role of the state was a scientific question and was actively engaged in the development of the tools to answer the question. Neoclassical methods, the forerunners of those that dominated the profession in the post-war era, were being developed, but there was an immense variety, which the labels neoclassical and institutionalist fail to capture. It was a period of genuine pluralism in economics (Morgan and Rutherford, 1998).

In retrospect, it is possible to discern the advance of neoclassical and more technical economics on a broad front. Young, Chamberlin, Hotelling, Samuelson and others were establishing a theoretical framework that could animate both microeconomic and macroeconomic work. However, rather than see this process as inevitable it is important to see the importance of external factors in determining the outcome of inter-war pluralism. The Great Depression exerted a profound effect; institutionalist planning was tainted by the failure of Roosevelt's first New Deal, in which planners such as Rexford Tugwell were heavily involved. The Second World War was perhaps even more important in helping change perceptions of what economics was and ideas about the position of economists in society. The rise of the Nazi party and their policies in Europe not only removed a major rival to the supremacy of Anglo-American economics, but caused an influx of economists into the United States who proved highly influential.

In addition, it is important not to exaggerate the extent of any neoclassical victory. Institutionalists remained strong in many fields. The NBER's work in establishing a statistical basis on which empirical analysis could be based was unrivalled. Furthermore, even where there would appear to be evidence for the conversion of institutionalists to other approaches, significant elements of institutionalism remained, as in J.M. Clark's work on the control of business or Hansen's use of Keynesian methods for analysing the business cycle. The legacy of institutionalism was widespread. There was a swing away from institutionalism, which can be documented in many ways (see, for example, Backhouse, 1998; Biddle, 1998) but the story was not linear, and in the 1930s and 1940s it was highly dependent on external events.

**How to cite this article**

After 1945, American economics was transformed as radically as in the previous half century. Economists’ involvement in the war effort compounded changes that originated in the 1930s to produce profound effects on the profession, and many of these were continued through institutions that developed during the Cold War. This article traces the way the institutions of the profession interacted with the content of economics to produce the technical economics centred on a core of economic theory and econometric methods that dominate it today. Attention is also drawn to the broader role of American profession in economics outside the United States.

The effect of the Second World War

The Second World War is more than a conventional dividing line, for it profoundly affected the course of economics in the United States. The interwar period had been one of pluralism within economics: there was a variety of competing approaches to the subject, none of which was dominant. It was also comparatively easy to discern distinctively ‘American’ trends in economics, which could be related either to the intellectual environment (notably the pragmatism of C.S. Peirce, William James and John Dewey) or to economic circumstances (such as the recent establishment of the Federal Reserve System). Within a decade of the Second World War, if not earlier, this had changed dramatically. Economics was becoming more technical, the foundations of an orthodoxy were being laid, and the position of the United States in relation to other countries was changing. The conventional explanation is the Keynesian revolution, reinforced by the rise of mathematical economics, but there is much more to the story than that.

The key to this picture is the so-called ‘old’ institutionalism. In the interwar period, Institutionalism was a very broad movement aimed at making economics more scientific through placing it on firmer empirical foundations. Though its boundaries were very blurred, it is reasonable to see it as covering economists as diverse in their empirical work as Wesley Mitchell, Simon Kuznets, Gardner Means, John Commons and John Maurice Clark. Though they had connections with economists in Europe, it was a distinctively American movement. Mathematical economics is inherently less culturally specific, but even here there were distinctive American approaches to the subject: Paul Samuelson’s early work, under E.B. Wilson, drew on a type of mathematics very different from that used by Europeans. The same could be said about the early econometricians, from Henry Ludwell Moore to Henry Schultz: there were important European parallels, but they were pursuing research in a way that was distinctive. Monetary economics illustrates both the distinctiveness of American economics and the blurred boundaries between different approaches to the subject. Because the Federal Reserve System had been established much later than the major European central banks, there was much more lively debate over the principles on which it should be run. The result was a rich mixture of arguments spanning the divides between neoclassical and institutionalist, Harvard and Chicago, Banking School and Currency School.

The Second World War was important for several reasons. First, economics became tied up with the war effort. Economists were clearly involved in places such as the Office of Price Administration, the Treasury or the War Production Board. It was in the last of these that national income statistics, first calculated in 1933, were developed into a system of national accounts, providing the basis for planning the massive shift of resources from civilian to military production that took place after 1941. However, perhaps more significantly, economists became involved in fighting the war, primarily through the Office of Strategic Services (OSS), forerunner of the Central Intelligence Agency which employed around 50 economists under Edward Mason in its Research and Analysis division (Leonard, 1991; Katz, 1989). In the OSS, economists and other social scientists were employed alongside physicists and other
scientists in tasks where economics shaded imperceptibly into statistics and engineering. They analysed intelligence, and became intimately involved in questions of military strategy and tactics, emerging from the war with an enhanced reputation: not only was economic analysis important, but many economists had proved themselves useful as general problem solvers. Operations research, a set of techniques centered on optimization subject to constraints, came to be much more central to economics.

At the end of the war, the Servicemen's Readjustment Act (1944), the so-called G.I. Bill, offered financial support to US ex-servicemen who wanted to continue their education. This fuelled a dramatic increase in the university system. The number of bachelor's degrees awarded in US higher education institutions, which had never risen above 187,000 before the war, rose to 271,000 in 1947–8 (317,00 if higher degrees are included too) and 432,000 in 1949–50, many of these choosing to study economics. This accelerated the generational shift that was taking place, providing academic openings for economists returning from government service to civilian life, many of these being in institutions that had not been prominent before the war. While some economics departments continued as before, there was a shift in the profession's center of gravity away from places such as Wisconsin (the leading centre for Institutionalism) towards ones like MIT, Berkeley and Stanford – other places, such as Columbia, Harvard, Chicago and Yale were important before and after the war (Barber, 1997; Backhouse, 1998).

The subject began to be taught using textbooks written by young economists (Kenneth Boulding, Lorie Tarshis and Paul Samuelson) during the 1940s, in place of ones that had their origins nearer the turn of the century.

The Cowles Commission and RAND

A particularly important center for quantitative work in the 1940s was the Cowles Commission, which had moved to Chicago in 1938, and of which Jacob Marshak became Research Director in 1943. He laid out a programme of research focusing on the development of new methods to take account of the specific features of economic data, perceived to be simultaneity, the importance of random disturbances and the prevalence of aggregate time-series data. This programme proved to be one that attracted American economists, many of whom were involved in the war effort, and many of the highly technical European emigrés such as Trygve Haavelmo, Tjalling Koopmans and Abraham Wald. Not surprisingly, the operations research side of economics was dominant here, not simply in obvious ways, such as the work by Koopmans and George Dantzig on linear programming and the simplex method, but in the broader conception of economics as engineering. This was not confined to the Cowles Commission (one can see such an influence at other places such as Massachusetts Institute of Technology, MIT) but such work clearly centred on Cowles.

The important idea that emerged from this phase of the Cowles Commission's work was that the economic system could be analysed as a probability distribution, the task of economics being to identify the properties of that distribution. General equilibrium theory, embracing individual optimization within a system of simultaneous equations, provided an account of the structural relationships. Statistical methods, pioneered by Haavelmo and Koopmans, provided the means for relating that theory to data that exhibited random shocks in addition to any systematic relationships between the data, not just estimating coefficients but also testing the theory. This has been called a probabilistic revolution (Morgan, 1991).

Controversy over these new methods erupted in 1947 when Koopmans (1947) challenged, head on, what had previously been considered the scientific way to do empirical economics – the National Bureau of
Economic Research’s (NBER) meticulous data-gathering and comparatively informal data-analysis – represented by *Measuring Business Cycles*, by Arthur Burns and Wesley Mitchell (1946). As Rutledge Vining (1949), replying for the NBER, justly claimed, Koopmans had written a manifesto for the Cowles Commission’s new methods, privileging the testing of theory over the search for hypotheses. In addition to the techniques mentioned above, its fruits ranged from the monetary theory that formed the heart of Don Patinkin’s *Money, Interest and Prices* (1956), the leading exposition of macroeconomic theory till the 1970s, and Lawrence Klein’s models of the US economy, from which developed much of macroeconometrics.

In the late 1940s, the RAND Corporation, in Santa Monica, California, emerged as a new focus for technical economic analysis. RAND was initially a division of the Douglas Aircraft Company, but from 1948 it became a non-profit organization, funded at first by the US Air Force, and later by other bodies, of which the Ford Foundation was the most important. It was an interdisciplinary environment where economists worked alongside scientists, mathematicians, engineers and other social scientists. It was established by senior figures in the US Air Force and was motivated by the Soviet threat and the emerging Cold War, and embodied lessons learned in the Second World War. Through H. Rowan Gaither, Chairman of RAND’s Board of Trustees and, from 1953, President of the Ford Foundation, RAND became closely linked to Ford: its overall product was ‘systems analysis’, a broad umbrella under which a range of mathematical work could be sponsored, linked primarily by certain sets of mathematical techniques and a vision of economics centered on rational choice. Though it was associated with much else, from Kenneth Arrow’s *Social Choice and Individual Values* (1951) to *Linear Programming and Economic Analysis* by Dorfman, Samuelson and Solow (1958), its main significance was in game theory, bringing together economists from Cowles (such as Arrow) with economists and mathematicians from Princeton (which included John Nash), the major academic centre of research into game theory during the 1950s.

The precise significance of the military involvement in economics is not yet clear. The Office of Naval Research (ONR) provided much funding, especially for game theory research, and the US Air Force was behind RAND. Clearly some projects were directly driven by military imperatives, such as working out a strategy for responding to (or anticipating) a Soviet nuclear strike. There are also clear links from systems analysis/operations research, and the techniques associated with these, to military requirements. Against this, those involved emphasize that researchers at RAND were given great freedom and military sponsorship had little or no effect on what they did (see Mirowski, 2002). However, even if researchers did have a high degree of freedom, there was certainly selection bias in the types of projects and researchers who received support from these sources, and the scale of such funding makes it plausible to argue that may have had a significant effect on the way the profession developed.

**Mathematics, technique and the ‘core’**

To say that economics has become more mathematical in the post-war period is too obvious to need justification. However, the significance of this process and the way it came about are far less obvious and need disentangling.

Mark Blaug (1999) has labelled what happened to economics after the 1950s ‘the formalist revolution’. However, within this lie a number of very different developments. One is the incursion into economics
of formalist mathematics. At the outset of The Theory of Value, Debreu (1959) wrote that he was approaching his subject with the degree of rigour associated with the contemporary formalist school of mathematics. His work formed part of a broader movement towards placing economic theory on an axiomatic foundation, and comprising the literature on existence, uniqueness and stability of general equilibrium (see Weintraub 2002). Even here, however, it is possible to discern strands that on closer inspection are very different. Ingroa and Israel (1990) distinguished the formal and interpretive branches, associating the former with Debreu and the latter with Arrow. Others have traced differences to disputes over formalism in mathematics (Weintraub, 2002). The most eminent mathematician to engage with economics, John von Neumann, was not only a critic of formalism (in the sense of Hilbert): his interest in economics stemmed from a broader concern with artificial intelligence that, Mirowski (2002) has argued, differentiated his views sharply from economists at the Cowles Commission and others pursuing general equilibrium analysis.

More significant than this is the fact that most economics, as Solow (1997) has observed, is not formalistic in this sense. Rather, what has happened is that economics has become more ‘technical’: he was probably right to argue that axiomatics was of no interest to most economists. Perhaps the most influential exponent of mathematics in economics, Paul Samuelson, whose Foundations of Economic Analysis (1947), written at Harvard and the basis for the style of economics he established at MIT, amounted to a manifesto for mathematical economics. His work, which arose from a mathematical tradition very different from the European traditions out of which von Neumann and Debreu came, sought to be rigorous without being based on axiomatization. Even further from formalism, but equally influential, was the Chicago School, dominated from the 1940s to the 1970s by Milton Friedman. Friedman favoured simpler models and was more sceptical about complex mathematical reasoning. Thus Hands and Mirowski (1998) have distinguished three schools in post-war neoclassical price theory – Stanford (Arrow), MIT (Samuelson) and Chicago (Friedman). Whether or not one accepts the claim made by Hands and Mirowski that these represent three responses to the failure of Henry Schultz's attempt to quantify demand theory before his death in 1938, this provides a useful way to represent the variety of ways in which a common theoretical core was developed.

However, becoming more technical is not synonymous with using mathematics. Another dimension is the separation of theory and application. Though the distinction between theory and applied work is taken for granted by most contemporary economists, the situation was very different before the Second World War. There was much work where it is impossible to draw any distinction between statements that are intended to describe the world and ones that are at the level of theory. In what we would now consider applied work, the practice of clearly separating theory and application is something that emerged only after the Second World War (see Backhouse, 1998). This change is reflected in the language economists began to use: they began to talk in terms of models. Though the idea of a model has deeper roots, talking in terms of models took off only from 1939, having been very rare before that. As the discipline changed, so did the curriculum, something in which the American Economic Association (AEA) became involved. During the 1940s, partly in response to demands of wartime, and partly because of broader uncertainty about how economics should be taught, the AEA established committees on undergraduate education, the main outcome being a report in 1950. Out of this rose the suggestion to review graduate education, resulting in a report by Howard Bowen, sponsored by the AEA and funded by Rockefeller, which appeared in 1953. On the grounds that ‘technical knowledge’ of
Economics would be useful for those working as economists in government, business and education, this argued that ‘there should be a “common core” for all students who are to be awarded advanced degrees in economics’ (Bowen, 1953, p. 2). This core consisted ‘primarily of economic theory including value, distribution, money, employment, and at least a nodding acquaintance with some of the more esoteric subjects such as dynamics, theory of games and mathematical economics’. No one, it was argued, had claim to an economics Ph.D. without ‘rigorous initiation’ into these and economic history, history of economic thought, statistics and research methods (Bowen, 1953, p. 43). Interestingly, mathematics was placed alongside Russian, German and Chinese: it was important to have some economists with knowledge of it, but it was not necessary for all to do so.

In Bowen's report, the core was still very broad – a statement of the range of knowledge – that economics Ph.D's should be expected to have. Over the following two decades it came to be used more narrowly. For example, Richard Ruggles (1962, p. 487) wrote of the function of graduate training being ‘to provide a common core of basic economic theory’ that would be used elsewhere in the programme, and observed that ‘at a great many universities’ training in mathematics was required. However, this was still discussed alongside language requirements. Though such questions had been raised as early as the Bowen Report, it was in the 1960s that the AEA meetings hosted debates over the role of economic history and history of economic thought in the graduate curriculum. Gordon (1965) conducted a survey implying, as Bowen had found a decade earlier, that though most graduate schools still offered the subject, history of economic thought was declining, and that there was pressure for it to decline further, particularly from younger faculty. In the survey by Nancy Ruggles (1970), the subject was defined in the now familiar way of a unifying core of micro and macro theory, quantitative methods (interestingly, econometrics, simulation, survey methods and operations research) and a range of applied fields that did not include any history.

These trends continued to the end of the century. They are best summed up by saying that economists were increasingly being trained, at Ph.D. level, as technicians rather than as scholars in the traditional sense of the term. In the 1940s, when concerns were raised about this in AEA meetings, it was still plausible to respond the demands of scholarship, and breadth of education, were compatible with mastering the necessary technical skills; but by the 1970s this was becoming more and more difficult. The demands of technique were pushing courses that provided breadth, symbolized by history of economic thought, out of the curriculum. By the end of the 1980s, this had gone so far that some Liberal Arts professors claimed that Ph.D.’s from the leading graduate schools were no longer equipped to teach at undergraduate level: not only did they know too little of the past and present literature on economics, but they did not know enough about the institutions of contemporary market economies. There were even signs that Ph.D. students themselves were sceptical about the value of the hurdles over which they were jumping (Colander and Klamer, 1987; 1990). In response to these concerns, the AEA established a Commission on Graduate Education in Economics, which reported in 1991 (Krueger, 1991; Hansen, 1991; see Coats, 1992a, for a comparison of this and Bowen's report). Though some changes were recommended, these were minor and had little effect (Colander, 1992). When Colander (2005) repeated his earlier survey a decade and a half later, he found much lower levels of dissatisfaction, though concluded that the students had adjusted to the more technical syllabus, not the other way round.

Economic analysis
The way the use of mathematics spread within economics was inextricably linked with developments in economic analysis. It was not simply a matter of making earlier, less rigorous, analysis more precise. To be able to use the mathematical techniques in the way they did, the basis on which economics rested had to change. For the institutionalists, very broadly interpreted, being scientific meant basing economics firmly on evidence about how the world worked. It was because he believed that empirical research would establish accounts of human behavior that were more complex than those offered by economic theorists that Mitchell (1925) had predicted that economists would lose interest in an abstract, artificial man. The result was that the 1930s and 1940s saw a wealth of empirical work on industrial organization, pricing, labour markets and many other aspects of economic behaviour. But mathematical theory, given the techniques then available to economists, necessitated working with simpler assumptions, in which agents were maximizers operating in markets where competitive structures were precisely defined, and if possible were perfectly competitive. It is perhaps because of the strong institutionalist element in American economics that the debates through which these simplifying assumptions were established were dominated by American economists.

The clash between institutionalism and new, technical approaches explicitly came to the surface in Koopmans's review (1947) of *Measuring Business Cycles*, by Arthur Burns and Wesley Mitchell (1946). Koopmans presented his approach as building on the work of those like Burns and Mitchell who simply measured: it was necessary to pass beyond that to the ‘Newton stage’ in economic theorizing, where theory and data analysis informed each other. Data would be used to test theory. Representing the old view, Rutledge Vining (1949) pointed out that the Cowles Commission methods involved more than this: that they presumed a specific type of theory and empirical methods. If one did not know what theory was suitable, different empirical methods were required. Burns and Mitchell, Vining argued, were concerned with discovery as much as with testing, for, in the absence of empirical work, economists did not know what form theory should take.

Substantially the same issue arose in the so-called ‘marginalist’ controversy, provoked by Richard Lester's article in the *American Economic Review* (1946). Though Lester was portrayed by critics as drawing naive conclusions from surveys, and as presenting a radical challenge to profit maximization, he is better seen as arguing that economics needed to be based firmly on the mass of evidence that had been accumulated during the previous decade or more on how firms behaved and on how labour markets worked. Controversy here was more prolonged and more complex, spilling over into discussion of industrial organization, where Lester's critics included economists on both sides of the divide between Harvard (dominated by Mason and Chamberlin) and Chicago (where Friedman and Stigler were; see Lee, 1984; Mongin, 1992). Fritz Machlup changed the debate into one about marginal analysis and, together with Friedman, established the principle that economics was about explaining behavior, not explaining how decisions were made. Though he did not intend it that way, Friedman's (1953) methodology of positive economics, with its emphasis on testing predictions, not assumptions, could be taken as vindicating economic theory's neglect of its empirical foundations.

It is no coincidence that these controversies took place in the pages of US journals, as did a less prominent one a few years later on the role of mathematics in economics (Novick, 1954, and ensuing discussion; see Mirowski, 2002, pp. 402–5). There were parallels in other countries, but it was in the United States, where in the 1930s institutionalists and neoclassicals had vied with each other, that the
most marked cleansing of approaches that could not be formalized so easily was taking place. In the 1950s and 1960s, formal modelling based on maximization and, increasingly, competitive markets spread throughout the discipline. Price theory became more formal and increasingly dominated what came to be known as microeconomics. Keynes's behavioural microfoundations (based on ‘propensities’ and imprecise generalizations from observed behaviour such as ‘animal spirits’) were replaced with optimizing ones and macroeconomics came to be seen through the lens of utility maximizing agents, as in Don Patinkin's *Money, Interest and Prices* (1956). General equilibrium analysis, summed up by Debreu's *Theory of Value* (1959), though never more than a minority activity, came to be seen as the fundamental theory on which more workaday theorizing rested.

During this period, however, there were limits to the application of formal theory. Though formal microfoundations could be provided for many of the functions, macroeconomics was seen as separate, not entirely reducible to a single, consistent microeconomic theory. In microeconomics, strategy and industrial structure remained outside the purview of formal theory, empirical work dominating work on industrial organization. Development economics offers another example of a field that stood apart from other fields, reflecting the assumption, held widely though not universally, that people in different societies behaved in different ways. Thus, although economists later came to see the rise of formal theory and mathematical methods as the key development during the period, its progress was slow, and it was anything but pervasive as late as the 1960s. The way in which less formal approaches, based on assumptions that ran directly counter to those underlying what later became dominant, is nicely illustrated by a project entitled ‘The Inter-University Study of Labor Problems and Economic Development’, undertaken by John Dunlop, Clark Kerr, Frederick Harbison and Charles Myers (see Cochrane, 1979). Its thesis, that industrialism required the development of a new type of man, ensured that, as the assumptions underlying modern theory became established, it came to be seen as a quaint relic of the past. However, its significance rests in its being a large project, lasting over 20 years, receiving $855,000 from the Ford Foundation and $200,000 from Carnegie, producing around 40 books and, in Cochrane's view, helping to define labour economics as that field existed in the late 1970s. Though its final report came as late as 1975, its objectives were framed against the background of thinking on labour questions that the older institutionalist economists would have understood; its analysis drew on sociology and industrial relations as well as on what would now be recognized as properly economic analysis.

However, from the 1970s things changed. Formal methods, based on individual optimization, were used to analyse problems of uncertainty and information, the most prominent exponent of this being Joseph Stiglitz. These ideas were applied to labour markets, finance, and many other fields. Macroeconomics turned away from what Lucas called ‘free parameter’ models – ones containing parameters that were not based on optimizing behaviour. Public choice theory, which emerged at the boundaries of economics and political science, brought government and much organizational behaviour within the scope of rational choice (see Medema, 2000). Initially, this was not widely considered to be economics, with the result that public choice scholars found it hard to publish in the major journals, leading James Buchanan, Gordon Tullock and their associates to establish the Public Choice Society, and to develop their own journals. However, fairly soon the main economics journals opened up to such work. Methods were found to build models of general equilibrium with monopolistic competition, these enabling trade theory to move away from assumptions of perfect competition that were thought unrealistic in many contexts. Game theory was introduced to analyse problems of strategy, first transforming industrial organization
and later being extended to almost every other field of economics. Development economics, like macroeconomics, ceased to be considered as resting on principles different from those in the rest of the discipline. Rational choice methods were even applied by economists with clear radical sympathies, such as in the rational choice Marxism of John Roemer and Jon Elster.

Most of these developments were international in their reach, but all were centred, squarely, in the United States. In none of the cases just mentioned would it be conceivable to write the story without discussing the role of American economists and economists based in the United States, whereas it would be possible (if not always the full picture) to do so without mentioning work in the rest of the world. The collective effect of these developments was to transform a discipline in which, though rational, maximizing behaviour was central, numerous exceptions and special cases existed, to one where it could plausibly be argued that economic theory was simply working out the implications of maximizing behaviour. Economic theory could be seen as resting on a single behavioural postulate.

Faced with this scenario, in which economic theory in the United States became, methodologically, narrower, some economists rebelled. Radical economists, stimulated by the Vietnam War, began to argue in the late 1960s, that economists were systematically ignoring questions such as power, class, and income distribution. Frustrated by their inability to persuade their more orthodox colleagues to take their ideas sufficiently seriously, they formed the Union of Radical Political Economy, setting up networks, conferences and a journal (Coats, 1992b; 2001). Shortly afterwards, inspired by Joan Robinson's Ely Lecture at the AEA in 1971, Alfred Eichner, Jan Kregel and others organized what developed into the grouping known as Post Keynesian economics (Lee, 2000). ‘Austrian economists’, influenced by the work of Ludwig von Mises, Friedrich Hayek, and Ludwig Lachmann, encouraged by Hayek's being awarded the Nobel Memorial Prize in 1974, also began to organize themselves. In all cases, the organization of these groups was motivated by the sense of exclusion they felt from the mainstream, represented by the meetings of the American Economic Association and the leading economics journals, who regarded their work as generally of low quality. These movements remained small, with strengths in particular institutions (Austrians at New York and Auburn; Post Keynesians at Rutgers and Tennessee; Public Choice in Virginia; Radicals at Amherst and the New School).

These self-consciously ‘heterodox’ groups were but part of a wider fragmentation of the discipline. Technological changes meant that economic print runs for books and journals fell during the period, and the costs of travel and communications fell. Together with the increased size of the economics profession, these developments made it easier for sub-fields of economics to organize, represented most clearly by the rapid rise in the number of specialist journals. The changing character of the profession was reflected in the Allied Social Science Association (ASSA), the main professional meeting of American economists, organized by the AEA. By 1998, though the AEA, the American Finance Association and the Econometric Society dominated the meetings, there were 52 societies affiliated with the ASSA (compared with 34 in 1980), and the AEA was having to restrict the number of sessions these societies were organizing, something it had not done two decades before.

The 1970s and 1980s were arguably years of integration, when the American economics became more homogeneous, the core of microeconomics based on individual optimizing behaviour being applied to more and more. More than ever before, and in dramatic contrast with the situation before the Second World War, there was an orthodoxy. However, this was questioned and developed at both empirical and theoretical levels. One reason was that developments in data collection and in computing meant that economists were able to analyse the behaviour of real individuals in a way that economists of earlier
generations (see, for example, Mitchell 1925) could do little more than dream about: ‘microeconometrics’ was recognized with the 2000 Nobel Memorial Prize for James Heckman and Daniel McFadden. It became possible to engage in quantitative analysis of microeconomics as never before. Another reason was that economists turned to experimentation as a source of data: experimental economics, considered esoteric as late as the 1970s, was given respectability with the debates over preference reversals in the pages of the American Economic Review and the award of the 2002 Nobel Memorial Prize to Daniel Kahneman and Vernon Smith. This rapidly spread throughout the profession. When ‘behavioural’ economics started being taken seriously in finance, a field where predictive power was always paramount, it was a sign that alternatives to conventional views of rationality were being taken very seriously. Bounded rationality, on which Herbert Simon had been working since the 1950s at Carnegie Mellon, and for which he got the Nobel Memorial Prize in 1978, moved from being something idiosyncratic, if respected, to being a mainstream technique. Evolutionary game theory and complexity theory offered new ways to think about economic change that expanded the boundaries of what was accepted in the subject. By the end of the century, though rational choice models remained immensely strong, it became much harder to describe economics as dominated by an orthodoxy. Once again, though these developments were international in their scope, they were centred on the United States, just as were the developments of the 1970s. Ideas whose main supporters were European, such as the competing views of consumer theory associated with Werner Hildenbrand (who derived demand functions from assumptions about distributions of characteristics across individual consumers), had far less influence.

Economists, ideology and policy

Ideology was never far from the surface. In the 1940s concern with ‘Reds’ was common in the United States, though economists might consider the problem only to dismiss it. After 1945, as the Cold War developed, these concerns with Communism grew, reaching their peak with Joseph McCarthy's search for Communist sympathizers. Economists had frequently been viewed with suspicion amongst businessmen, some of whom were important patrons of higher education, but the stakes were raised. Planning was suspect, a legacy from the days of the New Deal, and Keynes provided a convenient focus, for he was a more real threat than Marx: according to the Chicago Tribune, he was the Englishman who ruled America (see C.D.W. Goodwin, 1998, on these episodes). Influential figures argued that Keynesianism was tantamount to Communism. Textbooks, such as those of Lorie Tarshis and Samuelson, that discussed Keynesian theory were attacked and sometimes removed from syllabi under pressure from aggrieved sponsors (Colander and Landreth, 1996; 1998).

The cases where economists were forced out of academic positions because of real or alleged Communist sympathies are comparatively easy to document (Goodwin, 1998; Lee, 2004). What is much harder to prove is the effect this had on how economics pursued their work. There were certainly great pressures to be technical, for arcane communications between specialists were much less likely to be considered suspect than ideas that reached out beyond academia. Using an evolutionary model, Goodwin (1998, p. 79) distinguishes between ‘conceptual variation’ and ‘intellectual selection’, arguing that the attitudes of economists’ patrons must have influenced the latter. However, doubts about its closeness to communism did not prevent Keynesianism from becoming widely accepted in academia, though that
may have contributed to its being expressed in more careful, technical language than might otherwise have been the case (see Colander and Landreth, 1996, p. 172).

This bias towards becoming more technical chimed with another pressure – to be seen as doing science. When the National Science Foundation was established in 1950, the inclusion of social science was controversial and did not take place till 1956. If economists were to obtain support, they had to ensure that their work was seen as scientific. Given prevalent beliefs about science at the time, this favoured narrower, more technical work, and worked against the pluralistic interdisciplinarity that had been more common before the war (Goodwin, 1998, pp. 65–7). Similar issues arose in the context of support by philanthropic foundations, of which Sloan, Russell Sage, Rockefeller and Ford were the most important. Here, concern with being rigorous was intertwined with suspicion of planning and doubts about Keynesianism.

Similar considerations affected the body that brought economists into the heart of the US government, the Council of Economic Advisers (CEA) established by the Employment Act of 1946. This was intended to be a conservative institution, providing expert advice with minimal government interference. Its first chair, Edwin G. Nourse, shared this view: unlike his colleagues on the CEA, he was careful to avoid being seen as an advocate for White House policy (Bernstein, 2001, pp. 110–11). Unlike his successor, Leon Keyserling, he viewed economics as providing technical, disinterested expertise. Despite criticism, the CEA survived, achieving its greatest influence in the Kennedy administration, when Walter Heller, Kermit Gordon and James Tobin applied Keynesian demand-management policy to the problem of reducing unemployment.

Given that President Lyndon Johnson would not let it compromise his Great Society program, the escalating war in Vietnam led to rising federal deficits. CEA members warned the President about the consequences of this, but the CEA’s Keynesian policies were nonetheless blamed for the inflation and dislocation that followed during the 1970s. After 1979, alongside the decline of Keynesianism in academia, influence on stabilization policy rapidly shifted to the Federal Reserve under Paul Volcker and later Alan Greenspan. This shift from the CEA to the Fed marked not a decline in the influence exerted by economists, but a change in its structure: there was a convergence between research done in academia and in central banks and other agencies (see McCallum, 2000, p. 123), and a shift of emphasis towards microeconomic policy. Economists increasingly saw their role, not as engineers advising on how to operate fiscal and monetary levers, but as designers of institutions and of systems that would achieve desired outcomes in a world where policymakers were seen as part of the system rather than outsiders manipulating it. Frequently this involved creating new markets, or ‘reinventing the bazaar’ (McMillan, 2002).

There were also more conscious attempts to impose an ideological agenda on economics. RAND, the most influential think tank in the 1950s, became closely involved with the Ford Foundation (these arguments are developed in Amadae, 2003). It was explicitly a non-political organization, directed towards impartial research. However, under the chair of its board of trustees, H. Rowan Gaither, also president of the Ford Foundation after 1953, RAND focused on ‘systems analysis’, based on principles of rational action. Rational choice, central to the work of RAND since its inception, could be seen as providing, though its focus on the independent individual, a justification for a free society, and an alternative to Communist collectivism (see Amadae, 2003). RAND’s ideology, like that of Ford, was one of technocratic management, by experts using rigorous quantitative techniques. This ideology became
prominent in government in the 1960s when applied by Robert McNamara, who came from the Ford Motor Company, as Secretary of Defense.

Others had a more explicit ideological agenda. The American Enterprise Institute (established 1943), The Foundation for Economic Education (1946) and the Liberty Fund (1960) were established specifically to propagate free-market ideas. There were followed in the 1970s by a series of think tanks specifically to develop and apply such ideas to policy. The Heritage Foundation (1973) was specifically seen as providing a counterweight to the Brookings Institution (established 1927), which had come to be seen as part of finely tuned liberal policymaking machine (liberal being understood in the American sense). The aim of its president, Edwin Feulner, was to create ‘a new conservative coalition that would replace the New Deal coalition which had dominated American politics for half a century’ (L. Edwards, 2005, p. 371). When Ronald Reagan took office, the Heritage Fund provided policy ideas ready to put before the new administration. Hayek, who had moved to Chicago in 1950, played a particularly influential role in stimulating such organizations, within the United States and elsewhere, being part of an influential network centred on the Mont Pèlerin Society, an international group of libertarian thinkers established in 1947, whose founders included four Chicago economists and representatives from the Foundation for Economic Education.

Businessmen and conservative foundations also sought to stimulate free market thinking within economics, many of them effectively targeting specific institutions and programs. Though tiny compared with the big foundations such as Rockefeller and Ford, the Volker Fund (which supported Hayek and Mises), the Earhart Foundation (with a programme of one-year fellowships), the Scaife, Bradley and Olin foundations (which between them targeted support at, inter alia, Chicago's Law and Economics programme, and various centres of public choice theory in Virginia) managed to achieve influence out of proportion to their size (see Backhouse, 2005).

The international dimension

After the Second World War, the United States dominated the economics profession. Not only had German economics been devastated by the Nazi Party, but the resulting emigration contributed enormously to the expansion of American economics. The United States was not the only home for German and other European exiles, many moving to Britain, but it received more than any other country. Britain experienced no such loss, but its university system was too small for it to be a serious rival. The result was that many ideas that had originated in Europe rapidly came to be associated with the United States. The clearest examples of this are general equilibrium theory and econometrics, where European emigrés, led by Jacob Marshak, were instrumental in developing ideas that rapidly lost any close connection with their European origins. For example, in the 1930s, general equilibrium analysis had been an almost exclusively Viennese phenomenon (in Karl Menger's seminar), whereas by the 1950s, not only had those who worked on it there (Wald and von Neumann) moved to the United States, but its leading practitioners were an American (Arrow) and a Frenchman (Debreu), but both based in the United States.

Another clear example of this process is Keynesian economics, central to the evolution of American economics from the 1940s to at least the 1980s. This clearly originated in Britain, and British economists such as John Hicks and James Meade played important parts in the subsequent Keynesian
revolution. However, Keynesianism was rapidly Americanized. The key figure here was Alvin Hansen, the force behind Harvard's fiscal policy seminar, and later author of the influential *A Guide to Keynes* (1953). As has been argued by Mehrling (1998), Hansen's 'conversion' did not involve a rejection of his earlier ideas; rather, Keynesianism provided a vehicle through which his ideas on policy, rooted in the American institutionalist tradition, could be developed. Lawrence Klein (1947) provided another interpretation of Keynesian economics, relating it to with the econometric approach emanating from the Cowles Commission. Samuelson (1948) integrated Keynesian ideas into a textbook aimed at American students. During the 1950s and 1960s, the most influential work on macroeconomics was, with few exceptions, undertaken in the United States. Friedman's work on the consumption function provides another example of Keynesian ideas being assimilated into an American tradition (the empirical studies of the NBER).

What was happening here is that economics was becoming more international, but centred on the United States, a development made possible by the openness of the American system at a time when the profession was expanding and opportunities for immigrants were great. The United States dominated, not simply because of its size, but because of its resources. During the interwar period, the Rockefeller Foundation had been instrumental in building up economics in key European institutions in Britain, Scandinavia and many other countries (cf. Goodwin, 1998). After 1945, given the close American involvement in Europe that resulted from the war and reconstruction, this influence increased, accelerated by the reduced cost of international travel. In country after country, the economics profession changed in several ways. Academic systems became more open and competitive, with increased emphasis on publication in journals. There was a movement away from publication in the native language towards publication in English. Journals moved away from being national organs to ones that published articles by economists from a wide range of countries. Graduate education moved towards the American model, away from the traditional European model of a major thesis, publishable as a book, towards a Ph.D. comprising advanced coursework and a short thesis that could be the basis for three journal articles. The mathematical demands made of students rose progressively. Many economists either undertook postgraduate study in the United States or spent sabbaticals in US universities.

The speed and extent of these changes varied enormously (see the case studies in Coats, 1997). For example, in the UK, the proportion of staff with a degree from an American university rose steadily from 1950 to the 1990s. The highest proportion was at the London School of Economics, where it reached 45 per cent by the mid 1990s, whereas in other universities it was only five per cent. In Belgium, CORE at the Université Catholique de Louvain was an important centre for economists with strong US connections. Similarly, there was variability in the speed with which Ph.D. requirements changed, some British universities adopting the American model in the 1950s and 1960s, while others did not require any coursework beyond undergraduate level till the 1990s. In Continental Europe, there was the complication of language, and in many cases of academic systems that were much more rigid and less rapid to change, but many of these changes still took place. Outside Europe, there was the further factor of decolonization. At the end of the Second World War, many countries were still closely linked to former colonial powers, and the changes involved a switch from those to the United States. There is dispute over whether this process should be labelled ‘Americanization’ or simply ‘internationalization’ (see Coats, 1997, pp. 395–9). The process certainly did involve
internationalization, and it was arguable that many changes (such as the move towards advanced coursework) were necessitated by the rising technical demands made by the subject. As has already been explained, many of the ideas on which the period’s economics was based were European, not American in origin. Arguably, the United States appeared to dominate what was primarily an international system simply because of its size. However, there are strong reasons for considering the process as involving Americanization. In many cases, in Europe and elsewhere, the United States provided an example that was deliberately copied. In other cases, changes were brought about through connections with US universities. Harry Johnson, Canadian, but a professor at Chicago and Geneva, was important in bringing about changes at LSE where he also held a chair in the 1960s. Chicago economists developed close links with Latin American countries, consciously exporting Chicago economics to Chile: Chilean students studied in Chicago, and Chicago staff taught at the Catholic University of Chile (see A. Harberger, 1997; Valdes, 1995). Similar developments took place in Brazil, though involving a much wider range of universities: Chicago, Berkeley, Harvard, Yale, Michigan, Illinois and Vanderbilt (see M. R. Loureiro, 1997). The US Agency for International Development and the Ford Foundation provided a significant role in funding several of these inter-university agreements.

Similar remarks could be made about the US role in the international organizations that emerged after 1945, notably the International Monetary Fund (IMF) and the World Bank: they were vehicles for the internationalization of economics, along a model dominated by the United States.

Conclusions

Since the Second World War, economics in the United States has been transformed as dramatically as in its previous half-century. It is inevitable that economists looking at these changes focus on the economic ideas themselves, usually telling the story as one of progress. However, this transformation involved changes in the structure of the profession (notably in the nature of graduate education) and its place in society as well as changes in economic analysis. It is natural for historians to focus on connections between economic ideas and the institutions out of which they arose. To do this raises the question of whether these external factors influenced the course of economic ideas: of whether things could have been different. The difficulty here is that it is hard to construct a plausible account of how things might have been different because, even if it was the result of adaptation to chance events, what actually happened generally looks inevitable in retrospect. However, what can be done is to sketch some of the possible routes that could have been taken but were not.

Different paths were open for American economics in the 1930s. During the New Deal, economists such as Gardner Means had built up an enormous body of statistical data on how product and labour markets operated. From this starting point, economists could have chosen to build models that were less general but more securely rooted in specific institutional detail than was Walrasian general equilibrium theory. The route the discipline actually took was determined, *inter alia*, by the Second World War and the Cold War and the encouragement it gave to certain types of theorizing and certain types of empirical work. Macroeconomics offers a second account of alternative paths that might have been taken. The interwar literature contained discussions of rational expectations, dynamics, intertemporal equilibrium and credibility of policy regimes (see Backhouse and Laidler, 2004). However economists did not pursue such ideas but developed a macroeconomics centred on a static equilibrium framework (the IS–LM
United States, economics in (1945 to present): The New Palgrave Dictionary of Economics

model); much of the dynamics that had been lost was then ‘rediscovered’ in the 1970s. Had they developed a different set of ideas from the interwar literature (even from Keynes's own work), macroeconomics could not have developed as it did.

To argue in this way is not to claim that one path was right and the other wrong, or even that economists were aware of the directions in which their own theoretical choices (aimed at solving specific problems) would lead. Instead, historical accounts generally rest on two pillars. First, the standards by which economists judge their work – their standards of scientific rationality – reflect the intellectual climate in which they are working. In some cases, likely factors can be identified. For example, Weintraub (1998) has argued that conceptions of what it meant to be rigorous changed dramatically as a result of developments in quantum mechanics. But many of the influences on the criteria economists use to assess their work are harder to identify and have to be disentangled, cautiously, out of the historical record. Second, evolution requires not simply a mechanism for generating new ideas but also a selection process. To understand the way economic ideas have developed since the Second World War, it is necessary to consider the demand for economic ideas as well as the supply: thus, even if the economists are resolutely impartial, applying high scientific standards to their work, the identities and view of their patrons may serve, through favouring some types of inquiry rather than others, to affect the evolution of the subject. We may be too close properly to understand many of the connections, but economics during this period, just as much as the economics of earlier centuries, cannot be divorced from the institutional setting in which it developed.

Article

A prominent Japanese Marxian economist known especially for his rigorous and systematic reformulation of Marx's *Capital*. Born in Kurashiki in western Japan in a year of intense social unrest, Uno early took an interest in anarcho-syndicalism and Marxism. Not being of an activist temperament, however, he strictly disciplined himself to remain, throughout his life, within the bounds of independent academic work. For this deliberate separation of theory (science) from practice (ideology) he was frequently criticized. After studying in Tokyo and Berlin in the early 1920s, Uno taught at Tohoku University (1924–38), the University of Tokyo (1947–58) and Hosei University (1958–68). During most of the war years he kept away from academic institutions. He authored many controversial books, especially after the war. His eleven-volume *Collected Works* were published by Iwanami-Shoten in 1973–4.

The problem with Marx's *Capital*, according to Uno, is that it mixes the theory and history of capitalism in a haphazard fashion (described as 'chemical' by Schumpeter) without cogently establishing their interrelation. Uno's methodological innovation lies in propounding a stages theory of capitalist development (referring to the stages of mercantilism, liberalism, and imperialism) and using it as a mediation between the two.

Capitalism is a global market economy in which all socially needed commodities tend to be produced as value (that is, indifferently to their use-values) by capital. This tendency is never consummated since many use-values in fact fail to conform to this requirement. Only in theory, which synthesizes ‘pure’ capitalism, can one legitimately envision a complete triumph of value over use-values. The inevitable gap between history, in which use-values appear in their raw forms, and pure theory, in which they are already idealized as merely distinct objects for use, must be bridged by stages theory, which structures itself around use-values of given types (as ‘wool’, ‘cotton’, and ‘steel’ respectively typify the use-values of the three stages).
Uno's emphasis on 'pure' capitalism as the theoretical object has invited many uniformed criticisms. His synthesis of a purely capitalist society as a self-contained logical system follows the genuine tradition of the Hegelian dialectic, and is quite different from axiomatically contrived neoclassical 'pure' theory. Unlike the latter which takes the capitalist market for granted, Uno's theory logically generates it by step-by-step syntheses of the ever-present contradiction between value and use-values. The pure theory of capitalism is thus divided into the three doctrines of circulation, production, and distribution according to the way in which this contradiction is settled. By specifically articulating the abiding dialectic of value and use-values, already present in Capital, Uno has given Marxian economic theory its most systematic formulation, a formulation which militates against the two commonest Marxist errors known as voluntarism and economism.

Uno's approach is not dissimilar to Karl Polanyi's in appreciating the tension between the substantive (use-value) and the formal (value) aspect of the capitalist economy. Unlike Polanyi, however, Uno ascribes more than relative importance to capitalism, in the full comprehension of which he sees the key to the clarification of both pre-capitalist and post-capitalist societies. Thus Uno's approach reaffirms and exemplifies the teaching of Hegel (and Marx) that one should 'learn the general through the particular', and not the other way round.

Urban agglomeration

William C. Strange
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Urban agglomeration is the spatial concentration of economic activity in cities. It can also take the form of concentration in industry clusters or in employment centres within a city. One reason that agglomeration takes place is that there exist external increasing returns, also known as agglomeration economies. Evidence indicates that there exist both urbanization economies, associated with city size, and localization economies, associated with the clustering of industry. Both effects attenuate geographically. Theoretical research has identified many sources of agglomeration economies, including labour market pooling, input sharing, and knowledge spillovers. Empirical research has offered evidence consistent with each of these.

Article

Urban agglomeration is the spatial concentration of economic activity in cities. It can also take the form of concentration in industry clusters or in centres of employment within a city. That both kinds of concentration exist is not debatable. Cities contain roughly 80 per cent of the US population, and urban population densities are approximately four times the national average. It is not just aggregate activity that is agglomerated; individual industries are concentrated too. There are many examples. Computer software is well-known for its spatial concentration, especially in the Silicon Valley. Automobile manufacturing, finance, business services, and the production of films and television programmes are other notable examples of industrial clustering. Agglomeration also takes place within cities in the form of densely developed downtowns and sub-centres. These patterns are not
urban agglomeration: The New Palgrave Dictionary of Economics

unique to the United States. Capital and labour are highly agglomerated in every developed country, and they are increasingly agglomerated in the developing world.

Localization and urbanization economies

There are two sorts of agglomeration economies. Urbanization economies are associated with city size or diversity. Localization economies are associated with the concentration of particular industries. The idea that a city's size or diversity contributes to agglomeration economies is often attributed to Jacobs (1969), while the idea that industrial localization increases productivity goes back to Marshall (1890). Economists have looked for evidence of these effects in a number of ways. Since agglomeration economies by definition enhance productivity, one natural approach is to estimate a production function. Estimating the production function requires establishment level data on inputs, including employment, land, capital, and materials. Data on labour is the easiest to obtain, although even the most detailed datasets are incomplete, for instance by omitting experience in a particular occupation. Although data on purchased materials are sometimes available, data on internally sourced inputs typically are not. Measuring a firm's capital presents serious problems, including accounting for depreciation. Finally, even with good input data it is necessary to control for endogeneity of input use. Despite the difficulties inherent in estimating a production function, a substantial body of research has estimated the impact of agglomeration on productivity. The very rough consensus is that doubling city size increases productivity by an amount that ranges from two to eight per cent. Some estimates are lower. The diversity of the local environment, another aspect of urbanization, has also been shown to be positively related to productivity. In addition, there is evidence of localization economies of roughly similar magnitude (see Rosenthal and Strange, 2004, for a review).

There are other ways to look for evidence of localization and urbanization economies. Glaeser and Mare (2001) identify the existence of an urban wage premium, with workers in cities of over a million residents earning roughly a third more in nominal wages than workers in cities of fewer than 100,000. Even after controlling for the selection of highly productive workers into cities, a significant premium remains. This is evidence of agglomeration economies because firms would not be willing to pay such premium in the absence of a corresponding productivity advantage. Rosenthal and Strange (2003) consider the arrival of new business establishments and find that diversity encourages arrivals and that localization economies are more important than urbanization economies for the industries examined. Finally, Henderson, Kuncoro and Turner (1995) analyse employment growth in the United States during the 1970–87 period. For mature industries, the specialization of employment at the metropolitan level is positively associated with growth. These papers are fairly typical of those that have measured the existence of agglomeration economies. The broad conclusion is that both urbanization and localization economies are present.

The sources of agglomeration economies: why do cities and clusters exist?

Marshall (1890) identifies three forces that can explain industry clustering: input sharing, labour market pooling, and knowledge spillovers. Input sharing exists when, for example, a clothing manufacturer in New York is able to purchase a great variety of relatively inexpensive buttons from a nearby company
that specializes in button manufacturing. Correspondingly, the button manufacturer also benefits because there will be many nearby clothing manufacturers to whom it can sell buttons. The process is, therefore, a circular one. Labour market pooling exists when a film production company in the Los Angeles area can quickly fill a position by hiring one of the many specialized production workers already present locally. Similarly, a specialized worker in Los Angeles can more easily find a new position without having to relocate. In both instances, labour pooling reduces search costs and improves match quality, providing valuable benefits for employers and workers. Knowledge spillovers exist when industrial engineers can learn the tricks of the trade from random interactions with other programmers in the same location. Any of these forces can explain industry clustering. They can also give rise to cities. The sharing of business service inputs can, for example, lead firms in very different industries to benefit from locating in close proximity to each other. Similar sorts of stories can be told about labour market pooling and knowledge spillovers.

Marshall's list is, of course, incomplete. Many other forces can lead to agglomeration. First, there is greater availability of consumer amenities in large cities. A major league sports franchise, for instance, requires a significant fan base in order to be economical. Second, natural advantage can explain both urbanization and localization. For instance, heavy manufacturing has historically developed near sources of minerals and where water transportation was possible. Third, internal economies of scale coupled with transactions costs can lead to self-reinforcing agglomeration. This explanation is the heart of the New Economic Geography (NEG, Fujita, Krugman and Venables, 1999), and it has received much attention in recent years.

Various approaches have been adopted in modelling agglomeration economies. Perhaps the simplest is to assume that there is some sort of public good that can be shared more economically in a larger city or cluster (Arnott, 1979). This force operates on both the production and consumption sides. Productivity is enhanced by infrastructure, and utility is increasing in public goods. An alternative is to assume that there are local externalities, with agents directly making their neighbours better off (that is, more knowledgeable). Agglomeration economies can also arise from thick market effects in search or matching (Helsley and Strange, 1990). The important common element from all these explanations is that agglomeration is associated with situations where market outcomes are not guaranteed to be efficient. Duranton and Puga (2004) provide a more detailed survey of the sharing, matching, and spillover micro-foundations of agglomeration.

The discussion thus far has suggested that agglomeration is always a positive outcome, at least as a second-best solution to market failures. This need not always be the case. Another reason to agglomerate is rent seeking. Ades and Glaeser (1995) show that there are many situations where urbanization can allow a city's residents to claim the output of other agents. They argue that imperial Rome supported a population of more than one million at least in part because the rewards of empire were distributed to residents of Rome as 'bread and circuses' in order to preserve domestic order. In this case, a city may exist, not because it adds to productivity, but because it allows redistribution.

Empirical work has provided evidence of the presence of Marshall's forces. Jaffe, Trajtenberg and Henderson (1993) provide direct evidence, showing that patent citations are geographically localized. Holmes (1999) considers local input sharing. He shows that more concentrated industries have a higher value of purchased input intensity, equal to purchased inputs divided by sales. This is consistent with the presence of input sharing. Costa and Kahn (2001) consider one aspect of labour pooling: matching...
between workers and employers. The key result is that ‘power couples’, where both partners have at least a college degree, have disproportionately and increasingly located in large metropolitan areas. After considering other possible explanations, they conclude that power couples have become increasingly urbanized at least in part because it easier for both individuals to find good matches for their specialized skills. There is also evidence of the non-Marshallian agglomeration economies. Glaeser, Kolko and Saiz (2001) provide evidence of consumption effects. Kim (1995) documents the importance of natural advantage. Evidence of effects predicted by NEG is reviewed by Head and Mayer (2004). Looking across industries at the sorts of industry characteristics associated with agglomeration, Rosenthal and Strange (2001) find that all of the factors discussed above contribute to industrial agglomeration. The evidence is strongest for labour market pooling.

The geography of agglomeration economies: cities and neighbourhoods

It is common to consider agglomeration economies at the city level. This is because it is significantly easier to carry out estimation of production functions, wage premiums, births, or growth in that sort of aggregate analysis. In the previous section's analysis, however, it is clear that agglomeration economies depend on the distance between agents rather than on the political boundaries of cities. Thus, it makes sense to consider the degree to which agglomeration economies are at work at different levels of geography. Are they a neighbourhood effect or do they operate at the city level? In a sense, this question about the boundary of an agglomeration is parallel to asking about the boundary of a firm. The canonical question in the theory of the firm literature is: make or buy? Should an activity be carried out internally or through market transactions? The parallel agglomeration question is: near or far? Should one activity take place in close proximity to another or at a great distance? Rosenthal and Strange (2003) address this issue by using geo-coding software to measure total employment and own-industry employment within a certain distance of an employer. Using these measures, the paper calculates the effects of the local environment on the number of firm births and on these new firms’ employment levels for six industries (computer software, apparel, food processing, printing and publishing, machinery, and fabricated metals). The key result is that agglomeration economies attenuate with distance. The effect of additional employment beyond five miles is shown to be roughly one-quarter to one-half of the effect of additional employment within a firm's own zipcode (postal code). This result is consistent with both the concentration of employment downtown and in sub-centres.

Agglomeration economies in a system of cities or regions

There has been considerable theoretical work on the implications of agglomeration economies for a system of cities or regions. Fujita and Thisse (2002) review and synthesize the literature. With apologies for oversimplification, the analysis in the literature proceeds as follows. First, it is assumed that there exists some sort of agglomeration economy. The specification may be of a reduced form shifting of the production function or of a particular agglomerative force. In the NEG literature (Fujita, Krugman and Venables, 1999), for instance, agglomeration arises from backward linkages between firms and input suppliers and forward linkages between firms and consumers. Second, equilibrium in the system is
characterized. The equilibration always involves the individual location decisions taken by firms and households. It may also involve some coordination by a large agent, either a local government or a profit-maximizing city developer. Finally, the dynamic properties of the equilibrium are considered.

The systems of cities literature obtains several results. First, the characteristics of cities in an equilibrium system depend crucially on the sorts of agglomeration economies at work. If there are only localization economies, then the system will feature cities that specialize by industry. If there are in addition, or instead, urbanization economies, then diverse cities can arise. Second, there can be multiple equilibria. This means, for example, that there is no guarantee that the largest city in the middle of North America would be where Chicago is. Third, history matters. Agglomeration economies can be a conservative force in that they make it difficult for firms and workers to change their locations. Fourth, there is potential for catastrophic change, with a small change in parameters inducing a large change in outcomes. The attraction of other firms can cause an agglomeration to persist beyond the point at which it would have arisen from *de novo* location decisions. Eventually, however, when the attractiveness of other locations becomes sufficiently great, the agglomeration collapses suddenly. Fifth, equilibrium is not likely to be efficient. This result arises most starkly in a model where city sizes are determined solely by individual migration decisions. This ignores the existence of private developers and governments, which are both rewarded from realizing more efficient cities. However, in order to realize an efficient allocation, a developer would require unlimited control of city formation, a condition that is unlikely to obtain (Helsley and Strange, 1997).

urban economics

John M. Quigley
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Urban economics emphasizes: the spatial arrangements of households, firms, and capital in metropolitan areas; the externalities which arise from the proximity of households and land uses; and the public policy issues which arise from the interplay of these economic forces.

Keywords

cities; congestion; density gradient; diversity (ethnic and racial); endogenous growth; external economies; housing markets; human capital; labour markets; land markets; land use; monopolistic competition; patents; pollution; price discrimination; property taxation; regional economics; residential segregation; road pricing; Schelling, T.; social externalities; spatial competition; suburbanization; tipping point models; transport costs; urban agglomeration; urban consumption externalities; urban economics; urban production externalities; von Thünen, J.; zoning

Article

Cities exist because production or consumption advantages arise from higher densities and spatially concentrated location. After all, spatial competition forces firms and consumers to pay higher land rents — rents that they would not be willing to pay if spatially concentrated economic activity did not yield cost savings or utility gains. Economists have long studied the forces leading to these proximities in location, focusing first and foremost upon the importance of transport costs. Early theorists (for example, von Thünen, as early as 1826; see Hall, 1966) considered land use and densities in an agrarian town where crops were shipped to a central market. Early models of location deduced that land closer to the market would be devoted to producing crops with higher transport costs and higher output per acre. Cities in the 19th century at this time were characterized by high transport costs for both goods and people, and manufactured goods were produced in close proximity to a central node — a port or a railway from which goods could be exported to world markets. The high costs of
transporting people also meant that workers’ residences were located close to employment sites. Transport improvements in the late 19th century meant that urban workers could commute cheaply by streetcar, thereby facilitating the suburbanization of population into areas surrounding the central worksite. More radical technical change in the first decades of the 20th century greatly reduced the cost of transporting materials and finished goods. The substitution of the truck for the horse and wagon finally freed production from locations adjacent to the export node. The introduction of the private auto a decade later further spurred the decentralization of US metropolitan areas.

**Spatial forces**

The seminal literature in urban economics provides positive models of the competitive forces and transport conditions which give rise to the spatial structure of modern cities. These models emphasize the trade-off between the transport costs of workers, the housing prices they face, and the housing expenditures they choose to make. Relatively simple models can explain the basic features of city structure – for example, the gradient in land prices with distance to the urban core; the house price gradient; the relationship between land and housing price gradients; the intensity of land use; and the spatial distribution of households by income (see Breuckner, 1987, for a review).

Empirical investigations of these phenomena reveal clearly that these gradients have been decreasing over time. Indeed, the flattening of price and density gradients over time has been observed in the United States since as long ago as the 1880s. (Early work is reported in Mills, 1972.) In interpreting these trends, it is important to sort out the underlying causes. The stylized model described above emphasizes the roles of transport cost declines (in part, as a result of technical change and the role of the private auto), increases in household income, and population growth in explaining suburbanization. These models also rely upon the stylized fact that the income elasticity of housing demand exceeds the income elasticity of marginal transport costs. The alternative, largely ad hoc, explanations stress specific causes, for example the importance of tax policies which subsidize low-density owner-occupied housing, the importance of neighborhood externalities which vary between cities and suburbs, or the role of variations in the provision of local public goods. There is a variety of empirical analyses of the determinants of the variations in density gradients over time and space. A general finding is that levels and intertemporal variations in real incomes and transport costs are sufficient to explain a great deal of the observed patterns of suburbanization.

**Durable capital**

But, of course, variations in many of these other factors are highly correlated with secularly rising incomes and declining commuting costs, so any parcelling out of root causes is problematic. The elegant and parsimonious models of urban form have proven easy to generalize in some dimensions – for example, to incorporate stylized external effects and variations in income distributions across urban areas. It has proven to be substantially harder to recognize the durability of capital in tractable equilibrium models. The original models assumed that residential capital is infinitely malleable, and that variations in income or transport costs would be manifest in the capital intensity of housing over space in a direct and immediate way. The decline in land rents with distance from the urban centre means that
developers’ choices of inputs vary with capital-to-land ratios – declining with distance to the core. Dwellings are small near the urban core and large at the suburban fringe. Tall buildings are constructed near the urban centre, and more compact buildings are constructed in peripheral areas. But, of course, these structures and housing units are extremely durable, with useful lives exceeding 40 years or more. Thus, insights derived from the perspective in which the capital stock adjusts instantly to its long-run equilibrium position in response to changed economic conditions are limited. Incorporating durable housing into models of residential location and urban form implies some recognition of the fact that ‘history matters’ in the structure and form of urban areas. Cities with the same distribution of income and demographics and with identical transport technologies may be quite different in their spatial structures, depending upon their historical patterns of development. Extensions of these simple models analyse the form of urban areas when developers have myopic or perfect foresight and when development is irreversible. With myopic developers, land is developed at each distance from the centre to the same density as it would have been built with malleable capital, but, once built, its capital intensity is frozen. Thus, with increasing opportunity costs of land over time, population and structural densities may increase with distance from the urban core. With perfect foresight, the developer maximizes the present value of urban rents per acre, which vary with the timing of urban development. The present value of a parcel today is its opportunity cost in ‘agriculture’ until development plus its market value after conversion (minus construction costs). With perfect foresight, developers choose the timing of the conversion of land to urban use as a function of distance to the urban core, and development proceeds in an orderly fashion over time. Locations are developed according to their distance from the centre. Of course, durable residential capital also implies that structures may depreciate or become obsolete. In particular, a historical pattern of development along concentric rings from the urban core, together with rising incomes, means that the most depreciated and obsolete dwellings are the more centrally located. But embedded in each of these parcels of real estate is the option to redevelop it in some other configuration. Obsolete and depreciated dwellings commanding low prices are those for which the option to exercise redevelopment is less costly. Models of development with perfect foresight in which residential capital depreciates imply that the timing of initial redevelopment of residential parcels depends only on their distance from the urban core (since that indexes their vintage of development). These models imply that the capital intensity of land use does not exhibit the smooth and continuous decline with distance from the core. Capital intensity does decline with distance, on average, but the relationship is not monotonic. With uncertainty, developers take into account their imperfect knowledge of future prices in making land use decisions today. But this means that developers may make mistakes by developing land too soon. As a consequence, land development may often proceed in a leapfrog pattern. Landowners may withhold some interior land from development in anticipation of higher rents and profitable development later on (see Capozza and Helsley, 1990, for a unified treatment). The key point in these modern models of urban form which incorporate durable residential capital is that the timing as well as the location of development affect the choices made by housing suppliers. History ‘matters’ in these models, just as it does in the decisions of housing suppliers in urban areas.

Externalities
Recent work has greatly extended these urban models to address explicitly the production and consumption externalities which give rise to cities. The basic models combine Marshallian notions of ‘economics of localized industry’ and Jacobs's (1969) notions of ‘urbanization economies’ with the perspective on monopolistic competition and product diversity introduced by Dixit and Stiglitz (1977).

On the consumption side, the general form of these models assumes that household utility depends on consumption of traded goods, housing, and the variety of local goods. The markets for traded goods and housing are competitive, while the differentiated local goods are sold in a monopolistically competitive market. If there is less differentiation among local goods, then variety loses its impact on utility; greater differentiation means that variety has a greater effect on utility. Under reasonable assumptions, the utility of a household in the city will be positively related to the aggregate quantity of local goods it consumes and the number of types of these goods which are available in the economy (see Quigley, 2001, for examples).

On the production side of the economy, the importance of a variety of locally produced inputs can be represented in a parallel fashion. For example, suppose that the aggregate production function includes labour, space and a set of specialized inputs. Again, the markets for labour and space can be taken as competitive, while the differentiated local inputs are purchased in a monopolistically competitive market. If there is less differentiation among inputs, then variety loses its impact on output; greater differentiation means that variety has a greater effect on output. For example, a general counsel may operate alone. However, she may be more productive if assisted by a general practice law firm, and even better served by firms specializing in contracts, regulation and mergers. Again, under reasonable conditions, output in the city will be related to quantities of labour, space, and specialized inputs utilized and also to the number of different producer inputs available in that city.

The theoretical models built along these lines yield a remarkable conclusion: diversity and variety in consumer goods or in producer inputs can yield external scale economies, even though all individual competitors and firms earn normal profits. In these models, the size of the city and its labour force will determine the number of specialized local consumer goods and the number of specialized producer inputs, given the degree of substitutability among the specialized local goods in consumption and among specialized inputs in production. A larger city will have a greater variety of consumer products and producer inputs. Since the greater variety adds to utility and to output, in these models larger cities are more productive, and the well-being of those living in cities increases with their size. This will hold true even though the competitive and monopolistically competitive firms in these models each earn a normal rate of profit (see Fujita and Thisse, 2002, for a comprehensive treatment).

Applications: pollution and transport

As emphasized above, however, the advantages of urban production and consumption are limited. Explicit recognition of the land and housing markets and the necessity of commuting suggests that, at some point, the increased costs of larger cities – higher rents arising from the competition for space, and higher commuting costs to more distant residences – will offset the production and consumption advantages of diversity. Other costs like air and noise pollution no doubt increase with size as well.
Nevertheless, even when these costs are considered in a more general model, the optimal city size will be larger when the effects of diversity in production and consumption are properly reckoned. Urban output will be larger and productivity will also be greater (see Quigley, 1998).

The empirical evidence assembled to support and test these theoretical insights about the regional economy is potentially very valuable. Hitherto, much of the discussion about the sources of economic growth was framed at that national level, and most of the aggregate empirical evidence—time series data across a sample of countries—was inherently difficult to interpret. By framing these theoretical propositions at the level of the region, it is possible to investigate empirically the sources of endogenous economic growth by using much richer bodies of data within a common set of national institutions. Geographical considerations of labour market matching and efficiency (Helsley and Strange, 1990), of the concentration of human capital (Rauch, 1993), and of patent activity (Jaffe, Trajtenberg and Henderson, 1993) have all been studied at the metropolitan and regional levels, and considerable effort is under way to use regional economic data to identify and measure more fully the sources of American economic growth. These are major research activities exploring urban externalities in urban economies throughout the developed world. This research programme is still in its infancy.

Of course, specialization, diversity and agglomeration are not the only externalities arising in cities. High densities and close contact over space reinforce the importance of many externalities in modern cities. Among the most salient are the external effects of urban transport—congestion and pollution. Most work trips in urban areas are undertaken by private auto. (Indeed, in 2000, less than four per cent of commuting was by public transit; see Small and Gomez-Ibanez, 1999.) In most US cities, automobiles are the dominant technology for commuting from dispersed origins to concentrated worksites. This technology is even more efficient for commuting from dispersed residences to dispersed worksites in metropolitan areas. Since commuting is concentrated in morning and evening hours, roads may be congested during peak periods, and idle during off-peak periods. Road users pay the average costs of travel when they commute during peak periods. They take into account the out-of-pocket and time costs of work trips, and in this sense commuters consider the average level of congestion in their trip-making behaviour. But commuters cannot be expected to account for the incremental congestion costs their travel imposes on other commuters. This divergence between the marginal costs of commuting and the average costs of commuting may be large during peak periods on arterial roadways. The imposition of congestion tolls, increasing the average costs paid by commuters to approximate the marginal costs they impose on others, would clearly improve resource allocation. In the absence of efficient road pricing, the rent gradients in metropolitan areas are flatter, and the patterns of residential location are more centralized than they would otherwise be. Land markets are distorted and the market price of land close to the urban core is less than its social value.

The obstacles to improved efficiency are technological as well as political. Until recently, mechanisms for charging road prices were expensive and cumbersome. But modern technology (for example, transponders to record tolls electronically) makes road pricing easy on bridges, tunnels and other bottlenecks to the central business district. Regular commuters affix a device to their autos, a device which can automatically debit the traveller’s account. It would be a simple matter to vary these charges by time of day or intensity of road use and to make the schedule of these changes easily available to commuters. So far, at least in the United States, about the only form of price discrimination on bridges, tunnels and bottlenecks has been by vehicle occupancy, not by time of day and intensity of road use. It is surely possible to profit from the experience of other countries (such as Singapore) in pricing scarce
Political resistance is a major factor inhibiting the diffusion of road pricing. Typically, tolls are imposed in new facilities and the proceeds are pledged to retire debt incurred in construction. Paradoxically, tolls are thus imposed on new uncongested roads. Later on, when the roads become congested, the initial debt has been retired, and there is political support for removing the toll. (After all, ‘the investment in the bridge has been repaid.’) This is surely an instance where economics can better inform public policy.

Applications: social, spatial and neighbourhood

Urban areas have always been characterized by social externalities as well. The close contact of diverse racial and ethnic groups in cities gives rise to much of the variety in products and services which enrich consumption. But the city is also characterized by the concentration of poverty and by the high levels of segregation by race and class.

The spatial concentration of households by income is, of course, predicted by the models of residential housing choice described above. A central question is the extent to which poverty concentrations give rise to externalities which disadvantage low-income households relative to their deprived circumstances in the absence of concentration. A great deal of qualitative research by other social scientists suggests that this is the case. Quite recent econometric research, however, suggests that this proposition is quite hard to demonstrate quantitatively by reliance on non-experimental data (see Manski, 1995.) Nevertheless, the view that concentrations of disadvantaged households lead to more serious social consequences simply because of concentration is widely shared. For example, in low-wage labour markets most jobs are found through informal local contacts. If unemployed workers are spatially concentrated, it follows that informal contacts will produce fewer leads to employment.

Economic models of residential location also suggest that households will be segregated by race – to the extent that race and income are correlated. Yet research clearly indicates that the segregation of black households in urban areas is far greater than can be explained by differences in incomes and demographic characteristics.

Until quite recently, these patterns of segregation could be explained by explicitly discriminatory policies in the housing market. During the period of black migration to northern cities, rents were substantially higher in black neighbourhoods than in white neighbourhoods. As levels of migration tapered off in the 1970s, price differentials declined. The patterns of residence by race may be explicable by the tipping point models of Thomas Schelling (1971). In these models, there is a distribution of tolerance among the population, reflecting the maximum fraction of neighbours of a different race tolerated by any household. In this formulation, the race of each household provides an externality to all neighbouring households. It is easy to show that the racial integration of neighbourhoods may be impossible to achieve under many circumstances.

Despite this, there is widespread evidence of conscious discrimination in the markets for rental and owner-occupied housing (Ross and Yinger, 2002), four decades after passage of the first Fair Housing legislation.

Racial segregation in housing markets may have particularly important welfare implications as jobs continue to suburbanize at a rapid rate. Racial barriers to opening up the suburbs for residence may lead to higher unemployment rates among minority workers (see Glaeser, Hanushek and Quigley, 2004.)
The barriers to the integration of the suburbs by race and income are also related to the fiscal externalities which are conferred by one category of residents upon another category. Most local tax structures emphasize *ad valorem* property taxes, and in most urban areas towns are free to vary property tax rates to finance locally chosen levels of public expenditure. If local tax revenues are proportional to house value, and if local public expenditures are proportional to the number of households served, local governments have strong incentives to increase the property value per household in their jurisdictions. To achieve this outcome, local governments may simply use zoning regulations to prohibit construction of housing appropriate to the budgets of lower-income households. The prohibition of high-density housing and multi-family construction, the imposition of minimum lot-size restrictions and the imposition of development fees can all be used as devices to increase property tax revenue per household. Importantly, these rules also increase the price of low-income housing. Many of these regulations can also be cloaked in terms of ecological balance and environmental protection. The inability of higher levels of government to achieve balance and equity in new residential development in US urban areas is quite costly.

**Summary**

The field of urban economics emphasizes the spatial arrangements of households, firms, and capital in metropolitan areas, the externalities which arise from the proximity of households and land uses, and the policy issues which arise from the interplay of these economic forces.

Abstract

Urban quality of life is a key determinant of where the educated choose to live and work. Recognizing the importance of attracting the high-skilled, many cities are investing to transform themselves into 'consumer cities'. This essay examines the supply and demand for non-market urban quality of life. It provides an overview of hedonic methods often used to estimate how much households pay for non-market urban attributes such as temperate climate and clean air.

Keywords

compensating differentials; congestion; crime; hedonic functions; internal migration; pollution; population density; quality of life; urban environment and quality of life; urban growth; urbanization

Article

Soon a majority of the world's population will live in cities. In 1950, 30 per cent of the world's population lived in cities. By 2000, this fraction had grown to 47 per cent. It is predicted to rise to 60 per cent by 2030 (United Nations Population Division, 2004). While the popular media focus on the growth of 'mega-cities', much urbanization occurs through the development of new cities and the growth of smaller metro areas (Henderson and Wang, 2004). People have migrated to cities in pursuit of better economic opportunities than are available in the countryside (Harris and Todaro, 1970). In the past, urbanization has been viewed as representing a trade-off. Urban workers earned higher wages than rural residents but suffered from a lower quality of life. In the 1880s, the average urbanite in the United States had a life expectancy ten years lower than that of the average rural resident (Haines, 2001). Frederick Engels bemoaned the density and the squalor in Britain's manufacturing cities in the mid-19th century. Urban historians have provided indelible descriptions of US cities in the past. In the 19th century, dead horses littered the streets of New York City, and thousands of tenement-dwellers were exposed to stinking water, smoky skies, and ear-
shattering din (Melosi, 1982; 2001). During the 19th and early 20th centuries, the skies above such major cities as Chicago and Pittsburgh were dark with smoke from steel smelters, heavy industrial plants, and burning coal.

Since the early 20th century, many major cities in the developed world have experienced sharp improvements in quality of life. By 1940, the urban mortality premium had vanished (Haines, 2001). Starting in the early 1970s, air pollution, water pollution and noise pollution have sharply fallen in many major US cities. While there are several causes of this progress, ranging from effective regulation to industrial transition from manufacturing to services and technological advance, the net result of this trend is that past ‘production cities’ are transforming themselves into ‘consumer cities’.

Cities that have high quality of life will have greater success at attracting the footloose highly educated to live there. Empirical studies have documented that a location's stock of educated people plays an important role in generating urban growth (Glaeser, Scheinkman and Shleifer, 1995).

First, I sketch how a city ‘produces’ quality of life. I then discuss the demand for urban quality of life using a household production function framework. While urban quality of life is a valued ‘commodity’, there are no explicit markets where it can be purchased. Utility maximizing households face a trade-off in choosing where to locate. In cities with higher quality of life, home prices are higher. Measuring this price premium for quality continues to be a major focus of much environmental and urban empirical research.

The supply of urban quality of life

Each city can be thought of as a differentiated product. Its attributes include some exogenous factors such as climate and risk of natural disasters, and endogenous factors such as average commuting times, pollution and crime. Some of these endogenous attributes are by-products of economic activity. A city of 10,000 bike-riding lawyers would have much cleaner air than another city with 500,000 old-car-driving steel workers. None of the steel workers driving old cars intends to pollute local air. Pollution represents an unintended consequence of their daily commuting mode and of local industrial production. This example highlights the importance of scale, composition and technique effects in determining local environmental quality. In the above example, scale refers to whether the city has 10,000 people or 500,000 people. Composition effects focus on consumption patterns (such as bike versus car) and industrial patterns (such as law firms versus steel plants). If one controls for a city's scale and composition, urban environmental quality can be high due to technique effects brought about by government regulation or the free market designing new capital with low emissions (for example, hybrid cars such as the Toyota Prius).

Early research in urban economics emphasized scale effects such that the biggest cities suffered more quality-of-life degradation as they expanded (Tolley, 1974). Anyone can migrate to a big city without paying an ‘entry fee’. When an extra person moves to a big city from a smaller city, this migration causes net social damage (due to extra congestion and pollution). Migrants will ignore the fact that their choice degrades local public goods in the destination city, but a benevolent planner would not. In the absence of a big city entry fee, the big city grows beyond its efficient size.

Cross-city empirical research has documented that such urban challenges as crime, pollution and congestion are all greater in big cities than in smaller cities (Glaeser, 1998; Henderson, 2002). But this
The ‘cost’ of city bigness is declining over time. In the 1990s, crime fell fastest in the largest US cities (Levitt, 2004). Ambient air pollution is improving in many major cities despite a continued increase in population (Glaeser and Kahn, 2004). The suburbanization of employment in all major US metropolitan areas has meant that that population ‘sprawl’ has not increased commute times.

City size is not a sufficient statistic for determining a city's quality of life. Other relevant factors are the city's geography, industrial and demographic composition, and government policy. A city's geography determines its climate and its capacity for handling local pollution. Put simply, some cities have it and some cities don’t. As Billy Graham once said, ‘The San Francisco Bay Area is so beautiful, I hesitate to preach about heaven while I'm here.’

Cities differ in their ability to absorb growth without suffering urban quality-of-life degradation. World Bank researchers have recently documented the importance of climate and topological features of the city in determining how much air pollution is caused by economic growth (see Dasgupta et al., 2004). Windier cities and cities that receive more rainfall suffer less ambient pollution from a given amount of emissions.

The composition of city economic activity also plays a key role in determining the supply of quality of life. All else equal, a city that specializes in manufacturing relative to services will have a lower quality of life. Such a city will have greater levels of ambient particulate and sulphur dioxide pollution. Water pollution will be greater, and more hazardous waste sites will be created. The rise and decline of manufacturing in the US rust belt over the 20th century provides dramatic evidence documenting these effects (Kahn, 1999). A similar ‘natural-experiment’ has played out as communism died. In major cities in the Czech Republic, Hungary and Poland air pollution improved in the 1990s because the phase out of energy subsidies contributed to the shutdown of communist era industrial plants (Kahn 2003). As major cities such as New York and London and Chicago have experienced an industrial transition from manufacturing to finance and services, more people work in the service and tourist industries, and these workers have a financial stake in keeping the city's quality of life high.

A city's demographics also play a role in determining its quality of life. A city filled with senior citizens will offer a different set of restaurants and cultural opportunities from a city filled with immigrants and young parents. If a city can attract the highly educated, then a virtuous circle can be set off. Since more highly educated people earn more income, this will attract better restaurants and other commercial amenities.

Government policy plays a role in determining a city's quality of life. Boston's Big Dig project has cost over US$14 billion and is intended to beautify Boston by submerging its ugly highways connecting the city centre to the waterfront and increasing the supply of green parks. Successful Clean Air Act regulation has sharply reduced vehicle emissions in Los Angeles. Rudy Giuliani, Mayor of New York City, achieved wide acclaim for improved policing that some have argued contributed to the sharp decline in the city's crime rate in the 1990s.

The supply of urban quality of life varies across cities and within cities. Some variation such as proximity to a major park or body of water is exogenously determined, but public policy can also have differential effects on quality of life across a city's neighbourhoods. The Clean Air Act has reduced Los Angeles’ smog by much more in inland Hispanic communities than along the Pacific Ocean (Kahn, 2001). Economists are just starting to investigate the general equilibrium impacts of regulations that differentially improve urban quality of life in some parts of a city relative to other parts of the same city.
Urban environment and quality of life: The New Palgrave Dictionary of Economics (Sieg et al., 2004). If the improvements in quality of life were unexpected, then homeowners in such areas will receive a windfall. Long-standing renters in communities that have experienced regulation-induced improvements in local public goods will pay higher rents and may no longer be able to afford to live in their old community.

**Demand for urban quality of life**

The household production function approach offers a framework for modelling the demand for non-market local public goods such as climate, street safety and local environmental quality. A person gains utility from being healthy, safe and comfortable. To achieve these goals, one purchases market goods such as doctor visits, home alarm systems and home entertainment systems. In addition, this person might choose a city and a residential community within this city featuring a temperate climate, low smog levels and safe streets.

Each household must choose a city and a community within that city to live in. Households that value quality of life face a trade-off in that each city represents a bundle of non-market attributes and economic opportunities. Some cities such as San Francisco are beautiful but home prices are very high. Other cities such as Houston offer warm winter weather and cheap housing but its residents face severe summer humidity. Market products can offset such city's disamenities. Before the advent and diffusion of cheap air conditioning, humid cities would feature much lower home prices to compensate households for summer humidity. The diffusion of the air conditioner has allowed households to enjoy the benefits of living in warmer cities such as Houston during winter without suffering from humidity in summer (Rappaport, 2003). This market product has increased the demand for living in humid cities.

Households may reveal different willingness to trade off non-market goods depending on the household's age, income and demographic circumstances. A household with children may place greater weight on communities with good schools. Households may differ in their demand for urban attributes. Asthmatics will avoid highly polluted cities and skiers will not mind the cold New England winters. Household demand may also hinge on idiosyncratic factors; for example, an individual who grew up in a specific city may want to remain living near his childhood friends.

**The hedonic equilibrium approach for valuing urban quality of life**

The theory of compensating differentials says that it will be more costly to live in ‘nicer’ cities (Rosen, 2002). This theory is really a ‘no arbitrage’ result. If migration costs are low across urban areas and if potential buyers are fully informed about the differences in non-market urban attributes bundles, then real estate prices will adjust such that homes in cities with higher quality of life will sell for a premium. An enormous empirical literature has estimated cross-city and within-city hedonic price functions to estimate the implicit compensating differentials for non-market goods. In these studies, the dependent variable is the price of home \( i \) in city \( j \) in community \( m \) in year \( t \). Define \( X_{it} \) as home \( i \)'s physical attributes in year \( t \). \( A_{jt} \) represents city \( j \)'s attributes in year \( t \) and \( A_{mjt} \) represents the attributes of community \( m \) located in city \( j \) in the year \( t \). Given this notation, a standard real estate hedonic regression will take the form:
Multivariate regression estimates of this regression yield estimates of the compensating differentials for city level local public goods (based on $\beta_2$) and community-level local public goods (based on $\beta_3$). These coefficients represent the marginal implicit prices for small increases in the consumption of local public goods. Studies that control for a vector of local public goods are able to pinpoint the relative importance of different features of cities and communities ranging from climate to air pollution to urban crime. Equation (1) highlights the fact that households face a rich set of choices both across cities and across communities within the same city.

Environmental studies have used this hedonic framework to estimate compensating differentials for a myriad of different environmental local characteristics. For example, Costa and Kahn (2003) examine the compensating differential for living in nice climate in 1970 and in the year 1990. In 1970, a person would have to pay $1,288 (1990 dollars) in higher home prices per year to purchase San Francisco's climate over Chicago's climate. In 1990, this yearly price differential increased by $6,259 (1990 dollars) to $7,547. Chay and Greenstone (2005) use 1980 and 1990 data for all US counties find that a ten per cent reduction in ambient total suspended particulates increased home prices by three per cent. While much of the urban quality of life literature has focused on US city data, a promising research trend is examining international evidence.

Conclusion

Urban economic development policymakers have pursued very different growth strategies. Some cities subsidize sports stadiums while others build airports or downtown cultural centres. Such targeted investment is unlikely to yield the key urban anchor. This essay has argued that cities than can provide and enhance urban quality of life will attract the high-skilled. An end result of attracting this group is a more vibrant, diversified local economy. As per-capita incomes continue to rise, the demand for living and working in high quality-of-life cities will increase. The empirical literature continues to inquire into what the key components of quality of life are.

urban growth

Yannis M. Ioannides and Esteban Rossi-Hansberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Urban growth’ refers to the process of growth and decline of economic agglomerations. The pattern of concentration of economic activity and its evolution have been found to be an important determinant, and in some cases the result, of urbanization, the structure of cities, the organization of economic activity, and national economic growth. The size distribution of cities is the result of the patterns of urbanization, which result in city growth and city creation. The evolution of the size distribution of cities is in turn closely linked to national economic growth.

Article

Urban growth – the growth and decline of urban areas – as an economic phenomenon is inextricably linked with the process of urbanization. Urbanization itself has punctuated economic development. The spatial distribution of economic activity, measured in terms of population, output and income, is concentrated. The patterns of such concentrations and their relationship to measured economic and demographic variables constitute some of the most intriguing phenomena in urban economics. They have important implications for the economic role and size distribution of cities, the efficiency of production in an economy, and overall economic growth. As Paul Bairoch's magisterial work (1988) has established, increasingly concentrated population densities have been closely linked since the dawn of history with the development of agriculture and transportation. Yet, as economies move from those of
traditional societies to their modern stage, the role of the urban sector changes from merely providing
services to leading in innovation and serving as engines of growth.
Measurement of urban growth rests on the definition of ‘urban area’, which is not standard throughout
the world and differs even within the same country depending upon the nature of local jurisdictions and
how they might have changed over time (this is true even for the United States). Legal boundaries might
not indicate the areas covered by urban service-providers. Economic variables commonly used include
population, area, employment, density or output measures, and occasionally several of them at once, not
all of which are consistently available for all countries. Commuting patterns and density measures may
be used to define metropolitan statistical areas in the USA as economic entities, but major urban
agglomerations may involve a multitude of definitions.

The study of urban growth has proceeded in a number of different directions. One direction has
emphasized historical aspects of urbanization. Massive population movements from rural to urban areas
have fuelled urban growth throughout the world. Yet it is fair to say that economics has yet to achieve a
thorough understanding of the intricate relationships between demographic transition, agricultural
development and the forces underlying the Industrial Revolution. Innovations were clearly facilitated by
urban concentrations and associated technological improvements. A related direction focuses on the
physical structure of cities and how it may change as cities grow. It also focuses on how changes in
commuting costs, as well as the industrial composition of national output and other technological
changes, have affected the growth of cities. Another direction has focused on understanding the
evolution of systems of cities – that is, how cities of different sizes interact, accommodate and share
different functions as the economy develops and what the properties of the size distribution of urban
areas are for economies at different stages of development. Do the properties of the system of cities and
of city size distribution persist while national population is growing? Finally, there is a literature that
studies the link between urban growth and economic growth. What restrictions does urban growth
impose on economic growth? What economic functions are allocated to cities of different sizes in a
growing economy? Of course, all of these lines of inquiry are closely related and none of them may be
fully understood, theoretically and empirically, on its own. In what follows we address each in turn.

Urbanization and the size distribution of cities

The concentration of population and economic activity in urban areas may increase either because
agents migrate from rural to urban areas (urbanization) or because economies grow in term of both
population and output, which results in urban as well as rural growth. Urban centres may not be
sustained unless agricultural productivity has increased sufficiently to allow people to move away from
the land and devote themselves to non-food producing activities. Such ‘symmetry breaking’ in the
uniform distribution of economic activity is an important factor in understanding urban development
(Papageorgiou and Smith, 1983). Research on the process of urbanization spans the early modern era
(the case of Europe having been most thoroughly studied; De Vries, 1984) to recent studies that have
applied modern tools to study urbanization in East Asia (Fujita et al., 2004). The ‘New Economic
Geography’ literature has emphasized how an economy can become ‘differentiated’ into an
industrialized core (urban sector) and an agricultural ‘periphery’ (Krugman, 1991). That is, urban
concentration is beneficial because the population benefits from the greater variety of goods produced
Urban growth: The New Palgrave Dictionary of Economics

Urban growth and forward linkages) and may be sustained because a larger population in turn generates greater demand for those goods (backward linkages). This process exploits the increasing returns to scale that characterize goods production but does not always lead to concentration of economic activity. The range of different possibilities is explored extensively in Fujita, Krugman and Venables (1999). These ideas have generated new lines of research; see several related papers in Henderson and Thisse (2004).

The process of urban growth is closely related to the size distribution of cities. As the urban population grows, will it be accommodated in a large number of small cities, or in a small number of large cities, or in a variety of city sizes? While cities have performed different functions in the course of economic development, a puzzling fact persists for a wide cross-section of countries and different time periods. The size distribution of cities is Pareto-distributed, is ‘scale-free’. Gabaix (1999) established this relationship formally. He showed that, if city growth is scale independent (the mean and variance of city growth rates do not depend on city size: Gibrat's Law) and the growth process has a reflective barrier at some level arbitrarily close to zero, the invariant distribution of city sizes is a Pareto distribution with coefficient arbitrarily close to 1: Zipf's Law. (Empirical evidence on the urban growth process as well as Zipf's Law is surveyed by Gabaix and Ioannides, 2004.)

These results imply that the size distribution of cities and the process of urban growth are closely related. Eeckhout (2004) extends the empirical investigation by examining in depth all urban places in the United States and finds that the inclusion of the lower end of the sample leads to a log-normal size distribution. Duranton (2004) refines the theory by means of a quality-ladder model of economic growth that allows him to model the growth and decline of cities as cities win or lose industries following technological innovations. Ultimately, the movements of cities up and down the hierarchy balance out so as to produce a stable, skewed size distribution. This theory is sufficiently rich to accommodate subtle differences across countries (in particular the United States and France) that constitute systematic differences from Zipf's Law. Rossi-Hansberg and Wright (2004) use a neoclassical growth model that is also consistent with observed systematic deviations from Zipf's Law: in particular, the actual size distribution of cities shows fewer smaller and larger cities than the Pareto distribution, and the coefficient of the Pareto distribution has been found to be different from 1 although centred on it. They identify the standard deviation of the industry productivity shocks as the key factor behind these deviations from Zipf's Law. The evident similarity of the conclusions of those two papers clearly suggests that the literature is closer than ever before to resolving the Zipf's Law ‘puzzle.’

Urban growth and city structure

Understanding urbanization and economic growth requires understanding the variety of factors that can affect city size and therefore its short-term dynamics. All of them lead to the basic forces that generate the real and pecuniary externalities that are exploited by urban agglomeration, on one hand, and congestion, which follows from agglomeration, on the other. Three basic types of agglomeration forces have been used, in different varieties, to explain the existence of urban agglomerations (all of them were initially proposed in Marshall, 1920): (a) knowledge spillovers, that is, the more biomedical research there is in an urban area, the more productive a new research laboratory will be; (b) thick markets for specialized inputs: the more firms that hire specialized programmers, the larger the pool from which an additional firm can hire when the others may be laying off workers; and (c) backward and forward

linkages. Local amenities and public goods can themselves be relevant agglomeration forces. The size of urban agglomerations is the result of a trade-off between the relevant agglomeration and congestion forces. Urban growth can therefore be the result of any city-specific or economy-wide change that augments the strength or scope of agglomeration forces or reduces the importance of congestion forces. One example that has been widely used in the literature is reductions in commuting costs that lead to larger cities in terms of area, population, and in most models also output (Chatterjee and Carlino, 1999). Another example is the adoption of information and communication technologies that may increase the geographical scope of production externalities, therefore increasing the size of cities.

Changes of underlying economic factors cause cities to grow or decline as they adjust to their new equilibrium sizes. Another more subtle factor is changes in the patterns of specialization that are associated with equilibrium city sizes. That is, the coexistence of dirty industry with high-tech industry generates too much congestion, and therefore cities specialize in one or the other industry. Adjustments in city sizes and patterns of specialization in turn may be slow, since urban infrastructure, as well as business structures and housing are durable, and new construction takes time (Glaeser and Gyourko, 2005). However, this type of change lead only to transitional urban growth, as city growth or decline eventually dies out in the absence of other city-specific or economy-wide shocks. Even when any of the economy-wide variables, such as population, grows continuously, the growth rate of a specific city will dwindle because of new city creation (Ioannides, 1994; Rossi-Hansberg and Wright, 2004).

Much attention has also been devoted to the effect that this type of urban growth has on urban structure. Lower commuting costs may eliminate the link between housing location choices and workplace location. This results in more concentration of business areas, increased productivity because of, say, knowledge spillovers, and lower housing costs in the periphery of the city. Urban growth can therefore lead to suburbanization as well as multiple business centres, as in Fujita and Ogawa (1982) or Lucas and Rossi-Hansberg (2002). Those phenomena become increasingly important because of the decline in transport and commuting costs brought about by the automobile along with public infrastructure investments. In other words, urban growth is associated with sprawl (Anas, Arnott and Small, 1998).

Urban and national economic growth

Most economic activity occurs in cities. This fact links national and urban growth. An economy can grow only if cities, or the number of cities, grow. In fact, Jacobs (1969) and Lucas (1988) underscore knowledge spillovers at the city level as a main engine of growth. The growth literature has also argued that, in order for an economy to exhibit permanent growth, the aggregate technology has to exhibit asymptotically constant returns to scale (Jones, 1999). If not, the growth rate in an economy will either explode or converge to zero. How is this consistent with the presence of scale effects at the city level? Eaton and Eckstein (1997), motivated by empirical evidence on the French and Japanese urban systems, study the possibility of parallel city growth, which is assumed to depend critically on intercity knowledge flows together with the accumulation of partly city-specific human capital across a given number of cities. Rossi-Hansberg and Wright (2004) propose a theory where scale effects and congestion forces at the city level balance out in equilibrium to determine the size of cities. Thus, the
urban growth: The New Palgrave Dictionary of Economics

The economy exhibits constant returns to scale through the number of cities increasing along with the scale of the economy. Hence, economic growth is the result of growth in the size and the number of cities. If balanced growth is the result of the interplay between urban scale effects and congestion costs, these theories have important implications for the size distribution of cities and the urban growth process. These implications turn out to be consistent with the empirical size distribution of cities, that is, Zipf's Law, and with observed systematic deviations from Zipf's Law.

To summarize: urban growth affects the efficiency of production and economic growth, and the way agents interact and live in cities. Understanding its implications and causes has captured the interest of economists in the past and deserves to continue doing so in the future.

Urban housing demand is a reflection of households’ desire to live in cities. In this article, I discuss possible reasons why US households have exhibited an increasing taste for urban living, including employment, urban amenities, and consumption opportunities. Next, I explain how growing urban housing demand led to rising house prices and a sorting of households across cities by income. That dynamic generated a divergence across housing markets in the value of the tax subsidy to owner-occupied housing as well as housing market risk. Those factors, in turn, had a feedback effect on urban housing demand.

Article

At its core, the demand for urban housing is just the manifestation of the demand for living in urban areas. On net, residence patterns suggest that most people want to live in or near cities, and that desire is increasing over time. In fact, by 1999, 75 per cent of US households lived in cities (Rosenthal and Strange, 2003). Today, urban America is where housing demand is most likely to exceed housing supply and generate rising house prices, where the tax system provides the greatest subsidy to owner-occupied housing, and where the housing market is the most volatile. In this article I discuss some of the causes and consequences of urban housing demand, and the supporting evidence.
The classic explanation for the concentration of households in cities is that people want to live close to their jobs. That notion, developed in the monocentric city model of Alonso (1964), Mills (1972) and Muth (1969), leads to a prediction that is rarely as evident in reality as it is in theory: housing costs should rise as the distance to the employment centre falls since households would be willing to pay more in order to save time getting to work. Instead, households often settle for a longer commute in exchange for other positive qualities of a non-urban community, such as the density of development, the calibre of the school system, local taxes and amenities, and the similarity of the other residents to themselves.

Since the 1960s, the patterns of where people live have begun to shift back to cities, even though people are now less likely to work in the downtown areas. According to Glaeser, Kolko and Sarz (2001), between 1960 and 1990 the rate of growth of commutes where the household lives in the city increased while the growth rate of commutes originating in the suburbs fell. Within cities, the high-income population has been moving closer to the central downtown area. Glaeser et al. argue that nowadays thriving cities are ‘consumer cities’, ones that attract highly educated households through appealing cultural amenities, such as museums, restaurants and opera. In fact, between 1977 and 1995, a temperate and dry climate, a coastal location, and more live performance venues and restaurants per capita predicted future population growth. By contrast, having more bowling alleys was correlated with population decline.

Indeed, the very congestion that urban economists typically point to as a reason that cities become unattractive may lead to an availability and quality of goods and services that are appealing. In a city, the large number of residents living in close proximity makes it feasible for even niche markets to be served since a critical mass of potential customers exists. Joel Waldfogel (2003), who in a series of papers termed this phenomenon ‘preference externalities’, found empirical support in the markets for broadcast radio, newspapers, and restaurants. For example, when there is a larger local consumer base for a certain format of radio station, calibre of newspaper, or style of restaurant, the more of them exist in a city. By revealed preference, that greater variety increases city dwellers’ welfare, because the more options there are for residents that share a particular set of tastes the more they consume.

Even the advent of the Internet has not dampened the consumption appeal of living in cities. Since the Internet makes information and goods universally available to anyone, no matter where they live, it substitutes for living in a city. However, Sinai and Waldfogel (2004) find that the number and variety of websites focused on a city increases with the city's population. By enhancing the welfare benefits of living in cities – perhaps by mitigating the effects of congestion or facilitating communication and connection among city residents – these sites have an offsetting positive effect on urban housing demand.

Urban housing demand and house prices

Two measures of the intensity of urban housing demand are house prices and the rate of house price growth. In some cities, housing is in inelastic supply because there is little or no open land and local regulations either restrict development or make it prohibitively expensive or slow. In that case, demand for a location leads to bidding up of the price of land in order to equilibrate housing demand with the available supply. Indeed, when one compares house prices across cities and town, areas that presumably have higher demand because they offer better amenities and fiscal conditions exhibit higher house prices (Roback, 1982). Another indication of high demand for a city is population growth, which occurs when
housing development is easy. I focus on high house prices because they can change the character of a city, which then has a further effect on urban housing demand. 

Since the 1950s, a handful of metropolitan areas experienced real house price growth that significantly exceeded the national average, leading to a widening gap across locations in average house prices. For example, in 1950 the average house price in San Francisco was 37 per cent higher than the average across all metropolitan areas. By 2000 the gap had grown to 218 per cent. In order for land prices to continually grow in one location relative to another, the demand for that location must be growing as well. One possible explanation is that productivity growth in a handful of cities has exceeded the national average, and residents pay more to live in productive cities because their wage rises with their productivity. Another potential rationalization is that some cities are becoming more appealing over time and residents are paying more for increasingly higher quality.

Another possibility is that the rapid growth in the number and earnings of high-income households in the United States has led to an increased willingness-to-pay for scarce locations. Since some cities are in such limited supply, households have to outbid each other to live there, leading to land prices that grow with the aggregate spending power of the clientele that prefers that particular city. In ‘Superstar Cities’, Gyourko, Mayer and Sinai (2006) show that inelastically supplied, high-demand cities have income distributions that are shifted to the right: low-income families can live there only if they have a very strong preference for the city, while high-income families can live there even if they only modestly prefer it. As the national high-income population grows, the greater number of high-income families outbid relatively low-income families (as well as some high-income families) who are unwilling or unable to pay a higher premium to live in their preferred location. Gyourko, Mayer and Sinai find that such superstar locations experience supra-normal house price growth and a shift of their income distributions to the right as they experience inflows of high-income households and outflows of their lowest-income residents. This pattern has been intensified as cities have begun to ‘fill up’ due to the growing national population. For example, in 1960 only Los Angeles and San Francisco were demonstrably inelastically supplied. By 2000 more than 20 cities were. Gyourko, Mayer and Sinai show that cities that ‘fill up’ experience a right-shift in their income distributions and higher price growth after their transition into superstar city status.

These findings imply that there must be something unique and attractive about superstar cities, otherwise potential residents would turn to cheaper locations and superstar cities would not be able to sustain excess price growth. A niche-market appeal may be due to particular amenities, or the kind of preference externalities described by Waldfogel. As preference agglomerations form, the highest willingness-to-pay households are those that share the same preferences. If such sorting is along income lines, rising house prices can lead to high-income homogeneity, which itself makes an area more desirable to high-income residents. That dynamic implies that certain urban markets will evolve into luxury areas and grow increasingly unaffordable for the average household.

The inelasticity of housing supply also leads to price changes, and a correlated change in the demand for urban housing, in cities that are experiencing declining demand. Glaeser and Gyourko (2005) point out that, since housing does not quickly depreciate once built, if the demand for a city declines then house prices must fall since quantity cannot easily adjust downwards. That decline in prices can spur demand by low-income households that cannot afford to live anywhere else, leading to sorting into low-income enclaves rather than high-income ones.
Differences in house prices among cities also affect the benefits homeowners obtain from their houses, which in turn affect the demand for urban housing. One such benefit in the United States that often is especially valuable in cities is the favourable Federal income tax treatment for owner-occupied housing, worth a total of $420 billion in 1999. The nature of these tax benefits is well-documented in this edition of the New Palgrave (housing policy in the United States). Gyourko and Sinai (2004) note that two conditions are necessary in order to receive a high value of this tax subsidy: a high-priced home, so that the subsidy operates on a larger base, and a high tax rate, which in the progressive US tax system follows from having a high income.

Because of this, the very same superstar city dynamic discussed earlier leads to an unequal distribution of the housing subsidy across the country. Superstar cities experience both house price growth and relatively high-income residents, and thus should also have the highest tax subsidies, further increasing the demand for urban housing in hot markets. Indeed, the tax subsidy is highly concentrated in a handful of cities, with just five metropolitan areas receiving more than 85 per cent of the total tax benefits in 1990. Between 1980 and 2000, the rise in house prices in superstar cities more than offset declining marginal tax rates, leading to a greater concentration of tax benefits in a handful of metropolitan areas. This tax subsidy has been shown to lead to higher house prices, either because the subsidy induces households to consume a larger quantity of housing or simply because house prices capitalize the present value of the future tax savings. Recent estimates of the after-tax price elasticity of housing demand cluster around −0.5, and the income elasticity around 0.25. Urban areas tend to exhibit relatively high demand elasticities, as demand is more readily capitalized into land prices rather than the limited new supply. By contrast, rural areas have much lower measured elasticities of housing demand.

Risk and the demand for urban housing

Since urban housing markets tend to have inelastic supply, they are more volatile as shocks to housing demand are transmitted more completely into rents and prices. That higher risk may deter households from living in urban areas since they would face more uncertainty over housing costs, whether they rented or owned. Also, house price volatility generates an additional cost because it distorts other investment decisions (Flavin and Yamashita, 2002). A mitigating factor, demonstrated in Sinai and Souleles (2005), is that long length-of-stay households can reduce their effective risk by owning their houses, in essence prepaying their housing costs. Other research suggests that uncertainty over house price growth simply may lead households to purchase housing in a city sooner than they otherwise would have in order to prevent housing costs from outpacing their income growth.

urban political economy

Robert W. Helsley
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Models of local public finance generally emphasize the roles of household mobility and community heterogeneity in the provision of local public services. In contrast, the emerging field of urban political economy examines how economic and political institutions influence the formation of local public policies. Key issues include the strength of the local executive, whether local politicians are elected ‘at large’ or to serve the interests of particular wards, the norms that govern behaviour and decision-making within city councils, and institutional innovation, especially the growth of so-called ‘private governments’.

Keywords

common pool problem; local public finance; minimum winning coalitions; parliamentary systems; presidential systems; principal and agent; private government; Tiebout hypothesis; urban political economy

Article

Economic models of local government applied to the United States generally suppress the roles of politics and political institutions. Indeed, the dominant model of local government, the Tiebout (1956) model of the provision of local public services to mobile residents, can be seen as an explicit attempt to eliminate the need for politics in cities. If individuals are highly mobile and communities offer a diverse menu of local taxes and expenditures, then there is no need for political expression – households can satisfy their demands for local public services by choosing to live in the community that provides their optimal bundle. Households ‘vote with their feet’. When local politics are explicitly considered, the political process is usually treated as an idealized form of majority rule in which residents vote directly on tax and spending programmes, and the political outcome corresponds to the most preferred policy of the median voter. This ‘institutionless’ view of local public finance has in fact been quite successful in,
Local political institutions

However, most local policy choices are not made directly by residents. According to the International City/Council Management Association (ICMA), 43.7 per cent of US municipalities with populations over 2,500 were governed by the combination of a mayor and a city council in 2000, while 48.3 per cent were governed by the combination of a city council and a city manager. Thus, 90 per cent of US municipalities were governed at least in part by a representative body. Council members may be elected ‘at-large’, that is, from the entire city, or by wards or districts within the city. Some cities adopt a mixed system, in which the council contains both at-large and ward representatives.

Mayors (or their offices) are traditionally classified as being either ‘strong’ or ‘weak’. Strong mayors have broad powers, including a veto over some city council decisions. Strong mayors also prepare the city's budget, and have hiring and firing authority over the heads of city departments. In weak mayoral systems, most executive and legislative authority rests with the city council; the mayor performs largely ceremonial and organizational functions. Strong mayors are generally elected independently from members of the city council, and are more common in mayor–council systems. Baqir (2002), based on a sample of roughly 2,000 US municipalities in 1990, reports that 98 per cent of mayors in mayor–council systems were independently elected, compared to 65 per cent of mayors in council–manager systems. Strong mayors are generally associated with fiscal discipline, and there is some support for this view in other branches in the political economics literature. For example, the literature on comparative politics suggests that presidential systems have greater accountability to voters and less collusion within and between the branches of government than parliamentary systems (Persson, Roland and Tabellini, 1997; 1998; 2000). Persson, Roland and Tabellini (2000) show that presidential systems have lower levels of government spending as a share of national product. Inman and Fitts (1990) show that between 1795 and 1988 ‘strong’ presidents (those with ‘independent political strength’, identified from a survey of historians) were associated with lower levels of federal spending in the United States. Baqir (2002) suggests that a strong mayor may have a similar disciplinary effect on local government spending.

Many studies of local political institutions in North America examine the impacts of the reform movement of the early 20th century. The reform movement brought a number of changes in local government structure that were allegedly designed to limit the exercise of private interest and patronage in city politics and promote the pursuit of public interests and professional management. Some of the specific institutional changes that followed included the introduction of at-large and non-partisan elections for city council (a change that has since been partially reversed), the council–manager form of local government, civil service exams as a basis for appointment and promotion in the bureaucracy, and, in some areas, the replacement of the mayor–council form with a group of city ‘commissioners’, each of whom had executive and legislative responsibility for a different city department.

Early studies of reform governments expressed the hope that managerial expertise and autonomy in personnel matters could lead to lower costs for the delivery of local public services, and in particular, lower labour costs for municipal governments. However, subsequent empirical studies provide little support for this view: public expenditure levels and patterns in US cities seem to have been largely unaffected by the adoption of city managers, at-large representation and non-partisan elections.
The most compelling study of the reform movement in the recent economics literature is Rauch (1995). Rauch’s hypothesis is that by creating a population of career bureaucrats in city government, the reform movement put in place incentives that encouraged investment in infrastructure and other ‘long-gestation-period’ projects. Rauch views the relationship between the city council and the bureaucracy as a principal–agent problem. Before reform, the agent, that is, the bureaucracy, is assumed to act as a political appointee who shares the council’s immediate focus on retaining office. After reform, the bureaucracy is professionalized and the agent is assumed to have some job security and therefore a longer time horizon. The agent may then use his ‘powers of information collection and expenditure oversight’, in combination with costly or imperfect monitoring by the principal to direct resources towards longer-term projects that may further the agent’s career. The implication is that this type of reform should increase the share of expenditures devoted to investment, as opposed to current public consumption. Using a panel of 144 cities over 23 years, Rauch regresses the infrastructure share of municipal expenditure on dummy variables for the use of civil service exams, the presence of a city manager, and the adoption of a commission form of local government. After accounting for the inertia generated by the durability of infrastructure investment, use of the civil service is found to have a positive impact on the share of expenditure devoted to infrastructure. Interestingly, in the cases where they are statistically significant, the presence of a city manager and the adoption of a commission form of government are both associated with lower levels of infrastructure spending.

Common pool problem in city councils

City councils are, in effect, local legislatures. One way to model the operation of a city council is by analogy with models of other legislative institutions. In that spirit, imagine a city council in which each councillor represents a well-defined local constituency. If councillors are elected by ward or district, then the constituencies will be geographic, as in most national, state and provincial legislatures. Councillors elected at-large may have non-geographic constituencies that are defined by a common ideology or policy initiative. Suppose that each councillor is motivated by holding office and that this gives him or her an incentive to pursue programmes and policies that provide net benefits to his or her constituents. It is generally assumed that the policies and programmes that are chosen by legislatures are ‘distributive’ in the sense that their costs are more widely distributed than their benefits. For example, benefits may be restricted to a particular district or group, while the supporting tax payments are made by residents of the entire city. Spending and tax choices are made by a majority vote of council members. The literature on legislative decision-making discusses a number of issues that relate to the efficiency of the policy choices that will emerge in this context. First, there is an incentive for ‘minimum winning coalitions’ within the legislature to form for the purpose of approving distributive policies (Riker, 1962). A minimum winning coalition is the smallest set of legislators that can guarantee passage of a proposal under majority voting. If proposals or projects have spillover costs and benefits, as distributive policies generally do, then the exclusion of the interests of delegates outside of a winning coalition will lead to inefficient choices. Second, minimum winning coalitions should be highly unstable, since excluded delegates have strong incentives to alter the coalition structure. Each member of the legislature faces some probability that he or she will be excluded from the minimum winning coalition for any particular policy proposal. Third, Weingast, Shepsle and Johnsen (1981), Shepsle and Weingast (1984), and others suggest that the resulting uncertainty helps explain the practice of ‘universalism’, in which the size of...
coalitions and the set of approved projects exceed the minimum winning size. In its extreme form, universalism involves a ‘norm of reciprocity’ in which each delegate supports the project of every other, and so a project for every delegate or constituency is approved. Finally, Weingast, Shepsle and Johnsen (1981) argue that politicians in such a setting have an incentive to count the resource costs of geographically earmarked programmes as benefits. They refer to this as the ‘Robert Moses’ effect: ‘pecuniary gains in the form of increased jobs, profits, and local tax revenues go to named individuals, firms, and localities from whom the legislator may claim credit and exact tribute’ (1981, p. 648). Such ‘political cost-accounting’ will obviously encourage individual representatives to support higher than efficient levels of public spending.

More formally, following Persson and Tabellini (2000, section 7.1), imagine that there are \( M \) seats on the city council and that the fixed population of each constituency is \( N \). Thus, the aggregate population of the city is \( MN \). If council members are elected by district or ward, so the constituencies are geographic, then the assumption of fixed constituencies implies that the population is immobile. Suppose that all residents are identical and have quasi-linear preferences of the form \( U(g) + x \), where \( g \) is per capita consumption of a publicly provided good, \( x \) is the numeraire and the sub-utility function \( U(\cdot) \) is increasing and strictly concave. All residents have the same exogenous income \( y \). Public services are financed through lump-sum taxes that balance the city’s budget. Each councillor is assumed to be a perfect representative of his or her constituent group.

If one takes utilitarianism as a normative benchmark, the efficient provision of public services in this symmetric setting maximizes aggregate utility \( M(U(g) + x) \) subject to the resource constraint \( MN(y - x - g) = 0 \). The first-order condition for this problem implies \( U'(g) = 1 \); the marginal benefit of the public service should equal its marginal cost in every constituency. Represent this efficient level of provision by \( g^* \).

In contrast, under extreme universalism, or with decentralized provision and centralized finance, each delegate chooses a level of the public service to maximize the utility of a representative constituent, taking the levels chosen by other delegates as fixed. If one lets \( g^0 \) represent the conjectured level chosen by others, the balanced budget requirement implies that the lump-sum tax \( \tau \) for any group satisfies \( \tau M = g + (M - 1)g^0 \). Thus, an individual delegate chooses \( g \) to maximize

\[
\frac{y - \frac{g + (M - 1)g^0}{M}}{M} + U(g).
\]

The first-order condition for this problem implies \( U'(g) = 1 / M \). Each member of the legislature perceives that they pay only a fraction \( 1/M \) of the costs of the public services that they acquire. This is known as the common pool problem. If one lets \( g^U \) represent the level of provision under this extreme form of universalism, the concavity of \( U(\cdot) \) implies \( g^U > g^* \). The common pool problem thus leads to overprovision. Persson and Tabellini (2000, p. 163) summarize the nature of the distortion as follows:
'The problem here lies in the collective choice procedure, in which the tax rate is residually determined once all spending decisions have been made in a decentralized fashion. Concentration of benefits and dispersion of costs lead to excessive spending when such spending is residually financed out of a common pool of tax revenue.'

The first-order condition for $g^U$ implies

$$\frac{dg^U}{dM} = -\frac{1}{MU''(g)} > 0$$

by concavity. Thus, the level of overprovision increases as the constituencies become smaller, *ceteris paribus*. Finally, if one allows $G^U = Mg^U$ to represent aggregate spending, we have

$$\frac{dG^U}{dM} = g^U + M\frac{dg^U}{dM} > 0.$$ 

This is an instance of Weingast, Shepsle and Johnsen's (1981) 'law of $1/n$': aggregate spending, and therefore the inefficiency of excessive spending increases with the number of constituencies or the size of the legislature.

This implication of the common pool problem seems to be supported by the evidence. Landbein, Crewson and Brasher (1996), based on a sample of 192 cities in 1980, all of which have a council–manager form of government and a weak mayor, find that local government expenditure per capita is positively related to the number of elected members of the city council. Baqir (2002) finds that the size of US local governments (measured by expenditures or employment per capita or expenditures as a share of total income) increases with the size of the city council. Baqir also finds that expenditures (per capita or as a share of total income) are not significantly different in councils where a majority of members are elected at-large, but that local government employment per capita is lower when at-large councillors are in the majority. However, evaluated at the sample means, employment per capita is actually higher where a majority of councillors are elected at large. This is consistent with the hypothesis that at-large councillors serve their (non-geographic) constituencies in much the same manner that ward councillors serve the interests of their wards. The positive relationship between the size of the government and the size of the council is unaffected by the presence of at-large elections. Baqir also examines the impact of a strong city executive, and finds that expenditures do not increase with council size when the city has a strong mayor with the power to veto city council decisions. As noted above, this is consistent with recent models and results from the literature on comparative politics.
Private government

Private governments are voluntary, exclusive organizations that supplement services provided by the public sector. There are two broad classes of private governments in the United States. Residential private governments, sometimes called residential community associations (RCAs), common interest developments (CIDs), or homeowner associations (HOAs), exist to further the interests of residential property owners. Commercial private governments, sometimes called business improvement districts (BIDs) or business investment areas (BIAs), exist to further the interests of their member firms. Private governments are highly controversial. Garreau (1991) labels them ‘shadow governments’, and argues that they are undemocratic, discriminatory, and operate outside of the constitutional restrictions that public governments face.

Residential private governments are an increasingly important component of housing markets and local government systems in North America. Garreau (1991, p. 189) estimates that there may have been as many as 130,000 RCAs in the United States in 1988. McKenzie (1996) reports that the number of CIDs in the United States grew from a few hundred in 1960 to 150,000 in 1993 and that they then housed 32 million people. The Community Associations Institute (an industry trade association) maintains that there were 231,000 RCAs in the United States in 2002, housing 57 million people. The 2001 American Housing Survey from the US Bureau of the Census reports that 28 per cent of all new-housing residents paid community association fees in 2001. Residential private governments provide security and sanitation services, and manage and maintain common facilities, including recreational facilities and infrastructure. They also regulate property use and individual conduct through covenants, codes, and restrictions in property deeds.

There are fewer commercial private governments, but their impacts are also substantial. Pack (1992) estimates that there were 400 BIDs in the United States in 1992, while Mitchell's (2001) survey found 404 independently managed BIDs in the United States in 1999. BIDs typically provide security, marketing and sanitation services. Mitchell reports that 94 per cent of BIDs engage in marketing, 85 per cent provide maintenance and sanitation services, and 68 per cent provide security. Mitchell's survey also found that 88 per cent of BIDs engaged in some form of policy advocacy, like lobbying governments on behalf of business interests. BIDs have become a key component of downtown revitalization strategies in many, if not most, major North American cities.

Private governments raise a number of interesting economic issues. First, they may have significant impacts on the traditional public sector. To the degree that private and public spending are substitutes, private governments provide a mechanism for the public sector to withdraw from certain activities. Helsley and Strange (1998; 2000a) show that such ‘strategic downloading’ is a characteristic of equilibrium in a game where public and private governments simultaneously choose levels of provision to maximize the welfare of their citizens and members, respectively. Cheung (2004) finds evidence of strategic downloading in a sample of California communities. Second, membership in private governments may be inefficient. Helsley and Strange (1999) argue that one of the essential features of gated communities is that they divert crime to other areas. This increases the incentive for other communities to engage in similar private policing activities (the activities are strategic complements), and may lead to excessive gated community development. Third, private governments have complex
welfare effects. Citizens with high demands for public services are generally made better off by this form of privatization. By joining the private government, they can supplement what is for them an inadequate level of public provision. If strategic downloading occurs, citizens with low demands, who choose not to join a private government, are also better off, since the level of public provision falls towards their optimal level. However, citizens in the middle of the distribution – whose demands were relatively well served by the traditional public sector – are made worse off.

The field of urban political economy is in its infancy. The roles that economic and political institutions play in the formation of local public policies are clearly deserving of further study.

urban production externalities

Antonio Ciccone
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Urban production externalities (agglomeration effects) are external effects among producers in areas with a high density of economic activity. Such external effects are the main explanation for why productivity is usually highest in those areas of a country where economic activity is densest. There is some disagreement about the strength of urban production externalities. What is clear, however, is that even weak urban production externalities can explain large spatial differences in productivity.

Article

Urban production externalities (agglomeration effects) are external effects among producers in areas with a high density of economic activity. Such external effects are the main explanation for why productivity is usually highest in those areas of a country where economic activity is densest. The best understood urban production externalities are technological externalities due to knowledge spillovers and non-transportable input sharing, both of which are already discussed by Marshall (1920). That local technological externalities translate into increasing returns at the city level is demonstrated formally by Henderson (1974). Building on the analysis of Chipman (1970), he also shows that such increasing returns are compatible with perfect competition. Abdel-Rahman (1988), Fujita (1988; 1989), and Rivera-Batiz (1988) present a rigorous analysis of decentralized market equilibria with increasing returns at the city level due to intermediate input sharing. These contributions build on the formalization...
urban production externalities: The New Palgrave Dictionary of Economics

of monopolistic competition of Spence (1976) and Dixit and Stiglitz (1977) to show how increasing returns to city size emerge when some intermediate inputs are non-transportable and produced subject to increasing returns at the plant level.

There is some disagreement about the strength of increasing returns to the density (or scale) of local economic activity and therefore about the strength of urban production externalities. This is partly because the best approach to estimation is still unclear. What is clear, however, is that even weak urban production externalities can explain much of the large spatial differences in productivity observed in many countries. This is because spatial differences in the density of economic activity are very large, so that even a small degree of increasing returns to density can explain sizable spatial productivity differences. Moreover, mobile physical capital and tradable intermediate inputs imply that the strength of increasing returns to density exceeds the strength of urban production externalities (by approximately a factor of two).

The remainder of this article first illustrates the link between the strength of urban production externalities and the strength of increasing returns to the density of economic activity (or increasing returns at the city level). It then turns to the advantages and drawbacks of different empirical approaches to urban production externalities.

A model of urban production externalities and increasing returns

The link between urban production externalities and increasing returns to the density of economic activity is easily illustrated using the technology-spillover model of Ciccone and Hall (1996) extended to include costlessly tradable intermediate inputs. This extension is important for understanding why the strength of increasing returns to density is approximately twice the strength of urban production externalities. Including urban production externalities due to non-transportable intermediate-input sharing in the model would be straightforward (see Ciccone and Hall, 1996) but not change any of the relevant conclusions.

Model set-up

Let \( f(n_f, k_f, m_f; Q_c, A_c) \) be the production function that describes the amount of output produced by firm \( f \) on an acre of space when employing \( n \) workers, \( m \) units of costlessly tradable intermediate inputs, and \( k \) units of capital (lower-case letters denote per-acre quantities). The acre is embedded in county \( c \) with total output \( Q \) and total acreage \( A \) (upper-case letters denote total county-level quantities). The simplest production function to deal with is one where the externality depends multiplicatively on the density of economic activity \( Q/A \), and the elasticity of \( f(n, k, m; Q, A) \) with respect to all its arguments is constant. In this case,

\[
q_f = \left( n_f^\alpha k_f^\beta m_f^{1-\alpha-\beta} \right)^{1-\rho} \left( \frac{Q_c}{A_c} \right)^\lambda
\]

(1)
\( \lambda \geq 0 \) captures the strength of urban production externalities (agglomeration effects); for example, \( \lambda = 2\% \) means that a doubling of the density of economic activity is associated with a two per cent increase in the output of the firm (for a given amount of inputs used by the firm). \( 0 \leq \alpha \leq 1 \) and \( 0 \leq \beta \leq 1 \) determine the relative importance of labour, capital and intermediate inputs in production. And \( 0 \leq \delta \leq 1 \) captures possible decreasing returns to labour, capital and intermediate inputs when holding the amount of land used in production constant (congestion effects).

Input demand and value added

Firms maximize profits taking factor prices and aggregate output in each county as given. Profit maximization implies that firms employ capital up to the point where its marginal product is equal to the national rental price of capital \( R \) (measured in units of output), which gives rise to a demand for capital equal to \( k_f = \beta (1 - \rho) q_f / R \). The demand for intermediate inputs can be determined analogously as \( m_f = (1 - \alpha - \beta) (1 - \rho) q_f \), where we have assumed that one unit of intermediate inputs can be produced with one unit of output. Substituting these factor demand functions in (1) and solving for output at the firm level yields that \( q_f \) is proportional to

\[
\left( \frac{n_f}{Q_c / A_c} \right)^{\alpha (1 - \rho) / (1 - \alpha) (1 - \delta)} \frac{1}{(1 - \beta) (1 - \delta)}
\]

Moreover, the demand for intermediate inputs implies that value added at the firm level (\( y \)) and county level (\( Y \)) are a fraction \( 1 - (1 - \alpha - \beta) (1 - \rho) \) of the total value of production at the firm and county level respectively, that is,

\[
y_f = q_f - m_f = (1 - (1 - \alpha - \beta) (1 - \rho)) q_f \quad \text{and} \quad Y_c = Q_c - M_c = (1 - (1 - \alpha - \beta) (1 - \rho)) Q_c.
\]

Hence, value added at the firm level is linked to firm-level employment and county-level value added by

\[
y_f = \left( \gamma \alpha \right) \frac{\frac{\alpha (1 - \rho)}{1 - (1 - \alpha) (1 - \delta)}}{\frac{\gamma}{Q_c / A_c} \frac{\lambda}{1 - (1 - \beta) (1 - \delta)}}
\]

where \( \gamma \) is an unimportant constant.

Increasing returns to density

The amount of labour \( N \) employed in a county is taken to be distributed uniformly in space; \( n_f = N_c / A_c \) for all firms \( f \) in the county. Substituted in (2), this yields that output per acre in a county is linked to employment per acre by
where the strength of increasing returns to the density of economic activity $\theta$ is given by

$$
\theta = \frac{(\lambda - \rho)}{\alpha (1 - \rho) - (\lambda - \rho)}.
$$

As expected, increasing returns to density are stronger when urban production externalities $\lambda$ are strong and congestion effects $\rho$ are weak. A necessary condition for productivity to be greater in areas with dense economic activity is that urban production externalities (agglomeration effects) more than offset congestion effects, $\theta > 0$.

From increasing returns to density to urban production externalities

The relationship between increasing returns to the density of economic activity $\theta$ and the strength of net agglomeration effects $\lambda - \rho$ in (4) depends on $\alpha (1 - \rho)$, the elasticity of output with respect to labour. In equilibrium, this elasticity equals the share of labour in the total value of production. In the United States, the share of labour in value added is around two thirds (for example, Gollin, 2002) and the share of intermediate inputs in value added around one half (for example, Basu, 1995), which implies a share of labour in the total value of production of around one third. To see that this implies that urban production externalities are magnified, note that for small values of $\lambda - \rho$ (4) implies

$$
\theta \approx \frac{\lambda - \rho}{\alpha (1 - \rho)} = 3 (\lambda - \rho),
$$

where we have made use of $\alpha (1 - \rho) = 1 / 3$. A one-point increase in the strength of urban production externalities therefore implies a three-point increase in the strength of increasing returns to the density of economic activity. Much of this magnification is due to the presence of intermediate inputs. In a model without intermediate inputs where physical capital earns one third of value added, the factor of magnification would have been (only) 3/2.
Empirical approaches and results

Increasing returns to city or industry size

Early empirical studies of urban scale effects by Sveikauskas (1975), Segal (1976), Moomaw (1981; 1985), and Tabuchi (1986) focused on the link between city size and productivity at the city and the city-industry level. The empirical results indicate that doubling city size increases productivity by between three and eight per cent. Nakamura (1985) and Henderson (1986; 2003) extend the analysis by distinguishing between urbanization economies and localization economies. Localization economies are increasing returns related to the size of city industries, while urbanization economies refer to increasing returns to overall city size. Henderson concludes that scale effects are mostly at the industry level, but Nakamura finds evidence for both urbanization and localization economies.

Most studies of the strength of agglomeration economies measure output as the value of production or value added from the U.S. Census Bureau's Census of Manufacturers. This data-set does not contain information on the value of services that plants purchase in the market or obtain from headquarters. Census of Manufacturers data will therefore overstate the value added of city industries. This bias is likely to be greater in larger cities, for two reasons. First, there is more service outsourcing in larger cities, due to the larger variety of services available (Holmes, 1999; Ono, 2007). Second, headquarter services are more likely to be counted twice in larger cities, as such cities are more likely to contain both a plant and its headquarters. The total value of production from the Census of Manufacturers has the additional disadvantage of counting twice all intermediate inputs traded within and across industries located in the same city.

Increasing returns to density and the productivity of US states

In the United States, the finest level of geographical detail with reliable data on value added is the state level. Ciccone and Hall (1996) therefore estimate increasing returns to the density of economic activity by combining state-level value added data with the model in (3). Aggregating county-level value added to the state level yields that labour productivity in state $s$, $\frac{Y_s}{N_s}$, is equal to

$$
\frac{Y_s}{N_s} = D_c(\theta) \equiv \sum_{c=1}^{C_s} \left( \frac{y N_c}{A_c} \right)^{1+\theta} \frac{N_c}{N_s}.
$$

(6)

where $C_s$ is the number of counties in the state. Hence, the strength of increasing returns to the county-level density of economic activity can be estimated by combining cross-state variation in labour productivity and the state-level density index $D_c(\theta)$, which depends on county-level employment density and the distribution of employment across counties. Ciccone and Hall find $\theta$ to be just above
Ciccone and Hall's work is about the degree of increasing returns to the density of economic activity, not about the strength of urban production externalities. Going from one to the other is rather straightforward, however. Using (5) yields that $\theta$ equal to five per cent corresponds to a net agglomeration effect $\lambda - \rho$ of 1.7 per cent. According to the *Flow of Funds Accounts of the United States, 1982–1990* prepared by the Board of Governors of the Federal Reserve System (1997), the share of land in the total value of production $\rho$ in the private sector outside of agriculture and mining is around 0.5 per cent. Hence, $\lambda$ is between 2 and 2.5 per cent, which implies that a doubling of the density of economic activity in a county is associated with a 2–2.5 per cent increase in the output firms produce with a given amount of inputs (see (1)). Mobile physical capital and tradable intermediate inputs therefore imply that the strength of increasing returns to density exceeds the strength of urban production externalities by a factor of two. Hence, more than half of the differences in output per worker across US states can be explained by rather weak urban production externalities.

An important concern when estimating agglomeration economies is potential feedback from productivity to the density of economic activity. To address this possibility, Ciccone and Hall (1996) use an instrumental variables approach. The instruments for the state-level density index used are the population and population density of US states between 1850 and 1880, as well as the presence or absence of a railroad in each state in 1860 and the distance of states from the eastern seaboard. The identifying assumption is that the original sources of agglomeration in the United States have remaining influences only through the preferences of people about where to live. The instrumental variables estimates of $\theta$ are between 5.5 and 6.1 per cent, and therefore very similar to the least squares estimates.

### Agglomeration effects in Europe

For many European countries, value added data is available at a much finer level of geographic detail than for the United States. Employing such data for France, Germany, Italy, Spain and the UK, Ciccone (2002) finds an average degree of increasing returns to the local density of economic activity of between four and five per cent, only slightly below estimates for the United States. Rice, Venables and Patacchini (2006) find a similar result using geographically detailed earnings data for the UK. They also take into account the scale of production in neighbouring locations weighted by travel times, and find that productivity benefits diminish quickly with travel distance.

### Human capital externalities?

An open question is whether there are agglomeration economies associated with the geographic concentration of human capital. Rauch (1993) examines this issue by augmenting a standard Mincerian wage regression (for example, Card, 1999) with data on the characteristics of cities where people live. His empirical model relates wages of individuals $i$ in cities $c$, $w_{ic}$ to relevant individual characteristics (for example, education, experience), $X_{ic}$, and to the average level of schooling of the city, $S_c$, and other
urban production externalities: The New Palgrave Dictionary of Economics

city characteristics, \( Z_c \),

\[
\log w_{ic} = aX_{ic} + bS_c + cZ_c + \epsilon_{ic}
\]  

(7)

where \( \epsilon_{ic} \) summarizes all other (unobserved) factors affecting individual wages across cities. Least-squares estimation of (7) using US data for 1980 yields a positive and significant coefficient on average schooling in the city \((b)\), and Rauch therefore concludes that there are human capital externalities at the city level.

A drawback of Rauch's approach is that it cannot account for time-invariant unobserved city characteristics that increase both schooling and wages. Another drawback is that city-level schooling is taken to be exogenous. Acemoglu and Angrist (2001) address these drawbacks by taking US states, rather than cities, to be the relevant aggregate unit in (7). In this case, the data allow for an analysis of the effects of increases in average state-level schooling on individual wages. Moreover, Acemoglu and Angrist show that changes in average schooling at the state level can be instrumented by state-level changes in compulsory-schooling and child-labour laws. Their approach yields no evidence of significant schooling externalities between 1960 and 1980.

Ciccone and Peri (2006) show that a positive effect of average schooling in a Mincerian wage equation like (7) may not reflect human capital externalities but a downward sloping demand function for human capital. They therefore propose an alternative approach, which exploits the fact that the wage differential between more and less educated workers reflects differences in marginal social products of the two worker types when human capital externalities are absent. This approach does not yield evidence of significant human capital externalities at the level of US cities or states between 1960 and 1990.

Moretti (2004a) finds that US cities where the labour force share of college graduates increased most between 1980 and 1990 also saw the largest wage increase for college graduates. Using Census of Manufacturers plant-level data, Moretti (2004b) finds that the output of plants in high-tech city industries rises with levels of schooling in other high-tech industries in the same city. This evidence is consistent with human capital externalities. An alternative explanation could be that skill-biased technological progress translated into increased productivity and wages of college graduates in high-tech industries. Cities that specialized in industries experiencing rapid productivity growth would in this case see faster output growth and attract more college graduates. This alternative hypothesis is especially plausible for the 1980–90 period, which was marked by rising college wage premia due to skill-biased technological progress (for example, Katz and Murphy, 1992).

urban transportation economics

Alex Anas
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Advances by economists in understanding the demand, capacity and supply, pricing, finance and performance of urban transportation systems is reviewed. The economics of urban transportation has emphasized externalities such as traffic congestion. The effects of transport systems and travel behaviour on real estate prices, urban land use and density and urban expansion as well as the reciprocal effects of urban form on the nature and utilization of transport systems are studied by economists.

Article

The study of transportation in urban areas relates to urban economics and to public economics and finance. The development of cities and their land use patterns cannot be understood without studying the transportation systems that shape them, nor can urban transportation systems be understood independently of the urban economy.

Unique aspects of urban transportation economics relate to demand, capacity and supply, the performance of urban transportation systems, and pricing and finance. We provide a discussion of the key conceptual issues and knowledge in each of these areas of the field and point out some challenges that remain. (For reviews of transportation economics focused less on its relationship to urban economics and more on technical issues internal to transportation, see Arnott and Kraus, 2003, and Small and Verhoef, 2006.)
Demand

The demand for transport is ‘derived demand’. Travel provides utility mostly because it is a means to an end, be it a consumer purchase, getting to work or to recreation. The travel itself usually has a disutility which varies according to the quality, reliability and safety of the transport system or the particular trip. Hence, virtually all transport choices involve a trade-off between the inconvenience and cost of a trip on the one hand and the frequency with which that trip is chosen relative to other trips on the other.

Beginning with the emergence of the telephone, the demands for travel and for communication have become increasingly interlinked in an urban setting. While travel and communication are substitutes because a phone call, fax or e-mail (or a messenger or letter in the pre-telephone days) may reduce the need for a trip, they are also complements because cheaper communication generates higher demand for goods, services and personal contacts. From this higher demand more travel is subsequently derived.

An important aspect of urban travel is the fact that the out-of-pocket cost of travel can be low relative to the value of time expended in that travel. As such, travel competes with leisure and with work as a key activity to which time must be allocated. The dominance of time-cost means that market prices are less important than full opportunity costs in the explanation and measurement of travel behaviour. Values of time vary greatly among consumers since wage rates vary but also because of other factors. Thus, consumers who undertake similar trips frequently incur vastly different opportunity costs.

The demand for urban travel by consumers is derived from a complex set of hierarchically linked choices. At the top of the hierarchy and slowest to change are decisions relating to where to work and where to reside. Lower in the hierarchy and more malleable are choices about the number and type of cars to own including the possibility of dispensing with cars and relying on walking or public transport for some trips. Yet lower on the hierarchy are choices about the destinations and frequency of discretionary trips, the frequency of commuting (to the extent that work arrangements do not require daily commuting), the destination of the commute being implicit in the residence–workplace choice, and the mode of transport (private automobile, taxi, public transit or walking) that will be used on each such round trip. There is the choice of the time of day during which particular trips are made and the trip chaining decision about whether several trips may be combined into a tour. In a tour, the trips are linked sequentially, beginning and ending at the point of origin (for example, the consumer's home). Finally, also important are the choices of particular routes (of the highway network, for example) on which trips occur. Firms make a similar set of choices. At the top of the hierarchy is the location of the plant vis-à-vis suppliers and markets, followed by the choice of a vehicle fleet and associated decisions of the modes (barge, rail, truck and so on) to use to get products to market or procure them from suppliers.

The study of travel demand using econometric techniques has not yet advanced to the point where a unified theory of travel can be tested that deals simultaneously with all or even most of the levels in the hierarchy. Led by McFadden (1973), transport economists have mostly focused on mode choice: the split of the demand for travel between competing modes such as auto, urban rail or bus and car pooling on a particular trip or round trip. This has resulted in the widespread use of a rich variety of discrete choice models (such as logit, nested logit or probit) that are designed to predict the probability that a randomly selected traveller will choose a particular mode to commute to work. Modelling the choice of residence or job locations has not received much attention from transportation economists. Virtually all studies in this area can be found in the urban economics literature, and some have emphasized the joint
choice of residence location and mode of commuting (Anas and Duann, 1985). Most travel demand studies focus exclusively on commuting, ignoring the fact that discretionary non-work travel is continually increasing with incomes, car ownership and suburbanization. And the trade off between commuting and discretionary trip-making under a time budget constraint has remained relatively unexamined.

Another area of demand that has received attention is the choice of travel route on a congested highway network. The work of Beckmann, McGuire and Winsten (1956) counterfactually conceived traffic on a network as a stationary state process of steady flow, rather than as a system of queues and bottlenecks causing complex flow dynamics. Despite this, the simplicity of the model led to the prolific development of static assignment models by operations researchers. These models use system optimization principles to simulate how travellers choose the least costly route on a congested network. Stochastic cost perceptions have been introduced into this type of stationary state models (Daganzo and Sheffi, 1977). More recently, a variety of dynamic simulation models that recognize the queue and bottleneck nature of traffic are under development based on the principle that travellers choose not only a route but also departure–arrival times (Arnott, de Palma and Lindsey, 1990).

Capacity and supply

One aspect of supply is that most transport is made possible in large part by consumer effort, time, and by inputs purchased by the consumer such as car, gasoline, vehicle maintenance and garage. Viewed this way supply becomes virtually inseparable from demand. As such it would make sense to model a part of the supply decision within a household production context.

Another aspect of supply is that the public sector is involved in the planning, provision and operation of most travel infrastructure. This includes highways as well as buses and urban rail. A key decision variable is capacity, measured as the throughput of passengers per hour that can be transported in a particular direction at a given time during the day on a particular facility. This throughput determines the user's travel time. Also important, however, are the safety, privacy, reliability and quality of the travel time and its components such as in-vehicle time, waiting at a station, searching for parking and time walking to and from stations and parking lots.

The key supply decision is the quantity of streets and highways and public transit rights-of-way. Road capacity relative to demand determines, in part, the level of traffic congestion in an area. Since land is the prime input in roads, more road building reduces the land available for other uses such as housing or production, raising the market price of land in such uses. In turn, the price of land chiefly determines how much land is allocated to create road capacity in an area. Thus, the most congested areas are also the ones where land is the most expensive. With extremely expensive land as in Tokyo, London, Paris or downtown New York, the substitution of capital for land results in tunnelling for transit systems (subways) and even for some roads.

An important supply question is whether economies of scale exist in congested highway traffic flow. Congestion occurs when the vehicles sharing the same road segment at the same time reach a critical value relative to road capacity. The addition of one more vehicle then begins to delay the other vehicles. The total cost experienced by the vehicle stream increases by a marginal cost that is higher than the cost privately born by the marginal vehicle's passengers. The difference between this social marginal cost and
the private average cost is the monetary value of the sum of delays the marginal vehicle imposes on all the vehicles travelling with it on the road segment. The evidence seems to suggest that this congestion process exhibits no economies of scale at least at a crude level. Scaling up (or down) road capacity and the volume of traffic in the same proportion, would not increase the average cost of travel. Capital costs of highways, on the other hand, were found to exhibit significant scale economies by the engineering estimates of Meyer, Kain and Wohl (1965), but since then Keeler and Small (1977) and others have found statistical evidence of weak or virtually no scale economies.

In contrast to highways, rail-based public transit systems are subject to scale economies and, more importantly, to economies of density. As more passengers use these systems (for example by reducing headways between successive trains), the per-passenger total average cost comes down because of the high fixed costs involved in system construction and maintenance. This is the chief reason why such rail infrastructure is uneconomical in US cities below some critical size such as one million or more people, or in suburban areas of low land use densities where the passengers’ time-costs of accessing transit stations can be high (Kim, 1979).

System performance

The reconciliation of supply and demand results in system performance. Unlike other markets in which price is the only salient outcome of market performance, in transport the outcomes include travel time, the level of congestion or travel delay, air pollution from car traffic, accidents, system reliability (that is, the variability of travel time from day to day or hour to hour), and pecuniary and non-pecuniary externalities caused by the transport system. While travel time, congestion and reliability costs are primarily born by the travellers, air pollution and accidents have costs that are born by travellers as well as by non-travellers. Thus, the economic performance of a transport system cannot be measured completely without evaluating the social costs and benefits created by these external effects.

The purely pecuniary externalities of transport are pervasive. For example, as noted, the creation of transport capacity has a direct effect on the supply and price of land available for other uses and can thus cause land scarcity. But this is only the direct effect of capacity provision. The indirect effect on land values and land use is quite different and works at both the extensive and intensive margins. At the extensive margin, cities endowed with more road and transit capacity can expand to land areas that were previously inaccessible. At the intensive margin, transport systems work by changing the relative accessibility of land parcels. Areas that are made relatively more accessible than before gain value, while areas made relatively less accessible lose value. As a result of these shifts, windfall gains and losses in land markets should be among the chief measures of transport system performance evaluation. The aggregate change in land values can be positive or negative. Since most land is owned by consumers (such as homeowners) transport system changes play an important role in redistributing private wealth and public revenues from ad valorem property taxes by changing an existing pattern of accessibility.

Transportation, land use and land prices are the central foci in urban economics and a variety of models have been developed. Virtually all of these assume that all jobs are located at a predetermined centre, an anachronism given that current downtowns in US cities contain no more than ten per cent of the jobs. Versions of this basic model based on linear programming have been developed to model road capacity
Other pecuniary externalities centre on the improved discretionary mobility enabled by transport systems. Such mobility improvements have received praise as well as criticism. Improved mobility enables easier, cheaper and more frequent contacts among firms and among firms and consumers. This should result in positive social benefits enhancing productivity and boosting economic growth. It has been noted in the large literature on *spatial mismatch* that central-city minorities in the United States who are less-mobility enabled, are at a disadvantage competing for suburban employment. While discrimination and suburban land use exclusion cause minorities to be clustered and socially cloistered in central cities, lower car ownership may also hinder their ability to compete for distant suburban jobs. Improved mobility induces economic agents to locate in a more spread out pattern, substituting cheaper outlying land for more expensive, centrally located land. The resulting urban land use pattern, common in the United States, has been dubbed ‘urban sprawl’. Sprawl has been blamed for a variety of ills stemming from the increased dependence on cars and reduced pedestrian mobility that sprawled land use promotes. Among such perceived ills, for example, is the alleged demise of social and neighbourhood cohesion and the rising obesity of American children and adults.

**Pricing and finance**

In practice, urban roads and transit systems are subsidized. In the United States a large part of the cost of highways and roads comes from general income taxes. The rest of the cost comes from taxes on gasoline and taxes on real property. Urban rail systems are also heavily subsidized with fares covering only about half of the operating and maintenance costs. Hence, for all forms of urban transport with the possible exception of unregulated taxis and jitneys, market-based user fees and marginal cost prices do not play the role they do in other markets.

What does economic theory tell us about how urban transport systems should be priced and financed? The answer will be different for highway and rail systems, primarily because the latter are subject to economies of scale. The congestion externality is key in highway pricing and investment (Vickrey, 1969). Economic efficiency requires that each traveller pay his full marginal social cost on each road segment that he uses. As we saw earlier, the full marginal social cost includes the monetary value of the delay each traveller imposes on his co-travellers. This is higher where congestion is high, falling to zero where congestion is not present. It has been shown that if congestion tolls can be properly calculated and levied on travellers, then with no economies of scale in roads, the tolls collected from the vehicles using a particular road segment would in the long run cover the amortized costs of road construction and maintenance. The only requirement is for road planners to build more (less) road capacity where toll revenue exceeds (falls short) of these amortized costs.

The congestion toll has three coincident theoretical interpretations. First, it is a Pigouvian tax (Pigou, 1947) because it levies, on the source of a negative externality, a tax that closes the gap between the social marginal cost and the private average cost. In this role, the toll causes travellers to economize on travel by internalizing the negative externality they create. Second, because a road can be viewed as a (congested) public good, the congestion toll in the long run serves to equate the marginal benefit of road capacity with the marginal cost of supplying it, the Samuelson rule for the optimal finance of a public
good (Samuelson, 1954). The toll itself is a marginal benefit since it measures the reduction in total travel cost that would be realized if one more unit of road capacity were to be added, while the marginal cost of the capacity is the cost of purchasing the additional capacity. Third, since the aggregate toll revenue from the road segment is equal to the land rent the road would fetch in an alternative use, the aggregate toll is equivalent to a confiscatory tax on the owners of the land, the Henry George rule (George, 1879). On the view that the land used for roads is privately owned and operated by competitive or contestable firms, the Pigouvian pricing described above would be the outcome of profit maximization, and the aggregate toll revenue would confiscate the profits of these private road owners. On the alternative view that the land used for roads is owned by society, the congestion tolls are the fees travellers pay society for the right to use the road, and in the long run these fees add up to the rent on land, provided land markets are competitive.

Keeler and Small (1977) empirically estimated what congestion tolls should be in the San Francisco Bay Area on the assumption of fixed land use. The effects of tolls on urban form have been studied within the naïve theoretical urban model that assumes all jobs are at a central point (Arnott and MacKinnon, 1978) or a central point and a suburban ring (Sullivan, 1983). Simple simulations based on such models show small efficiency gains of up to one per cent of income for reasonably congested cities. Recent studies, based on modern assumptions of completely dispersed employment, show similar efficiency gains (Anas and Xu, 1999). All of these studies show that congestion tolls could significantly reduce travel times. But the welfare benefits of tolls would come mostly from changes in travel mode and the timing of travel during the day, rather than from land use adjustments.

Congestion tolls have become more popular in recent years and have seen such prominent implementation as in central London. But the correct calculation of first-best tolls is a quagmire. Chief among the difficulties is the fact that one must know how the value of travel time is distributed among travellers using the same road segment. If I share the road with higher (lower) income drivers, the toll on me should be higher (lower). Without knowledge of the distribution, accurate first-best tolls cannot be computed because values of time vary so widely among people. A second difficulty is that road use varies enormously throughout the day, requiring that first-best tolls should similarly vary. The problem is simplified somewhat by dividing the day into peak and off-peak periods. A third difficulty is that the technology used to detect congestion and calculate tolls should not be so obtrusive on travel as to create more congestion than the tolls would alleviate. Automatic vehicle identification by several means is feasible and not expensive. This may contribute to a wider use of tolls in the future.

Although the calculation of first-best tolls is highly daunting, a number of second-bests are available. Tolls levied on major roads but not on local roads may be effective second-bests. A tax on the market price of parking in heavily congested destinations such as the downtowns of major cities would achieve some of the efficiencies of first-best tolls. Taxes on gasoline are not nearly as effective, because gasoline usage is not closely related to the congestion created on a trip. Such taxes heavily penalize driving on congestion-free roads, for example.

Unlike highways, rail transit should be priced as a regulated natural monopoly. Since marginal cost is below average cost at any scale, marginal cost pricing ensures efficiency but requires a subsidy to the transit operator to cover fixed costs. Thus for transit systems, theory tells us that fares should be set to cover variable operating costs, while other taxes should be used to purchase the fixed inputs, including land (right-of-way). The debate then, should be about what these other taxes should be. Considerable
Evidence exists showing that land around transit stations appreciates in value after a transit investment is announced or constructed. Anas and Duann (1985) used an empirically estimated general equilibrium model to predict prior to construction that residential property values around the proposed stations of the Chicago Midway line would increase, with the increase sharply tapering off with distance from the stations. They estimated that the aggregate increase could pay for about 40 per cent of the construction cost. McMillen and McDonald (2004) used ex post data on housing sales and confirmed that these predictions were accurate. Taxing such windfall gains is one source of revenue for fixed facilities, although there are practical complications about how to accurately measure and document the land value appreciation in a legal-administrative context.

Transportation as a tool to shape land use

It has been observed that the underpricing of road travel, especially as it relates to the unpriced congestion externality makes travel cheaper than its marginal cost. This not only causes excessive urban expansion but also induces planners to use faulty cost–benefit measures and thus invest in too much road building as argued by Kraus, Mohring and Pinfold (1976). Excessive road capacity in turn reinforces the excessive urban expansion.

In view of the many pecuniary externalities of transportation, and since perfect pricing is not possible, a combination of judicious capacity provision and land-use zoning to ensure better accessibility to main roads and rail lines could have significant benefits. Such economies of transport–land use interdependence may be possible to exploit in urban planning and urban design at the level of smaller areas and neighbourhoods. Boarnet and Crane (2000) have examined whether land use policy and urban form can significantly affect travel behaviour in such settings. Similar concerns exist at the macro urban level (Gordon, Kumar and Richardson, 1989). In the future, planners could use such knowledge when major decisions are made on how much capacity to supply, where to supply it and how much to restrict development around it. More often than not, however, when urban planners intervene with land use controls they may fail to find the golden rule, causing distortions in land markets that could outweigh the efficiencies that can be gained by influencing travel.

urbanization

Sukkoo Kim
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Cities first arose in the Fertile Crescent a few thousand years after the discovery of agriculture. Yet the history of urbanization is not one of steady progress. Pre-industrial urbanization rose with technological advances in agriculture and transportation which fostered population growth and trade, but fell with famine and disease. Just as important, cities rose and fell with the military fortunes of city states, territorial empires and nation states. With the Industrial Revolution, urbanization rose dramatically. As population shifted out of agriculture into manufacturing and services, cities became the dominant landscape of human civilization.

The rise of cities in the ancient Middle East

The first city in human history is believed to have emerged around 3200 bc in Sumer, Mesopotamia, between the Tigris and Euphrates rivers, as a consequence of the Neolithic Revolution which saw a shift in food production from hunting and gathering to agriculture based on domesticated plants and animals (Childe, 1950). The emergence of cities in Sumer marked the beginning of an ‘urban revolution’, but the revolution was an exceedingly slow one. Since agriculture began in the Fertile Crescent around 8500 bc, the first city emerged several thousand years after the discovery of agriculture. Moreover, the emergence of cities was not unique to Mesopotamia. Interestingly, cities emerged independently in at least two other places, China and the New World, places where major domestication of plants and animals arose.
While it is extremely difficult to determine the causes of the emergence of cities in ancient times, scholars such as Childe (1950) and Bairoch (1988) believe that agriculture caused cities to form because it increased population growth and provided surplus food for a non-agricultural population. Since demand for food is believed to be income inelastic, an increase in income from a rise in agricultural productivity will increase demand for secondary and tertiary products (Wrigley, 1987). The urban concentration of secondary and tertiary employment, such as crafts and commerce, enabled the exploitation of the division of labour, fostered technological innovations in many areas of the economy from irrigation, transportation, metallurgy to writing, and lowered the costs of coordinating long-distance trade.

Even more importantly, cities were centres of states before the rise of territorial empires and nation states. A city state was composed of a governing city and its food-producing hinterlands. It was a distinct geographical, political and economic unit of organization. By establishing a body of formal and informal rules of property rights, city states provided their citizens with the incentives to improve productivity or, more fundamentally, to acquire more knowledge (North, 1981). Cities probably became centres of government because close face-to-face interactions between the ruling elite and its administration increased the efficiency of governing by lowering the costs of generating, collecting and processing information. In addition, dense, walled cities provided effective defence against raiders. The cities that arose in Sumer, Mesopotamia, were independent city states. Archaeological evidence indicates that there may have been as many as 15 city states by 3000 bc. A typical city state may have contained population of 25,000 with rural population of about 500,000. Hammond (1972) suggests that the impetus for city states in Sumer may have been the need to coordinate the provision of public goods such as large-scale irrigation, drainage, communal storage, and defence against other city states. Over the following millennium, the number and size of cities grew in this region, some reaching populations of 100,000 or more.

When the Sumerian cities were conquered by Babylon by 1800 bc, the era of early city states gave way to the era of territorial empires such as those of Babylon, Egypt and Canaan. Scholars generally believe that urbanization suffered under these empires except for cities, like Babylon, that served as political and military centres. Babylon at its height may have reached populations of 200,000–300,000. While the exact causes of the rise of these territorial empires are not clear, among them may have been the growing benefits of trade over longer distances and changes in military technology which allowed for the control of larger areas.

Of the major empires, it was in Egypt that cities declined most significantly. Indeed, many scholars would argue that Egypt was an empire without cities. To the extent that cities existed in Egypt, they were centres of religion and administration. The lack of cities in Egypt is often attributed to the Pharaoh's centralized control of irrigation, trade and all other facets of the economy (Hammond, 1972). Cities also declined in the other territorial empires, but probably less, as many remained relatively independent. Despite the general decline of urbanization during this period, a new type of coastal city emerged in Phoenicia. These cities, which grew in numbers around 1200 bc, arose principally to trade goods throughout the Aegean and the Mediterranean.

Cities first emerged in the Middle East, but reached their greatest heights in the Mediterranean in the ancient era. Most likely, cities arose later in the Mediterranean because agriculture arrived in this region a century and a half after its discovery in the Fertile Crescent. It arose first in the Fertile Crescent.
because of favourable geography and climate, which provided an abundance of indigenous species suitable for domestication (Diamond, 1997). From there, agriculture spread about 0.7 miles per year and reached the Mediterranean region sometime between 7000 and 6000 bc. By 2000–1450 bc, Aegean civilization seems to have constructed small city states with relatively limited agricultural hinterland and trade. However, urbanization flourished under the Greek and Roman civilizations, as the Mediterranean Sea became the highway of transport and communications.

The Greeks formed small, independent city states composed of coastal cities and their adjoining farmlands between 800 and 146 bc. Their largest city, Athens, may have reached 100,000 in population, but most other cities rarely exceeded 40,000. Bairoch (1988) estimates that perhaps as much as 15–25 per cent of the Greek population lived in cities with more than 5,000 inhabitants. Because the Greek soil was relatively poor, a large portion of the population was engaged in local and long-distance trade in the Mediterranean. The Greek invention of coined money facilitated market exchanges. The Greek cities are also known for their political innovations. While most city states and territorial empires, with the exception of the Phoenician city states, were ruled by monarchy or aristocracy, democracy arose in many Greek cities.

The formation of the Roman Empire between 146 bc and ad 300 represented the largest political and economic integration of territory in the ancient world. Rome, as the military and administrative centre, grew to an astonishing size, surpassing 800,000 inhabitants and perhaps reaching a million by ad 2. Unlike in the earlier territorial empires such as Egypt, cities prospered under the Roman Empire. Politically, cities became military and administrative centres and collected taxes from the surrounding countryside for Rome; economically, cities acted much like independent city states. Under conditions of peace and uniform law a great numbers of cities emerged as commercial activity increased. Bairoch (1988) estimates that about 8–15 per cent of the population resided in cities. While most cities were small, 20 or more may have reached 20,000 or more inhabitants.

When the Roman Empire disintegrated around ad 476, it signalled the decline of the Mediterranean world. In the resulting so-called Dark Ages between ad 500 and 800, urbanization fell as frequent wars and invasions contributed to economic insecurity. But the two centuries following this period were a period of urban renaissance. By this time, Europe was divided into two regions. The southern Mediterranean part was conquered by Arab Muslims while the northern part was composed of Christian Europe. In Muslim Spain, the urban population rose rapidly. In Christian Europe, urbanization grew in some places for defensive reasons, but in Italy commercial city states rose to great heights (Bairoch, 1988). Ruled by merchant elites, Italian city states engaged in extensive long-distance trade using newly developed technology such as the compass, but cities like Venice also grew because their naval powers provided protection for their ships in the Adriatic Sea and beyond (Lane, 1973).

**The growth of cities in western Europe**

The period called the Middle Ages, between ad 1000 and 1500, marked the beginning of the rise of western Europe. Because this region was further away from, and possessed a very different climate from the Fertile Crescent, agriculture arrived between 6000 and 2500 bc, much later than in the Mediterranean (Diamond, 1997). In the Middle Ages, technological advances such as the heavier plough, horse collar, and the three-field system increased the agricultural productivity of western Europe significantly.
Between 1000 and 1340, there was a strong growth in urbanization based on feudal city states. Under feudalism, a lord provided protection using a castle and knights; in exchange for protection, slaves, serfs and free labourers offered free labour.

The rise of western Europe was interrupted between 1300 and 1490 as famine, disease and wars led to major losses of population and de-urbanization. Famines between 1315 and 1317, the plague and the Black Death between 1330 and 1340 and between 1380 and 1400, and series of wars, civil wars, feudal rebellion and banditry afflicted much of Europe and contributed to the decline of the medieval economy (Palmer and Colton, 1965). Urbanization fell as feudal city states crumbled. North (1981) argues that a series of major technological advances in military warfare, such as the introduction of the pike, longbow, cannon, and eventually the musket, as well as a growing market for mercenaries, contributed to the decline of feudalism since a feudal lord could no longer provide adequate protection for his manor against these new military developments.

The modern period in history begins with the year 1500. Between 1500 and 1800, the opening of Atlantic commerce and the formation of nation states fundamentally transformed Europe and the world. Advances in ocean shipping, which led to the discovery of maritime routes to the Americas and Asia, ushered in a new era of international trade. Although cities in the Mediterranean remained important, the focus of urbanization shifted toward the Atlantic as urbanization grew rapidly in nations with easy access to the open ocean such as Portugal, Spain, the United Kingdom and the Netherlands. In addition, nation states based on monarchies arose throughout Europe and established colonies in Africa and the New World. These new nation states were supported by an unprecedented growth in military and civil administration financed by taxes and debt (Brewer, 1990).

The rise of western Europe and globalization were accompanied by a significant growth in urbanization. In Europe, while the upward trend was not uniform over time, de Vries (1984) finds that the number of cities with populations of at least 10,000 rose from 154 to 364 between 1500 and 1800. The growth in urbanization was concentrated in the very largest cities, whose main functions were to serve either as a government capital or as a port city (de Vries, 1984; Bairoch, 1988). The concentration of merchants in cities lowered the costs of financing and coordinating trade around the globe. Likewise, governments became concentrated in cities since the efficiency of military and government operations involved the collection and processing of an enormous amount of information (Brewer, 1990).

The pre-industrial cities in the Middle East and Europe possessed a variety of political regimes across space and over time. Most often, city states were ruled by kings with absolute power, but in some instances they were ruled by merchant elites. While the rulers of city states provided order and stability, they also imposed heavy tax burdens on their subjects. Between 1000 and 1800, city states that were ruled by absolutist governments grew much less significantly than those governed by merchants or assemblies (De Long and Shleifer, 1993).

**Industrialization and urbanization**

The Industrial Revolution, which began in Britain around 1700, transformed the modern world in a short period of time. In pre-industrial times, which spanned thousands of years from the ancient and medieval periods to the first two centuries of the modern era, cities became important centres of government, trade and artisan manufacturing, but most of the population lived in rural farms and villages. Yet, within a
little over a century after the onset of the Industrial Revolution, the majority of people in Britain lived in cities. As industrialization spread to other European nations and the United States in the 19th century, and eventually to an ever growing list of nations in the 20th century, world urbanization rose rapidly. The Industrial Revolution's transformation of the urban order began in the countryside. The early factories arose in rural villages and towns rather than in established major urban centres, and less urbanized places industrialized more rapidly in Europe and in the United States (Bairoch, 1988). However, as industrialization matured it was significantly correlated with urbanization. The rise of the manufacturing sector was not only responsible for the emergence of new industrial cities, but also contributed to the growth of traditional urban centres. Between 1800 and 1900, the share of the urban population in industrialized countries almost tripled, from 11 to 30 per cent (Bairoch, 1988). It remains unclear why early industrialization was rural or why late industrialization was urban. Scholars generally believe that early factories chose rural locations because of the availability of water power, coal or unskilled labour (Bairoch, 1988). Because early factories used women and child labour intensely, Goldin and Sokoloff (1984) believe that, in the United States, early industrialization arose in rural New England rather than in the rural South because the relative labour productivity of women and children was less than that of men in the former region. For Rosenberg and Trajtenberg (2004), industrialization caused urbanization as firms adopted the Corliss steam engine as their primary power source. Kim (2005a; 2005b) suggests that explanations of why industrialization led to urbanization are likely to rest on the rise of division of labour and the labour market. Prior to industrialization, goods were produced by self-employed artisans who made the entire product. With industrialization, factory owners hired workers in a labour market and employed them in specialized tasks. Because early industrialization was concentrated in a limited number of industries and was limited in scale, firms located in rural places since the costs of recruiting workers were relatively modest. However, as industrialization rose in scale and spread to numerous industries, the agglomeration of workers and firms in cities deepened the extent of the division of labour and lowered labour market transaction costs.

One of the major developments associated with the Industrial Revolution was a transportation revolution. In the pre-industrial period, the bulk of long-distance trade occurred over bodies of water such as canals, rivers, lakes, seas and oceans. With the introduction of the railroad and later trucks and airplanes, overland transportation costs fell dramatically. In the United States, the integration of regional economies led to a significant increase and then decrease in regional specialization (Kim, 1995). The rise of US regional trade led to the rise of many large inland cities like Chicago, which emerged to coordinate the increase in domestic trade.

In the second half of the 20th century, although the rate of urbanization slowed in industrialized nations, cities remain a vital component of the modern economy. Scholars believe that one or more factors, such as Marshallian externalities (technological spillovers, non-traded industry specific inputs, and labour market pooling), market size and natural advantages, cause the formation and growth of cities (Henderson and Thisse, 2004). Moreover, while economic factors are much more significant in modern than in pre-modern times, political factors, such as tariffs and dictatorships, remain important for urbanization (Ades and Glaeser, 1995).

Patterns of world urbanization
Urbanization was not confined to the Middle East and Europe. Cities arose indigenously in India (1000–400 bc), China (700–400 bc) and the New World (100 bc). Cities diffused to Korea (108 bc–ad 313) and Japan (ad 650–700) from China, and to south-west Asia (ad 700–800) from China and India. In the New World, cities arose independently in Mesoamerica in Mexico and the Andes in South America. With the arrival of maize agriculture from Mesoamerica, urbanization reached the south-western and eastern parts of North America. Whereas China and Japan contained some of the largest pre-industrial cities, and had urbanization rates comparable to, or perhaps even higher than, pre-industrial European societies, the cities in the New World were smaller, fewer in number, and less stable.

In Africa, there is considerable uncertainty as to whether agriculture and cities arose independently. While there is evidence of domesticated agriculture in Sahel (5000 bc) and tropical West Africa (3000 bc), scholars remain unsure whether founder crops arrived from elsewhere (Diamond, 1997). There is evidence of cities in Africa as early as 1000 bc, but it is also not clear whether these cities resulted from outside influences (Bairoch, 1988). In Australia, no cities arose indigenously as the aboriginal population remained hunters and gatherers.

The coming of the modern era in 1500 not only transformed western Europe but also decisively altered the path of development around the world. As European nations colonized the New World and parts of Africa and Asia, they transplanted their technologies, agriculture, germs and political institutions to their colonies. From the colonies, the Europeans extracted new plants and resources and traded them around the globe. The demography of the New World colonies was fundamentally altered as the native population suffered and, to a varying extent, was supplanted by European immigrants and African slaves. In general, colonization and globalization were accompanied by a rapid growth in urbanization in Europe and the colonies.

In the 19th and the 20th centuries, the uneven diffusion of the Industrial Revolution around the globe determined the patterns of world urbanization. While there is no general consensus on the causes of uneven economic development, explanations usually rest on one or more factors related to geography, technology, trade and institutions (see Aghion and Durlauf, 2005). In nations that developed, industrialization led to a rapid growth in urbanization; in those that did not, urbanization remained relatively low. In addition, most of the urban population in poor nations became concentrated in a handful of very large cities.

Summary

Cities in history arose with the advent of agriculture as they became centres of governments, crafts, religion and universities. As markets and trade developed, cities became centres of finance and commerce. While the patterns of urbanization differed greatly over space and time, the causes of urbanization were the same around the world. Pre-industrial urbanization rose with technological advances in agriculture, artisan manufacturing, transportation and trade, but fell with environmental degradation, famine and disease. Just as importantly, cities rose and fell with military and administrative efficiency of city states, territorial empires and nation states.

With the Industrial Revolution, cities became centres of factories and offices. Although early industrialization began in rural areas, the shift in the employment composition from agriculture to manufacturing and services led to rapid urbanization. The formation and growth of industrial or modern cities are attributed to benefits from a variety of market and non-market factors such as the division of
labour, lower search costs of matching specialized workers and firms, information spillovers, market size, and non-traded intermediate inputs (Henderson and Thisse, 2004). With the rise in disposable incomes, cities became centres of arts, entertainment and other amenities.

The history of civilization is the history of urbanization. Without cities, the pillars of civilization – literature, science and the arts – would not exist. But as the industrial era gives way to the information era, will cities disappear? Leamer and Storper (2001) believe that face-to-face interactions in cities are likely to remain important for some time to come. For these scholars, the coordination of complex, unfamiliar and innovative activities depends on the successful transfer of uncodifiable messages and requires long-term relationships, trust, closeness and agglomerations. Wherever the new innovative activity may arise, be it in commerce, finance, politics, arts or science, the future of civilization is likely to rest on the success of its citizens.

Andrew Ure, MD, was professor of chemistry and natural science at Anderson's College, Glasgow from 1804 to 1830. In 1830, he introduced the word ‘thermostat’ into the English language in conjunction with a patent that he secured (Standfort, 1982, p. 659). At about the same time, he moved to London to serve as a consultant in analytical chemistry to the Board of Customs. From 1832 to 1834, his major research assignment was to ascertain the wastage rate of raw material in sugar refining in order to determine the rebates on raw sugar import duties that British refiners could legitimately claim. Ure (1843, p. iv) complained that his research saved the exchequer £300,000 but yielded him only £800 in remuneration and cost him his health.

To recuperate, he ‘spent several months in wandering through the factory districts of Lancashire, Cheshire, Derbyshire, &c., with the happiest results to his health; having everywhere experienced the utmost kindness and liberality from the mill-proprietors’ (Ure, 1835, p. viii). Two important books were the result. The Philosophy of Manufactures (1835) and The Cotton Manufacture of Great Britain (1836) are detailed technical treatises on the industry at the heart of Britain's industrial revolution, interlaced with commentary on the salutary moral, intellectual and physical effects of factory life on the workers. Ironically, it was Karl Marx who established Ure's place in the history of economics. Ure's blatantly pro-capitalist stance, combined with his obvious technical expertise, made him the perfect ‘horse's mouth’ in Marx's attempt to show how capitalists used technology to throw adult males out of work and turn women and children into mere appendages of the machine. Marx (1867 [1977], pp. 560, 563–4) invoked the authority of Ure, who, in the conflict-ridden 1830s, argued that the diffusion of more automated technology would ‘put an end … to the folly of trades' unions’, proving that ‘when capital enlists science into her service, the refractory hand of labour will be taught docility’ (Ure, 1835, pp. 23, 368).

Writing some three decades later, however, Marx failed to distinguish pro-capitalist ideology from ongoing reality. Contrary to Ure and Marx, adult male workers had not been definitively humbled, even...
in the presence of mechanization. Rather, certain groups of workers had maintained substantial control
of work organization and had built up considerable union power (Lazonick, 1979). In effect, Marx's
uncritical use of Ure provided the ‘evidence’ needed to confirm that, in their confrontation with
capitalists armed with technology, workers had ‘nothing to lose but their chains’. Theory and history
were parting company in Marx's theory of capitalist development (Lazonick, 1986).

The genealogy of the term ‘user fees’ (or, synonymously, ‘user charges’) is neither long nor coherent. Neither Marshall nor Pigou appears to have used the term. The term was in common usage in the USA during the early post-World War II years; see e.g. Stockfisch (1960). Throughout its short history, the term seems to have been employed much more frequently in the United States than elsewhere. Since about 1970, the term has appeared in the indexes of most US public finance textbooks. No writer has provided a careful definition of the term or distinguished it from similar terms. Rosen (1985) defines a user fee as a price charged for a commodity or service produced by a government. Some writers appear to restrict the term to charges for services produced by governments. To add confusion, many writers apply the term ‘user fee’ to charges levied by a government for the discharge of wastes to the air and water environment. In this usage, the term is synonymous with ‘effluent fee’. Although most economists believe that governments should protect the environment by fees or regulations, since the environment has the characteristics of a public good, the environment is not in any reasonable sense a commodity or service produced by a government.

How is a user fee distinguished from two related concepts, a benefit tax and a price? There is a legal and constitutional difference between fees and taxes levied by governments, but the issue here is the economic content of the terms. A benefit tax is any tax levied proportionately to benefits received by the taxpayer from a commodity or service provided by a government. The appropriate distinction is that a fee is paid only if the consumer decides freely to consume the commodity or service, whereas the taxpayer may be forced to pay a benefit tax even though he or she is not free to decide whether to consume the commodity or service. If the term ‘benefit tax’ is restricted to taxes whose amounts are no greater than the value to the taxpayer of the commodity or service consumed, the important distinction disappears. No rational consumer would refuse to pay a tax which is less than the benefit which the consumer receives from commodities or...
services financed by the tax. Thus, the distinction between voluntary and involuntary payment becomes unimportant. In practice, governments levy many taxes in the name of benefits even though they are larger than the benefits derived from the commodity or service provided. Most ostensibly benefit taxes are only approximations to fees for the commodity or service consumed. A gasoline tax is an approximation to a fee for road consumption or congestion and pollution externalities. The Tiebout theory (1956) implies that all local government taxes can be viewed as benefit taxes.

There seems to be no important distinction between a user fee and a price except that the term ‘user fee’ is used when government is the supplier. Public finance economists frequently use the term ‘user fee’ when reference is to a service, such as electricity, provided by government, even though the service is sometimes provided by private suppliers and the charge is then referred to as a price.

Why make the distinction between a user fee and a price? There seems to be no justification except to identify the supplier. Yet that typically is, and always could be, clear from the context. It appears to be unjustified to coin a different, and indeed clumsy, term merely to identify the supplier. One suspects that some intellectual product differentiation is behind the distinction.

Usher, Abbot Payson (1884–1965)

William N. Parker

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Clapham, J. H.; economic history; inventions; Kondratieff cycles; measurement; Schumpeter, J. A.; technical change; Usher, A. P.

Article

Usher occupied the chair of European economic history at Harvard University from 1936 to 1949 and was surely the most productive and original scholar to occupy this post. For economists of later decades, his most significant book was *A History of Mechanical Inventions* (1st edn, 1929; 2nd edn, 1954). In it he identified invention as a four-stage process in which the individual inventor, being seized of a problem in the presence of the intellectual and physical elements for a solution, achieves the primary insight (called by Usher the ‘saltatory act’ and by his students the ‘ah-ha!’ or ‘Eureka’ moment) and completes the invention through a stage of ‘critical revision’. Usher's work here became noticed by economists when it was taken up by J.A. Schumpeter to form the historical basis of his descriptive and theoretical work on *Business Cycles* (1939) and also through its relation to the Kondratieff ‘long waves’ based on the clustering of a few major inventions at discrete points in and around the 19th century (1770–80, 1840–60, 1890–1910). At a time when economists treated technological change as an element as exogenous to economics as physical geography, Usher alone thought it worth examining as a complex socio-economic ‘thread’ in history. In this he was the forerunner of such modern students as Schmookler, Mansfield, Ruttan, Nelson and Rosenberg, though his book largely emphasized the technical (supply-side) aspects of the process.

The identification of Usher with the study of technological change is unfortunate, since his many monographs and articles, his two textbooks, and his classroom teaching reveal a comprehensive grasp of the experience of the West in economic life and organization in all its major aspects. It is perhaps fair to say that his mind was fascinated with those points where societies face nature. Population growth, geographical resource patterns, transport, industrial location, technology, physical costs and physical constraints on social action and organization were the themes around which his view of economic history was organized. His insights were those of the engineer, not those of the sociologist.
This bias in Usher's work undoubtedly derived from a deep-seated liberal ideology which regulated both his topics and his methods of research. He looked on economic history not simply as an interesting outlet for scientific curiosity but as an instrument to help societies achieve a rational control over their environment. But, himself the most modest and unpolitical of men, he evidently saw little use to studies where the social control to which they could lead impinged on the individual's personal and private life and values. And methodologically Usher was a committed empiricist. He evinced, and often reiterated, a deep distrust of what he called the idealistic formulations of Marx, Weber and Parsons. Yet his admiration of the British school typified by Clapham was moderated by an uneasiness over its commitment to a purely literary or descriptive methodology. He was most at home in the study of specific limited topics in which a quantifiable trend could be observed over a long period and where measurement and economic theory of a Marshallian variety could be employed. His concrete applications of the German theories and models of industrial location were particularly powerful, and inspired the later work of E. Hoover, W. Isard and others. He must be accounted, along with S. Kuznets and A. Gerschenkron as a patriarch of the so-called 'new' economic history in the United States, and of those three, Usher's grasp of the relation between theory, measurement and the phenomena of historical change must be accounted to have been the most philosophical and careful, and the best exemplified in concrete historical studies.

**Selected works**

A bibliography of Usher's writings is contained in Lambie (1956). This volume also contains an essay on Usher's thought and writings. See also the article by John Dales in the *International Encyclopedia of the Social Sciences*, vol. 16 (1968), and the generous memorial tribute by A. Gerschenkron, retained in the files of the Harvard Department of Economics.

Among Usher's books and articles, *A History of Mechanical Inventions* (1929; 1954), and his two advanced level texts, *An Introduction to the Industrial History of England* (1920) and (with W. Bowden and M. Karpovich) *An Economic History of Europe since 1750* (1937), were the most durable and highly valued by students. His major contributions to early modern European economic history are *The History of the Grain Trade in France, 1400–1710* (1913) and *The Early History of Deposit Banking in Mediterranean Europe* (1943). Usher's attitudes toward economic history and methodology are best stated in three articles, (1932, 1949 and 1951) and in Chapter 4 of *A History of Mechanical Inventions*. His attitude toward economics and economic policy is well stated in his 1934 address to the American Economic Association.

1934. A liberal theory of constructive statecraft (Address to the American Economic Association). 

Bibliography

Utilitarianism is a family of moral and political philosophies according to which general utility or social welfare is ultimately the sole ethical value or good to be maximized. Normative economics endorsed a hedonistic version of utilitarianism from the latter part of the 18th century well into the 20th century. Despite the ordinalist revolution, some version of utilitarianism continues implicitly to serve as the ethical basis for economic policy judgements. While there are signs that this may be changing, economic theory has not yet moved decisively beyond utilitarianism, nor is it clear that it should.

Article

Utilitarianism is a family of moral and political philosophies according to which general utility or social welfare is ultimately the sole ethical value or good to be maximized. Amartya Sen (1979) suggests that members of the family typically combine ‘outcome utilitarianism’,
which, at least if population is not a variable, identifies the goodness of an outcome with the sum of individual utilities at that outcome, and some version of ‘consequentialism’, which focuses on selected means of achieving outcomes, such as acts, rules, dispositions, or some combination of these, and identifies the right means in any situation as those which result in an optimal feasible outcome according to outcome utilitarianism. (For analysis of the issues raised when population is a variable, see Blackorby, Bossert and Donaldson, 2005.) Outcomes can be defined to include the acts, rules, or other means that lead to them. Thus, for any set of possible outcomes, a typical version of utilitarianism calculates social welfare $W(x)$ at any outcome $x$ by adding together the individual utilities at $x$:

\[
W(x) = \sum u_i(x).
\]

The doctrine then prescribes as best an outcome $x^*$ at which the sum of utilities is maximized, that is,

\[
W(x^*) = \max \sum u_i(x).
\]

As Sen also points out, outcome utilitarianism can be factorized into ‘sum-ranking’, the claim that the proper way to aggregate individual utilities is to add them, and ‘welfarism’, the principle that the goodness of an outcome is an increasing function of the set of individual utilities so that non-utility information relating to any outcome is of no ethical import. Welfarism implies ‘Paretianism’, the claim that one outcome is better than another if (but not only if) at least somebody has more utility whereas nobody has less utility in the one outcome than in the other. Full axiomatizations of outcome utilitarianism have been provided by d’Aspremont and Gevers (1977) and Maskin (1978).

Different versions of utilitarianism may vary not only in terms of their consequentialist structures but also in terms of their conceptions of utility. Hedonistic utilitarianism conceives of utility as pleasure including freedom from pain, for example, whereas rational choice utilitarianism conceives of utility as a numerical representation of a preference revealed by consistent choice behaviour which is in principle observable. Sen himself arguably takes a quite restricted view of the utilitarian family because he seems to take for granted that utility, although capable of bearing plural interpretations, can be seen only as a simple phenomenon that remains the same whatever its sources and intended objects. As a result, welfarism and Paretianism cannot accommodate the idea of different aspects or kinds of utility, some of which may be intrinsically more valuable than others, where each kind is inseparably associated with a distinctive mix of human capacities, resources and/or institutional activities. Thus, as an alternative to utilitarianism, Sen (1980) introduces the family of ‘utility-supported moralities’, in which the goodness of an outcome still depends on utility but non-utility information is needed to distinguish among different kinds of utility and assign them distinct intrinsic values. Sen's move, although reflecting conventional wisdom, appears to be unnecessary and to that extent encourages an overly hasty dismissal of utilitarianism's potential normative appeal (Edwards, 1979; Riley, 1988; 2001; 2006a; 2007b; 2007c; 2009).

Normative economics, or that portion of economic theory that evaluates institutions such as markets and policies such as tax proposals with a view to offering prescriptions for society, is not necessarily linked...
utilitarianism and economic theory: The New Palgrave Dictionary of Economics
to any version of utilitarianism. Nevertheless, as an historical matter, economists generally endorsed
hedonistic utilitarianism from the latter part of the 18th century, when both classical economics (or
political economy) and classical hedonistic utilitarianism first began to emerge as systematic bodies of
thought, well into the 20th century, long after the marginalist revolution of the 1870s when classical
economics evolved into neoclassical economics. Even today, economists typically appeal to some
version of utilitarianism, although utility is rarely defined in hedonistic terms. As Kenneth Arrow says:
‘The implicit ethical basis of economic policy judgement is some version of utilitarianism’ (1973, p.
246).
Jeremy Bentham (1789) and his followers, including, among others, James Mill, David Ricardo, and, for
a time in his youth, John Stuart Mill, constituted the original school whose hedonistic version of
utilitarianism remained dominant for so long within economics, although the doctrine was modified to
some extent and combined with other ingredients largely as a result of Henry Sidgwick's influence on
the early neoclassical economists such as W. Stanley Jevons, Alfred Marshall and, especially, Francis Y.
Edgeworth. But the Benthamites were certainly not the first to preach a doctrine of general utility.
Sidgwick traced the doctrine to Richard Cumberland's De Legibus Naturae (1672), for example,
although Cumberland was not a hedonist. Bentham admitted that his hedonistic utilitarianism owed
much to the writings of Claude Adrien Helvétius and David Hume. Hume, like his contemporaries Francis Hutcheson and Adam Smith, asserted that human sentiments are approved of as prudent, virtuous or just only if they are seen as useful or agreeable either to the individual or to others. To be sure, none of these thinkers claimed that moral sentiments such as the sentiment of justice originate in the individual's idea of general utility. Despite various differences in their accounts, they seem to agree that an innate moral sense immediately feels a peculiar pleasure at the propriety of virtuous acts and dispositions towards other people, and that this pleasure can be made a powerful motive by suitably encouraging and educating the individual's natural sympathy for other human beings. But Bentham and Mill did not claim that moral sentiments originated in the individual's conception of general welfare either, although they rejected the notion of an innate moral sense. Bentham seems to have believed that people are predominantly motivated by self-love but that self-interest can be made to harmonize with the general welfare by giving the egoist incentives to comply with a utilitarian legal code. The sentiment of justice reduces to cooperating with others in terms of the code, which any rational egoist will do provided he is threatened with sufficient punishment by others for non-compliance. Mill did not rely exclusively on enlightened self-interest and external punishment but instead argued (rather as Hume did, especially in the Enquiry Concerning the Principles of Morals, 1751) that natural sympathy for fellow human beings can be raised to such a pitch through moral education that the individual comes to feel far more pleasure when he sacrifices his self-love to the extent required for conscientious mutual cooperation in terms of utilitarian laws and customs that distribute reciprocal rights and duties.
Smith, Hume and Hutcheson may not have been fully fledged hedonistic utilitarians like Bentham and
Mill, who were prepared to assert that general welfare can demand the radical reform of rules commonly
alleged to be dictates of an innate moral sense. But they may be fairly depicted as what Sidgwick called
‘conservative’ utilitarians, who sought to explain that common sense morality is generally compatible
with public utility. In any case, Hume and Hutcheson appear to have supplied crucial ingredients for
Mill's utilitarianism, the one through his account of the moral sentiment of justice, the other through his
distinction among different kinds of pleasure, some of which are more intrinsically valuable than others.

Benthamite utilitarianism

Bentham's assumption that individuals are primarily self-interested fits well with economic theory. He took for granted that pleasure, including freedom from pain, is a single kind of agreeable feeling whose properties are invariant across different sentient beings. Any competent person can estimate the amount of pleasure which he or she experiences in any situation, he argued, by considering factors such as intensity, duration, certainty, propinquity, fecundity and purity. Yet he apparently did not intend to claim that much precision is possible. Indeed, as Mitchell (1918) documents, Bentham frankly admitted at times that intensity of pleasure cannot be measured and that interpersonal comparisons of pleasure cannot be based on the facts. Nevertheless, he insisted that alternative institutions and policies must be evaluated in terms of their consequences for each and every sentient being's pleasure and pain. Thus, rough estimates of aggregate net pleasure must be constructed before moral and political reasoning can even get started.

To obtain such estimates, Bentham seems to have assumed that everyone shares certain vital concerns, including security of expectations, subsistence, abundance and equality, and that different persons ought to be counted as if they are the same person when society chooses how to distribute the means of attaining these vital ingredients of anyone's happiness. The upshot is that the maximization of aggregate net pleasure becomes inseparably associated with a legal code that distributes equal rights and correlative duties for the purpose of providing the greatest total amount of security (in effect, equal marginal security) for every individual's vital concerns (Rosen, 1983; Kelly, 1990). These legal rights must include, among others, a right to subsistence and, consistently with that, rights to keep or trade the fruits of one's own labour and saving so as to foster abundance. Bentham's implicit premise, apparently, is that such legal rights are any rational egoist's source of his greatest amount of net pleasure, especially when duration and fecundity are taken into account, and that, to ensure universal compliance with the law, the egoist will endorse external punishment for violations of the correlative duties. Other animals can also be afforded some rights to protect their vital interests to some degree, although the power to exercise such claims must rest with humans.

At the same time, Bentham argued that the laws of property should be designed to promote an egalitarian distribution of income and wealth so far as is consistent with maximizing general security under an optimal code of equal rights. He gave priority to security, including a guarantee of subsistence as well as rights to own the means of production, over perfect equality of income and wealth as a source of pleasure for any rational individual. But he also endorsed the assumption that any individual experiences declining increments of pleasure from additional units of money or other material assets after subsistence is assured.

According to Benthamite utilitarianism, rational hedonistic egoists must be given incentives to act as they would act if they were aiming to maximize the general good conceived in terms of security, subsistence, abundance and equality. Admittedly, egoists will not face the threat of legal penalties with respect to private conduct that is left unregulated by the public authorities. Even so, as Sidgwick (1877; 1886) concluded, Bentham seems to have maintained that enlightened self-interest is always in harmony with virtue, not only in an ideal world but also in the world of actual experience, so that vicious conduct always involves a miscalculation. If Sidgwick's reading is correct, then Bentham prescribed external
sanctions to discourage miscalculations of genuine self-interest, apparently on the assumption that such mistakes are likely to be observed to any considerable degree only when the egoist holds power over others, inadequate checks exist against the abuse of power, and the unchecked power corrupts the egoist's judgement.

J.S. Mill's qualitative utilitarianism

Although he said that he found much of permanent value in Bentham's doctrine, Mill made clear that he wished to ‘enlarge’ Benthamite utilitarianism by making room for higher moral and aesthetic sentiments which Bentham had largely ignored as a result of his focus on self-interest. Unlike Bentham, Mill argued that human nature is highly plastic and that many people in civil societies are observed to have developed characters in which sympathy for others and a conscientious desire to do right are powerful motives that would restrain self-interest even in the absence of any threat of external punishment. He agreed that pleasure is the only thing of intrinsic value but maintained that there are plural kinds such that higher kinds are intrinsically more valuable than lower kinds, with the implication that competent people who experience both will not give up even a bit of the higher for any amount of the lower ‘which their nature is capable of’ (1861a, p. 211).

Mill apparently classified among the highest kinds of pleasurable feeling the complex moral sentiment of justice as he understood it. As he explains in the final chapter of Utilitarianism (1861a), this complex feeling of security (or what others might call the feeling of freedom) can be fully experienced only by cooperating with others in terms of an optimal code that distributes equal rights and correlative duties to all individuals. In his view, this higher kind of pleasure can become such a powerful motive that the just individual rarely if ever even considers pursuing his self-interest to the point of violating others’ rights. If so, Mill's pluralistic utilitarian doctrine is able to provide a more stable foundation than Bentham's purely quantitative doctrine can provide for a liberal system of weighty rights and duties. At the same time, individuals can still be permitted to freely pursue their selfish concerns in competitive markets, provided they comply with the code of justice.

Despite his qualitative gloss, which was probably suggested to him by Hutcheson's discussion of different kinds of pleasure in A System of Moral Philosophy (1755), Mill's doctrine remains rather similar to Bentham's, at least in broad outline. To be sure, there are important differences. In On Liberty (1859), Mill emphasized the importance of individuality as an ingredient of happiness, for instance, and he argued that a right to complete liberty of ‘purely self-regarding’ conduct is essential to promote individuality. He also went beyond Bentham by taking seriously the possibility of a decentralized socialism. Yet they agree on the need to maximize security by giving suitable priority to an optimal code of equal rights, and they also agree that institutions and policies should promote an egalitarian distribution of income and wealth so far as is consistent with the rights distributed by the code. Moreover, like Bentham, Mill seems to have despaired of the possibility of ever acquiring data sufficiently precise to permit factual calculations of aggregate net pleasure. Rather, Mill argued that the test of quantity as well as quality of any two pleasures or pains was the unanimous judgement of competent persons who had experienced both, or, in case of disagreement, the majority judgement of such persons, where judgements are apparently assumed to be nothing more than preference orderings defined over the relevant net pleasures. By implication, for any pair of possible outcomes x and y, any
competent individual $i$ who estimates that the quantity of net pleasure $u_i(x)$ which he will experience at $x$ is at least as great as the quantity of the same kind of net pleasure $u_i(y)$ which he can expect at $y$, forms a weak judgement or preference $R_i$ defined over pleasures which then, by virtue of hedonism, determines his preference over outcomes:

$$\text{for all } x, y: u_i(x) R_i u_i(y) \rightarrow xR_i y,$$

(2)

where $R_i$ includes an asymmetric factor $P_i$ denoting that $i$ forms a strict preference if he estimates that $u_i(x) > u_i(y)$, and a symmetric factor $I_i$ denoting that he is indifferent when he estimates that $u_i(x) = u_i(y)$.

The information about quantities of pleasure is no more precise than that contained in the fallible individuals’ estimates, even if any competent person makes use of Bentham's guidelines to consider intensity, duration and so forth, and also accepts such common psychological generalizations as declining marginal pleasure of income beyond some threshold of subsistence. Given the Benthamite dictum that ‘everybody is to count for one’, aggregating over the individual judgements largely boils down to majority rule, which is consistent with the strongly majoritarian forms of representative democracy defended by Bentham in his *Constitutional Code* (1830) and by James Mill in his *Essay on Government* (1820). Yet majority rule does not rely on interpersonal comparisons of pleasure. Strictly speaking, each person's judgement might be counted as one by being represented by the same interpersonally comparable ordinal utility function as everyone else's in the modern economic sense of utility. In this case, even though any positive monotonic transformation of the single utility function used to represent each person's estimates of pleasure is permissible, adding the utility numbers to form hedonistic utilitarian judgements will usually (but not always) select majority winners if such outcomes exist and always resolve majority preference cycles when they occur (Riley, 2007c).

J.S. Mill also argued that any competent individual who judges that the kind of pleasure which he will experience at $x$ is higher in quality than the kind of pleasure which he can expect at $y$, would never sacrifice even a bit of $u_i(x)$ for any amount of $u_i(y)$. In effect, the two kinds are incommensurable and cannot be traded off against one another in terms of the same scale of value. If the pleasure of the moral sentiment of justice is higher in quality than the enjoyable feelings of ordinary expediency, for instance, then a competent individual refuses to trade off even a little of his or anyone else's security of equal rights for, say, any quantity of enjoyment associated with ill-gotten income. The kind of painful insecurity associated with violating rights always outweighs the amount of merely expedient pleasure that might be gained by means of the violation. Because he feared that the popular majority might not be sufficiently educated to be competently acquainted with the pleasures of equal justice, Mill was less inclined than James Mill, his father, and Bentham were to support majoritarian democracy. Indeed, he seems to have been impressed by Thomas Macauley's objections that the Benthamites' methodology was flawed in so far as they attempted to deduce political conclusions on the assumption that individuals are rational self-interested agents without emotional ties to existing institutions (Lively and Rees, 1978).
A more historical approach was needed, one that recognized the danger of majority tyranny and did not ignore as irrational those traditional institutions, attitudes and practices that might help to combat it. Thus, in *Considerations on Representative Government* (1861b), Mill argued for a limited form of representative democracy in which a distinctive system of checks and balances is designed to give more power to highly educated minorities, whose special expertise is generally acquired in traditional ways outside the democratic political system, to promote competent government and security of equal rights (Riley, 2007a). Nevertheless, Mill's qualitative hedonism was generally dismissed as incoherent, and his model of liberal democracy was rejected as undemocratic. Under the influence of leading philosophers and economists, utilitarianism took a turn towards false quantitative precision, and the links with democracy were obscured.

**Sidgwick and the early neoclassical economists**

Sidgwick (1874), who billed himself as a hedonistic utilitarian, played a central role in all of this. He was in fact a rational intuitionist who argued that utilitarianism presupposed certain rational intuitions such as the axiom that an ethical agent must be impartial between one person's pleasures and another's. His argument muddied the hedonistic utilitarian tradition, which held with Hume that intrinsic value is not a function of a priori reason but rather of feelings of pleasure wherever located, whose origins and properties can in principle be inferred by reason only on the basis of experience. Moreover, although he claimed to be a strong admirer of J.S. Mill, Sidgwick asserted that a consistent hedonism must be purely quantitative because qualitative hedonism implicitly relies on some intrinsic value besides pleasure to distinguish among different qualities of pleasure. His assertion was apparently accepted as gospel by his friends Jevons (1874), Edgeworth (1877; 1881) and Marshall (1884). His student Moore later repeated it in the course of accusing Mill of spreading 'contemptible nonsense' (1903, p. 72). Yet Sidgwick and his followers merely beg the question against Mill because they assume that pleasure is a simple agreeable feeling that always exhibits the same properties. They never consider the possibility that pleasure is a term that covers a family of agreeable feelings, some of which are intrinsically more valuable than others.

Sidgwick also raised serious doubts about the rationality of a purely quantitative hedonistic utilitarianism by arguing that practical reason is ‘divided against itself’ because it cannot resolve basic conflicts between rational egoism and rational benevolence in some situations. This ‘dualism of practical reason’ is said to be manifested when a reasonable wish to preserve one's own life or other vital interests that ought to be protected by rights apparently collides with reasonable utilitarian duties to promote others’ welfare by sacrificing one's own life and enjoyments. Some such ethical dualism or pluralism is now a staple of the philosophical literature. Many argue that genuine maximizing utilitarianism conflicts with individual rights so fundamentally that an impartial rational resolution of the conflict is impossible. Moore went even further than Sidgwick and insisted that a ‘naturalistic fallacy’ is committed if intrinsic goodness is defined to be synonymous with pleasure or desire-satisfaction or any other natural property. Rather, goodness is said to be an indefinable non-natural quality that emanates in mysterious fashion from certain complex ‘organic wholes’ consisting of plural natural ingredients including, perhaps, pleasure as an essential ingredient, although Moore struggled to make up on his mind on this point (see,
for example, Edwards, 1979). But Sidgwick rejected Moore's anti-hedonistic view that ideals of goodness are directly intuited by anyone capable of appreciating the relevant ‘organic unities’. Indeed, without defining goodness to mean pleasure, Sidgwick accepted that pleasure including freedom from pain might ultimately be found to be the only thing of intrinsic value. He endorsed Bentham's ‘empirical method’ of ascertaining quantities of pleasure and pain, albeit reluctantly given the difficulties which he saw in applying that method. He also argued that quantitative hedonistic utilitarian reasoning accords with the bulk of common moral intuitions, upon which it can thus legitimately rely as rules for calculating right and wrong actions, and called for formal models of a utilitarian calculus under ideal conditions to help clarify its implications.

Early neoclassical economists, especially Edgeworth, answered the call and used the tools of mathematical calculus to formulate ideal versions of quantitative hedonistic utilitarianism. Unlike Bentham or Mill, Edgeworth assumed that natural units (‘just perceivable increments’) of pleasure and pain can in principle be ascertained and aggregated over varying populations and time horizons. Rather than consider individuals’ judgements of the quantities of net pleasure to be expected from feasible options as in (2) above, he imagined an ideal situation in which the quantities are definitely known such that, for any individual $i$, a unique natural utility function can be specified which, by virtue of hedonism, determines what $i$'s preferences over outcomes ought to be:

$$\text{for all } x, y, u_i(x) \geq u_i(y) \rightarrow x R_i y.$$  

(3)

There is no longer any need for $i$'s estimates of pleasure because the utility numbers are assumed to be already known with fantastic precision. There is not even any need for $i$ to form or express his preferences over outcomes. Person $i$'s natural utility function indicates the exact amount of interpersonally comparable natural pleasure which $i$ can reasonably expect to experience at any given option, whether or not $i$ appreciates this fact. Any competent ‘impersonal observer’ with the requisite individual utility information can then determine a best option by adding up the unique individual utility numbers at each option to see which option has the greatest sum total of pleasure net of pain. A utilitarian calculus is thus no longer necessarily linked to majoritarian aggregation procedures as it was with Bentham and Mill. Indeed, an authoritarian elite might perform and enforce the utilitarian calculations. Sidgwick and Edgeworth seem to have been surprisingly open to the possibility of some such utilitarian elite.

The marginalists also found more or less ingenious ways to overcome Sidgwick's ‘dualism of practical reason’. They imported the idea of an evolutionary process as they understood it, whereby ignorant and selfish individuals might eventually evolve into intelligent and virtuous ones through cultural and (as Herbert Spencer suggested) even biological transmission of the relevant concepts and dispositions. Jevons went so far as to endorse the Hegelian notion that this evolutionary solution was under divine direction. Edgeworth did not go so far. Yet, like Jevons, he took for granted that the more highly evolved members of a refined minority have greater capacities than the masses do for pleasure (the minority can enjoy ‘higher pleasures’ in the sense of larger quantities of pleasure viewed as a single kind...
of agreeable feeling), and he emphasized that utilitarianism does not necessarily imply equal distribution of the ‘means of pleasure’ or of the work required to produce the means.

Moreover, Edgeworth was specific about the way in which Sidgwick’s ‘dualism of practical reason’ could be overcome in the economic arena. After calculating the ‘contract curve’ of Pareto-efficient allocations that self-interested traders could willingly negotiate and enforce as contracts, and showing that the contract curve converges on a perfectly competitive equilibrium only as the number of bargainers goes to infinity, he stressed the indeterminacy faced by any finite number of bargainers in selecting among efficient contracts. He then suggested that under certain conditions, including equal prior probabilities of any particular efficient contract being selected, the selfish bargainers would agree to accept a utilitarian contract as a just compromise because it is one of the efficient options on the contract curve, ignoring instances where the utilitarian bargain might make an individual worse off than his initial endowment (Creedy, 1986, pp. 79–92; Newman 2003, pp. xxxvii–xlvii). This contractualist argument for utilitarianism is interesting not only because it anticipates John Harsanyi (1977; 1992) but also because Edgeworth was well aware that a utilitarian bargain is typically distinct from a competitive equilibrium and thus calls for redistributive measures.

The ordinalist revolution

By the turn of the 20th century, hedonism was under siege in both psychology and philosophy as evolutionary psychology and behaviourism came to the fore along with philosophical idealism, pragmatism and ethical pluralism. Hedonism was largely abandoned within economics during the ordinalist revolution of the 1930s and 1940s, whose leading figures included Lionel Robbins, John Hicks, R.G.D. Allen, Abram Bergson and Paul Samuelson. The ordinalists, who registered doubts about meaningful interpersonal comparability as well as cardinal measurability of utility, recognized that the analysis of efficient allocations does not require either a hedonistic theory of motivation or rich interpersonally comparable cardinal utility information. They redefined the concept of utility to denote not pleasure but rather a formal numerical representation of any preference ordering revealed by consistent choice behaviour, without reference to the motivations or reasons underlying the revealed preference. In effect, utility merely represents what the agent is disposed to choose, independently of any psychological explanation or ethical justification for the given dispositions. Thus, in contrast to (2) or (3) above, any individual \( i \)'s utility function is independent of hedonism and simply recapitulates the information which is contained in \( i \)'s revealed preference ordering over outcomes:

\[
\forall x, y: u_i(x) \succeq u_i(y) \iff x \succeq_R y.
\]

Moreover, any positive monotonic transformation of the utility function is also an admissible utility function because such transformations preserve the information in the preference ordering which is being represented.

Given the restriction to such impoverished individual utility information, purely ordinal and bereft of...
any ethical standards, it is hardly surprising that there was an impulse to push aside issues of distributive justice, relegating them to other disciplines such as political philosophy. Normative economics could then concentrate on relatively uncontroversial Pareto efficiency considerations, including clarification of the conditions under which a general competitive equilibrium is efficient, for instance, and of the different conditions under which an efficient allocation can be achieved as a competitive equilibrium (cf. the ‘fundamental theorems’ of welfare economics).

Arrow's (1951) ‘general impossibility theorem’ may initially have reinforced the impulse to sidestep distributive issues because the theorem shows in effect that a social welfare function must reflect the preferences of a dictator if it is required to rely exclusively on purely ordinal utility information to generate rational social or moral choices from any set of distinct individual preferences. Yet normative economics cannot plausibly ignore distributive justice and the consequent need for interpersonal comparisons. In this regard, Arrow's negative result has also stimulated a large literature in which social choice theorists and game theorists have clarified many different forms of social decision functions and games, including their various informational requirements, and thereby clarified alternative theories of justice and morality which might be employed within normative economics. In addition to Arrow himself, Amartya Sen (1970; 1982; 2002; 2007) has played a leading role in this literature. But numerous others, including John C. Harsanyi (1955; 1977; 1992) and Kenneth Binmore (1994; 1998; 2005), have made noteworthy contributions.

It remains unclear what impact this ongoing literature will ultimately have on normative economics. Perhaps, as has been suggested (Mongin, 2006; see also Mongin and d’Aspremont, 1998), another revolution is under way, what might be called a non-utility revolution in so far as the thrust of it is to argue that a social welfare procedure ought to rely at least in part on information about the outcomes which is not reflected in individual preferences. Yet economists continue to defend and employ versions of utilitarianism. Indeed, Ng (1975; 1985) has made a case for redepolying within normative economics a so-called Benthamite doctrine that brings back Edgeworth’s notion of ‘just perceivable units’ of pleasurable feeling. But economists have tended to adopt rational choice versions of utilitarianism which, unlike the forms of utilitarianism typically discussed by modern philosophers such as Hare (1981), Ng and Singer (1981), Gibbard (1987; 1990) and Brandt (1992), do not tie the idea of utility to pleasure, desire-satisfaction, norm-expression, or any other motivation. Harsanyi’s doctrine is a leading example (for a cogent summary of its main features, see Hammond, 1987).

**Harsanyi's rational choice utilitarianism**

Harsanyi defines utility as merely a numerical indicator of any preference revealed by rational choice behaviour but he also argues that utility functions can be viewed as cardinal and interpersonally comparable rather than purely ordinal. He builds various conditions into his idea of what constitutes fully rational and moral behaviour so that meaningful interpersonal comparisons can be made of the gains or losses of utility that represent relative intensities of revealed preferences, that is, how much one outcome is preferred or opposed relative to another. Technically, this implies that a person's utility function can be subjected to any positive linear (but not nonlinear) transformations but, if any person's utility function is transformed, then every other person's must also be transformed in the same way. Such interpersonally comparable cardinal utility information is needed to operate a rational choice utilitarian
utilitarianism and economic theory: The New Palgrave Dictionary of Economics

calculus in anything like the manner imagined by neoclassical economists such as Edgeworth. Like John Rawls (1971; 1993), Harsanyi assumes that rational moral agents will imagine themselves in an original position under a veil of uncertainty about their particular social circumstances in order to calculate a fair social contract, that is, a conception of justice in terms of which they mutually agree to cooperate despite their different personal preferences. Unlike Rawls, however, Harsanyi assumes that rational choice behaviour under risk and uncertainty conforms to standard expected utility theory. He argues that individual attitudes towards risk should be used to infer personal preference intensities over outcomes, in which case the von Neumann–Morgenstern method of cardinalization becomes appropriate and a cardinal expected utility function represents an individual’s revealed preferences under risk and uncertainty. Also, a moral agent must become an impersonal observer by forgetting his actual circumstances and imagining that he has an equal chance of occupying any person's social position with that person's preference intensities over outcomes. To avoid double counting, any impersonal observer must also ignore what Ronald Dworkin (1977, p. 234) calls ‘other-oriented’ preferences defined over other persons’ positions. All impersonal observers are guaranteed to make identical interpersonal comparisons and moral choices because human beings supposedly share a fundamentally similar psychology, which is left unspecified, though hedonism is rejected as naive. Finally, impersonal observers will jointly choose to constrain themselves, Harsanyi claims, by making a binding commitment to the same optimal code of moral rules. A person whose revealed preferences satisfy all these conditions is behaving as if he were a rule utilitarian, whatever his desires, feelings or other motivations might be.

Harsanyi’s theory is vulnerable to various serious objections. It is not clear that revealed attitudes towards risk measure intensity of subjective feelings or that they would have much normative significance even if they did, for instance, even when individuals can be assumed to be concerned exclusively with outcomes and to ignore the process of assigning probabilities (‘gambling’) per se. Also, as Diamond (1967) has pointed out, Harsanyi’s claim that moral and social utility must be a linear function of the individual utilities seems overly rigid because it ignores the distribution of the utilities. Rather than define morality so that it always demands the simple addition or averaging of individual utilities, a more appealing approach would insist that the process of moral and social decision-making should give everyone a ‘fair shake’. Fairness might be thought, for instance, to require a quasi-Rawlsian concern to maximize the utility of those individuals or groups with the worst utility levels in comparison to others. (For further discussion of this quasi-Rawlsian approach known in the literature as ‘leximin’, see, for example, Hammond 1976; 1977; and Deschamps and Gevers, 1978. Unlike Rawls’s maximin theory, which works in terms of ‘primary goods’ that every rational person is presumed to want, the leximin theory works in terms of utility levels.)

Doubts about the von Neumann–Morgenstern method of cardinalization and the fairness of sum-ranking have prompted some leading economists, including Arrow, Diamond and James Mirrlees, to take seriously an ordinalist variant of rational choice utilitarianism.

Ordinalist utilitarianism

Ordinalist utilitarianism presupposes that interpersonally comparable ordinal utility information is available. In other words, it must be assumed that meaningful interpersonal comparisons can be made of
the levels of utility which represent revealed preference orderings. Technically, this implies that a
person's utility function can be subjected to any positive monotonic transformations, but if any person's
utility function is transformed, then every other person's must be similarly transformed.
An ordinalist utilitarian calculus is quite flexible in terms of its functional form. In contrast to (1) above,
social welfare is calculated as the sum of utilities with a particular concave transformation \( f(\cdot) \) applied
to each person's utility function:

\[
W(x) = \sum f(u_i(x)) = f\left(\sum u_i(x)\right).
\]

But \( f(\cdot) \) may be subjected to any positive monotonic transformations without affecting \( W \) because the
aggregation process is meaningful only for ordinal (rather than cardinal) comparable utility information.
Arrow (1973) has shown that this ordinalist utilitarian approach subsumes the quasi-Rawlsian leximin
theory of distributive justice as a special case, namely, the case in which the concavity of \( f(\cdot) \) is extreme
because each person is assumed to be highly risk-averse. Another important application is in the modern
theory of optimal taxation (Mirrlees, 1971; 1982; Diamond and Mirrlees, 1974; Stiglitz, 1987). Indeed,
optimal tax theory can be viewed as the further development and refinement of a body of thought that
includes Edgeworth (1897) as well as Mill's and even Bentham's recommendation that a tax system
ought to satisfy a principle of equal marginal sacrifice above some threshold of subsistence guaranteed
for all.
Nevertheless, ordinalist utilitarianism also seems vulnerable to serious objections. Arrow remains
reluctant to accept interpersonal comparisons of ordinal utility, for example, because he fears that they
imply a denial of individuality: ‘the autonomy of individuals, an element of mutual incommensurability
among people seems denied by the possibility of interpersonal comparisons’ (1977, p. 225). Individual
rights to freely pursue one's own good in one's own way, of the sort defended by Mill, seem to be of
peculiar moral importance, and should not be overridden by considerations of general utility based on
putative interpersonal comparisons. Moreover, as Arrow also remarks, it is disappointing that, even if
meaningful ordinalist comparisons are assumed possible, seemingly mild conditions (including a weak
equity axiom) confine us to the quasi-Rawlsian ‘leximin’ theory of justice. But leximin is arguably too
extreme because it absolutely forbids institutions and policies that fail to maximize the utility level of
the worst-off, even if those measures result in massive utility gains for everyone else. Finally, as
Gibbard (1987) suggests, ordinalist utilitarianism, like any other version of rational choice utilitarianism,
needs an ‘empirically adequate’ psychology as well as a convincing theory of ethical deliberation, even
if hedonism continues to be rejected as both a psychology and an ethical theory. Grounds for right action
cannot simply be equated with what people are disposed to choose. Rather, utility, and thus welfarism
and Paretoism, must be tied to a normative theory that identifies any individual's morally significant
interests in any given social context and also justifies which choice dispositions ought to be formed to
achieve the relevant interests in this or that situation. Such a normative theory must in turn be tied to a
psychology that supplies empirically adequate psychic concepts and explains how dispositions to choose
are formed in terms of the concepts.
Beyond utilitarianism?

Binmore, inspired by his reading of Hume, presents a provocative proportional bargaining theory of ‘natural justice’, which, like Harsanyi’s utilitarian theory, relies on cardinal comparable utility functions to represent the preferences revealed by moral choices. Unlike Harsanyi, though, Binmore assumes that moral agents remain predominantly selfish and are inclined to cheat on bargains unless they are threatened with sufficient punishment by others for non-compliance. He builds inequalities of bargaining power into his theory of moral behaviour by assuming that even bargainers who place themselves in an original position under a veil of ignorance will rely on cultural standards of interpersonal comparison which are associated with a given Nash bargaining equilibrium. His theory thus relies in part on non-utility information. The relevant Nash bargaining outcome supplies the cultural norms which agents in the original position use to calculate a proportional bargaining equilibrium, for instance, and it has a privileged status as a fallback position if these agents fail to agree to coordinate on the proportional bargaining solution. As a result, Binmore concludes that, in general, utilitarian bargains would not be willingly enforced by rational expected utility maximizers seeking justice.

Binmore apparently assumes that people are predominantly selfish because human behaviour is ultimately constrained in accord with the selfish gene paradigm. But there is no compelling scientific evidence for that paradigm. Rather, human nature appears to be highly plastic. If so, rational agents might eventually be moulded by cultural forces into social and moral actors who effectively believe that they are the same person – no different from anyone else – when it comes to certain vital personal interests that ought to be treated as rights. In this context, a utilitarian bargain, involving some code of justice that distributes equal rights and correlative duties whose content is held by the culture to be extremely valuable for every person’s well-being, is an efficient and fair Nash equilibrium point. Even in the absence of any threat of punishment by others, compliance with the rules is enforced by the actor’s own conscience, a powerful internal ‘judicious spectator’ which threatens to inflict harsh punishment in the form of intense feelings of guilt for cheating. Indeed, there is textual evidence that Hume himself took seriously this possibility of utilitarian justice (Riley, 2006b).

Sen also advocates the use of non-utility information in the course of proposing a pluralistic theory of ethical evaluation and distributive justice that involves protecting a list of basic human functionings and capabilities or ‘freedoms’ for each member of society (Sen, 1985; 2002; 2007). Moreover, his Paretian liberal impossibility result (Sen, 1970) shows that a social welfare function cannot in general simultaneously satisfy utility-based Paretian values and non-utility-based liberal rights as he conceives them. His work contains deep insights into the sort of moral and political philosophy which normative economics seems to require, and it also casts serious doubt on whether any version of welfarism can accommodate such insights.

Nevertheless, it is not entirely obvious that a move beyond utilitarianism is required, especially if the utilitarian family is defined (as it arguably should be) to include what Sen calls ‘utility-supported moralities’. A case can be made, for example, that genuine maximizing utilitarianism involves an
optimal code that distributes weighty equal rights and correlative duties, as many leading utilitarians, including Bentham and Mill as well as Brandt, Hare, and Harsanyi, have insisted (Riley, 2006a). Moreover, it may even be possible to combine welfarism with a normative theory that interprets any individual's morally significant interests in terms of functionings and capabilities, the most vital of which ought to be protected by strong rights. A moral individual is presumably able to form dispositions to make the relevant moral choices, at least after engaging in a process of impartial deliberation about the functionings and capabilities of the different people implicated in any choice situation. Consistent ethical behaviour may reveal preference orderings that can be represented by utility functions. If so, an ethical version of welfarism could perhaps subsume Sen's ethical theory. The more general point is that, by itself, rational choice welfarism is essentially a formal shell that needs to be filled in with a substantive psychology and ethical theory. It can be filled in with various theories besides hedonism, to which it has no essential tie (Riley, 2001).

Normative economists evidently face numerous competing candidates when attempting to select a ‘reasonable’ social welfare procedure that is both efficient and fair. Yet ordinalist utilitarianism perhaps has more appeal than has so far appeared. Objections similar to Arrow's are often voiced against any version of utilitarianism (see, for example, Smart and Williams, 1977; Sen and Williams, 1982; Scheffler, 1982). Yet the objection that even ordinalist utilitarianism cannot accommodate reasonable principles of distributive justice arguably turns on an improper formulation of interpersonal comparisons of utility. As usually formulated in terms of extended sympathy, where one person places himself in another's position and imagines that he experiences the same psychic phenomena as the other experiences in that position, interpersonal comparisons involve the sort of double counting against which Harsanyi and Dworkin caution (see also Gibbard, 1987, p. 144). Reformulating interpersonal comparisons so that they do not involve double counting of any person's utility can liberate ordinalist utilitarianism from being chained to ‘leximin’. Arrow's other worry – that the possibility of interpersonal comparisons seems to deny individuality and personal integrity – might also be met by limiting the permissible scope of interpersonal comparisons so as to preserve weighty rights of individuality or self-development. Such an ethical limitation may be endorsed by utilitarians if a code that distributes such rights and correlative duties is deemed essential to the maximization of general utility.

Gibbard rightly objects that ordinalist utilitarianism by itself can hardly provide an acceptable ethical theory if utility merely represents given dispositions to choose, independently of any ethical justification for the dispositions. He advises that ethical thinking must rely on ‘rough quantitative’ estimates of which outcomes are ‘more worth wanting’ than others: ‘we should settle for some vagueness and indecision, epistemological and normative’ (1987, p. 148). This is wise advice, although it may be possible to combine ordinalist utilitarianism with an appealing ethical theory such that ‘some vagueness and indecision’ surrounds the ‘psychic magnitudes’ used in ethical thinking whereas utility functions represent revealed preferences that reflect the relevant ethical thinking. Indeed, a form of qualitative ordinalist utilitarianism along Millian lines deserves further study (Edwards, 1979; Riley, 1988; 2007b; 2007c; 2009). Such a qualitative ordinalist utilitarianism might incorporate what is taken to be Mill's theory of ethical thinking, including his suggested order of priority among intrinsically different kinds of ethical judgements, without making any commitment to psychological or ethical hedonism. Eventually, though, the time may come when some version of hedonism is again taken seriously (see, for example, Kahneman, Diener and Schwarz, 1999; Feldman, 2004).

Article

Utility is a term which has a long history in connection with the attempts of philosophers and political economists to explain the phenomenon of value. It has most frequently been given the connotation of ‘desiredness’, or the capacity of a good or service to satisfy a want, of whatever kind. Its use with that meaning can be traced back at least to Gershom Carmichael's 1724 edition of Pufendorf's De Officio Hominis et Civis Iuxta Legam Naturalem, and arguably came down to him through the medieval schoolmen from Aristotle's Politics.

Utility in the sense of desiredness is a purely subjective concept, clearly distinct from usefulness or fitness for a purpose – the more normal everyday sense of the word and the first meaning given for it by the Oxford English Dictionary.

While most political economists of the 18th and 19th centuries used the term in this subjective sense, the distinction was not always kept clear, most notably in the writings of Adam Smith. In a famous passage in the Wealth of Nations Smith wrote:

The word VALUE, it is to be observed, has two different meanings, and sometimes expresses the utility of some particular object, and sometimes the power of purchasing other goods which the possession of that object conveys. The one may be called ‘value in use’; the other, ‘value in exchange’. The things which have the greatest value in use have frequently little or no value in exchange; and, on the contrary, those which have the
greatest value in exchange have frequently little or no value in use. Nothing is more useful
than water; but it will purchase scarce any thing; scarce any thing can be had in exchange
for it. A diamond, on the contrary, has scarce any value in use; but a very great quantity of
other goods may frequently be had in exchange for it. (1776, Book I, ch. IV)

Smith has sometimes been accused, because of the wording of this passage, of falling into the error of
claiming that things which have no value in use can have value in exchange, which is tantamount to
saying that utility is not a necessary condition for a good to have value. It would appear, however, that
Smith was not here using the theme ‘value in use’, or utility, in the subjective sense of desiredness but in
other classical economists and even Smith himself in his Lectures on Jurisprudence used the term in its
subjective sense, but the passage in the Wealth of Nations gave rise to considerable confusion and
misinterpretation. Nor was this the only source of confusion in the early writing on the subject: even
those who used the term utility in its subjective sense were not always clear as to whether it should be
considered a feeling in the mind of the user or a property of the good or service used. Thomas De
Quincey, for example, referred to the ‘intrinsic utility’ of commodities (Logic of Political Economy,
1844, p. 14).

Most classical economists, however, were not greatly concerned with the subtleties of meaning which
the term utility might contain. Generally they used it in the broad sense of desiredness, and Ricardo
employed it in a typically classical way when he wrote

Utility then is not the measure of exchangeable value, although it is absolutely essential to
it. If a commodity were in no way useful – in other words, if it could in no way contribute
to our gratification – it would be destitute of exchangeable value, however scarce it might
be, or whatever quantity of labour might be necessary to procure it. (Principles of
Political Economy and Taxation, 1817, ch. 1, sect. I)

‘Useful’ here is interpreted as ‘contributing to gratification’ but the very word carries an echo of Smith's
confusion.

For Ricardo and others in the mainstream classical tradition down to J.S. Mill and Cairnes utility became
a necessary but not a sufficient condition for a good to possess value. In this context, the utility referred
to was generally the total utility of the good to the purchaser, or the utility of a specific quantity which is
all that is available in the circumstances of the example – for example, the utility of a single item of food
to a starving person.

As a result of this approach it followed, in the words of J.S. Mill, that ‘the utility of a thing in the
estimation of the purchaser is the extreme limit of its exchange value: higher the value cannot ascend;
peculiar circumstances are required to raise it so high’ (Principles of Political Economy, 1848, Book III,
ch. II, §. 1). Classical economists like Mill accepted the view put forward by J.B. Say that ‘labour is not
creative of objects, but of utilities’ but could see the weakness in Say's contention that price measured
utility. Clearly in the case of competitively produced commodities it did not and it was cost of
production and not utility (in the total sense) which determined value.

Since the classical economists were mainly interested in ‘natural’ rather than ‘market’ price, that is, in
long-run normal values which were mainly determined by supply and cost, the fact that they had no
to explain fully the relationships between utility, demand and market price was not a matter of
concern to most of them. Nevertheless in the period from about 1830 to 1870 a number of attempts were
made to work out these relationships more fully or to clarify aspects of them. Some of these attempts
took place in Britain, within the framework of the classical system, but not surprisingly some of the best
work was done at this time in France, where the tradition of demand analysis was stronger.
The full explanation of the relation between utility and demand requires the distinction between total
utility and increments of utility, and the recognition of the principle that consumption of successive
increments of a commodity yields not equal but diminishing increments of satisfaction or utility to the
consumer. A number of writers in the mid-19th century showed an understanding of this point, but only
a few stated it explicitly and correctly. Among those in Britain who did so were William Foster Lloyd (A
Lecture on the Notion of Value, delivered before the University of Oxford in Michaelmas Term, 1833)
and Nassau Senior (Outline of the Science of Political Economy, 1836), but neither proceeded to develop
his insights into a complete theory of the relationship between utility, demand and market values.
The French engineer A.J. Dupuit was the first to present an analysis which clearly explained the concept
of marginal utility and related it to a demand curve, in his paper ‘On the Measurement of the Utility of
Public Works’ (Annales des Ponts et Chaussées, vol. 8, 1844; English translation in International
Economic Papers, No. 2, 1952, pp. 83–110). Dupuit also extended his analysis to show that the total
area under the demand curve represents the total utility derived from the commodity; deducting from
this the total receipts of the producer he arrived at the ‘utility remaining to consumers’ or what was later
to be termed ‘consumers’ surplus’.
The significance of Dupuit's contribution is now well recognized, but at the time of appearance it had
little impact. The same is even more true of the work of Hermann Heinrich Gossen, one of the few
German contributors to utility theory in this period. His book Entwicklung der Gesetze des Menschlichen
Verkehrs, published in 1854, contained not only a statement of the ‘law of satiable wants’, or
diminishing marginal utility, but also of the proposition that to maximize satisfaction from any good
capable of satisfying various wants it must be allocated between those uses so as to equalize its marginal
utilities in all of them.
Gossen's analysis of the principles of utility maximization was thus more complete than any which had
preceded it. Yet his one book, which foreshadowed many features of general equilibrium as well as
utility theory, received virtually no attention until 1878, 20 years after the author's death, when Robert
Adamson, W.S. Jevons's successor as Professor of Philosophy and Political Economy at Manchester,
obtained a copy of it and drew it to the attention of Jevons himself.
By that time the whole character of utility analysis and its place in economic theory had begun to change
significantly. This change is usually dated from the very nearly simultaneous publication of Jevons's
Theory of Political Economy in England and Menger's Grundsätze der Volkswirtschaftslehre Austria,
both in 1871, and Walras's Eléments d'économie politique pure in Switzerland in 1874. All these works
contained a treatment of the theory of value in which the analysis of diminishing marginal utility (under
a variety of other names) played a considerable part, but each of the three authors seems to have arrived
independently at the main ideas of his theory without indebtedness to the others or to the predecessors
already mentioned above.
This remarkable example of multiple discovery in the history of ideas has come to be known as ‘the
Marginal Revolution’. Discussion of its causes and character lies outside the scope of this article, but it is generally accepted that, as Sir John Hicks has said, ‘the essential novelty in the work of these economists was that instead of basing their economics on production and distribution, they based it on exchange’ (Hicks, 1976, p. 212).

A major element in this ‘shift in attention’ undoubtedly was a change from the classical concept of value in use, or total utility, as a necessary but not sufficient condition to explain the normal values of freely reproducible commodities, to the concept of what Jevons called ‘the degree of utility’ and of adjustments in it, through exchange of quantities of goods held or consumed, in order to maximize satisfaction. Marginal analysis can, however, be applied to questions of production and distribution as well as consumption, and hence the ‘Marginal Revolution’ involved more than a new stage in the development of utility theory.

Although all three pioneers of the Marginal Revolution did contribute to that development they also contributed in other ways to the theory of pricing and exchange. Perhaps only for Jevons was the theory of utility genuinely central to the structure of his economic work. On the opening page of his Theory of Political Economy he emphatically asserted that ‘value depends entirely upon utility’ and he went on to say that ‘Political Economy must be founded upon a full and accurate investigation of the conditions of utility’ (1871, p. 46). Jevons indeed appears to have shared with his classical predecessors the view that a theory of value must go beyond the phenomena of demand and supply to some more fundamental explanation which for him was to be found in utility rather than in labour. ‘Labour is found often to determine value, but only in an indirect manner, by varying the degree of utility of the commodity through an increase or limitation of supply’ (Jevons, 1871, p. 2).

Apart from differences of terminology, Walras’s treatment of utility in relation to the problem of exchange had substantial similarities with that of Jevons; but Walras saw the problem in a different context.

His whole attention was focused on market phenomena and not on consumption … while the driving force in the theory of exchange is, as Walras saw it, the endeavour of all traders to maximise their several satisfactions, it is marketplace satisfactions rather than dining-room satisfactions which Walras had in mind. (Jaffé, 1973, pp. 118–19)

For Menger, as for Walras, the concepts of utility theory formed only a part of a much larger analytical structure (concerned in his case not so much with equilibrium as with development), but unlike both Walras and Jevons he refused to state his theories in mathematical terms.

Menger developed a theory of economizing behaviour showing how the individual would seek to satisfy his subjectively felt needs in the most efficient manner. In the process he elaborated the essential propositions of a theory of maximizing behaviour for the consumer, but he expressed them in terms of the satisfaction of needs by the consumption of successive units of goods. In his discussion of this process Menger used the same phrases – use-value and exchange-value – which Smith had used almost a century earlier, and with similar connotations. Use-value he defined as ‘the importance that goods acquire for us because they directly assure us the satisfaction of needs that would not be provided for if we did not have the goods at our command. Exchange value is the importance that goods acquire for us because their possession assures the same result indirectly’ (Menger, 1871, p. 228). Menger did use the
term ‘utility’, but not as a synonym for use-value; he viewed it as an abstract relation between a species of goods and a human need, akin to the general term ‘usefulness’. As such it constituted a prerequisite for a good to have economic character, but had no quantitative relationship to value.

The three pioneers of the Marginal Revolution thus saw the problem of the relationship of utility to exchange value in different contexts and expressed their solutions to it in different ways. Inevitably also their first solutions were incomplete in various respects. For example, the precise relationships between the individual's utility function and demand function, the market demand function and the market price were not clearly specified in some of the earlier formulations; it remained for later contributors such as Marshall, Wicksteed and Edgeworth to deal with these points.

Nevertheless, despite their differences of terminology and approach, the writings of the pioneers did contain a common core which gradually gained wider acceptance, and by 1890 with the appearance of Marshall's *Principles of Economics* it seemed that the new analysis of market values had been effectively integrated with an analysis of supply and cost which served to explain long-run ‘normal’ values. It did provide some things which the classical system had not contained, among them a consistent theory of consumer behaviour, expressed in terms of utility.

So in 1899 it was possible for Edgeworth to write that:

> the relation of utility to value, which exercised the older economists, is thus simply explained by the mathematical school. The value in use of a certain quantity of commodity corresponds to its total utility; the value in exchange to its marginal utility (multiplied by the quantity). The former is greater than the latter, since the utility of the final increment of commodity is less than that of every other increment. (Edgeworth, 1899, p. 602)

At this stage utility analysis appeared to have evolved to something approaching finality, and in 1925 Jacob Viner could still say:

> In its developed form it is to be found sympathetically treated and playing a prominent role in the exposition of value theory in most of the current authoritative treatises on economic theory by American, English, Austrian, and Italian writers.

Yet Viner immediately went on to add:

> In the scientific periodicals, however, in contrast with the standard treatises, sympathetic expositions of the utility theory of value have become somewhat rare. In their stead are found an intermittent series of slashing criticisms of the utility economics. (Viner, 1925, p. 179)

The principal criticisms which Viner noted were the apparent involvement of utility theory with hedonistic psychology and the problems of measuring welfare in terms of utility. In later years questions of the measurement and summation of utility came to trouble economists more and more.

The two basic problems involved here are whether utility can be measured cardinally or simply...
ordinally, and whether interpersonal comparisons of utility are possible. The pioneers of the Marginal Revolution were not unaware of these problems; Jevons nowhere attempted to define a unit of utility, and indeed said that ‘a unit of pleasure or pain is difficult even to conceive’, but he went on to say that ‘it is from the quantitative effects of the feelings that we must estimate their comparative amounts’ (Jevons, 1871, p. 14). However they may be estimated, Jevons did not hesitate to refer to ‘quantity of utility’, and his whole analysis proceeds by treating utility as if it could be measured. The question was not examined in detail by Walras or Menger, but both their analyses treat utility as cardinally measurable.

On the question of interpersonal comparisons of utility, Menger and Walras seemed to find no difficulty, and Walras was prepared to speak of a ‘maximum of utility’ for society (Walras, 1874, p. 256). Jevons on the other hand declared that ‘every mind is … inscrutable to every other mind, and no common denominator of feeling seems possible’ (Jevons, 1871, p. 211) – but this did not always prevent him from comparing and aggregating utilities.

In the early editions of his Principles of Economics Marshall fully accepted the idea of utility as cardinally measurable and allowed the possibility if not of interpersonal certainly of inter-group comparisons of utility (1890, pp. 151 and 152). In later years he became more reticent and defensive on these points, and he was always more concerned than Jevons with the effects of feelings rather than the feelings themselves; yet cardinal utility always remained the basis of Marshall's demand theory.

Now, as Sir John Hicks said:

if one starts from a theory of demand like that of Marshall and his contemporaries, it is excessively natural to look for a welfare application. If the general aim of the economic system is the satisfaction of consumer wants, and if the satisfaction of individual wants is to be conceived of as a maximising of utility, cannot the aim of the system be itself conceived of as a maximising of utility – universal utility, as Edgeworth called it? If this could be done and some measure of universal utility could be found, the economist's function could be widened out, from the understanding of cause and effect to the judgement of the effects – whether, from the point of view of want-satisfaction, they are to be judged as successful or unsuccessful, good or bad. (Hicks, 1956, p. 6)

This was, in effect, the task which was undertaken by Marshall's successor, A.C. Pigou, in his Economics of Welfare (1920; earlier version published under the title Wealth and Welfare, 1912). Pigou made no attempt to establish a measure of universal utility; instead he took what Marshall had called ‘the national dividend’, aggregate real income, as the ‘objective counterpart’ of economic welfare. Pigou argued that economic welfare would be greater when aggregate real income increased, when fluctuations in its amount were reduced, and when it was more equally distributed among persons. It was in the context of this last point that interpersonal utility comparisons were most evident; Pigou argued that

the old ‘law of diminishing utility’ thus leads securely to the proposition: Any cause which increases the absolute share of real income in the hands of the poor, provided that it does not lead to a contraction in the size of the national dividend … will in general, increase economic welfare. (1920, p. 89)
In the 1930s most economists became increasingly uncomfortable with the idea of measurement and interpersonal or intergroup comparisons of utility. In 1934, in a famous article entitled ‘A Reconsideration of the Theory of Value’, Hicks and Allen used the technique of indifference curves originated by Edgeworth and developed by Walras's successor at Lausanne, Vilfredo Pareto, in presenting a theory of consumer behaviour involving only ordinal comparisons of satisfaction. A few years later a further step towards eliminating what were now considered dubious psychological assumptions from that theory was taken by treating consumer behaviour solely on the basis of revealed preference.

Accompanying these changes there was a movement away from the type of welfare economics developed on the basis of utility theory by Marshall and Pigou towards that based on Pareto's concept of an economic optimum as a position from which it is impossible to improve anyone's welfare without damaging that of another.

Indifference analysis and revealed preference theory are now standard features of microeconomic theory; but the utility concept has not disappeared; the most widely used introductory economics texts still tend to begin their treatments of household behaviour with an account of utility theory.

value elicitation

Glenn W. Harrison
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Economists are interested in eliciting values at the level of the individual because market values do not provide the information needed to measure consumer surplus, value new products, or value goods that have no market. Direct and indirect procedures have been developed to elicit values, and each has some strengths and weaknesses. The evidence points to several recommendations for best practice in the reliable elicitation of values, trading off transparency and rigour.

Keywords

auctions; bias correction; cheap talk; conjoint choice; contingent valuation; cost–benefit analysis; English auction; latent choice models; maximum likelihood; multiple price lists; revealed preference theory; second-price auction; value elicitation; Vickrey auction

Article

Why elicit values? The prices observed on a market reflect, on a good competitive day, the equilibrium of marginal valuations and costs. They do not quantitatively reflect the infra-marginal or extra-marginal values, other than in a severely censored sense. We know that infra-marginal values are weakly higher, and extra-marginal values are weakly lower, but beyond that one must rely on functional forms to extrapolate. For policy purposes this is generally insufficient to undertake cost–benefit calculations. When producers are contemplating a new product or innovation they have to make some judgement about the value that will be placed on it. New drugs, and the R&D underlying them, provide an important example. Unless one can heroically tie the new product to existing products in terms of shared characteristics, and somehow elicit values on those characteristics, there is no way to know what price the market will bear. Value elicitation experiments can help fill that void, complementing traditional marketing techniques (see Hoffman et al., 1993).

Many goods and services effectively have no market, either because they exhibit characteristics of
Public goods or it is impossible to credibly deliver them on an individual basis. These non-market goods have traditionally been valued using surveys, where people are asked to state a valuation ‘contingent on a market existing for the good’. The problem is that these surveys are hypothetical in terms of the deliverability of the good and the economic consequences of the response, and this understandably generates controversy about their reliability (Harrison, 2006).

Procedures

Direct methods for value elicitation include auctions, auction-like procedures and ‘multiple price lists’. Sealed-bid auctions require the individual to state a valuation for the product in a private manner, and then award the product following certain rules. For single-object auctions, the second-price (or Vickrey) auction awards the product to the highest bidder but sets the price equal to the highest rejected bid. It is easy to show, to students of economics at least, that the bidder has a dominant strategy to bid his true value: any bid higher or lower can only end up hurting the bidder in expectation. But these incentives are not obvious to inexperienced subjects. A real-time counterpart of the second-price auction is the English (or ascending bid) auction, in which an auctioneer starts the price out low and then bidders increase the price to become the winner of the product. Bidders seem to realize the dominant strategy property of the English auction more quickly than in comparable second-price sealed-bid auctions, no doubt due to the real-time feedback on the opportunity costs of deviations from that strategy (see Rutström, 1998; Harstad, 2000). Familiarity with the institution is also surely a factor in the superior performance of the English auction: first encounters with the second-price auction rules lead many non-economists to assume that there must be some ‘trick’.

Related schemes collapse the logic of the second-price auction into an auction-like procedure due to Becker, DeGroot and Marschak (1964). The basic idea is to endow the subject with the product, and to ask for a ‘selling price’. The subject is told that a ‘buying price’ will be picked at random, and that, if the buying price that is picked exceeds the stated selling price, the product will be sold at that price and the subject will receive that buying price. If the buying price equals or is lower than the selling price, the subject keeps the lottery and plays it out. Again, it is relatively transparent to economists that this auction procedure provides a formal incentive for the subject to truthfully reveal the certainty-equivalent of the lottery. One must ensure that the buyout range exceeds the highest price that the subject would reasonably state, but this is not normally a major problem. One must also ensure that the subject realizes that the choice of a buying price does not depend on the stated selling price; a surprising number of respondents appear not to understand this independence, even if they are told that a physical randomizing device is being used.

Multiple price lists present individuals with an ordered menu of prices at which they may choose to buy the product or not. In this manner the list resembles a menu, akin to the price comparison websites available online for many products. For any given price, the choice is a simple ‘take it or leave it’ posted offer, familiar from retail markets. The set of responses for the entire list is incentivized by picking one at random for implementation, so the subject can readily see that misrepresentation can only hurt for the usual revealed preference reasons. Refinements to the intervals of prices can be implemented, to improve the accuracy of the values elicited (see Andersen et al., 2006). These methods have been widely used to elicit risk preferences and discount rates, as well as values for products (see Holt and Laury,
Indirect methods work by presenting individuals with simple choices and using a latent structural model to infer valuations. The canonical example comes from the theory of revealed preference, and confronts the decision-maker with a series of purchase opportunities from a budget line and asks him to pick one. By varying the budget lines one can ‘trap’ latent indifference curves and place nonparametric or parametric bounds on valuations. The same methods extend naturally to variations in the non-price characteristics of products, and merge with the marketing literature on ‘conjoint choice’ (for example, Louviere, Hensher and Swait, 2000; Lusk and Schroeder, 2004). Access to scanner data from the massive volume of retail transactions made everyday promises rich characterizations of underlying utility functions, particularly when merged with experimental methods that introduce exogenous variation in characteristics in order to statistically condition and ‘enrich’ the data (Hensher, Louviere and Swait, 1999). One of the attractions of indirect methods is that one can employ choice tasks which are familiar to the subject, such as binary ‘take it or leave it’ choices or rank orderings. The lack of precision in that type of qualitative data requires some latent structure before one can infer values, but behavioural responses are much easier to explain and motivate for respondents.

One major advantage of undertaking structural estimation of a latent choice model is that valuations can be elicited in a more fundamental manner, explicitly recognizing the decision process underlying a stated valuation. A structural model can control for risk attitudes when choices are being made in a stochastic setting, which is almost always the case in practical settings. Thus one can hope to tease apart the underlying deterministic valuation from the assessment of risk. Likewise, non-standard models of choice posit a myriad of alternative factors that might confound inference about valuation: respondents might distort preferences from their true values, they might exhibit loss aversion in certain frames, and they might bring their own home-grown reference points or aspiration levels to the valuation task. Only with a structural model can one hope to identify these potential confounds to the valuation process. Quite apart from wanting to identify the primitives of the underlying valuation free of confounds, normative applications will often require that some of these distortions be corrected for. That is only possible if one has a complete structural model of the valuation process.

A structural model also provides an antidote to those that claim that valuations are so contextual as to be an unreliable will-o’-the-wisp. If someone is concerned about framing, endowment effects, loss aversion, preference distortions, social preferences, and any number of related behavioural notions, it is impossible to generate a scientific dialogue without being able to write out a structural model and jointly estimate it.

**Lessons and concerns**

The most important lesson that has been learned from decades of experimental research into the behavioural properties of these procedures to elicit values is: keep it simple. This refers primarily to the nature of the task given to respondents. It can be dangerous to rely on fancy rules that ensure incentives to truthfully reveal valuations only if everyone sees a complete chain of logic, even if that logic is apparent to trained economists. Of course, one can use ‘cheap talk’ and just tell people to reveal the truth since it is in their best interests, but one cannot be sure that such admonitions work reliably. Cultural familiarity with institutions counts for a lot when subjects are otherwise placed in an artefactual setting.
value elicitation: The New Palgrave Dictionary of Economics

The desire to keep it simple has a corollary: the use of more rigorous statistical techniques to infer valuations. This implication follows from the need to make inferences about valuations on a cardinal scale when responses are often between subject and qualitative. Progress has been made in the use of numerical simulation methods for the maximum likelihood estimation of random utility models that allow extraordinary flexibility (for example, Train, 2003).

We also have a better understanding now of the manner in which valuations may be biased by being hypothetical, due to procedural devices in the institution being employed, and because of field context (for example, Harrison, Harstad and Rutström, 2004). More constructively, methods have been developed to undertake ex ante ‘instrument calibration’ to remove biases using controlled experiments, and to implement ex post ‘statistical calibration’ to filter out any remaining systematic biases (see Harrison, 2006).

Finally, the manner in which valuations change with states of nature is starting to be understood. Insights here again come from thinking about valuation as a latent, structural decision process. If we observe the same person state a different value for the same product at two different times, is it because he has a shift in his utility function, a change in some argument of his utility function, a change in his perceived opportunity set, or something else? If valuation is viewed as a process we can begin to design procedures that can help us identify answers to these questions, and better understand the valuations that are observed.

value judgements

John C. Harsanyi
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Harsanyi, J. C.; preferences; public choice; value judgements

Article

The claim of objective validity

One may define value judgements as judgements of approval or disapproval claiming objective validity. Many of our judgements of approval and disapproval do not involve such claims. When I say that I like a particular dish, I do not mean to imply that other people ought to like it too or that those disliking it are making a mistake. All I am doing is expressing my personal preference and my personal taste. (But an expert chef or an expert food critic may very well claim that his judgements about food have some degree of objective validity – in the sense that other gastronomic experts would tend to agree with his judgements. Of course, it is an empirical question whether his claim would be justified and, more generally, how much agreement there is in fact among expert judges of food.) Yet when I say that Hitler's murder of many millions of innocent people was a moral outrage, I do mean to do more than express my personal moral attitudes and do mean to imply that anybody who tried to defend Hitler's actions would be morally wrong.

In claiming objective validity, value judgements resemble factual judgements (both those dealing with empirical facts and those dealing with logical–mathematical facts). But they resemble judgements of personal preference in expressing human attitudes (those of approval or disapproval) rather than expressing beliefs about matters of fact, as factual judgements do. But this immediately poses a difficult philosophical problem: We can understand what it means for factual judgements to be objectively valid, that is, to be true, or to be objectively invalid, that is, to be false. They will be true if they describe the relevant facts as these facts actually are, and will be false if they fail to do so. But in what sense can judgements expressing human attitudes be objectively valid or invalid?

It seems to me that this can happen in at least two different ways. Such judgements can be objectively invalid either because they are contrary to the facts or because they are based on the wrong value...
Value judgements can be contrary to the facts in the following sense: When we form our attitudes, we do so on the basis of some specific factual assumptions so that our attitudes and our judgements expressing these attitudes will be contrary to the facts if they are based on false factual assumptions. Mistaken factual assumptions may vitiate both our value judgements about instrumental values and those about intrinsic values. Thus, if I approve of using A as a means to achieve some end B, I will do this on the assumption that A is causally effective in achieving B. Hence, my approval will be mistaken if this assumption is incorrect. Likewise, if I approve of A as an intrinsically desirable goal, I will do this on the assumption that A has some qualities I find intrinsically attractive. My approval will be mistaken if in fact A does not possess these qualities.

Another way of value judgement may be objectively invalid is by being based on a value perspective different from the one it claims to have. For example, I may claim that my support for some government policy is based on its being in the public interest, even though actually it is based on its being in my own personal interest. Or, I may praise a very undistinguished novel as a great work of art merely because it supports my own political point of view. When a person claims to base his value judgement on one value perspective though actually he bases it on another, he may be simply lying, being fully aware of not telling the truth. Another possibility is that he is unaware, or only half aware, of using a value perspective different from the one he claims to use. (Likewise, when a person is making a value judgement based on false factual assumptions, he may or may not be fully aware of the falsity of these assumptions.)

Disagreements in value judgements

As we all know, disagreements in value judgements are extremely common and in many cases are very hard, or even impossible, to resolve. It seems to me that in most cases careful analysis would show that these disagreements about values are based on disagreements about the facts. Yet they may be very hard to resolve because these factual disagreements may be about very subtle facts about which reliable information is very hard, or even impossible, to obtain. For instance, our value judgements about a person's behaviour will often crucially depend on what we think his motives are. Some observers may attribute very noble motives to him, while others may do the opposite. Yet the available evidence might be consistent with either assumption. Other value judgements we make may hinge on our predictions about future facts. Thus, different economists may advocate very different economic policies because they have very different expectations on the likely effects of specific policies – even if their ultimate policy objectives are much the same. Yet, at the present stage of our knowledge about the economic system, we may be unable to tell with any degree of confidence which predictions are right and which are wrong.

Of course, we could avoid most of these disagreements if we refrained from making value judgements until we could ascertain with some assurance that the factual assumptions underlying the value judgements we want to make are correct. But this would require more intellectual self-discipline than most of us can muster. We have to act one way or another; and it is psychologically much easier for us to act if we can manage to entertain value judgements justifying our actions – even if the factual assumptions underlying these value judgements go far beyond, or are even clearly inconsistent with, the available evidence.

Let me add that most disagreements in value judgements are not disagreements about what the basic
values of human life actually are. Rather, most disagreements are about the relative weights and the relative priorities to be assigned to different basic values. Some individuals and some societies will learn from their experience – possibly based on a very idiosyncratic personal or national history – that things tend to work out best if value A is given far greater weight than value B is. Other individuals and other societies will reach very much the opposite conclusion on the basis of their experience. Once a given ranking of these two values has been adopted, it may be retained for a long time even when conditions change and make this ranking utterly inappropriate. For instance, an individual or a society that suffered a good deal from lack of individual freedom may be so preoccupied with political liberty as to neglect the need for social discipline – even under conditions that would make the need for social discipline paramount.

Besides disagreements about the facts, another source of value conflicts is philosophical disagreements about the correct value perspectives to be used in making various classes of value judgements. For instance, even if two people agree about all the relevant facts, they may still make conflicting moral value judgements if they disagree about the nature of morality and, therefore, disagree about the nature of the moral perspective to be used in making moral value judgements. (For instance, one individual may favour a utilitarian interpretation of morality – see, for example, Harsanyi, 1977 – while the other may favour an entitlement interpretation – see Nozick, 1974.) In the same way, disagreements about the nature of the aesthetic perspective to be used in making aesthetic value judgements may lead to disagreements about the artistic quality of various works of art.

Value judgements in economics

There was a time when many economists wanted to ensure the objectivity of economic analysis by excluding value judgements, and even the study of value judgements, from economics. (A very influential advocate of this position has been Robbins, 1932.) Luckily, they have not succeeded; and we now know that economics would have been that much poorer if they had. After some important preliminary work in the 1930s and the 1940s, mainly in welfare economics, a new era in the study of economically relevant value judgements, has started with Arrow's Social Choice and Individual Values (1951). This book has shown how to express alternative value judgements in the form of precisely stated formal axioms, how to investigate their logical implications in a rigorous manner, and how to examine their mutual consistency or inconsistency. Arrow's book and the research inspired by it have greatly enriched economic theory not only in welfare economics but also in several other fields, including the theory of competitive equilibrium. It has given rise to a new sub-discipline called public choice theory, which is a rigorous study of voting and of alternative voting systems and which has made important contributions to the study of alternative political systems and of alternative moral codes and, more indirectly, to the study of alternative economic systems as mechanisms of social choice.

Of course, value judgements often play an important role in economics even when they are not the main subjects of investigation. They influence the policy recommendations made by economists as long as it is work of high intellectual quality and as long as the economists concerned know what they are doing, know the qualifications their conclusions are subject to, and tell their readers what these qualifications are. In particular, intellectual honesty
value judgements: The New Palgrave Dictionary of Economics

requires economists to state their political and moral value judgements and to make clear how their conclusions differ from those that economists of different points of view would tend to reach on the problems under discussion. What is no less important, they should make clear how uncertain many of their empirical claims and their predictions actually are. This is particularly important in publications addressed mainly to people outside the economist profession.

value of life

W. Kip Viscusi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The economic approach to valuing risks to life focuses on risk–money trade-offs for very small risks of death, or the value of statistical life (VSL). These VSL levels will generally exceed the optimal insurance amounts. A substantial literature has estimated the wage–fatality risk trade-offs, implying a median VSL of $7 million for US workers. International evidence often indicates a lower VSL, which is consistent with the lower income levels in less developed countries. Preference heterogeneity also generates different trade-off rates across the population as people who are more willing to bear risk will exhibit lower wage–risk trade-offs.

Article

Issues pertaining to the value of life and risks to life are among the most sensitive and controversial in economics. Much of the controversy stems from a misunderstanding of what is meant by this terminology. There are two principal value-of-life concepts – the amount that is optimal from the standpoint of insurance, and the value needed for deterrence. These concepts address quite different questions that are pertinent to promoting different economic objectives.

The insurance value received the greater attention in the literature until recent decades. The basic principle for optimal insurance purchases is that it is desirable to continue to transfer income to the post-accident state until the marginal utility of income in that state equals the marginal utility of income when healthy. In the case of property damage, it is desirable to have the same level of utility and marginal utility of income after the accident as before. In contrast, fatalities and serious injuries affect one's utility function, decreasing both the level of utility and the marginal utility for any given level of income, making a lower income level after a fatality desirable from an insurance standpoint. Thus, the value of life and limb from the standpoint of insurance may be relatively modest.

The second approach to valuing life is the optimal deterrence amount. What value for a fatality sets the appropriate incentives for those avoiding the accident? In the case of financial losses, the optimal insurance amount, the optimal deterrence amount, and the ‘make whole’ amount are identical; however, for severe health outcomes, such as fatalities, the optimal deterrence amount will exceed the optimal level of compensation.

The economic measure for the optimal deterrence amount is the risk–money trade-off for very small risks of death. Since the concern is with small probabilities, not the certainty of death, these values are referred to as the value of statistical life (VSL). Economic estimates of the VSL amounts have included evidence from market decisions that reveal the implicit values reflected in behaviour as well as the use of survey approaches to elicit these money–risk trade-offs directly. Government regulators in turn have used these VSL estimates to value the benefits associated with risk reduction policies. Because of the central role of VSL estimates in the economics literature, those analyses will be the focus here rather than income replacement for accident victims.

Valuing risks to life

Although economics has devoted substantial attention to issues generally termed the ‘value of life’, this designation is in many respects a misnomer. What is at issue is usually not the value of life itself but rather the value of small risks to life. As Schelling (1968) observed, the key question is how much people are willing to pay to prevent a small risk of death. For small changes in risk, this amount will be approximately the same as the amount of money that they should be compensated to incur such a small risk. This risk–money trade-off provides an appropriate measure of deterrence in that it indicates the individual's private valuation of small changes in the risk. It thus serves as a measure of the deterrence amount for the value to the individual at risk of preventing accidents and as a reference point for the amount the government should spend to prevent small statistical risks. Because the concern is with statistical lives, not identified lives, analyses of government regulations now use these VSL levels to monetize risk reduction benefits.

Suppose that the amount people are willing to pay to eliminate a risk of death of 1/10,000 is $700. This amount can be converted into a value of statistical life estimate in one of two ways. First, consider a group of 10,000 individuals facing that risk level. If each of them were willing to contribute $700 to eliminate the risk, then one could raise a total amount to prevent the statistical death equal to 10,000 people multiplied by $700 per person, or $7 million. An alternative approach to conceptualizing the risk is to think of the amount that is being paid per unit risk. If we divide the willingness to pay amount of $700 by the risk probability of one in 10,000, then one obtains the value per unit risk. The value per statistical life is $7 million using this approach as well.

Posing hypothetical interview questions to ascertain the willingness-to-pay amount has been a frequent survey technique in the literature on the value of life. Such studies are often classified as ‘contingent valuation surveys’ or ‘stated preference surveys’, in that they seek information regarding respondents’ decisions given hypothetical scenarios (see Jones-Lee, 1989; Viscusi, 1992). Survey evidence is most useful in addressing issues that cannot be assessed using market data. How, for example, do people value death from cancer compared with acute accidental fatalities? Would people be interested in purchasing pain-and-suffering compensation, and does such an interest vary with the nature of the accident? Potentially, survey methods can yield insights into these issues.

Evidence from actual decisions that people make is potentially more informative than trade-offs based on hypothetical situations if suitable market data exists. Actual decision-makers are either paying money to reduce a risk or receiving actual compensation to face a risk, which may be a quite different enterprise from dealing with hypothetical interview money. In addition, the risks to them are real so that they do not have to engage in the thought experiment of imagining that they face a risk. It is also important, however, that individuals accurately perceive the risks they face. Surveys can present respondents with information that is accurate. Biased risk perceptions may bias estimates of the money–risk trade-off in the market. Random errors in perceptions will bias estimates of the trade-off downward. The reason for this result can be traced to the standard errors-in-variables problem. A regression of the wage rate on the risk level, which is measured with error, will generate a risk variable coefficient that will be biased downward if the error is random. The estimated wage–risk trade-off will consequently underestimate its true value.

**Empirical evidence on the value of statistical life**

A large literature has documented significant trade-offs between income received and fatality risks. Most of these studies have examined wage–risk trade–offs but many studies have focused on product and housing risks as well. The wage-risk studies have utilized data from the United States as well as many other countries throughout the world. The primary implication of these results is that estimates of the value of life in the United States are clustered in the $4 million to $10 million range, with an average value of life in the vicinity of $7 million.

Since the time of Adam Smith (1776), economists have observed that workers will require a ‘compensating differential’ to work on jobs that pose extra risk. These wage premiums in turn can be used to assess risk–money trade-offs and the value of life. The underlying methodology used for this analysis derives from the hedonic price and wage literature, which focuses on ‘hedonic’ or ‘quality-adjusted’ prices and wages. Rosen (1986) and Smith (1979), among others, review this methodology.

To see how the hedonic model works, let us begin with the supply side of the market. The worker's risk decision is to choose the job with the fatality risk p that provides the highest level of expected utility (EU). The worker faces a market offer curve \(w(p)\) that is the outer envelope of the individual firms’ market offer curves. Let there be two states of the world: good health with utility \(U(w)\) and death with utility \(V(w)\), where this term is the worker's bequest function. The utility function has the property that good health is preferable to ill health, and workers are risk-averse or risk-neutral, or \(U(w) > V(w); U'( > 0;\ and \ U'' , V' <= 0\). The job choice is to

\[
\max_p EU = (1 - p)U(w(p)) + pV(w(p)),
\]

leading to the result...
The wage-risk trade-off $\frac{dw}{dp}$ based on the worker's choice of a wage–risk combination for a job is the value of statistical life, which equals the difference in utility between the two health states divided by the expected marginal utility of consumption. What trade-off rate $\frac{dw}{dp}$ the worker will select will depend not only on worker preferences but also on the shape of the market offer curve. The best available market opportunities will be those that offer the highest wage for any given level of risk, or the outer envelope of the offer curves for the individual firms. Each individual firm will offer a wage that is a decreasing function of the level of safety. The cost function for producing safety increases with the level of safety, so the wage decline associated with incremental improvements in safety must be increasingly great to keep the firm on its isoprofit curve.

Figure 1 illustrates the nature of the hedonic labour market equilibrium. The curves $OC_1$ and $OC_2$ represent two possible market offer curves from firms with risky jobs. As the risk level is reduced, firms will offer lower wages. $EU_1$ and $EU_2$ are expected utility loci of two workers, both of whom have selected their optimal job risk from available market opportunities. The curve $w(p)$ represents the locus of market equilibria, which consists of the points at which worker indifference curves are tangent to the market offers. Thus, the empirical estimation of the hedonic labour market equilibrium focuses on the joint influence of demand and supply.

Figure 1
Market process for determining compensating differentials
The trade-offs reflected in market equilibria do not represent a schedule of individual VSL trade-off values at different risks, but rather different VSLs for different workers. Worker 1 chooses risk $p_1$ with associated wage $w(p_1)$, and worker 2 chooses risk $p_2$ for wage $w(p_2)$. However, worker 1 would not accept risk $p_2$ for $w(p_2)$ even when that is the point on the hedonic equilibrium curve. Rather, worker 1 will require wage $w_1(p_2) > w_2(p_2)$ to accept this risk. The canonical hedonic wage equation is

$$\ln w_i = \alpha + X_i'\beta + \gamma_1 p_i + \gamma_2 q_i + \gamma_3 W_{Ci} + \epsilon_i,$$

where $w_i$ is worker $i$'s wage, $X_i$ is a vector of personal characteristics and job characteristics, $p_i$ is the worker's fatality risk, $q_i$ is the nonfatal injury and illness risk, and $W_{Ci}$ is a measure of the worker's compensation benefits. Not all labour market studies of VSL include the $q_i$ and $W_{Ci}$ terms. Moreover, there are some differences in the form of the workers' compensation benefit term that is included. The most common is the expected workers' compensation replacement rate, which is the product of the injury risk and the benefit level divided by the wage rate. These differences in the empirical specification account for some of the differences across studies in the estimated VSL.

As a practical matter, there are many systematic differences that have become apparent in these studies. Workers at very high-risk jobs tend to have lower values of life on average since they have self-selected themselves into the very risky occupation. Through their job choices these individuals have revealed their greater willingness to endanger their lives. Workers at lower-risk jobs typically have greater reluctance to risk their lives, which accounts for their selection into these safer pursuits. Such differences are apparent in practice, as the estimated values of life for workers in the average risk jobs tend to be several times greater than those for workers in very risky jobs. Other differences correlated with worker affluence are also evident. Health status is a normal economic good, and individuals’ willingness to pay to preserve their health increases with income. Blue-collar workers, for example, have a lower value of life than do white-collar workers. In addition, there is a positive income elasticity of the estimated values of risks to life and health. Based on a sample of 50 wage–risk studies from ten countries, Viscusi and Aldy (2003) estimate that VSL has an income elasticity of 0.5 to 0.6.

These differences by income level in the VSL amounts are also borne out in the international evidence on wage-risk trade-offs, such as the study of Australia and Japan by Kniesner and Leeth (1991). Table 1 summarizes representative VSL studies from throughout the world. More affluent countries such as Japan and Canada tend to have higher revealed VSL levels than countries such as South Korea, India and Taiwan. The major international anomaly is the United Kingdom, for which labour market estimates have been very unstable across studies and sometimes quite high. Deficiencies of the UK fatality risk data or correlation of these values with other unobservables may account for this pattern. Because of these limitations, the benefit assessments for risk reductions in the UK are based on stated preference values rather than labour market values, which is the approach taken by US regulatory agencies.

**Note:** All estimates are in year 2000 US dollars. **Source:** Viscusi and Aldy (2003). For concreteness, single representative studies are drawn from their Table 4.

Because of individual heterogeneity in preferences and resources, it is not surprising that estimated values of life often differ considerably across empirical studies. These differences are not a sign that such studies are necessarily in error. These samples often consist of workers with quite different risk levels and who are situated differently. International comparisons, for example, consistently reveal differences across countries, not only because of the aforementioned aspects of heterogeneity, but because of the differences in the social insurance and workers’ compensation arrangements that may be present in these countries.

The role of heterogeneity is evidenced in estimates for the implicit value for non-fatal job injuries for different worker groups. This analysis follows the same general methodological approach as does the literature on the implicit value of life. The difference is that the focus is on non-fatal job risks rather than fatalities. On average, workers value non-fatal loss injuries on the job at values ranging from $20,000 to $70,000 per expected job injury. Thus, for example, a worker at the high end of this range would require $2,000 to face a one chance in 25 of being injured that year.

The estimates of the implicit values of injuries for other labour market groups who have different attitudes towards risk vary substantially from this amount. Interestingly, women often work at hazardous jobs and appear to have wage–risk trade-offs similar to those of men. Other personal characteristics generate more evidence of heterogeneity in preferences. Cigarette smokers and people who don use seat belts in their automobiles work on risky jobs for less per expected injury than do people who don’t smoke and who use seat belts in their automobiles. What is noteworthy is that these results are not hypothetical willingness-to-pay values that these groups have expressed with respect to risks. Rather, they represent actual differences in compensation based on observed patterns of decisions in the marketplace. Markets work as expected in that they match workers to the jobs that are most appropriate for their preferences. This is a constructive role of market sorting that promotes a more efficient match-up than if, for example, all individuals were constrained to have the same job riskiness.

Preference heterogeneity has additional implications. Recall from Figure 1 that workers may settle along different points of the available market opportunities. However, if workers face the same opportunities locus, then the worker choosing the higher risk $p_2$ must always be paid a wage $w(p_2)$ greater than $w(p_1)$ if $p_2 > p_1$. Interestingly, that pattern does not always hold. As shown by Viscusi and Hersch (2001), smokers choose jobs that are riskier than non-smokers’ jobs but offer less additional wage compensation for incurring the risks. Smokers and non-smokers face different market offer curves and, most important, these offer curves provide for a flatter wage–risk gradient for smokers. There may be an efficiency-based rationale for these differences, as smokers are more prone to job accidents, so that there is safety-related productivity loss.

Studies of the money–risk trade-offs are not restricted to the labour market. There have been a number of efforts to assess price–risk trade-offs for a variety of commodities. The contexts analysed by economists include the choice of highway speed, seat belt use, installation of smoke detectors, property values in polluted areas, and prices of automobiles. The most reliable of these studies outside the labour market are those pertaining to automobile prices in that they follow the same kind of approach as is used in the wage–risk literature. In particular, the analysts obtain price information on a wide variety of automobile models. Using regression analysis, they assess the incremental contribution of the safety characteristics per se to the product price, controlling for other product attributes. The results of these studies suggest a value of life around $5 million.

**The duration and quality of life**

The value-of-life terminology is misleading to the extent that risk reduction efforts do not confer immortality but simply extend life. Because of that, the major concern should not be with the value of life but with the value of extending life for different periods. In the case of preventing the risk of death to a young person, the increase in life expectancy that will be generated will exceed that for preventing a risk of death to older people. Some kind of age adjustment may be appropriate. The quantity of life matters, but which years of life matter...
most? Is a year of life at age 45 more valuable than a year of life at age 5 or age 70? How do various health impairments correlated with age affect the value one should attach to such years of life, and should the fact that very young children have not yet received the value of the education and rearing by their parents matter? The total ‘human capital’, which is the set of personal attributes such as education and training that affect one’s income, will be greater for older children who are further along in their development. Resolving such questions remains highly problematic.

Considerable attention has been devoted to economic analysis of age effects, including studies by Shepard and Zeckhauser (1984) and Johansson (2002). If capital markets were perfect, then VSL would steadily decline with age, reflecting the shortening of life expectancy. If, however, there are capital market imperfections, then VSL will display an inverted U-shaped relationship with age. A similar pattern is exhibited empirically by lifetime consumption patterns, which some theoretical models have linked to VSL levels over the life cycle. Although empirical estimates of the age effects are still being refined, the available evidence from survey data and market-based studies suggests that there is an inverted-U-shaped relation. The main empirical controversies concern the tails of the age distribution. To what extent is there a flattening of the VSL–age relation for the very old age groups, and how should VSL levels be assigned to children?

The quality of the life of the years saved clearly matters as well. Life years in deteriorating health may be less valuable to the individual than years in good health. Some analysts have suggested that the measure should focus on quality-adjusted life years. Making these quality adjustments has yet to receive widespread empirical implementation and is often controversial. There may be quite legitimate fears of government efforts to target expenditures by denying health care to those whose life quality is deemed to be low. People often adapt to changes in health status so that external observers may overstate the decline in well-being that occurs with serious illnesses.

Conclusion

Economic estimates of the trade-offs people make between risk and either prices or wages serve a variety of functions. First, they provide evidence on how people make decisions involving risk in labour market and product market contexts. The fact that there are probabilistic health effects does not imply that markets cease to function. Second, these estimates have proved useful in providing a reference point for how the government should value the benefits associated with regulations and other policies that reduce risk. Third, the existence of these estimates and economists’ continuing efforts to refine the values has served to highlight many of the fundamental ethical issues involved, such as how society should value reducing risks to people in different age groups.

**How to cite this article**

Time is a scarce resource or, to use a popular adage – ‘time is money’. The value of time depends on its usage and the complementary resources used with it. Firms pay for their workers’ time according to the workers’ value or marginal product. Households naturally place a value on their time when they sell it in the market, but they also assign a value to the time they use in the home sector. This value determines (and is sometimes determined by) the optimum combination of activities a person engages in, and the optimum combination of goods and time used in each activity. It affects the supply of labour and the demand for goods.

The recognition of the importance of time for many economic decisions related and unrelated to the labour market (e.g., schooling; transportation) is not new. The generalization of the model is associated with Becker's (1965) theory of home production. Becker (following Mincer, 1963) reformulates traditional consumption theory by shifting the focus of analysis from goods to activities ('commodities', in his terms). By this approach the source of the household's welfare is its activities, which in turn, are a combination of goods and time. Welfare is maximized subject to home technology, the budget constraint, and the time constraint. Formally, the welfare function depends on the activity levels \( Z_i \)

\[
U = U(Z_1, ..., Z_n)
\]

where each activity is ‘produced’ through a combination of goods \( X_i \) and time \( T_i \)

\[
Z_i = d_i(X_i, T_i).
\]
\[ \sum P_i X_i = W(Z_n) + V \]

and the time constraint

\[ \sum T_i = T, \]

where \( P_i \) denote prices, \( W(Z_n) \) is labour income (\( Z_n \) denoting the activity work in the market), \( V \) is non-labour income, and \( T \) is the total time available.

The maximization of welfare subject to the home production technology and the time and budget constraints yields the optimum allocation of activities:

\[ \frac{\partial U}{\partial Z_i} = \lambda \tilde{\Pi}_i \]

and the optimum combination of inputs in the production of each activity

\[ \left( \frac{\partial Z_i}{\partial T_i} \right) / \left( \frac{\partial Z_i}{\partial X_i} \right) = \frac{\hat{W}}{P_i} \]

where \( \lambda \) denotes the marginal value of income, \( \tilde{\Pi}_i \) is the shadow price of activity \( i \), and \( \hat{W} \) is the shadow price of time. The shadow price of the activity equals its marginal cost of production

\[ \tilde{\Pi}_i = P_i \left( \frac{\partial X_i}{\partial Z_i} \right) + \hat{W} \left( \frac{\partial T_i}{\partial Z_i} \right). \]

Thus an increase in the shadow price of time leads to substitution of time in favour of goods and a substitution from time-intensive to goods-intensive activities.

When there are no external constraints on hours of market work the value people place on their time depends on their marginal wage rate
\[ \hat{W} = w + (u_n / \lambda), \]

where \( w \) is the marginal wage rate (the change in earnings as a result of a change in market work net of taxes and any expenditures associated with work) and \( u_n \) denotes the marginal utility of labour. However, even when one is not free to change one's working hours the shadow price of time increases with wages and with income because of the increase in time scarcity.

The importance of the value of time to allocative decisions has been shown in a wide range of contexts: fertility (Becker, 1960; Willis, 1973; Schultz, 1975), health (Grossman, 1972) and most notably, labour supply and transportation. Thus, women with higher wages have higher opportunity costs of raising children and therefore tend to reduce fertility, substituting 'quality' for 'quantity'. Travellers who place a high value on their time prefer faster but more expensive modes of transport to slower and cheaper modes. Married women with young children or with high earning husbands place higher value on their time and are, therefore, more reluctant to participate in the labour force.

Theory predicts that the shadow price of time changes with the person's wage rate. It does not imply that the two are equal; they differ if the marginal net wage differs from the average wage, when labour involves direct utility (or disutility), or when it is assumed that the utility generated by an activity depends on the time inputs involved (Bruzelius, 1979).

The value of time saving is a major component of the benefits of the investment in many transportation projects (Beesley, 1965; Tipping, 1968). To evaluate the shadow price of time transportation economists studied the trade-off between time and money implicit in the choice of modes of transport, choice of route, location decision, and demand for travel. Studying commuter choices it is found that the value placed by commuters on their time is only 1/5 to 1/2 of their wage rate. The value of walking and waiting time is found to be 2.5–3.0 times greater than the value of in-vehicle time. Differences in convenience, comfort, effort etc. are reflected in estimates of time value in bus travel that are higher than travel by car, and values that tend to increase with the length of the trip. Finally, differences between the gross and the net wage and constrained working hours result in estimates that are higher for business travel than for personal travel. (For a recent discussion of the estimating methods and results see Bruzelius, 1979.)

A second source for the study of the value of time at home is labour-force-participation behaviour. A person is supposed to participate in the labour force if the wage he is offered exceeds the value of his marginal productivity at home – that is, his value of home time. Studying the labour force participation patterns of US married women Gronau (1973) found that the value of time of these women increases with their schooling (most noticeably with college attendance). It is little affected by the husband's schooling and income and by age, and increase sharply when the family has children. Having a child under 3 years of age increases the value of its mother's time at home by over 25 per cent (in particular if she has a college education), but this effect diminishes as the child grows older.

A value-added tax (VAT) is a tax on the value created in goods or services during production, distribution, and sales. VATs are generally constructed as consumption taxes. In principle, a consumption VAT is neutral in its treatment of savings and consumption. In practice, VATs are often designed with exemptions and zero-ratings that generate consumption distortions. An important issue for VATs is their implementation in a federal system. A number of modifications of the basic VAT structure have been proposed to strike a balance between the efficiency of a common rate across political units and the desire for country-specific VAT rates.

**Keywords**

compensating VAT (CVAT); consumption taxation; depreciation; tax evasion; tax neutrality; value-added tax; vertical integration; viable integrated VAT (VIVAT)

**Article**

A value-added tax (VAT) is a tax on the value created in a good or service by a business at any stage of production, distribution or sales.

**Definitions and equivalencies**

Value-added is simply the difference between the value of the goods and services sold and the value of goods and services purchased as intermediate inputs. Consider the general cash flow equation for a firm.

\[ S + K^+ = L + M + K^- \]

(1)
The equation states that cash comes into a firm from capital inflows ($K^+$) – new equity and borrowing – and proceeds from sales. Cash is used for payments for labour ($L$) and intermediate goods ($M$). Capital purchases are generally included in $M$. This makes a VAT a consumption tax. If capital depreciation is included in $M$, then this would be an income-type VAT. If no capital deduction of any form is allowed, then this would be a gross output VAT. For the remainder of the article, I focus on a consumption-type VAT. In addition, cash is retained or used for dividend and interest payments as well as any retirement of debt and equity ($K^-$).

Value added was defined above as the difference between revenue from sales and the cost of inputs:

$$VA = S - M = L + (K^--K^+).$$

Equation (2) demonstrates that there are several ways to impose a VAT. We could tax gross sales net of intermediate input purchases at each stage of production. This forms the basis for a ‘subtraction method’ VAT. Alternatively, we could tax gross sales and allow a credit for taxes paid by registered suppliers of intermediate inputs to the firm. The ‘credit method’ VAT works in this fashion. A third method is to tax the factor payments to capital and labour. This forms the basis for an ‘addition method’ VAT.

Value-added taxes are common throughout the world with the notable exception of the United States. Most countries use the credit method, arguing that this method is self-enforcing since the ability to take a credit for VAT paid at an earlier stage of production requires suppliers to provide an invoice detailing their VAT payments.

**Tax neutrality**

As described at this most general level, a VAT shares all the attributes of a broad-based consumption tax. If comprehensively applied, it is neutral across all forms of purchased consumption. And since capital purchases are expensed (immediately deducted from the tax base), the rate of return on capital is unaffected by the tax. As with all consumption taxes, the efficiency gains from a switch from income to consumption taxation depend significantly on the tax treatment of old capital; on this point, see Auerbach and Kotlikoff (1987). In practice, VATs are not neutral for a number of reasons. First, if capital is not expensed, returns to capital are affected by the tax. Most VATs are consumption-type VATs so this is not a significant problem. Second, as noted by Cnossen (1998), some countries extend the VAT up through the manufacturing or wholesale stage but not through the retail stage. This creates distortions across consumption given the different ensuing tax rates on different commodities. Finally, many VATs exempt certain sectors from the tax, ‘zero-rate’ sectors or commodities, or apply a reduced rate to certain commodities (for example, food for home preparation). Zero-rating in a credit method VAT means that firms apply a zero rate to their tax base but receive a credit for all VAT paid by...
suppliers. Zero-rating has no impact if applied at an intermediate stage of production since any taxes forgone at one stage are made up at the next stage. Zero-rating at the retail stage means the commodity is untaxed by a VAT. Exempting sectors from the VAT process may create peculiar outcomes. If an intermediate sector is exempted from taxation, downstream stages of production will pay a VAT not only on their value added but on the value added created in sectors upstream from the exempt sector for which no credit was received. The result is that exemptions at an intermediate stage of production can lead to the effective VAT rate being higher than the nominal rate. For this reason, many countries that exempt certain sectors (generally small businesses) allow voluntary participation in the VAT system. Note too that exemptions at the retail stage create incentives for vertical integration to increase the proportion of value added exempt from taxation.

**Design issues**

A VAT can be levied on an ‘origin’ or ‘destination’ basis. An origin VAT taxes value added in the country in which the value added is produced, while a destination VAT taxes value added where it is consumed. Most countries employ a destination VAT and use a border tax adjustment whereby a VAT is applied to the value of imports and a rebate provided for the value of exports. While it is popularly believed that border tax adjustments favour export industries, a flexible exchange rate in general leads to the same trade balance whether the VAT is applied on an origin or destination basis. Grossman (1980) demonstrates that this proposition fails in a world with trade in intermediate goods. Border tax adjustments are commonly applied by customs authorities, and this has given rise to special problems for the European Union with its abolition of border controls in 1992. Keen and Smith (1996) note conflicts between two important goals: maximum autonomy for individual countries to set their own tax rates and a system of country VAT structures that does not impede the creation of a single European market. Keen and Smith propose a ‘viable integrated VAT’ (VIVAT) to address this problem. The VIVAT applies a harmonized VAT rate to intermediate producers in all European countries and a different rate for final consumption sales. The rate on final sales would vary across countries based on individual country preferences. The VIVAT can be thought of as a harmonized EU-wide VAT and a system of individual country retail sales taxes, a point that reminds us of the close connection between a VAT and a retail sales tax. McLure (2000) notes that the VIVAT requires firms to charge different rates to different classes of customers, a non-trivial burden. He also notes that a destination-based system of VATs in a sub-national system can give rise to tax evasion by households or unregistered firms importing goods (which are zero-rated at the exporting country's border). McLure proposes a compensating VAT (CVAT), essentially an additional federal-level tax to guarantee the tax revenues that might otherwise be lost to cross-border tax evasion. The key point here is that considerable administrative complexity comes into play when a VAT is implemented by a group of countries (or states) within a common trading system (or federal government).

As with any other consumption tax framework, taxing housing and financial services is problematic with a VAT. One approach for treating housing services follows from an arbitrage argument that the present value of the stream of future consumption services from housing is equal to its purchase price. With this assumption, a tax-prepayment approach levies the VAT on the first sale of a house (but not subsequent
value-added tax: The New Palgrave Dictionary of Economics

sales) as well as additions or maintenance. With constant tax rates, this tax payment is equal to the present value of the taxes that would be paid on the housing services enjoyed by occupants of the house. If tax rates rise (fall) in the future, the tax prepayment approach raises less (more) revenue than if the housing services were taxed directly. Alternatively, the sale of all residential housing and rental income are subject to tax while the purchase of residential housing is deductible. This approach treats housing like any other capital asset which produces services (housing). Measuring and taxing the imputed rental income on owner occupied housing is a significant problem for this approach. For this reason, most consumption taxes favour the tax prepayment approach.

Financial services are even more difficult to handle under consumption taxes. One approach is to tax the net cash flow from financial services. In the terminology of Meade (1978), this would be an R+F (real plus financial) consumption tax. As Auerbach and Gordon (2002) point out, this creates considerable administrative problems since other transactions are treated on an R basis, thus giving rise to arbitrage opportunities to avoid the tax. In the European Union financial services are exempt from VAT, though Huizanga (2002) has argued that it is increasingly feasible to bring this sector into the VAT system. This sanguine perspective is not shared by all economists.

**Tax incidence and impacts on saving and labour supply**

Because a VAT in its purest form is a consumption tax, its distributional impact as well as behavioural impacts are the same as those of any broad-based consumption tax. To the extent that the VAT is implemented in non-neutral ways (exemptions and zero-rating of sectors, multiple tax rates, and so forth) consumption distortions will arise similar to those of any differential rate commodity tax system. Many countries apply a VAT tax structure with lower rates on perceived necessities (food, for example) on distributional grounds. Most economic analyses of VAT proposals recommend a uniform tax rate on all commodities to avoid consumption distortions, and recommend using an income tax to effect desired income redistribution. Cnossen (1998), however, recommends a dual rate system for developing countries on the grounds that income taxes are administratively unfeasible in these countries. While reducing tax rates on food and other necessities provides benefits to low-income households, this is a blunt instrument for redistribution given the resulting reduction in taxes to wealthy people's purchase of food (and other low or zero-rated commodities).

Article

Variance decomposition is a classical statistical method in multivariate analysis for uncovering simplifying structures in a large set of variables (for example, Anderson, 2003). For example, factor analysis or principal components are tools that are in widespread use. Factor analytic methods have, for instance, been used extensively in economic forecasting (see for example, Forni et al. 2000; Stock and Watson, 2002). In macroeconomic analysis the term ‘variance decomposition’ or, more precisely, ‘forecast error variance decomposition’ is used more narrowly for a specific tool for interpreting the relations between variables described by vector autoregressive (VAR) models. These models were advocated by Sims (1980) and used since then by many economists and econometricians as alternatives to classical simultaneous equations models. Sims criticized the way the latter models were specified, and questioned in particular the exogeneity assumptions common in simultaneous equations modelling. VAR models have the form

\[ Y_t = \sum_{i=1}^{p} A_i Y_{t-i} + \epsilon_t \]

(1)

where \( Y_t = (Y_{1t}, \ldots, Y_{Kt})' \) (the prime denotes the transpose) is a vector of \( K \) observed variables of...
interest, the $A_i$'s are $(K \times K)$ parameter matrices, $p$ is the lag order and $u_t$ is a zero mean error process which is assumed to be white noise, that is, $E(u_t) = 0$, the covariance matrix, $E(u_t'u_t') = \Sigma_u$, is time invariant and the $u_i$'s are serially uncorrelated or independent. Here deterministic terms such as constants, seasonal dummies or polynomial trends are neglected because they are of no interest in the following. In the VAR model (1) all the variables are a priori endogenous. It is usually difficult to disentangle the relations between the variables directly from the coefficient matrices. Therefore it is useful to have special tools which help with the interpretation of VAR models. Forecast error variance decompositions are such tools. They are presented in the following.

An $h$ steps ahead forecast or briefly $h$-step forecast at origin $t$ can be obtained from (1) recursively for $h = 1, 2, \ldots$, as

$$V_{t+h} = A_1 V_{t+h-1} + \cdots + A_p V_{t+h-p}.$$  

(2)

Here $V_{t+h} = V_t + j$ for $j \leq 0$. The forecast error turns out to be

$$V_{t+h} - V_{t+h} = u_{t+h} + \sum_{i=1}^{h-1} \Phi_i u_{t+h-i} \sim \left(0, \Sigma_h = \Sigma_u + \sum_{i=1}^{h-1} \Phi_i \Sigma_u \Phi_i'\right),$$

that is, the forecast errors have mean zero and covariance matrices $\Sigma_h$. Here the $\Phi_i$'s are the coefficient matrices of the power series expansion $(\Lambda - \Lambda z - \cdots - \Lambda p z^p)^{-1} = \Lambda + \sum_{i=1}^{\infty} \Phi_i z^i$. Note that the inverse exists in a neighbourhood of $z=0$ even if the VAR process contains integrated and cointegrated variables. (For an introductory exposition of forecasting VARs, see Lütkepohl, 2005.)

If the residual vector $u_t$ can be decomposed in instantaneously uncorrelated innovations with economically meaningful interpretation, say, $u_t = \beta \varepsilon_t$ with $\varepsilon_t \sim (0, \Lambda)$, then $\Sigma_u = \beta \beta'$ and the forecast error variance can be written as $\Sigma_h = \sum_{i=0}^{h-1} \Theta_i \Theta_i'$, where $\Theta_0 = \beta$ and $\Theta_i = \Phi_i \beta$. Denoting the $(n,m)$th element of $\Theta_j$ by $\theta_{nm,j}$, the forecast error variance of the $k$th element of the forecast error vector is seen to be

$$\sigma_k^2(h) = \sum_{j=0}^{h-1} (\theta_{k1,j}^2 + \cdots + \theta_{kK,j}^2) = \sum_{j=1}^{K} \left(\theta_{kj,0}^2 + \cdots + \theta_{kj,h-1}^2\right).$$
The term \( \left( \theta^2_{kj,0} + \cdots + \theta^2_{kj,h-1} \right) \) may be interpreted as the contribution of the \( j \)th innovation to the \( h \)-step forecast error variance of variable \( k \). Dividing the term by \( \sigma^2_{k}(h) \) gives the percentage contribution of innovation \( j \) to the \( h \)-step forecast error variance of variable \( k \). This quantity is denoted by \( \omega_{kj,h} \) in the following. The \( \omega_{kj,h}, \ j = 1, \ldots, K \), decompose the \( h \)-step ahead forecast error variance of variable \( k \) in the contributions of the \( \varepsilon_t \) innovations. They were proposed by Sims (1980) and are often reported and interpreted for various forecast horizons.

For such an interpretation to make sense it is important to have economically meaningful innovations. In other words, a suitable transformation matrix \( B \) for the reduced form residuals has to be found. Clearly, \( B \) has to satisfy \( \Sigma_u = BB' \). These relations do not uniquely determine \( B \), however. Thus, restrictions from subject matter theory are needed to obtain a unique \( B \) matrix and, hence, unique innovations \( \varepsilon_t \). A number of different possible sets of restrictions and approaches for specifying restrictions have been proposed in the literature in the framework of structural VAR models. A popular example is the choice of a lower-triangular matrix \( B \) obtained by a Choleski decomposition of \( \Sigma_u \) (for example, Sims, 1980).

Such a choice amounts to setting up a system in recursive form where shocks in the first variable have potentially instantaneous effects also on all the other variables, shocks to the second variable can also affect the third to last variable instantaneously, and so on. In recursive systems it may be possible to associate the innovations with variables, that is, the \( j \)th component of \( \varepsilon_t \) is primarily viewed as a shock to the \( j \)th observed variable. Generally, the innovations can also be associated with unobserved variables, factors or forces and they may be named accordingly. For example, Blanchard and Quah (1989) consider a bivariate model for output and the unemployment rate, and they investigate effects of supply and demand shocks. Generally, if economically meaningful innovations can be found, forecast error variance decompositions provide information about the relative importance of different shocks for the variables described by the VAR model.

Estimation of reduced form and structural form parameters of VAR processes is usually done by least squares, maximum likelihood or Bayesian methods. Estimates of the forecast error variance components, \( \omega_{kj,h} \), are then obtained from the VAR parameter estimates. Suppose the VAR coefficients are contained in a vector \( \alpha \), then \( \omega_{kj,h} \) is a function of \( \alpha \), \( \omega_{kj,h} = \omega_{kj,h}(\alpha) \). Denoting the estimator of \( \alpha \) by \( \hat{\alpha} \), \( \omega_{kj,h} \) may be estimated as \( \hat{\omega}_{kj,h} = \omega_{kj,h}(\hat{\alpha}) \). If \( \hat{\alpha} \) is asymptotically normal, that is, \( \sqrt{T}(\hat{\alpha} - \alpha) \overset{d}{\to} \mathcal{N}(0, \Sigma_{\alpha}) \), then, under general conditions, \( \sqrt{T}(\hat{\omega}_{kj,h} - \omega_{kj,h}) \overset{d}{\to} \mathcal{N}(0, \sigma^2_{kj,h} + \sum_{\alpha} \frac{\partial \omega_{kj,h}}{\partial \alpha} \Sigma_{\alpha} \frac{\partial \omega_{kj,h}}{\partial \alpha}) \), provided the variance of the asymptotic distribution is non-zero. Here \( \frac{\partial \omega_{kj,h}}{\partial \alpha} \) denotes the vector of first-order partial derivatives of \( \omega_{kj,h} \) with respect to the elements of \( \alpha \) (see Lütkepohl, 1990, for the specific form of the partial derivatives). Unfortunately, \( \sigma^2_{kj,h} \) is zero even for cases of particular interest, for example, if \( \omega_{kj,h} = 0 \) and, hence, the \( j \)th innovation does not contribute to the \( h \)-step forecast error variance of.
variance decomposition: The New Palgrave Dictionary of Economics

variable $k$ (see Lütkepohl, 2005, section 3.7.1, for a more detailed discussion). The problem can also not easily be solved by using bootstrap techniques (cf. Benkwitz, Lütkepohl and Neumann, 2000). Thus, standard statistical techniques such as setting up confidence intervals are problematic for the forecast error variance components. They can at best give rough indications of sampling uncertainty. The estimated $\omega_{kj,h}$’s are perhaps best viewed as descriptive statistics.

Analysis of variance (ANOVA) is a statistical procedure for summarizing a classical linear model—a decomposition of sum of squares into a component for each source of variation in the model—along with an associated test (the $F$-test) of the hypothesis that any given source of variation in the model is zero. More generally, the variance decomposition in ANOVA can be extended to obtain inference for the variances of batches of parameters (sources of variation) in multilevel regressions. ANOVA is a useful addition to regression in that it structures inferences about batches of parameters.

Article

1 Introduction

Analysis of variance (ANOVA) represents a set of models that can be fit to data, and also a set of methods for summarizing an existing fitted model. We first consider ANOVA as it applies to classical linear models (the context for which it was originally devised; Fisher, 1925) and then discuss how ANOVA has been extended to generalized linear models and multilevel models. Analysis of variance is particularly effective for analysing highly structured experimental data (in agriculture, multiple treatments applied to different batches of animals or crops; in psychology, multi-factorial experiments manipulating several independent experimental conditions and applied to groups of people; industrial experiments in which multiple factors can be altered at different times and in different locations). At the end of this article, we compare ANOVA with simple linear regression.

2 Analysis of variance for classical linear models

2.1 ANOVA as a family of statistical methods

When formulated as a statistical model, analysis of variance refers to an additive decomposition of data into a grand mean, main effects, possible interactions and an error term. For example, Gawron et al. (2003) describe a flight-simulator experiment that we summarize as a 5x8 array of measurements under five treatment conditions and eight different airports. The corresponding two-way ANOVA model is $y_{ij} = \mu + \alpha_i + \beta_j + \epsilon_{ij}$. The data as described here have no replication, and so the two-way interaction becomes part of the error term.
This is a linear model with $1 + 4 + 7$ coefficients, which is typically identified by constraining the $\sum_{i=1}^{5} \alpha_i = 0$ and $\sum_{j=1}^{8} \beta_j = 0$. The corresponding ANOVA display is shown in Table 1:

1. For each source of variation, the degrees of freedom represent the number of effects at that level, minus the number of constraints (the five treatment effects sum to zero, the eight airport effects sum to zero, and each row and column of the 40 residuals sums to zero).
2. The total sum of squares – that is, $\sum_{i=1}^{5} \sum_{j=1}^{8} (y_{ij} - \bar{y}_{.})^2$ – is $0.078 + 3.944 + 1.417$, which can be decomposed into these three terms corresponding to variance described by treatment, variance described by airport, and residuals.
3. The mean square for each row is the sum of squares divided by degrees of freedom. Under the null hypothesis of zero row and column effects, their mean squares would, in expectation, simply equal the mean square of the residuals.
4. The $F$-ratio for each row (except for the last) is the mean square, divided by the residual mean square. This ratio should be approximately 1 (in expectation) if the corresponding effects are zero; otherwise we would generally expect the $F$-ratio to exceed 1. We would expect the $F$-ratio to be less than 1 only in unusual models with negative within-group correlations (for example, if the data $y$ have been renormalized in some way, and this had not been accounted for in the data analysis).
5. The $p$-value gives the statistical significance of the $F$-ratio with reference to the $F_{\nu_1, \nu_2}$ where $\nu_1$ and $\nu_2$ are the numerator and denominator degrees of freedom, respectively. (Thus, the two $F$-ratios in Figure 1 are being compared to $F_{4.28}$ and $F_{7.28}$ distributions, respectively.) In this example, the treatment mean square is lower than expected (an $F$-ratio of less than 1), but the difference from 1 is not statistically significant ($p$-value of 82 per cent), hence it is reasonable to judge this difference as explainable by chance, and consistent with zero treatment effects. The airport mean square is much higher than would be expected by chance, with an $F$-ratio that is highly statistically significantly larger than 1; hence we can confidently reject the hypothesis of zero airport effects.

Classical two-way analysis of variance for data on five treatments and eight airports with no replication

More complicated designs have correspondingly complicated ANOVA models, and complexities arise with multiple error terms. We do not intend to explain such hierarchical designs and analyses here, but we wish to alert the reader to such complications. Textbooks such as Snedecor and Cochran (1989) and Kirk (1995) provide examples of analysis of variance for a wide range of designs.

2.2 ANOVA to summarize a model that has already been fitted

We have just demonstrated ANOVA as a method of analysing highly structured data by decomposing variance into different sources, and comparing the explained variance at each level with what would be expected by chance alone. Any classical analysis of variance corresponds to a linear model (that is, a regression model, possibly with multiple error terms); conversely, ANOVA tools can be used to summarize an existing linear model. The key is the idea of ‘sources of variation’, each of which corresponds to a batch of coefficients in a regression. Thus, with the model $Y = X \beta + \epsilon$, the columns of $X$ can often be batched in a reasonable way (for example, in Table 1, a constant term, four treatment indicators, and seven airport indicators) and the mean squares and $F$-tests then provide information about the amount of variance explained by each batch.

Such models could be fitted without any reference to ANOVA, but ANOVA tools could then be used to make some sense of the fitted models, and to test hypotheses about batches of coefficients.

2.3 Balanced and unbalanced data

In general, the amount of variance explained by a batch of predictors in a regression depends on which other variables have already been included in the model. With balanced data, however, in which all groups have the same number of observations (for example, each treatment applied exactly eight times, and each airport used for exactly five observations), the variance decomposition does not depend on the order in which the variables are entered. ANOVA is thus particularly easy to interpret with balanced data. The analysis of variance can also be applied to unbalanced data, but then the sums of squares, mean squares, and $F$-ratios will depend on the order in which the sources of variation are considered.
Analysis of variance represents a way of summarizing regressions with large numbers of predictors that can be arranged in batches, and a way of testing hypotheses about batches of coefficients. Both these ideas can be applied in settings more general than linear models with balanced data.

### 3.1 F-tests

In a classical balanced design (as in the example in Table 1), each F-ratio compares a particular batch of effects to zero, testing the hypothesis that this particular source of variation is not necessary to fit the data. More generally, the F-test can compare two nested models, testing the hypothesis that the smaller model fits the data adequately (so that the larger model is unnecessary). In a linear model, the F-ratio is

\[
\frac{SS_2 - SS_1}{df_2 - df_1}
\]

where \(SS_1\), \(df_1\) and \(SS_2\), \(df_2\) are the residual sums of squares and degrees of freedom from fitting the larger and smaller models, respectively. For generalized linear models, formulas exist using the deviance (the log-likelihood multiplied by \(-2\)) that are asymptotically equivalent to F-ratios. In general, such models are not balanced, and the test for including another batch of coefficients depends on which other sources of variation have already been included in the model.

### 3.2 Inference for variance parameters

A different sort of generalization interprets the ANOVA display as inference about the variance of each batch of coefficients, which we can think of as the relative importance of each source of variation in predicting the data. Even in a classical balanced ANOVA, the sums of squares and mean squares do not exactly do this, but the information contained therein can be used to estimate the variance components (Cornfield and Tukey, 1956; Searle, Casella and McCulloch, 1992). Bayesian simulation can then be used to obtain confidence intervals for the variance parameters. As illustrated in this article we display inferences for standard deviations (rather than variances) because these are more directly interpretable. Compared with the classical ANOVA display, our plots emphasize the estimated variance parameters rather than testing the hypothesis that they are zero.

### 3.3 Generalized linear models

The idea of estimating variance parameters applies directly to generalized linear models as well as unbalanced data-sets. All that is needed is that the parameters of a regression model are batched into ‘sources of variation’. Figure 1 illustrates with a multilevel logistic regression model, predicting vote preference given a set of demographic and geographic variables.

### 3.4 Multilevel models and Bayesian inference

Analysis of variance is closely tied to multilevel (hierarchical) modelling, with each source of variation in the ANOVA table corresponding to a variance component in a multilevel model (see Gelman, 2005). In practice, this can mean that we perform ANOVA by fitting a multilevel model, or that we use ANOVA ideas to summarize multilevel inferences. Multilevel modelling is inherently Bayesian in that it involves a potentially large number of parameters that are modelled with probability distributions (see, for example, Goldstein, 1995; Kreft and De Leeuw, 1998; Snijders and Bosker, 1999). The differences between Bayesian and non-Bayesian multilevel models are typically minor except in settings with many sources of variation and little information on each, in which case some benefit can be gained from a fully Bayesian approach which models the variance parameters.

### 4 Related topics

#### 4.1 Finite population and super-population variances

So far in this article we have considered, at each level (that is, each source of variation) of a model, the standard deviation of the corresponding set of coefficients. We call this the finite-population standard deviation. Another quantity of potential interest is the standard deviation of the hypothetical super-population from which these particular coefficients were drawn. The point estimates of these two variance parameters are similar – with the classical method of moments, the estimates are identical, because the super-population variance is the expected value of the finite-population variance – but they will have different uncertainties. The inferences for the finite-population standard deviations are more precise, as they
Figure 2 illustrates the finite-population and super-population inferences at each level of the model for the flight-simulator example. We know much more about the five treatments and eight airports in our data-set than for the general populations of treatments and airports. (We similarly know more about the standard deviation of the 40 particular errors in our data-set than about their hypothetical super-population, but the differences here are not so large because the super-population distribution is fairly well estimated from the 28 degrees of freedom available from these data.)

Figure 2
Median estimates, 50% intervals and 95% intervals for (a) finite population and (b) super-population standard deviations of the treatment-level, airport-level and data-level errors in the flight-simulator example from Table 1. Note: The two sorts of standard deviation parameters have essentially the same estimates, but the finite-population quantities are estimated much more precisely. (We follow the general practice in statistical notation, using Greek and Roman letters for population and sample quantities, respectively.)
There has been much discussion about fixed and random effects in the statistical literature (see Eisenhart, 1947; Green and Tukey, 1960; Plackett, 1960; Yates, 1967; LaMotte, 1983; and Nelder, 1977; 1994, for a range of viewpoints), and unfortunately the terminology used in these discussions is incoherent (see Gelman, 2005, sec. 6). Our resolution to some of these difficulties is to always fit a multilevel model but to summarize it with the appropriate class of estimand – super-population or finite population – depending on the context of the problem. Sometimes we are interested in the particular groups at hand; at other times they are a sample from a larger population of interest. A change of focus should not require a change in the model, only a change in the inferential summaries.
Contrasts are a way to structuring the effects within a source of variation. In a multilevel modelling context, a contrast is simply a group-level coefficient. Introducing contrasts into an ANOVA allows a further decomposition of variance. Figure 3 illustrates for a 5×5 latin square experiment (this time, not a split plot): the left plot in the figure shows the standard ANOVA, and the right plot shows a contrast analysis including linear trends for the row, column and treatment effects. The linear trends for the columns and treatments are large, explaining most of the variation at each of these levels, but there is no evidence for a linear trend in the row effects.

Figure 3
ANOVA displays for a 5×5 latin square experiment (an example of a crossed three-way structure): (a) with no group-level predictors, (b) contrast analysis including linear trends for rows, columns and treatments. Note: See also the plots of coefficient estimates and trends in Figure 4.
Figure 4 shows the estimated effects and linear trends at each level (along with the raw data from the study), as estimated from a multilevel model. This plot shows in a different way that the variation among columns and treatments, but not among rows, is well explained by linear trends.

Figure 4

Estimates ±1 standard error for the row, column, and treatment effects for the latin square experiment summarized in Figure 3. Note: The five levels of each factor are ordered, and the lines display the estimated linear trends.
Column effects

(a) Row
4.3 Non-exchangeable models

In all the ANOVA models we have discussed so far, the effects within any batch (source of variation) are modelled exchangeably, as a set of coefficients with mean 0 and some variance. An important direction of generalization is to non-exchangeable models, such as in time series, spatial structures (Besag and Higdon, 1999), correlations that arise in particular application areas such as genetics (McCullagh, 2005), and dependence in multi-way structures (Aldous, 1981; Hodges et al., 2005). In these settings, both the hypothesis-testing and variance-estimating extensions of ANOVA become more elaborate. The central idea of clustering effects into batches remains, however. In this sense, ‘analysis of variance’ represents all efforts to summarize the relative importance of different components of a complex model.

5 ANOVA compared with linear regression

The analysis of variance is often understood by economists in relation to linear regression (for example, Goldberger, 1964). From the perspective of linear (or generalized linear) models, we identify ANOVA with the structuring of coefficients into batches, with each batch corresponding to a ‘source of variation’ (in ANOVA terminology). As discussed by Gelman (2005), the relevant inferences from ANOVA can be reproduced by using regression – but not always least-squares regression. Multilevel models are needed for analysing hierarchical data structures such as ‘split-plot designs’, where between-group effects are compared with group-level errors, and within-group effects are compared with data-level errors.

Given that we can already fit regression models, what do we gain by thinking about ANOVA? To start with, the display of the importance of different sources of variation is a helpful exploratory summary. For example, the two plots in Figure 1 allow us to quickly understand and compare two multilevel logistic regressions, without getting overwhelmed with dozens of coefficient estimates.

More generally, we think of the analysis of variance as a way of understanding and structuring multilevel models – not as an alternative to regression but as a tool for summarizing complex high-dimensional inferences, as can be seen, for example, in Figure 2 (finite-population and super-population standard deviations) and Figures 3 and 4 (group-level coefficients and trends).

Varying coefficient models offer a compromise between fully nonparametric and parametric models by allowing for the desired flexibility of the response coefficients of standard regression models to uncover hidden structures in the data without running into the serious curse of the dimensionality issue.

Keywords
functional coefficient models; heteroskedasticity; least squares; linear regression models; maximum likelihood; nonparametric estimation; parameter heterogeneity; random coefficients model; smooth coefficient models; tuning variables; varying coefficient models

Article
One of the most interesting forms of nonlinear regression models is the varying coefficient model (VCM). Unlike the linear regression model, VCMs were introduced by Hastie and Tibshirani (1993) to allow the regression coefficients to vary systematically and smoothly in more than one dimension. It is worth noting the distinction between the VCM and the so-called random coefficients model, which assumes that the coefficients vary non-systematically (randomly). Versions of the VCM are encountered in the literature as functional coefficient models (see Cai, Fan and Yao, 2000) and smooth coefficient models (see Li et al., 2002).

VCMs are very useful tools in applied work in economics as they can be used to model parameter heterogeneity in a general way. For example, Durlauf, Kourtellos and Minkin (2001) estimate a version of the Solow model that allows the parameters for each country to vary as functions of initial income. This work is extended in Kourtellos (2005), who finds parameter dependence on initial literacy, initial life expectancy, expropriation risk and ethnolinguistic fractionalization. Li et al. (2002) use the above smooth coefficient model to estimate the production function of the non-metal mineral industry in China. Stengos and Zacharias (2006) use the same model to examine an intertemporal hedonic model of
the personal computer market, where the coefficients of the hedonic regression were unknown functions of time. Hong and Lee (2003) forecast the nonlinearity in the conditional mean of exchange rate changes using a VCM that allows the autoregressive coefficients to vary with investment positions. Ahmad, Leelahanon and Li (2005) apply the VCM in the estimation of a production function in China's manufacturing industry to show that the marginal productivity of labour and capital depends on the firm's R&D values. Mamuneas, Savvides and Stengos (2006) study the effect of human capital on total factor productivity in an empirical growth framework. In what follows we present the basic structure of the standard VCM specification as it appears in the literature and then proceed to discuss certain aspects of estimation and some of its recent generalizations.

**Basic specification**

Consider the following VCM

\[ y_i = \beta(z_i)'X_i + u_i \]  

(1)

with \( E(u_j|X_j) = 0 \), where \( X_i = (1, x_{i1}, \ldots, x_{ip})' \) is a \( p \) dimensional vector of slope regressors and \( \beta(z_i)' = (\beta_1(z_{i1}), \beta_2(z_{i2}), \ldots, \beta_p(z_{ip})) \) is a \( p \) dimensional vector of varying coefficients, which take the form of unknown smooth functions of \( z_{i1}, z_{i2}, \ldots, z_{ip} \), respectively. Notice that \( \beta_1(z_i) \) is a varying intercept that measures the direct relationship between the tuning variable \( z_i \) and the dependent variable in a nonparametric way. We refer to the variables \( z_i \)'s as tuning variables, and they can be one-dimensional or multidimensional. These functions map the tuning variables into a set of local regression coefficient estimates that imply that the effect of \( X_i \) on \( y_i \) will not be constant but rather it will vary smoothly with the tuning variables. These tuning variables could take the form of a scalar like time or it could be a vector of dimension \( q \). A common situation in the literature arises when the \( z_j \) is the same for all \( j \).

It is worth noting that the VCM (1) is a very flexible and rich family of models. One of the reasons is that the general additive separable structure of (1) offers also a very useful compromise to the general high-dimensional nonparametric regression that is known to suffer from the curse of dimensionality. This allows for nonparametric estimation even when the conditioning regressor space is in high dimensional. Another is that it nests many well-known models as a special case. For instance, consider the following cases. If \( \beta_j(z_{ij}) = \beta_j \), for all \( j \) then we are dealing with the usual linear model. If \( \beta_j(z_{ij}) = \beta_j^1 z_{ij} \) for some variable \( j \), we simply have the interaction term \( \beta_j x_{ij} z_{ij} \) entering the regression function. If \( x_i = c \) (a constant) or if \( z_{ij} = x_{ij} \) for all \( j = 1, \ldots, p \), then the model takes the generalized additive form where the additive components are unknown functions (see Hastie and Tibshirani, 1990;
We now set out some estimation issues. A popular estimation approach is based on local polynomial regression, as illustrated by Fan (1992), Fan and Gijbels (1996), and Fan and Zhang (1999), which we present in the context of a random sample design. Given a random sample \( \{(z_i, X_i, Y_i)\}_{i=1}^{n} \), the estimation procedure solves a simple local least squares problem. To be precise, for each given point \( z_0 \) the functions \( \beta_j(z) \), \( j = 1, \ldots, p \) are approximated by local linear polynomials \( \hat{\beta}_j(z) \approx c_{j0} + c_{j1}(z - z_0) \) for \( z \) in a neighborhood of \( z_0 \). This leads to the following weighted local least squares problem:

\[
\sum_{i=1}^{n} \left[ v_i - \sum_{j=1}^{p} \left( c_{j0} + c_{j1}(z - z_0) \right) X_{ij} \right]^2 K_h(z_i - z_0)
\]

for a given kernel function \( K \) and bandwidth \( h \), where \( K_h(\cdot) = K(\cdot/h) / h \). While this method is simple, it is implicitly assumed that the functions \( \beta_j(z) \) possess the same degrees of smoothness and hence can be approximated equally well in the same interval. Fan and Zhang (1999) allow for different degrees of smoothness for different coefficient functions by proposing a two-stage method. This is similar in spirit to what Huang and Shen (2004) do for global smoothers using regression splines but allowing each coefficient function to have different (global) smoothing parameters.

An attractive alternative to local polynomial estimation is a global smoothing method based on general series methods such as polynomial splines and trigonometric approximation (see Ahmad, Leelahanon and Li, 2005; Huang, Wu and Zhou, 2004; Huang and Shen, 2004; Xue and Yang, 2006a). All these papers emphasize the computational savings from having to solve only one minimization problem. Ahmad, Leelahanon and Li stress the efficiency gains of the series approach over a kernel-based approach when one allows for conditional heteroskedasticity. We should note that the inference for the estimated coefficients will differ for different choices of approximation, and the asymptotic properties of such estimators are generally not easy to obtain.

Although the model was initially developed for i.i.d. data, it has been extended for time series data by Chen and Tsay (1993), Cai, Fan, and Yao (2000), Huang and Shen (2004), and Cai (2007) for strictly stationary processes with different mixing conditions. The coefficient functions typically now become functions of time and/or lagged values of the dependent variable. It is worth noting that estimation issues such as bandwidth selection are similar, as in the i.i.d. data case (see Cai, 2007). The varying coefficient model has also been employed to analyse longitudinal data (see Brumback and Rice (1998), Hoover et al. (1998), and Huang, Wu and Zhou (2004).

The partially linear varying coefficient model
An interesting special case of eq. (1), where the unknown coefficient functions depend on a common \( z_i \), is the partially linear VCM. Here some of the coefficients are constants (independent of \( z_i \)). In that case, eq. (1) can be rewritten as

\[
y_i = \alpha' W_i + \beta(z_i)' X_i + u_i
\]

where \( W_i \) is the \( i \)th observation on a \((1 \times q)\) vector of additional regressors that enter the regression function linearly. The estimation of this model requires some special treatment as the partially linear structure may allow for efficiency gains, since the linear part can be estimated at a much faster rate, namely, \( \sqrt{n} \).

The partially linear VCM has been studied by Zhang, Lee and Song (2002), Xia, Zhang and Tong (2004), Ahmad, Leelahanon and Li (2005), and Fan and Huang (2005). Zhang, Lee and Song (2002) suggest a two-step procedure where the coefficients of the linear part are estimated in the first step using polynomial fitting with an initial small bandwidth using cross validation (see Hoover et al., 1998). In other words, the approach is based on under-smoothing in the first stage. Then these estimates are averaged to yield the final first-step linear part estimates which are then used to redefine the dependent variable and return to the environment of eq. (1), where local smoothers can be applied as described above. Alternatively, Xia, Zhang and Tong (2004) separate the estimation of \( \gamma \) from that of \( \beta(z_i) \) by noting that the former can be estimated globally, but the latter locally. This is what they call a ‘semi-local least squares procedure’, and they achieve a more efficient estimate of \( \gamma \) without under-smoothing using standard bandwidth selection methods. Once \( \gamma \) has been estimated, then again the linear part can be used to redefine the dependent variable and return to the environment of eq. (3).

More recently, Fan and Huang (2005) use a profile least squares estimation approach to provide a simple and useful method for (3). More precisely, they construct a Wald test and a profile likelihood ratio test for the parametric component that share similar sampling properties. More importantly, they show that the asymptotic distribution of the profile likelihood ratio test under the null is independent of nuisance parameters, and follows an asymptotic \( \chi^2 \) distribution. They also propose a generalized likelihood ratio test statistic to test whether certain parametric functions fit the nonparametric varying coefficients. This hypothesis test includes testing for the significance of the slope variables \( X \) (zero coefficients) and the homogeneity of the model (constant coefficients). Other work on specification testing includes Li et al. (2002), Cai, Fan and Yao (2000), Cai (2007), Yang et al. (2006) that mainly rely on bootstrapping in their implementation.

**Generalizations and Extensions**

A useful generalization of (1) is to allow the dependent variable to be related to the regression function
nonlinearly $m(X_i, Z_i) = \beta(z_i)'X_i$ via some given link function $g(\cdot)$

$$y_i = g(\beta(z_i)'X_i) + u_i$$

This generalization is known as the generalized varying coefficient model and was originally proposed by Hastie and Tibshirani (1993). Cai, Fan, and Li (2000) study this model using local polynomial techniques and propose an efficient one-step local maximum likelihood estimator. Notice that if $g(\cdot)$ is the normal CDF then (4) generalizes the standard tool of the discrete choice literature, namely the probit model.

Another strand of the literature allowed for a multivariate tuning variable $z_l$, $l = 1, 2, ..., q$. Although Hastie and Tibshirani (1993) proposed a back-fitting algorithm to estimate the varying coefficient functions, they did not provide any asymptotic justification. The most notable advance in this context has been by Xue and Yang (2006a), who propose a generalization of the VCM as in (1) that allows the varying coefficients to have an additive coefficient structure on regression coefficients to avoid the curse of dimensionality

$$\beta_j(z) = \gamma_{j0} + \gamma_{j1}(z_1) + \cdots + \gamma_{jq}(z_q) \text{ for all } j.$$

Under mixing conditions, Xue and Yang (2006a) propose local polynomial marginal integration estimators, while Xue and Yang (2006b) study this model using polynomial splines.

Finally, Cai et al. (2006) have shifted the discussion to consider a structural VCM. They examine the case of endogenous slope regressors, and propose a two-stage IV procedure based on local linear estimation procedures in both stages. We believe that this line of research is fruitful for economic applications.

**Conclusion**

VCMs have increasingly been employed as useful tools that allow for a compromise between fully nonparametric and parametric models. This compromise allows for the desired flexibility to uncover hidden structures that underlie the response coefficients of standard regression models without running into the serious curse of the dimensionality issue. More importantly, the structure of the VCM that allows the regression coefficients to vary with a tuning variable is very appealing in many economic applications, for it has a natural interpretation of non-constant marginal effects.

Veblen goods

B. Curtis Eaton

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

conspicuous consumption; leisure; leisure class; relative consumption trap; status and economics; upward-sloping demand curves; Veblen goods; Veblen, T.; well-being

Article

The utility that an individual derives from a Veblen good is an increasing function of the individual's consumption of the good relative to the consumption of others.

In The Theory of the Leisure Class, Thorstein Veblen observed that people value status, and further that in modern societies one's status is determined primarily by one's relative consumption of highly visible goods. ‘In order to gain and hold the esteem of men it is not sufficient merely to possess wealth … The wealth … must be put in evidence, for esteem is awarded only on evidence’ (1899, p. 36). The evidence consists of the conspicuous consumption of certain costly goods as prescribed by ‘the accredited cannons of [conspicuous] consumption, the effect of which is to hold the consumer up to a standard of expensiveness and wastefulness in his consumption of goods’ (1899, p. 116). Veblen was certainly not the first person to articulate the view that esteem can be achieved by conspicuous displays of wealth, but he saw more clearly than others the futility and wastefulness of this form of status seeking.

Following Leibenstein (1950), much of the literature on Veblen goods has focused on the possibility that the demand curve might be upward sloping. The inefficiency or wastefulness associated with Veblen goods is perhaps a more serious matter – see Hopkins and Kornienko (2004) for a theoretical analysis. Veblen seems to have thought that beyond some modest level of affluence societies get caught in what might be called the relative consumption trap in which all added productivity is soaked up by the wasteful consumption of Veblen goods with no effect on well-being: ‘The need of conspicuous waste … stands ready to absorb any increase in the community's industrial efficiency or output of goods, after the most elementary physical wants have been provided for’ (1899, p. 110).

The recent literature on perceived well-being suggests that affluent societies may in fact be caught in this trap. A number of studies have shown that the correlation of average well-being and per capita income in affluent societies is very weak, in some cases non-existent. Much of the evidence is surveyed
Veblen goods: The New Palgrave Dictionary of Economics

in Robert Frank's (1999) provocative book, *Luxury Fever*. Others have shown that an individual's well-being is negatively associated with the incomes of one's neighbours, and further that the effects on one's well-being of an increase in one's own income and an increase of the same magnitude in the average income of one's neighbours are approximately offsetting (see Luttmer, 2005, for example).

With the aid of a simple representative agent model, we can readily see how affluent societies can get stuck in the relative consumption trap. There is a continuum of agents, all of whom have identical preferences and budgets. Preferences of a representative person are captured in the following utility function:

$$U_r(x_r, y_r, v_r) = D(v_r - v) + F(x_r) + G(y_r),$$

where $v_r, x_r, y_r$ are, respectively, quantities of a pure Veblen good, leisure, and a standard consumption good, and $v$ is average consumption of the Veblen good. The Veblen good is pure in the sense that the utility derived from it, $D(v_r - v)$, is dependent only on relative consumption, $v_r - v$. The functions $D, F$ and $G$ are strictly increasing and concave. Leisure and the standard good are essential, but the Veblen good is not ($D'(0)$ is finite). Each individual is endowed with 1 unit of time to be allocated to leisure and work, and with asset income $a$. The wage rate is $w$, and the prices of the Veblen and standard goods are both 1.

For an interior solution to the individual's choice problem, the following marginal conditions must hold:

$$\frac{F'(x_r)}{w} = G'(y_r) = D'(v_r - v).$$

In addition the budget constraint, $wx_r + vy_r + v_r = w + a$, will be satisfied.

Since everyone is identical, in equilibrium $v_r = v$, so the conditions that characterize an interior equilibrium are

$$\frac{F'(x^*)}{w} = G'(y^*) = D'(0),$$

and
Notice that, in equilibrium, the marginal value of the Veblen good, $D'(0)$, is independent of $w$ and $a$, and since $G'(y^*) = D'(0)$, so too is the equilibrium quantity of the standard good.

What happens as $a$ increases? Clearly, $y^*$ doesn't change, and neither does $x^*$, since $F'(x^*)/w = G'(y^*)$ and $w$ hasn't changed. So all of the added purchasing power is devoted to the Veblen good, and, since no one's relative consumption of the Veblen good has changed, there will be no change in equilibrium utility.

What happens as $w$ increases? As in the first scenario, $y^*$ doesn't change, but $w$ having increased, $x^*$ must decrease to satisfy $F'(x^*)/w = G'(y^*)$. But this implies that the increase in expenditure on the Veblen good ($dv^*$) exceeds the increase in full income ($dw^*$), so in this case more than all of the added purchasing power is soaked up by the Veblen good. In addition, since neither $y^*$ nor equilibrium relative consumption of the Veblen good changes, and $x^*$ decreases, equilibrium utility decreases.

So, in this model, if the equilibrium is interior, then

$$
\frac{dy^*}{da} = 0, \frac{dx^*}{da} = 0, \frac{dv^*}{da} = 1, \frac{dy^*}{dw} = 0, \frac{dx^*}{dw} < 0, \frac{dv^*}{dw} > 1, \frac{du^*}{dw} < 0.
$$

Of course, the equilibrium is not necessarily interior. In particular, since $D'(0)$ is finite, unless the society is sufficiently affluent, in equilibrium nothing is spent on the Veblen good ($v^*=0$). But once the society is affluent enough so that it begins to squander its resources on the wasteful Veblen good, it is stuck in the relative consumption trap.

Veblen, Thorstein Bunde (1857–1929)

Geoffrey M. Hodgson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article outlines the work of the American institutional economist Thorstein Veblen (1857–1929), stressing his critique of neoclassical economics and his development of an alternative, evolutionary approach to the analysis of social, economic and technological change. Veblen's analytical approach to both technology and institutions is discussed, as well as his explicit application of the evolutionary ideas from Darwinian biology to economics.

Article

Thorstein Veblen was one of the most influential economists of the early 20th century and one of the founders of the American school of institutional economics. Veblen was the fourth son and sixth child of Norwegian immigrants who settled in eastern Minnesota in the United States. Educated at Carleton College, Johns Hopkins University, Yale University and Cornell University, he took various university posts at Chicago, Stanford, Missouri and New York. At Johns Hopkins he came in contact with the pragmatist philosopher Charles Sanders Peirce, and at Yale he was influenced by William Graham Sumner. Veblen read widely in biology, psychology and philosophy, as well as the social sciences. The works of Immanuel Kant, Charles Darwin, William James, Karl Marx, William McDougall and Herbert Spencer also made an enduring mark. Despite the popularity of his ideas, Veblen's career was marred by scandal and he never held a senior academic post (Jorgensen and...

Jorgensen, 1999). He died in meagre circumstances in California.

Several of his most important theoretical works date from the 1890s, when he was at the University of Chicago. In 1898 he published his classic article ‘Why is Economics Not an Evolutionary Science?’ in the Quarterly Journal of Economics. The following year saw the appearance of his first book The Theory of the Leisure Class. Although this is an original and sophisticated theoretical work, its mockery of the wasteful rich turned it into a bestseller. Other academic articles followed in the Quarterly Journal of Economics, the Journal of Political Economy and elsewhere, the most important of which have been collected in The Place of Science in Modern Civilization and Other Essays (1919). These articles provided a critique of ‘neoclassical’ economics (a term he coined to refer to equilibrium-oriented approaches involving individual utility maximization) and suggestions of a new approach to economics on ‘evolutionary’ and ‘Darwinian’ lines.

He is remembered today as the founder of the school of ‘institutional economics’ that prospered in the United States between the first and second world wars. This school involved leading American economists such as John Maurice Clark, John Rogers Commons and Veblen’s student, Wesley Clair Mitchell.

However, Veblen and his followers did not construct an integrated system of economic theory. This is partly because the original foundations of Veblenian institutionalism were challenged. Pragmatist philosophy, instinct-habit psychology and evolutionary ideas had been foundational for Veblen's thought. However, by the 1920s they had lost much of their former popularity. Thus, at the high point of its influence, American institutionalism faced fundamental philosophical and theoretical difficulties. After 1940, the ‘old’ institutional economics lost ground to the rising generation of formal and mathematically inclined theorists. By the 1960s the American institutional school was confined to a small minority of adherents. However, in economics in recent years there has been a revival of interest in both evolutionary ideas and the legacy of the ‘old’ institutional school.

Veblen (1919, p. 73) argued that neoclassical economics adopted a faulty and ‘hedonistic’ psychology, involving ‘a passive and substantially inert and immutably given human nature’. He criticized the idea of the individual as a given ‘globule of desire’, lambasting the neoclassical picture of the optimizing and omniscient economic agent as ‘a lightning calculator of pleasures and pains’. He saw this ‘economic man’ as having ‘neither antecedent nor consequent’, lacking an account of how human wants are formed and portraying humans as utility-maximizing automata. Veblen (1914) proposed an alternative theory of human agency, in which ‘instincts’ such as ‘workmanship’, ‘emulation’, ‘predatoriness’ and ‘idle curiosity’ play a major role. Habit and instinct replaced the utilitarian pleasure-pain principle.

Following the pragmatist philosophy of Peirce and James, Veblen rejected the Cartesian notion of the supremely rational and calculating individual, instead seeing agents as propelled in the main by habits and customs. Habits of thought provide the point of view from which facts and events are interpreted. When they are shared and reinforced within a society or group, individual habits assume the form of socio-economic institutions. In turn, institutions create and reinforce habits of action and thought: ‘The situation of today shapes the institutions of tomorrow through a selective, coercive process, by acting upon men's habitual view of things, and so altering or fortifying a point of view or a mental attitude handed down from the past’ (Veblen, 1899, pp. 190–1).

In The Theory of the Leisure Class and elsewhere, he argued that consumption is a ‘conspicuous’ and social process. Through consumption, humans signal status and social position, and thereby stimulate the desires of others. Accordingly, individual tastes are malleable and the idea of unalloyed ‘consumer
Veblen saw conventions, customs and institutions as repositories of social knowledge. Institutional adaptations and behavioural norms were stored in individual habits and could be passed on by education or imitation to succeeding generations. His explanations of economic growth privileged knowledge and institutions, rather than the accumulation of physical assets.

Veblen addressed the ‘evolutionary’ processes of innovation and transformation in a modern economy. Neoclassical theory is defective in this respect because it indicated ‘the conditions of survival to which any innovation is subject, supposing the innovation to have taken place, not the conditions of variational growth’ (Veblen, 1919, pp. 176–7). He saw it as important to consider why innovations take place, and not merely to dwell over equilibrium conditions with given technological possibilities. The question for him was not how things stabilize themselves in a ‘static state’, but how they endlessly grow and change.

Veblen saw Darwinian evolutionary principles as crucial to the understanding of the processes of institutional and technological development in a capitalist economy. He was the first economist to argue at length that Darwinian evolutionary principles should be applied to economics. He upheld that economics should become an ‘evolutionary’ and ‘post-Darwinian’ science. There is a current revival in ‘evolutionary’ approaches in economics but the Veblenian precedent for this type of approach is not always acknowledged.

Darwinian evolution involves three essential features. First, there must be sustained variation among the members of a species or population. Variations may be random or purposive in their origin, but without them, as Darwin insisted, natural selection cannot operate. Second, there must be some principle of heredity or continuity involving some mechanism through which individual characteristics are passed on to succeeding generations. Third, natural selection operates because better-adapted organisms leave increased numbers of offspring, or because the variations that are preserved bestow advantage in the struggle for survival.

Veblen applied the same three Darwinian principles to economic evolution. He recognized the role of creativity and novelty with his concept of ‘idle curiosity’. Habits and institutions were regarded as relatively durable heritable traits. Concerning selection, Veblen (1899, p. 188) wrote: ‘The life of man in society, just as the life of other species, is a struggle for existence, and therefore it is a process of selective adaptation. The evolution of social structure has been a process of natural selection of institutions.’ This did not mean that social phenomena were to be explained wholly or largely in biological terms, but that Darwinian principles could be applied to social and economic units and processes.

Veblen saw Darwinian evolutionary processes as open-ended and suboptimal. Unlike advocates of laissez faire, he did not use Darwinian principles to justify market competition. He was critical of apologetic tendencies in social science which regard existing institutions as necessarily efficient or optimal. He described particularly regressive or disserviceable institutions as ‘archaic’, ‘ceremonial’ or even ‘imbecile’. Furthermore, he used Darwinian ideas to rebut of Marx's teleological suggestions that history was leading inevitably to a communist future.

Like Darwin, Veblen emphasized the importance of processual, causal explanation. Although he did not use the word, he had an appreciation of Darwinian evolution as an ‘algorithmic’ process. Veblen used phrases such as ‘cumulative causation’, ‘theory of a process, of an unfolding sequence’ and ‘impersonal sequence of cause and effect’ to connote the same idea. This focus on algorithmic processes is revolutionary and modern; it directs attention to ongoing processes rather than static equilibria alone.
Consequently, rather than taking individual reasons or preferences as themselves sufficient to understand motivations, Veblen pointed to the need for causal explanations of reasons or preferences themselves. He did not underestimate the importance of human intentionality – but it had to be explained rather than assumed. Such explanations involved the evolution of social institutions and their interplay with biological and psychological characteristics. He thus acknowledged processes of dual inheritance or coevolution (again to use modern terms) where there was evolution and transmission at both the instinctive and the cultural levels.

Along with the assumption of fixed preference functions, Veblen also criticized the widespread assumption in economic theory of a fixed set of technological possibilities. Technological change can challenge established institutions and vested interests. In *The Theory of Business Enterprise* and elsewhere Veblen distinguished between industry (making goods) and business (making money). This dichotomy parallels the earlier suggestion in *The Theory of the Leisure Class* that there is a distinction between serviceable consumption to satisfy human need and conspicuous consumption for status and display. Subsequently, institutionalists such as Clarence E. Ayres elevated the different conflict between technology and institutions into a universal principle, and dubbed it the ‘Veblenian dichotomy’. This is misleading, because Veblen never saw such a conflict as universal, and he saw institutions as the indispensable fabric of economic life (Hodgson, 2004).

In the last two decades of the 20th century, evolutionary and institutional ideas again become prominent in economics. Pragmatism has again become fashionable in philosophy and the concept of habit has returned to psychology. Many of Veblen's ideas, including those on institutional evolution and the role of knowledge in economic growth, now seem strikingly modern. The conditions exist for a deeper appreciation of his contribution to economics and social science.

vector autoregressions

Tao Zha
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Vector autoregressions are a class of dynamic multivariate models introduced by Sims (1980) to macroeconomics. These models have been primarily used to bring empirical regularities out of the time series data, to provide forecasting and policy analysis, and to serve as a benchmark for model comparison. Economic applications often impose more restrictions on vector autoregressions than originally thought necessary. Recent econometric developments have made it feasible to handle vector autoregressions with a wide class of restrictions and have narrowed the gap between these models and dynamic stochastic general equilibrium models.

Keywords

Article

Vector autoregressions (VARs) are a class of dynamic multivariate models introduced by Sims (1980) to macroeconomics. These models arise mainly as a response to the ‘incredible’ identifying assumptions embedded in traditional large-scale econometric models of the Cowles Commission. The traditional approach uses predetermined or exogenous variables, coupled with many strong exclusion restrictions, to identify each structural equation. VARs, by contrast, explicitly recognize that all economic variables are interdependent and thus should be treated endogenously. The philosophy of VAR modelling begins with a multivariate time series model that has minimal restrictions, and gradually introduces identifying information, with emphasis always placed on the model's fit to data.
While the traditional econometric approach allows disturbances or shocks to structural equations to be correlated, the VAR methodology insists that structural shocks ought to be independent of one another. The independence assumption plays an essential role in achieving unambiguous economic interpretations about structural shocks such as technology and policy shocks; it can be tested using recently developed econometric tools (Leeper and Zha, 2003). The bulk of VAR work has focused on identifying structural shocks as a way to specify the contemporaneous relationships among economic variables. With most dynamic relationships unrestricted, the intent of such an identifying strategy is to construct models that have both economic interpretability and superior fit to data. Dynamic responses to a particular shock, called impulse responses, are often used as economic interpretations to the model. They summarize the properties of all systematic components of the system and have become a major tool in modern economic analysis.

Modelling policy shocks explicitly is important in addressing the practical importance of the Lucas critique. If policy switches regime, such a change may be viewed as a sequence of random shocks from the public's viewpoint (Sims, 1982). If this sequence displays a persistent pattern, the public will adjust its expectations formation accordingly and the Lucas critique may be consequential. For the practice of monetary policy, however, it is an empirical question how significant this adjustment is. Leeper and Zha (2003) construct an econometric measure from the sequence of policy shocks implied by regime switches to gauge whether the public's behaviour could be well approximated by a linear model. This measure is particularly useful if counterfactual exercises regarding the effects of policy changes are conducted with respect to the Lucas critique.

VARs have also been used for other tasks. Armed with a Bayesian prior, VARs have been known to produce out-of-sample forecasts of economic variables as well as, or even better than, those from commercial forecasting firms (Litterman, 1986; Geweke and Whiteman, 2006). Because of their ability to forecast, VARs have given researchers a convenient diagnostic tool to assess the feasibility or plausibility of real-time policy projections of other economic models (Sims, 1982). VARs have been increasingly used for policy analysis and as a benchmark for comparing different dynamic stochastic general equilibrium (DSGE) models. Restrictions on lagged coefficients have been gradually introduced to give more economic interpretations to individual equations. All these developments are positive and help narrow the gap between statistical and economic models.

This article discusses these and other aspects of VARs, summarizes some key theoretical results for the reader to consult without searching for different sources, and provides a perspective on where future research in this area will be headed.

**General framework**

**Structural form**

VARs are generally represented in a structural form of which the reduced form is simply a byproduct. The general form is
\[ y_t' A = \sum_{l=1}^{p} y_{t-l}' A_l + z_t' D + \epsilon_t' \]

(1)

where \( y_t \) is an \( n \times 1 \) column vector of endogenous variables, \( A \) and \( A_l \) are \( n \times n \) parameter matrices, \( z_t \) is an \( h \times 1 \) column vector of exogenous variables, \( D \) is an \( h \times n \) parameter matrix, \( p \) is the lag length, and \( \epsilon_t \) is an \( n \times 1 \) column vector of structural shocks. The parameters of individual equations in (1) correspond to the columns of \( A, A_l, \text{ and } D \). The structural shocks are assumed to be i.i.d. and independent of one another:

\[
E(\epsilon_t | y_{t-s}, s > 0) = \mathbf{0}_{n \times 1}, \quad E(\epsilon_t \epsilon_t' | y_{t-s}, s > 0) = \mathbf{I}_{n \times n},
\]

where \( \mathbf{0}_{n \times n} \) is the \( n \times n \) matrix of zeros and \( \mathbf{I}_{n \times n} \) is the \( n \times n \) identity matrix. It follows that the reduced form of (1) is

\[ y_t' = \sum_{l=1}^{p} y_{t-l}' B_l + z_t' C + u_t', \]

(2)

where \( B_l = A_l A_l^{-1}, C = D A_l^{-1}, \text{ and } u_t' = \epsilon_t' A_l^{-1} \). The covariance matrix of \( u_t \) is \( \Sigma = (AA')^{-1} \).

In contrast to the traditional econometric approach, the VAR approach puts emphasis almost exclusively on the dynamic properties of endogenous variables \( y_t \) rather than exogenous variables \( z_t \). In most VAR applications, \( z_t \) simply contains the constant terms.

**Identification**

One main objective in the VAR literature is to obtain economically meaningful impulse responses to structural shocks \( \epsilon_t \). To achieve this objective, it is necessary to impose at least \( n(n-1)/2 \) identifying restrictions, often on the contemporaneous coefficients represented by \( A \) in the structural system (1). In his original work, Sims (1980) makes the contemporaneous coefficient matrix \( A \) triangular for identification. The triangular system, often called the recursive identification, has a ‘Wold chain causal’
Interpretation which is based on the timing of how shocks affect variables contemporaneously. It assumes that some shocks may influence only a subset of variables within the current period. This identification is still popular because it is straightforward to use and can yield some results that match widely held views. Christiano, Eichenbaum and Evans (1999) discuss extensively how recursive identification can be used in policy analysis.

There are fundamental economic applications that require identification under alternative assumptions rather than the recursive system. One familiar example is the determination of price and quantity as discussed in Sims (1986) and Gordon and Leeper (1994). Both variables are often determined simultaneously by the supply and demand equations in equilibrium; this simultaneity is inconsistent with recursive identification. Bernanke (1986) and Blanchard and Watson (1986) pioneered other applications of non-recursive identified VARs. Estimation of non-recursive VARs presents technical difficulties that are absent in recursive systems. These difficulties help explain the use of recursive VARs even if this maintained assumption is implausible. Recent developments in Bayesian econometrics, however, have made it feasible to estimate non-recursive VARs.

All of these works focus on the contemporaneous coefficient matrix. There are other ways to achieve identification. Blanchard and Quah (1993) and Gali (1992) propose using identifying restrictions directly on short-run and long-run impulse responses, which have been used in quantifying the effects of technology shocks and various nominal shocks, although the unreliable statistical properties of long-run restrictions are documented by Faust and Leeper (1997).

Many VAR applications rely on exact identification: the number of identifying restrictions equals \( n(n - 1)/2 \). This counting condition is necessary but not sufficient for identification. To see this point, consider a three-variable VAR with the following restrictions:

\[
A = \begin{bmatrix} * & * & 0 \\ 0 & * & * \\ * & 0 & * \end{bmatrix}
\]

where '*'s indicate unrestricted coefficients and 0's indicate exclusion restrictions. This VAR is not identified because in general there exist two distinct sets of structural parameters that deliver the same dynamics of \( Y_t \). For larger and more complicated systems with both short-run and long-run restrictions, there has been, until recently, no practical guidance as to whether the model is identified. The paper by Rubio-Ramirez, Waggoner and Zha (2005) develops a theorem for a necessary and sufficient condition for a VAR to be exactly identified. This theorem applies to a wide range of identified VARs, including those used in the literature. The basic idea is to transform the original structural parameters to the \((mp + n) \times n\) matrix \( F \) (which is a function of \( A, A_1, \ldots A_p, D \)) so that linear restrictions can be applied to each column of \( F \). The linear restrictions for the \( i \)th column of \( F \) can be summarized by the matrix \( Q_i \) of rank \( q_i \), where \( q_i \) is the number of restrictions. According to their theorem, the VAR model is exactly identified if and only if \( q_i = n - i \) for \( 1 \leq i \leq n \). This result gives the researcher a practical way to determine whether a VAR model is identified.
When the number of identifying restrictions is greater than \( \frac{n(n - 1)}{2} \), a VAR is over-identified. Allowing for over-identification is important since economic theory often implies more than \( \frac{n(n - 1)}{2} \) restrictions. Moreover, many economic applications call for restrictions on the model's parameters beyond the contemporaneous coefficients (Cushman and Zha, 1997). Restrictions on the lag structure, such as block recursions, offer an effective way to handle over-parameterization when the lag length is long (Zha, 1999). Classical or Bayesian econometric procedures can be used to test over-identifying restrictions. A review of theoretical results for Bayesian estimation and inference for both exactly identified and over-identified VARs is discussed below.

### Impulse responses

Impulse responses are most commonly used in the VAR literature and are defined as \( \frac{\partial \mathbf{y}_t + \epsilon_s}{\partial \epsilon_t} \) for \( s \geq 0 \). Let \( \Phi_s \) be the \( n \times n \) impulse response matrix at step \( s \) and the \( i \)th row of \( \Phi_s \) be responses of the \( n \) endogenous variables to the \( i \)th one-standard-deviation structural shock. One can show that the impulse responses can be recursively updated as

\[
\phi_s = \phi_{s-1}\mathbf{B}_1 + \ldots + \phi_{s-p}\mathbf{B}_p
\]

(3)

with the convention that \( \phi_0 = \mathbf{A}^{-1} \) and \( \phi_v = \mathbf{0} \) \( n \times n \) for \( v < 0 \).

The concept of impulse response is economically appealing and is used in strands of literature other than VAR work. For example, impulse responses to technology shocks or monetary policy shocks in a DSGE have been often compared to those in a VAR model. In empirical monetary economics, impulse responses of various macroeconomic variables to policy shocks have been a focal point in the recent debate on the effectiveness of monetary policy. These shocks can be thought of as shifts (deviations) from the systematic part of monetary policy that are hard to predict from the viewpoint of the public. It is sometimes argued that identified VARs are unreliable because certain conclusions are sensitive to the specific identifying assumptions. This argument is a sophism. All economic models, DSGE model and VARs alike, are founded on ‘controversial’ assumptions, and the results can be sensitive to these assumptions. What researchers should do is to select a class of models based on how well they fit to the data, analyse how reasonable the underlying assumptions are, and examine whether there are robust conclusions across models.

Christiano, Eichenbaum, and Evans (1999) and Rubio-Ramirez, Waggoner and Zha (2005) show some important robust results across different VAR models that have reasonable assumptions and fit to the data equally well. One prominent example is the robust conclusion that a large fraction of the variation in policy instruments, such as the short-term interest rate, can be attributed to the systematic response of policy to shocks originating from the private economy. Such a conclusion is expected of good monetary policy, but it also explains the subtle and difficult task of identifying monetary policy shocks separately.
vector autoregressions: The New Palgrave Dictionary of Economics

Estimation and inference

Bayesian prior

When one estimates a VAR model for macroeconomic time series data, there is a trade-off between using short and long lags. A VAR with a short lag is prone to mis-specification, and a VAR with a long lag length is likely to suffer from the over-fitting problem. The Bayesian prior proposed by Sims and Zha (1998) is designed to eliminate the over-fitting problem without reducing the dimension of the model. It applies to not only reduced-form but also identified VARs.

To describe this prior simply, let \( D \) contain only a constant term and thus \( D \) is a \( 1 \times n \) vector of parameters. Rewrite the structural system (1) in the compact form of \( y_t' A = x_t' F + \varepsilon_t' \), where

\[
x_t' = \left[ y_{t-1}' \Lambda y_t' - p z_t' \right], \quad F' = \left[ A' \Lambda A' \rho D' \right],
\]

and \( k = np + h \). For \( 1 \leq j \leq n \), let \( a_j \) be the \( j \)th column of \( A \) and \( f_j \) be the \( j \)th column of \( F \). The first component of the prior is that \( a_j \) and \( f_j \) have Gaussian distribution

\[
a_j \sim N(0, S) \quad \text{and} \quad f_j | a_j \sim N(Pa_j, H),
\]

where \( P' = \begin{bmatrix} 1 & 0 & \cdots & 0 & 0 \\ n \times n & n \times n & \cdots & n \times n & n \times 1 \end{bmatrix} \), which is consistent with the reduced-form random walk prior of Litterman (1986). The covariance matrices \( S \) and \( H \) are assumed to be diagonal matrices and are treated as hyperparameters. In principle, one could estimate these hyperparameters or integrate them out in a hierarchical framework. In practice, the values of these hyperparameters are specified before estimation. The \( i \)th diagonal element of \( S \) is \( \lambda_0 / \sigma_i \). The diagonal element of \( H \) that corresponds to the coefficient on lag 1 of variable \( i \) in equation \( j \) is \( (\lambda_0 \lambda_1 \lambda_2^\delta(i,j)) / (\sigma_j \lambda_3) \), where \( \delta(i,j) \) equals 1 if \( i = j \) and 0 otherwise. The diagonal element of \( H \) corresponding to the constant term is the square of \( \lambda_0 \lambda_4 \). The hyperparameter \( \lambda_0 \) controls the overall tightness of belief about the random walk feature, as well as tightness on the prior of \( A \) itself; \( \lambda_1 \) further controls the tightness of belief on random walk and the relative tightness on the prior of lagged coefficients; \( \lambda_2 \) controls the influence of variable \( i \) in equation \( j \); \( \lambda_3 \) controls the rate at which the influence of lag decreases as its length increases; and \( \lambda_4 \) controls the
relative tightness on the zero value of the constant term. The hyperparameters \( \sigma_i \) are scale factors to make the units uniform across variables, and are chosen at the sample standard deviations of residuals from univariate autoregressive models fitted to the individual time series in the sample (Litterman, 1986).

A VAR with many variables and a long lag is likely to produce relatively large coefficient estimates on distant lags and thus volatile sampling errors. The prior described here is designed to reduce the influence of distant lags and the unreasonable degree of explosiveness embedded in the system. It is essential for ensuring reasonable small-sample properties of the model, especially when there are relatively few degrees of freedom in a large VAR.

The aforementioned prior, however, does not take into account the features of unit roots and cointegration relationships embedded in many time series. For this reason, Sims and Zha (1998) add another component to their prior. This component uses Litterman's idea of dummy observations to express beliefs on unit roots and cointegration. Specifically, there are \( n + 1 \) dummy observations added to the original system, which can be written as

\[
Y_d A = X_d F + E,
\]

where \( E \) is a matrix of random shocks,

\[
Y_d = \begin{bmatrix}
\mu_5 \bar{v}_1^0 & 0 & 0 \\
0 & \ddots & 0 \\
0 & 0 & \mu_5 \bar{v}_n^0 \\
\mu_6 \bar{v}_1^0 & \cdots & \mu_6 \bar{v}_n^0
\end{bmatrix}, \quad c_d = \begin{bmatrix}
0 \\
\vdots \\
0 \\
\mu_6
\end{bmatrix},
\]

\[
X_d = \begin{bmatrix}
Y_d & \cdots & Y_d & c_d
\end{bmatrix},
\]

and \( \bar{v}_i^0 \) is the sample average of the \( p \) initial conditions for the \( i \)th variable of \( Y_t \) and \( \mu_5 \) and \( \mu_6 \) are hyperparameters. The first \( n + 1 \) dummy-observation equations in (5) express beliefs that all variables are stationary with means equal to \( \bar{v}_i^0 \)'s or cointegration is present. The larger the values of \( \mu_5 \) and \( \mu_6 \), the stronger these beliefs. Since the values of \( \lambda \)'s and \( \mu \)'s move in opposite directions to increase or loosen the tightness of the prior, the two symbols \( \lambda \) and \( \mu \) are kept distinct. In applied work, the values of the hyperparameters for quarterly data are typically set to \( \lambda_0 = 1, \lambda_1 = 0.2, \) and \( \lambda_2 = \lambda_3 = \lambda_4 = \mu_5 = \mu_6 = 1.0 \). For monthly data, \( \lambda_0 = 0.6, \lambda_1 = 0.1, \lambda_2 = 1.0, \lambda_4 = 0.1, \) and
vector autoregressions: The New Palgrave Dictionary of Economics

$\mu_5 = \mu_6 = 5.0$, while the choice of the lag decay weight $\lambda_3$ is somewhat complicated and is elaborated in Robertson and Tallman (1999).

By taking into account the cointegration relationships among macroeconomic variables, this additional component of the prior helps improve out-of-sample forecasting, reduces the difference in forecasting accuracy between using the vintage and final data, and produces robust impulse responses to monetary policy shocks across VARs with different identification assumptions (Robertson and Tallman, 1999; 2001). Furthermore, Leeper, Sims and Zha (1996) demonstrate that with this prior it is feasible to estimate VAR models with as many as 18 variables – far more than the current DSGE models can handle. Because the prior proposed by Sims and Zha (1998) reflects widely held beliefs in the behaviour of macroeconomic time series, it has been often used as a base line prior in the Bayesian estimation and inference of VAR models.

Marginal data density

If a model is used as a candidate for the ‘true’ data-generating mechanism, it is imperative that the model's fit to the data is superior to those of alternative models. Recent developments in Bayesian econometrics have made it feasible to compare nested and non-nested models for their fits to the data (Geweke, 1999). With a proper Bayesian prior, one can numerically compute the marginal data density (MDD) defined as

$$\int_{\Theta} \mathcal{L}(\mathbf{Y}_T | \varphi) \rho(\varphi) \, d\varphi,$$

(6)

where $\varphi$ is a collection of all the model’s parameters, $\Theta$ is the domain of $\varphi$, $\mathbf{Y}_T$ is all the data up to $T$, and $\mathcal{L}(\mathbf{Y}_T | \varphi)$ is the proper likelihood function. To determine the goodness of fit of a DSGE model, for example, one can compare its MDD with that of a VAR model (Smets and Wouters, 2003; Del Negro and Schorfheide, 2004).

As a VAR is often used as a benchmark for comparing different models, it is important that one compute its MDD efficiently and accurately. For an unrestricted reduced-form VAR as specified in (2), there is a standard closed-form expression for (6) so that no Markov chain Monte Carlo (MCMC) method is needed to obtain the MDD. For restricted (tightly parameterized) VARs implied by a growing number of economic applications, there is in general no closed-form solution to (6), and a numerical approximation to (6) is needed. Because of a high dimension in the VAR parameter space and possible simultaneity in an identified model, popular MCMC approaches such as importance sampling and modified harmonic mean methods require a long sequence of posterior draws to achieve numerical reliability in approximating (6), and thus are computationally very demanding. Chib (1995) offers a procedure for accurate evaluations of the MDD that requires the existence of a
The New Palgrave Dictionary of Economics

Gibbs sampler by partitioning $\mathbf{\Phi}$ into a few blocks. One can sample alternately from the conditional posterior distribution of one block of parameters given other blocks. While sampling between blocks entails additional simulations, the Chib algorithm can be far more efficient than other methods because each conditional posterior probability density function (PDF) can be evaluated in closed form. The objects needed to complete this algorithm are the closed-form prior PDF and the conditional posterior PDF for each block.

Because the prior discussed so far includes the dummy observations component, there is a question as to whether this overall prior has a standard PDF. To answer this question, it can be shown from (4) and (5) that the overall prior PDF is

$$a_j \sim N(0, \mathbf{\bar{S}}) \quad \text{and} \quad f_j a_j \sim N(\mathbf{P}a_j, \mathbf{\bar{H}}),$$

(7)

where $\mathbf{\bar{S}} = \mathbf{S}$ and $\mathbf{\bar{H}} = \left(\mathbf{X}_d^T \mathbf{X}_d + \mathbf{H}^{-1}\right)^{-1}$. The result (7) follows from the two claims:

$$\left(\mathbf{X}_d^T \mathbf{X}_d + \mathbf{H}^{-1}\right)^{-1} \left(\mathbf{X}_d^T \mathbf{Y} + \mathbf{H}^{-1} \mathbf{P}\right) = \mathbf{P},$$

$$\mathbf{Y}_d^T \mathbf{Y}_d + \mathbf{P}' \mathbf{H}^{-1} \mathbf{P} = \left(\mathbf{Y}_d^T \mathbf{X}_d + \mathbf{P}' \mathbf{H}^{-1}\right) \mathbf{P}.$$  

Given the prior (7), Waggoner and Zha (2003a) develop a Gibbs sampler for identified VARs with the linear restrictions studied in the VAR literature. These restrictions can be summarized as

$$Q_j a_j = \mathbf{0}_{n \times 1}, \quad R_j f_j = \mathbf{0}_{n \times k}, \quad j = 1, \ldots, n.$$  

(8)

If there are $q_j$ restrictions on $a_j$ and $r_j$ restrictions on $f_j$, the ranks of $Q_j$ and $R_j$ are $q_j$ and $r_j$. 

Let \( \mathbf{U}_j (\mathbf{R}_j) \) be an \( n \times q_j (n \times r_j) \) matrix whose columns form an orthonormal basis for the null space of \( \mathbf{Q}_j (\mathbf{R}_j) \). The conditions in (8) are satisfied if and only if there exist a \( q_j \times 1 \) vector \( \mathbf{b}_j \) and an \( r_j \times 1 \) vector \( \mathbf{g}_j \) such that \( \mathbf{a}_j = \mathbf{U}_j \mathbf{b}_j \) and \( \mathbf{f}_j = \mathbf{V}_j \mathbf{g}_j \). The vectors \( \mathbf{b}_j \) and \( \mathbf{g}_j \) are the free parameters of \( \mathbf{a}_j \) and \( \mathbf{f}_j \) dictated by the conditions in (8). It follows from (7) that the prior distribution of \( \mathbf{b}_j \) and \( \mathbf{g}_j \) is jointly normal.

As for the conditional posterior PDFs, it can be shown that the posterior distribution of \( \mathbf{g}_j \) conditional on \( \mathbf{b}_j \) is normal and that the posterior distribution of \( \mathbf{b}_j \) conditional on \( \mathbf{b}_i \) for \( i \neq j \) has a closed-form PDF and can be simulated from it exactly. These results enable one to use the efficient method of Chib (1995). The MDD calculated this way is reliable and requires little computing time. For example, it takes less than one minute to obtain a very reliable estimate of the MDD for a large VAR with 13 lags and 10 variables. Such accuracy and speed make it feasible to compare a large number of identified VARs with different degrees of restriction.

### Error bands

Because impulse responses are of central interest in interpreting dynamic multivariate models and helping guide the directions for new economic theory to be developed (Christiano, Eichenbaum and Evans, 2005), it is essential that measures of the statistical reliability of estimated impulse responses be presented as part of the process of evaluating models. The Bayesian methods reviewed so far in this essay make it feasible to construct the error bands around impulse responses. The error bands can contain any probability and are typically expressed in both .68 and .90 probability bands to characterize the shapes of the likelihood implied by the model.

The error bands of impulse responses reported in most VAR works are constructed as follows. One begins with the Gibbs sampler to draw \( \mathbf{b}_j \) and \( \mathbf{g}_j \) for \( j = 1, \ldots, n \). For each posterior draw, the free parameters \( \mathbf{b}_i \)'s and \( \mathbf{g}_i \)'s are transformed to the original structural parameters \( \mathbf{A}, \mathbf{A}_I (i = 1, \ldots, p) \), and \( \mathbf{D} \); then the impulse responses are computed according to (3). The empirical distribution for each element of the impulse responses is formed and the equal-tail .68 and .90 probability intervals around each element are computed. The probability intervals have exact small-sample properties from a Bayesian point of view; and .90 or .95 probability intervals have been used in the empirical literature to approximate classical small-sample confidence intervals when the high dimensional parameter space and a large number of nuisance parameters make it difficult or impossible to obtain exact classical inferences.

One issue related to the error bands around impulse responses, whose importance is beginning to be recognized, is normalization. A normalization rule selects the sign of each draw of impulse responses from the posterior distribution. If there is no restriction imposed on the sign of each column of the contemporaneous coefficient matrix \( \mathbf{A} \), then the likelihood or the posterior function remains the same when the sign of a column of \( \mathbf{A} \) is reversed. Without any sign restriction, the error bands for impulse responses would be symmetric around zero and thus the estimated responses would be determined to be imprecise.

The conventional normalization is to keep the diagonal of \( \mathbf{A} \) always positive, based on the notion that a choice of normalization cannot have substantive effects on the results. But this notion is mistaken. If an
identified VAR is non-recursive, normalization can generate ill-determined or unreasonably wide error bands around some impulse responses because some coefficients on the diagonal may be insignificantly different from zero.

Waggoner and Zha (2003b) show that normalized likelihoods can be different across normalization rules and that inappropriate normalization tends to produce a multi-modal likelihood. They propose a normalization rule designed to prevent the normalized likelihood from being spuriously multi-modal and thus avoid unreasonably wide error bands caused by the multi-modal likelihood. The algorithm for their normalization is straightforward to implement: for each posterior draw of $a_j$, keep $a_j$ if $e_j' A^{-1} a_j > 0$ and replace $a_j$ with $-a_j$ if $e_j' A^{-1} a_j < 0$, where $e_j$ is the $j$th column of the $n \times n$ identity matrix. This algorithm works for not only short-run but also long-run restrictions (Evans and Marshall, 2002).

Another important issue related to error bands, not addressed until recently, is the characterization of the uncertainty around estimated impulse responses not only at one particular point but also around the shape of the responses as a whole. Let $\Phi s(l, j)$ be the $s$-step impulse response of the $j$th variable to the $i$th structural shock. The associated error band is only pointwise. It is very unlikely in economic applications, however, that uncertainty about $\Phi s(l, j)$ is independent across $j$ or $s$. For example, the response of output to a policy shock is likely to be negatively correlated with the response of unemployment, and the response of inflation this period is likely to be positively correlated with the previous and next responses.

The procedure proposed by Sims and Zha (1999) takes into account these possible correlations across variables and across time. To use this procedure, one can simply stack all the relevant impulse responses into a column vector denoted by $\tilde{c}$, where the tilde refers to a posterior draw. From a large number of posterior draws, the mean $\tilde{c}$ and covariance matrix $\Omega$ of $\tilde{c}$ are computed. For each posterior draw $\tilde{c}$, the $k$th component $\tilde{c}_k = (\tilde{c} - \bar{c})' \bar{W}_k$ is calculated, where $\bar{W}_k$ is the eigenvector corresponding to the $k$th largest eigenvalue of $\Omega$. From the empirical distribution of $\tilde{c}_k$, one can tabulate different quantiles such as $\tilde{c}_k, .16$ and $\tilde{c}_k, .84$. Thus, the .68 probability error bands explained by the $k$th component of variation in the group of impulse responses can be computed as $\tilde{c}, .16 = \bar{c} + \tilde{c}_k, .16 \bar{W}_k$ and $\tilde{c}, .84 = \bar{c} + \tilde{c}_k, .84 \bar{W}_k$.

For a particular economic application, if it turns out that only one to three eigenvalues dominate the covariance matrix of $\tilde{c}$, these kinds of connecting-dots error bands can be useful in understanding the magnitudes and directions of uncertainty among a group of interrelated impulse responses. This method has proven to be particularly useful in economic applications that characterize the uncertainty around the entire paths, not just points one at a time (Cogley and Sargent, 2005; Nason and Rogers, 2006).

Markov-switching VARs

The class of VARs discussed thus far assumes that the parameters are constant over time. This assumption is made mainly for the technical constraint on estimation and inference, however. Many macroeconomic time series display patterns that seem impossible to capture by constant-parameter VARs. One prominent example is changes in volatility over time. In the VAR framework, volatility changes mean that the reduced-form covariance matrix $\Sigma$ is not constant. In policy analysis, there is a serious debate on whether the coefficients in the policy rule have changed over time, or whether the...
variances of shocks in the private sector have changed over time, or both. Time-varying VARs are designed to answer these kinds of questions. Stock and Watson (2003) use the reduced-form VAR framework to show that fluctuations in US business cycles can be largely explained by changes in $\Sigma$. Sims and Zha (2006b) identify the behaviour of monetary policy from the rest of the VAR system and show that changes in the coefficients in monetary policy are, at most, modest and the variance changes in shocks originating from the private sector dominate aggregate fluctuations.

There have been a number of studies on time-varying VARs that allow the coefficients or the covariance matrix of residuals or both to change over time. These models typically let all the coefficients drift as a random walk or persistent process. To the extent that this kind of modelling tries to capture possible changes in the model's parameters, the model tends to over-fit because the dimension of time variation embedded in the data is much lower than the model's specification. Conceptually, there is a problem of distinguishing shocks to the residuals from shocks to the coefficients. The inability to distinguish among these shocks makes it difficult to interpret the effects of, say, monetary policy shocks.

The Markov-switching VAR introduced by Sims and Zha (2006a) is designed to overcome the over-fitting problems present in the other time-varying VARs and, at the same time, maintain clear interpretation of structural shocks. It builds on the Markov-switching model of Hamilton (1989), but emphasizes ways to restrict the degree of time variation allowed in the VAR. It has a capability to approximate parameter drifts arbitrarily well with the growing number of states, while restricting the transition matrix to be concentrated on the diagonal. This feature also allows discontinuous jumps from one state to another, which appears to matter for aggregate fluctuations.

To see how this method works, suppose that the parameter $z_t$ drifts according to the process $z_t = \rho z_{t-1} + v_t$ where $v_t \sim N(0, \sigma^2)$. By discretizing this autoregressive process, one can let the probability of the transition from state $j$ to $i$ be proportional to

$$
\Pr \left[ z_t \in \left( \frac{\tau_i \sigma}{\sqrt{1 - \rho^2}}, \frac{\tau_{i+1} \sigma}{\sqrt{1 - \rho^2}} \right) \right] = \frac{\rho}{\sqrt{1 - \rho^2}} \left( 1 - \Phi \left( \frac{\tau_i - \tau_{i+1}}{\sqrt{1 - \rho^2}} \right) \right) - \Phi \left( \frac{\tau_i - \tau_{i+1}}{\sqrt{1 - \rho^2}} \right) - \frac{\rho}{\sqrt{1 - \rho^2}} \left( 1 - \Phi \left( \frac{\tau_{i+1} - \tau_{i+2}}{\sqrt{1 - \rho^2}} \right) \right) - \Phi \left( \frac{\tau_{i+1} - \tau_{i+2}}{\sqrt{1 - \rho^2}} \right),
$$

where $\Phi(\cdot)$ is the standard normal cumulative probability function. The values of $\tau$ divide up the interval between $-2$ and 2 (two standard deviations). For nine states, for example, one has $\tau_1 = -2$, $\tau_2 = -1.5$, $\tau_3 = -1$, ..., $\tau_8 = 1.5$, and $\tau_9 = 2$. Careful restrictions on the degree of time variation, as well as on the constant parameters themselves, will put VARs a step closer to DSGE modelling. Recent work by Davig and Leeper (2005) shows an example of how to use a DSGE model to restrict a VAR on monetary and fiscal policy.

Conclusion
There is a tension between models that have clear economic interpretations but offer a poor fit to data and models that fit well but have few a priori assumptions and are therefore less interpretable (Ingram and Whiteman, 1994; Del Negro and Schorfheide, 2004). The original philosophy motivating VARs assumes that the economy is sufficiently complex and that simplified theoretical models, while useful in organizing thought about how the economy works, generally abstract from important aspects of the economy. VAR modelling begins with the minimal restrictions on dynamic time-series models, explores empirical regularities that have been ignored by simple models, and insists on the model's fit to data. The emphasis on fit has begun to bear fruit, as an increasing array of dynamic stochastic general equilibrium models have been tested and compared with VARs (Christiano, Eichenbaum and Evans, 2005; Smets and Wouters, 2003). Markov-switching VARs go a step further in bringing VARs even closer to the data and thus provide a new benchmark for model comparison.

At the same time, considerable progress has been made to narrow the gap between VARs and DSGE models. Some results from VARs have provided empirical support to the key assumption made by real business cycle (RBC) models that monetary policy shocks play insignificant roles in generating business fluctuations. Nason and Cogley (1994) and Cogley and Nason (1995) discuss similar results from both VAR and RBC approaches. Fernandez-Villaverde, Rubio-Ramirez and Sargent (2005) provide conditions and examples under which there exists the VAR representation of a DSGE model. Sims and Zha (2006a) display a close connection between an identified VAR and a DSGE model, and provide a measure for determining whether the ‘invertibility problem’ is a serious issue.

Undoubtedly there are payoffs in moving beyond the original VAR philosophy by imposing more restrictions on both contemporaneous relationships and lag structure while the restrictions are guided carefully by economic theory. Although moving in this direction is desirable, it is essential to maintain the spirit of VAR analysis as originally proposed by Sims (1980). This requires that heavily restricted VARs be subject to careful evaluation in terms of fit. Recent advances in Bayesian estimation and inference methods of restricted VARs make it feasible to compute the MDD accurately and efficiently and, therefore, to determine whether the restrictions have compromised the fit. These methods, however, still fall short of handling VARs with cross-equation restrictions implied by DSGE models. Thus, the challenge ahead of us is to develop new tools for VARs with possible cross-equation restrictions.

**How to cite this article**

Venture capital is independently managed, dedicated capital focusing on equity or equity-linked investments in privately held, high-growth companies. The first venture firm, American Research and Development, was formed in 1946 and invested in companies commercializing technology developed during the Second World War. Because institutions were reluctant to invest, it was structured as a publicly traded closed-end fund and marketed mostly to individuals, a structure emulated by its successors.

By 1978 limited partnerships had become the dominant investment structure. Limited partnerships have an important advantage: capital gains taxes are not paid by the limited partnership. Instead, only the taxable investors in the fund pay taxes. Venture partnerships have predetermined, finite lifetimes. To maintain limited liability, investors must not become involved in the management of the fund.
Activity in the venture industry increased dramatically in early 1980s. Much of the growth stemmed from the US Department of Labor's clarification of Employee Retirement Income Security Act's 'prudent man' rule in 1979, which had prohibited pension funds from investing substantial amounts of money into venture capital or high-risk asset classes. The rule clarification explicitly allowed pension managers to invest in high-risk assets, including venture capital.

The subsequent years saw both very good and trying times for venture capitalists. Venture capitalists backed many successful companies, including Apple Computer, Cisco, Genentech, Google, Netscape, Starbucks, and Yahoo! But commitments to the venture capital industry were very uneven, creating a great deal of instability. The annual flow of money into venture funds increased by a factor of ten during the early 1980s. From 1987 through 1991, however, fund-raising steadily declined as returns fell. Between 1996 and 2003, this pattern was repeated.

Venture capital investing can be viewed as a cycle. In this article, I follow the cycle of venture capital activity. I begin with the formation of venture funds. I then consider the process by which such capital is invested in portfolio firms, and the exiting of such investments. I end with a discussion of open research questions, including those relating to internationalization and the real effects of venture activity.

**Fund-raising**

Research into the formation of venture funds has focused on two topics. First, the commitments to the venture capital industry have been highly variable since the mid-1970s. Understanding the determinants of this variability has been a topic of continuing interest to researchers. Second, the structure of venture partnerships has attracted increasing attention.

First, Poterba (1987; 1989) notes that the fluctuations could arise from changes in either the supply of or the demand for venture capital. It is very likely, he argues, that decreases in capital gains tax rates increase commitments to venture funds, even though the bulk of the funds are from tax-exempt investors. The drop in the tax rate may spur corporate employees to become entrepreneurs, thereby increasing the need for venture capital. The increase in demand due to greater entrepreneurial activity leads to more venture fund-raising.

Gompers and Lerner (1998b) find empirical support for Poterba's claim: lower capital gains taxes have particularly strong effects on venture capital supplied by tax-exempt investors. This suggests that the primary mechanism by which capital gains tax cuts affect venture fund-raising is the higher demand of entrepreneurs for capital. The authors also find that a number of other factors influence venture fundraising, such as regulatory changes and the returns of venture funds.

A second line of research has examined the contracts that govern the relationship between investors (limited partners) and the venture capitalist (general partner). Gompers and Lerner (1999) find that compensation for older and larger venture capital organizations is more sensitive to performance than that of other venture groups. Also, the cross-sectional variation in compensation terms for younger, smaller venture organizations is considerably lower. The fixed component of compensation is higher for smaller, younger funds and funds focusing on high-technology or early stage investments. Finally, Gompers and Lerner do not find any relationship between the incentive compensation and performance. The authors argue that these results are consistent with a learning model in which neither the venture capitalist nor the investor knows the venture capitalist's ability. With his early funds, the venture capitalist will work hard even without explicit pay-for-performance incentives: if he can establish a good
reputation, he can raise subsequent funds. These reputation concerns lead to lower pay for performance for smaller and younger venture organizations. Once a reputation has been established, explicit incentive compensation is needed to induce the proper effort.

Covenants also play an important role in limiting conflicts in venture partnerships. Their use may be explained by two hypotheses. First, because negotiating and monitoring covenants are costly, they will be employed when monitoring is easier and the potential for opportunistic behaviour is greater. Second, in the short run the supply of venture capital services may be fixed, with a modest number of funds of carefully limited size raised each year. Increases in demand may lead to higher prices when contracts are written. Higher prices may include not only increases in monetary compensation, but also greater consumption of private benefits through fewer covenants.

Gompers and Lerner (1996) show that both supply and demand conditions and costly contracting are important in determining contractual provisions. Fewer restrictions are found in funds established during years with greater capital inflows and funds, when general partners enjoy higher compensation. The evidence illustrates the importance of general market conditions on the restrictiveness of venture partnerships. In periods when venture capitalists have relatively more bargaining power, the venture capitalists are able to raise money with fewer stings attached.

Lerner and Schoar (2004) examine rationales for constraints on liquidity. Venture groups often impose severe restrictions on transfers of partnership interests beyond what is required by securities law. They argue that these curbs allow general partners to screen for long-term investors. A limited partner who expects many liquidity shocks would find these restrictions especially onerous. Thus, the limited partners investing will be highly liquid, facilitating fund-raising in follow-on funds. The authors show that restrictions on liquidity are less common in later funds organized by the same venture group, when information problems are presumably less severe.

Investing

A second broad area of research has focused on the ties between venture capitalists and the firms in which they invest.

This literature emphasizes the informational asymmetries that characterize young firms, particularly in high-technology industries. These problems make it difficult for investors to assess firms, and permit opportunistic behaviour by entrepreneurs after finance is received. Specialized financial intermediaries, such as venture capitalists, address these problems by intensively scrutinizing firms before providing capital and monitoring them afterwards.

Economic theory examines the role that venture capitalists play in mitigating agency conflicts between entrepreneurs and investors. The improvement in efficiency might be due to the active monitoring and advice that is provided (Cornelli and Yosha, 2003; Hellmann, 1998; Marx, 1994), the screening mechanisms employed (Chan, 1983), the incentives to exit (Berglöf, 1994), the proper syndication of the investment (Admati and Pfleiderer, 1994), or investment staging (Bergemann and Hege, 1998; Sahlman, 1990).

Staged capital infusion is the most potent control mechanism a venture capitalist can employ. The shorter the duration of an individual round of financing, the more frequently the venture capitalist monitors the entrepreneur's progress. The duration of funding should decline and the frequency of re-
evaluation increase when the venture capitalist believes that conflicts with the entrepreneur are likely. If monitoring and information gathering are important – as models such as those of Amit, Glosten and Muller (1990) and Chan (1983) suggest – venture capitalists should invest in firms where asymmetric problems are likely, such as early stage and high-technology firms with intangible assets. The capital constraints faced by these companies will be large and these investors will address them.

Gompers (1995) shows that venture capitalists concentrate investments in early stage companies and high-technology industries where informational asymmetries are significant and monitoring is valuable. He finds that early stage firms receive significantly less money per round. Increases in asset tangibility are associated with longer financing duration and reduce monitoring intensity.

In a related paper, Kaplan and Strömberg (2003) document how venture capitalists allocate control and ownership rights contingent on financial and non-financial performance. If a portfolio company performs poorly, venture capitalists obtain full control. As performance improves, the entrepreneur obtains more control. If the firm does well, the venture capitalists relinquish most of their control rights but retain their equity stake.

Related evidence comes from Hsu (2004), who studies the price entrepreneurs pay to be associated with reputable venture capitalists. He analyses firms which received financing offers from multiple venture capitalists. Hsu shows that high investor experience is associated with a substantial discount in firm valuation.

Venture capitalists usually make investments with peers. The lead venture firm involves other venture firms. One critical rationale for syndication in the venture industry is that peers provide a second opinion on the investment opportunity and limit the danger of funding bad deals.

Lerner (1994a) finds that in the early investment rounds experienced venture capitalists tend to syndicate only with venture firms that have similar experience. He argues that, if a venture capitalist were looking for a second opinion, then he would want to get one from someone of similar or greater ability, certainly not from someone of lesser ability.

The advice and support provided by venture capitalists is often embodied in their role on the firm's board of directors. Lerner (1995) examines whether venture capitalists' representation on the boards of the private firms in their portfolios is greater when the need for oversight is larger, looking at changes in board membership around the replacement of CEOs. He finds that an average of 1.75 venture capitalists are added to the board between financing rounds when a firm's CEO is replaced in the interval; between other rounds 0.24 venture directors are added. No differences are found in the addition of other outside directors.

Hochberg (2005) studies the influence of venture capitalists on the governance of a firm following its initial public offering (IPO). Venture-backed firms manage earnings less in the IPO year, as measured by discretionary accounting accruals. Venture-backed firms also experience a stronger wealth effect when they adopt a poison pill, which implies that investors are less worried that the poison pill will entrench management at the expense of shareholders. Finally, venture-backed firms more frequently have independent boards and audit and compensation committees, as well as separate CEOs and chairmen.

It is natural to ask why other financial intermediaries (such as banks) cannot duplicate these features of the venture capitalists, and undertake the same sort of monitoring. Economists have suggested several explanations for the apparent superiority of venture funds in this regard. First, because regulations limit
banks’ ability to hold shares, they cannot freely use equity. Second, banks may not have the necessary
skills to evaluate projects with few collateralizable assets and significant uncertainty. Finally, venture
funds’ high-powered compensation schemes give venture capitalists incentives to monitor firms closely.
Banks sponsoring venture funds without high-powered incentives have found it difficult to retain
personnel.
So far, this section has highlighted the ways in which venture capitalists can successfully address agency
problems in portfolio firms. During periods when the amount of money flowing into the industry grows
dramatically, however, competition between venture groups can introduce distortions.
Gompers and Lerner (2000) examine the relation between the valuation of venture deals and inflows into
venture funds. Doubling inflows leads to a 7–21 per cent increase in valuation levels. But success rates
don’t differ significantly between investments made during periods of low inflows and valuations on the
one hand and those made in booms on the other. The results indicate that the price increases reflect
increasing competition for investment.

Exiting

A third major area of research has been the process whereby venture funds exit investments. This topic
is important because, in order to make money on their investments, venture capitalists must sell their
equity stakes.
Initial research into the exiting of venture investments focused on IPOs. This reflects the fact that
typically the most profitable exit opportunity is an IPO. Barry et al. (1990) and Megginson and Weiss
(1991) document that venture capitalists hold significant equity stakes and board positions in the firms
they take public, which they continue to hold a year after the IPO. They argue that this pattern reflects
the certification they provide to investors that the firms they bring to market are not overvalued.
Moreover, they show that venture-backed IPOs have less of a positive return on their first trading day, a
finding that has been subsequently challenged (Lee and Wahal, 2004; Kraus, 2002). The authors suggest
that investors need a smaller discount because the venture capitalist has certified the offering’s quality.
Subsequent research has examined the timing of the exit decision. Several potential factors affect when
venture capitalists choose to bring firms public. Lerner (1994b) examines how the valuation of public
securities affects when venture capitalists choose to finance companies in another private round in
preference to taking the firm public. He shows that investors take firms public when market values are
high, relying on private financings when valuations are lower. Seasoned venture capitalists appear more
proficient at timing IPOs.
Another consideration may be the venture capitalist’s reputation. Gompers (1996) argues that young
venture firms have incentives to ‘grandstand’, or take actions that signal their ability to potential
investors. Specifically, young venture firms bring companies public earlier than older one to establish a
reputation and successfully raise new funds. Gompers shows that the effect of recent IPOs on the
amount of capital raised is stronger for young venture firms, providing them with greater incentives to
bring companies public earlier.
Lee and Wahal (2004) propose a variant of the ‘grandstanding’ hypothesis: they posit that venture firms
have an incentive to underprice IPOs. The publicity surrounding a successful offering will enable the
venture group to raise more capital than it could otherwise. Lee and Wahal confirm this hypothesis by
venture capital: The New Palgrave Dictionary of Economics

showing a positive relationship between first-day returns and subsequent fund-raising by venture firms. The typical venture firm, however, does not sell its equity at the time of the IPO. After some time, venture capitalists usually return money to their limited partners by distributing their shares. Gompers and Lerner (1998a) examine distributions. After significant increases in stock prices prior to distribution, abnormal returns around the distribution are negative. Cumulative excess returns for the 12 months following the distribution also appear to be negative. While the overall level of venture capital returns does not exhibit abnormal returns relative to the market (Brav and Gompers, 1997), there is a distinct rise and fall around the time of the stock distribution. The results are consistent with venture capitalists possessing inside information and with the (partial) adjustment of the market to that information.

A related research area is venture-fund performance. Kaplan and Schoar (2005) show substantial persistence across consecutive venture funds. General partners that outperform the industry in one fund are likely to outperform in the next fund, while those who underperform in one fund are likely to underperform with the next fund. These results contrast with those of mutual funds, where persistence is difficult to identify.

Cochrane (2005) estimates the returns of venture capital investments. He notes that many analyses of returns focus only on investments that go public, get acquired, or go out of business. Such calculations may produce biased returns by concentrating only on the portfolio’s ‘winners’ and outright failures. Cochrane develops a maximum likelihood estimate that uses existing data, but adjusts for these selection biases. While these papers – as well as Gompers and Lerner (1997) and Jones and Rhodes-Kropf (2003) – represent a first step towards understanding these issues, much more work remains to be done.

**Future research**

While financial economists know much more about venture capital than they did a decade ago, there are many unresolved issues. I highlight here three promising areas. The rapid growth in the US venture capital market has led institutional investors to look abroad. In a pioneering study, Jeng and Wells (2000) examine the factors that influence venture fund-raising internationally. They find that the strength of the IPO market is an important determinant of venture commitments, supporting Black and Gilson's (1998) hypothesis that the key to a successful venture industry is the existence of robust IPO markets. Jeng and Wells find, however, that the IPO market does not influence commitments to early-stage funds as much as those to later-stage ones. Much more remains to be explored regarding the internationalization of venture capital.

One provocative finding from Jeng and Wells's analysis is that government policy can dramatically affect the health of the venture sector. Researchers have only begun to examine the ways in which policymakers can catalyse the growth of venture capital and the companies in which they invest (Irwin and Klenow, 1996; Lerner, 1999; Wallsten, 2000). Clearly, much more needs to be done in this arena. A final area is the thorniest: the impact of venture capital on the economy. Demonstrating a causal relationship between innovation, job growth and venture activity is a challenging empirical problem. Kortum and Lerner (2000) examine the influence of venture capital on patented inventions in the United States over three decades, finding that increases in venture capital activity in an industry are associated with significantly higher patenting rates. One dollar of venture capital, they suggest, is three times more
likely than one dollar of corporate R&D to stimulate patenting. (Hellmann and Puri, 2000, also explore the impact of venture capital on innovation.) Many research opportunities remain in this arena.

Verri, Pietro (1728–1797)

Peter Groenewegen

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

balance of production and consumption; consumption taxation; marginalism; mathematical economics; tax incidence; Verri, P.

Article

Italian economist, administrator and philosopher, Verri was born in Milan in 1728, educated in Rome and Parma, served with Austria in the Seven Years War and at this time was introduced to the study of economics by General Henry Lloyd (Venturi, 1978; 1979). His economic writings of the 1760s, such as Elementi di Commercio (1760) and the dialogues on monetary disorders in the State of Milan (1762), led to his appointment to a number of positions in the Austrian civil service in Milan. His administrative achievements include the abolition of tax farming (1770) and lowering and simplifying the tariff (1786). From 1764 to 1766 he edited with his brother Alessandro the periodical Il Caffè, which attracted contributions on economics from Beccaria and Frisi as well as himself (Verri, 1764). His most important economic publication, Reflections on Political Economy, appeared in 1771, went through numerous editions and was translated into French, German and Dutch and more recently into English. Other economic works on monetary and trade questions, including his 1769 pamphlet advocating freedom of the domestic corn trade, contribute to his reputation as a most important 18th-century Italian economist (MuCulloch, 1845, pp. 26–7). More recently he has been noted for inspiring early developments in mathematical economics (Theocharis, 1961, pp. 27–34). He died in 1797.

Verri's Reflections is a complete treatise on political economy, reminiscent of Turgot's Reflections on the Production and Distribution of Wealth (1766) with its tight, logical framework and division into fairly short sections. Although these cover a wide range of subjects, they are interconnected by the basic theme of the work, the increase in annual reproduction of the nation through trade of surplus product which Verri related to the balance of production and consumption. This ratio or balance is the key concept in Verri's economic analysis, since it not only influences economic growth but also value (it approximates the ratio of sellers to buyers at home and abroad), the rate of interest (it represents thriftiness conditions) and, via its influence on the balance of trade, it also determines national money supply. An excess of
production over consumption lowers the price level and the rate of interest, expands the money supply, animates industry and facilitates the collection of taxes. Some features of this analysis may be specifically noted. Verri does not appear to have been aware of the importance of capital, as is demonstrated in his general discussion of production (sections 26–8) and his treatment of the interest rate as a monetary phenomenon (sections 14–15). Secondly, his emphasis on supply and demand (used to determine all prices including the rate of interest) combined with references to utility and scarcity in the context of value (section 4) explains why this part of his work has been linked with marginalist economics. The last 11 sections discuss taxation and public finance, including a presentation of five canons of taxation (section 30), a tax incidence analysis arguing against the Physiocratic view that all taxes fall on the landlord (sections 32–3) and a plea for indirect consumption taxation as a fair and administratively easy way to raise revenue. Anti-Physiocratic elements in his economics are not confined to tax issues, but apply to his discussion of special classes (section 24), the importance of agriculture (section 28) and are apparent in his view that free trade should be largely confined to domestic activity (section 40). Verri's Reflections were highly regarded when they appeared, and could be found, for example, in Smith's library. His work, though now largely ignored, may therefore have exerted greater influence than is generally believed.

vertical integration

Michael H. Riordan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Modern economics takes a two-way approach to vertical integration. The theory of the firm approach focuses on how the unified control of successive production and distribution processes changes investment incentives, while the industrial organization approach studies how vertical integration affects the exercise of market power.

Keywords

asset specificity; backward integration; bargaining costs; bilateral vertical contracts; Chicago School; commitment; control rights; double markups; enforceable contracts; exclusive dealing; firm, theory of; foreclosure; forward integration; free-rider problem; hold-up problem; imperfect information; incomplete contracts; industrial organization; market exchange; market power; quasi-rent; raising rivals’ costs; relationship-specific assets; transaction costs; variable proportions distortions; vertical integration

Article

Vertical integration is the unified ownership and operation of successive production and distribution processes by a single firm. Backward integration occurs when a manufacturer controls the production of inputs, and forward integration occurs when the manufacturer controls distribution. The alternative (market exchange) is to procure inputs and distribution services from independent suppliers. Vertical integration is a matter of degree, as firms often are only partially integrated in one direction or the other. Vertical integration raises issues for business strategy and public policy. A major theme in the theory of the firm literature is that vertical integration remedies underinvestment in relationship-specific assets due to opportunistic bargaining when contracts are incomplete. Accordingly, vertical integration enhances operational efficiency by improving investment incentives and reducing bargaining costs. Major themes of the industrial organization literature are that vertical integration reduces a firm's procurement or distribution costs, or raises those of its rivals. Accordingly, vertical integration is a
strategy for competitive advantage. Policy issues concern whether the prevention or regulation of vertical integration improves consumer and social welfare.

Theory of the firm approach

The neoclassical theory of the firm assumes managers choose inputs and outputs to maximize profits subject to a production function, on the assumption that the governance of transactions is costless. The modern theory, in contrast, focuses explicitly on transaction costs, including efficiency losses, arising within and between firms. The transaction-cost approach views vertical integration as a response to difficulties negotiating and executing market contracts (Coase, 1937; Klein, Crawford and Alchian, 1978; Williamson, 1975; 1985; 1996). The transaction-cost advantages of vertical integration over market exchange are most pronounced when contracts are incomplete, and uncertain future transactions require prior investments in relationship-specific assets for operational efficiency. In these circumstances, market exchange runs afoul of the hold-up problem. Relationship-specific assets by definition are strictly more valuable in a particular transactional relationship than in alternative uses; the difference in use value is called a quasi-rent. Thus asset specificity locks investors into bilateral relationships, while contractual incompleteness exposes them to costly bargaining over quasi-rents. Bargaining costs include failures to adapt transactions efficiently to unfolding circumstances and the direct costs of dispute resolution. Vertical integration improves operational efficiency by replacing dysfunctional bargaining with centralized authority over transactions, but adds bureaucratic costs, including efficiency losses from low-powered managerial incentives. A key hypothesis is that bargaining costs of market exchange rise with asset specificity faster than the bureaucratic costs of vertical integration, leading to two propositions: first, vertical integration is more likely the more important asset specificity is for efficiency; second, vertical integration supports more investment in relationship-specific assets than market exchange (Riordan and Williamson, 1985). Empirical research generally bears out the implied positive correlation between vertical integration and the level of asset specificity (Shelanski and Klein, 1995).

The more formal property-rights approach studies how ex post bargaining when contracts are incomplete distorts ex ante relationship-specific investments (Grossman and Hart, 1986; Hart and Moore, 1990; Hart, 1995). Ownership confers control rights over the use of non-human assets used in production. While some specific control rights may be contracted away, the residual rights are held by the owners. Furthermore, managers make non-contractable relationship-specific investments to increase the value of these assets. The hold-up problem is manifest because ex post bargaining distributes the returns from these investments. Owner-managers who control the non-human assets of a firm undertake relationship-specific investments to the extent that the hold-up problem does not discourage them. Employee-managers, however, have less incentive because owners of the complementary non-human assets appropriate much of the investment returns. Thus vertical integration has mixed effects on managerial incentives. By eliminating the hold-up problem of market exchange, vertical integration improves investment incentives of owner-managers, while converting owner-managers into employees diminishes their incentives. Accordingly, the direction of vertical integration matters. Backward integration enhances investment incentives of downstream managers and degrades managerial incentives upstream, while forward integration has opposite effects. Optimal vertical integration depends on the importance
of relationship-specific investments by managers at each stage of production and distribution. For example, forward integration is predicted when upstream managerial effort is particularly important for operational efficiency. Predictions of the property-rights approach depend sensitively on managers’ investment opportunities to improve efficiency, and are difficult to test empirically (Whinston, 2003). Vertical integration also improves efficiency by reducing information imperfections at the root of bargaining costs (Arrow, 1975; Riordan, 1990). At the same time, the changed information structure diminishes investment incentives of employee-managers by aggravating the hold-up problem. This perspective reconciles with the property-rights approach by interpreting business information as an asset for which the owner has control rights. An open question is how the change in information structure derives from primitive conditions (Hart, 1995).

Vertical integration might be motivated by the pursuit of greater bargaining leverage, rather than just greater efficiency (Bolton and Whinston, 1993). A vertically integrated supplier with scarce capacity over-invests in its downstream unit in order to negotiate better terms from independent customers. The unfortunate effect is to discourage independents’ investments in relationship-specific assets. Consequently, vertical integration tends to be excessive from a social welfare perspective.

**Industrial organization approach**

While the theory of the firm deals mainly with the reasons for vertical integration, industrial organization is more concerned with its effects on competition. Building on the neoclassical theory of the firm, industrial organization studies how market power distorts transactions. Much of this literature presupposes that transactions are governed by uniform prices for inputs and outputs. In this context, the Chicago School approach identifies efficiencies of vertical integration arising from a more profitable exercise of market power, including output expansion resulting from the elimination of ‘double markups’ when vertically related firms each exercise market power, the correction of ‘variable proportions distortions’ when independent downstream firms substitute towards more competitively supplied inputs, and the prevention of free-riding on point-of-sale services (Perry, 1989).

The post-Chicago approach, by contrast, studies how foreclosure resulting from vertical integration reduces competition and raises rivals’ costs (Ordover, Saloner and Salop, 1990; Riordan, 1998; Salinger, 1988; Salop and Scheffman, 1987). Foreclosure might drive up procurement costs or deny scale economies. Accordingly, an appropriate policy analysis weighs efficiencies against possible anti-competitive effects of vertical integration (Riordan and Salop, 1995). The post-Chicago approach demonstrates conditions for anti-competitive foreclosure more rigorously than the traditional foreclosure doctrine attacked by the Chicago School (Bork, 1978).

Another recent approach to vertical foreclosure studies the commitment problem of a supplier with market power who deals with customers bilaterally (Hart and Tirole, 1990; Rey and Tirole, 2007). Multilateral contracts involving a supplier and several downstream rival customers might be prevented by antitrust policy, or be unenforceable due to monitoring problems. Allowing more sophisticated contracting than just uniform pricing, the privacy of bilateral vertical contracts nevertheless fosters opportunism. A supplier has an adverse incentive to negotiate individual contracts that disadvantage other rival customers. Consequently, equilibrium supply contracts with favourable terms result in more downstream competition than would maximize total profits. Vertical integration restores monopoly
power because the vertically integrated supplier is loath to set terms that hurt its own downstream division. The vertically integrated supplier offers less favourable terms to downstream rivals, raising their variable costs and causing higher downstream prices. Enforceable contracts with multilateral elements, such as exclusive dealing, also improve profits. Moreover, a vertically integrated firm has a greater incentive to enter into exclusive supply deals that foreclose upstream competitors and effectively cartelize a downstream industry (Chen and Riordan, 2007). Such non-efficiency motives for vertical integration sometimes are contrary to consumer and social welfare, but are inconsequential if market power is absent.

Vickrey, William Spencer (1914–1996)

Richard Arnott
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

William Spencer Vickrey was awarded the 1996 Nobel Prize in Economics ‘for his fundamental contributions to the economic theory of incentives under asymmetric information’. While best known as the father of auction theory, he made important contributions on a broad range of topics including social choice, marginal cost pricing, the design of tax systems, transportation economics, urban economics, and macroeconomics.

Keywords

asymmetric information; auctions (theory); congestion pricing; cumulative averaging taxation; efficient allocation; estate taxes; Gibbard–Satterthwaite theorem; Groves–Clark–Vickrey mechanisms; land use; land value taxation; marginal cost pricing; Mirrles, J. A.; natural rate of unemployment; optimal income tax; philanthropy; philosophy and economics; Ramsey pricing; responsive pricing; revelation of preferences; second best; Shoup, C. S.; site value taxation; social choice; strategic misrepresentation; transport economics; urban economics; user fees; veil of ignorance; Vickrey second-price auction; Vickrey, W. S.

Article

William Spencer Vickrey was awarded the 1996 Bank of Sweden Prize in Economic Sciences in Memory of Alfred Nobel, jointly with James A. Mirrlees, ‘for [his] fundamental contributions to the economic theory of incentives under asymmetric information’ (Royal Swedish Academy of Sciences, 1996). His most influential papers, as well as a comprehensive bibliography, are contained in Public Economics: Selected Papers by William Vickrey (Arnott et al., 1994). Articles that pay tribute to his contributions include Arnott (1998), Drèze (1995), Harriss (2000), and Laffont (2003).

Vickrey was born in Victoria, Canada, where his maternal grandfather had built a group of department
stores. Towards the end of the First World War, his father, a Congregational minister, became actively involved in the relief of Armenian and Greek refugees from the Ottoman Empire. In conjunction with this work, the family moved to New York and later Switzerland. Vickrey attended high school in Scarsdale, NY, and Phillips Andover Academy. He received his bachelor's degree in engineering and mathematics from Yale University in 1935. He then moved to Columbia University for graduate studies in economics. After two years of course work, he went to Washington, DC, to work for the National Resources Committee, in a group pioneering studies on the structure of the US economy. During the Second World War, as a conscientious objector, he served in the Division of Tax Research of the Department of the Treasury, working on broad macroeconomic issues related to war finance and more specific issues of tax structure. In 1946 he returned to Columbia to teach and to complete his doctoral dissertation, published as *An Agenda for Progressive Taxation* (1947). Apart from sabbaticals and missions abroad, he remained at Columbia until his death.

Throughout his career, Vickrey had considerable practical policy experience. As part of Carl Shoup's team, he helped design several countries’ tax systems, including Japan's after the Second World War. He also advised many public utilities, and even introduced skip-stop scheduling to the Indian rail service. But he was never a major player on the policy front. His legacy is his body of publications. He published eight longer works, including graduate textbooks in microeconomics and macroeconomics, three technical monographs, and two co-authored country tax system studies, as well as his thesis. Apart from his thesis, however, he is best known for his some 200 papers.

Though covering an unusually broad range of topics, his papers are consistent in theme and style. While his choice of topics stemmed from social and moral concerns, his treatments of them stressed improvements in resource allocation. ‘Greater efficiency for the common good’ would be an appropriate slogan for his work. His style of writing and reasoning is idiosyncratic and paradoxical. Most of his papers advocate specific policy innovations. To reach a broader audience, he developed his ideas primarily verbally, and with literary flair, but the precision and sophistication of his economic reasoning largely defeated this purpose. He also tended to emphasize practical issues of policy implementation, while presenting in an offhand manner the novel theoretical and conceptual insights for which the papers have been remembered. Many of his policy recommendations, though derived with impeccable logic, were impractical at the time he proposed them. (Technological advances have since rendered some, such as auto congestion pricing and land value taxation, more practical.) These smaller paradoxes can be resolved by understanding Vickrey as a social crusader with a theorist's cast of mind. The larger paradox is that the tension between crusader and theorist was the source first of his creativity, and then of the neglect for many years of much of his work, and ultimately of the distinction of his intellectual legacy. Many of his ideas were overlooked until they were independently discovered many years later, while others lay dormant until their time had come.

Vickrey's major contributions lie in four areas: social choice and resource allocation mechanisms, taxation, marginal cost pricing, and urban transportation.

Vickrey is best known as the father of auction theory, due to his seminal paper, ‘Counterspeculation, Auctions, and Competitive Sealed Tenders’ (1961). The question posed by Vickrey in that paper is how to achieve efficiency in resource allocation with a small number of buyers or sellers under asymmetric information. He presented and analysed two classes of mechanisms that circumvent the strategic misrepresentation of costs and preferences. The first is auctions. Consider the simplest auction in which there is a single item for sale, for which bidders have different private valuations. Efficiency entails the
item being sold to the bidder with the highest valuation. If the item is sold to the highest bidder at his bid, then each bidder has an incentive to bid less than his valuation, since if he bids his valuation he gains no surplus from purchase of the item. In deciding on his bid, each bidder must guess others’ valuations, and there is no guarantee that the item will be sold to the bidder with the highest valuation. Suppose instead that the item is sold to the highest bidder but at the second highest bid (the Vickrey second-price auction). Whatever other bidders do, if a particular bidder bids more than his valuation he will win more often but only when the second-highest bid, and therefore the price he pays, exceeds his valuation, while if he bids less than his valuation he will win less often and only when the winning bid falls short of his valuation. Since bidding one's private valuation is the dominant strategy, the item should go to the bidder with the highest valuation, achieving efficiency. Auction theory has developed from this insight. Auctions are now extensively used in the allocation of goods with a small number of buyers; timber and drilling rights, bandwidth, Treasury bills and sealed bid tenders are well-known examples. Vickrey's paper also investigated a class of demand-revealing mechanisms – now known as Groves–Clark–Vickrey mechanisms – that elicit truthful revelation of preferences, for pure public goods for example.

Vickrey made several other contributions to the literature on social choice and resource allocation mechanisms. In ‘Measuring Marginal Utility by Reactions to Risk’ (1945), he provided the first statement of social choice based on the maximization of expected utility behind the veil of ignorance, which was independently stated by Harsanyi (1955) a decade later, and also the first formulation of the optimal income tax problem, which was not solved until a quarter-century later by James Mirrlees (1971). ‘Utility, Strategy, and Social Decision Rules’ (1960) provides a masterful survey of social choice theory as of that date and conjectures what is now known as the Gibbard–Satterthwaite theorem. The efficiency of marginal cost pricing in general and of short-run marginal-cost pricing in particular were well understood when Vickrey was a graduate student. Vickrey's contributions were in communicating the breadth of application of the principles and in conceiving ingenious technological schemes for their implementation. From the early 1950s he was a strong advocate of responsive marginal cost pricing, whereby the current price reflects the current realization of stochastic demand and supply; for instance, he proposed varying the parking meter rate on a city block according to the meters’ realized occupancy rate (1959) and dealing with airline overbooking via responsive pricing (1972). His crusading for congestion pricing in transportation, for site value taxation (1970), and for the extended application of user fees to finance local public services (1963) are examples of his advocacy of marginal cost pricing in novel contexts.

His major contributions to the theory of taxation derived from his experience in the Department of the Treasury during the Second World War. All are contained in his thesis, which was a tour de force. The goal of the thesis was the comprehensive design of a practical, coherent, fair, and efficient tax system. At the time, a steeply progressive income tax was the primary source of federal tax revenue. Rates had been increased sharply to generate the revenue needed to finance the war effort. The combination of steep progression and high rates encouraged taxpayers to devote considerable effort to altering the timing of expenditures and receipts in order to average income. To eliminate this waste, Vickrey proposed cumulative averaging, a method of taxing individuals on their discounted lifetime incomes, with a minimum of accounting. A steeply progressive estate tax was also in place, which wealthy individuals avoided through generation-skipping trusts. Vickrey proposed an integrated successions tax, which retained the progressivity of the tax while reducing the incentives for complex tax avoidance
schemes. Since then, income and estate tax rates have been lowered and made less progressive, mitigating the problems that Vickrey's proposed reforms addressed. His contributions lie not so much in his specific proposals, however, as in his conception of redesigning the tax system from basic principles.

How much influence his book had on the Carter Commission in Canada, the Meade Committee in the UK, or the Reagan tax reforms is hard to say, but they are in the same spirit.

While best known for his auctions paper, Vickrey was also the pre-eminent transport economic theorist of his generation. As a transport economist, he is famous for his 50-year-long advocacy of auto congestion pricing (of charging drivers for the externality cost each imposes on other drivers by slowing them down), and in North America at least is known as the father of congestion pricing. After many years of political resistance, urban auto congestion pricing is slowly being adopted, first in Singapore and more recently in London and Stockholm. His first work on the subject (1955) was a proposed fare structure for New York City's subway system, based on marginal cost pricing principles. His empirical research on the project entailed travelling the subway system, stopwatch in hand, while his discussion of deviations from first-best marginal cost pricing to take into account equity concerns and the transit authority's budgetary constraints anticipates the theory of the second best. His second work (1959) detailed an automobile congestion-pricing scheme for downtown Washington, DC. A schedule gives the prices of traversing major intersections by time of day. Each car is equipped with a transponder. When the car enters an intersection, its transponder sends a signal to a roadside receptor and is conveyed to a central computer, which adds the appropriate charge to the car's bill. The theoretical work on the project included an independent derivation of Ramsey pricing with a marginal cost of public funds. His later work in urban transport economics is noteworthy in two respects. He, more than any other urban transport economist, grappled with the complex physics of auto congestion. He also introduced the bottleneck model of traffic congestion (1969), the first analytically tractable model of equilibrium rush-hour traffic dynamics. Each commuter decides when to leave home in the morning, trading off schedule inconvenience against congestion delay. Congestion takes the form of a queue behind a bottleneck of fixed flow capacity, with the queue length (and hence the departure time distribution) evolving to achieve equilibrium.

His other work spans a diversity of topics. Viewing unemployment as a tragic waste of human resources, he wrote many macroeconomic papers arguing against a natural rate of unemployment and for Keynesian macroeconomic stabilization. He also made important contributions to urban economics, most noteworthy of which are pioneering papers on traffic congestion and land use (Solow and Vickrey, 1971) and on the Henry George theorem (1977) – which states that efficient spatial economies can be decentralized via marginal cost pricing, with land rents being used to cover the deficits deriving from the economies of scale underlying agglomeration. His miscellaneous papers cover such topics as game theory, student loans, gerrymandering, international dispute resolution, cost-of-living indices, equivalence scales and sorting theory. One paper on the economics of traffic accidents (1968), another on the economics of philanthropy (1962), and another on economics and philosophy (1950) have been influential. The last of these papers provides insight into the moral purpose underlying Vickrey's work. Prior to his receipt of the Nobel Prize, Vickrey's work, apart from his justly celebrated auctions paper, was not well known to most economists. But Vickrey is much more than just a 'one-paper economist'. The same intellectual qualities that spawned the auctions paper are evident in the rest of his work. Perhaps the whole of the rest of his work is greater than the sum of the individual papers, demonstrating the wealth of ideas that are generated when a brilliant economic theorist applies his creativity to devising
solutions to practical public policy problems.

Karl Vind was born in a small provincial town in Denmark on 3 April 1933. His mother died when he was only a few years old, and his father was often absent from home, so Karl and his two brothers were taken care of by relatives. The family reports early interest and skill in economics and mathematics. Karl Vind finished his school years in 1951. He studied economics at the University of Copenhagen, and attended lectures in mathematics by Werner Fenchel (known for his contributions to the theory of convexity). He graduated in 1958, and after finishing military service was employed at the Faculty of Social Sciences; he also had a position as scientific researcher at what was later known as the Institute of Economics. His future scientific orientation was formed in the years 1962–3, which he spent as a Rockefeller Fellow at the University of California (Berkeley), where he was inspired by the highly fertile research environment around Gerard Debreu. He returned to Berkeley as visiting associate professor from 1964 to 1966. While at Berkeley Karl Vind was married in 1962 to Anni (Mortensen); they had sons named Lars and Jacob and adopted a daughter named Dorthe.

After his return to Copenhagen in 1966 Karl Vind obtained a position as professor in economics, later changed to a chair in mathematical economics, which he held until his retirement in April 2003 at the age of 70. He spent several long periods in Berkeley as well as at the Center for Operations Research and Analysis (CORE) in Louvain. After retirement, he retained his office at the institute and participated in its everyday activities until his death in July 2004 after a short illness.

Karl Vind's published research covers many fields – international trade theory, control theory, general equilibrium, game theory, the theory of choice under uncertainty – so that his publication record is consistent with his own interpretation of mathematical economics as ‘the derivative of economic theory’ – what is mathematical economics today becomes economic theory tomorrow. However, most of the
topics he studied engaged him over long periods; some of the results appearing in the later years were at least partially obtained in the early years of his career.

In the years after graduating, Karl Vind had been interested in mathematical statistics and control theory, something which is witnessed by his work on optimal control with jumps in the state variables (1967). He never returned to control theory, but it usefully inspired him to apply Lyapunov's theorem, which at that time was known to control theorists but not to researchers in general equilibrium. Vind demonstrated that it could be used to show the equivalence of core and Walrasian equilibria in large economies (1964). This was a major breakthrough at the time, achieved independently by Aumann (1964). The approach using Lyapunov's theorem was innovative and offered a new approach to modelling large economies.

Also from this period is the short piece on the core of an exchange economy (1965), which pioneers the extension of the results obtained for economies with infinitely many agents to economies with a finite number of agents. Vind's result does not go all the way to establishing a connection between core and equilibrium, something which was achieved only several years later. This later development might perhaps have been simpler and faster if researchers had followed Vind's early approach; he had the bad luck of being ahead of his time.

In the following years, Vind's published research dealt with extensions of the general equilibrium model in several directions. An example is the paper written with David Schmeidler (1972) on fair net trades, proposing a new approach to the concept of fairness as well as an elegant formalism. In much of his work from this period Karl Vind was concerned with the structural properties of exchanges. His concept of an exchange equilibrium was intended to capture the essential properties of trade in markets. He was, however, not quite satisfied with the initial formulations of the exchange equilibrium, which were never published. After several reformulations the concept appeared in 1983 as ‘equilibrium with coordination’. In the late 1960s Karl Vind started on another project, dealing with utility representations of preferences, which remained at the draft stage until it was finally published as a monograph in 2003. His work on the so-called mean groupoids was inspired by the need to extend the general equilibrium model to include time and uncertainty, which at that time seemed to call for specific functional forms of utility representations. Vind realized that there was a common structure behind utility representations over time and under uncertainty, related to the operation of taking mixtures of consumption programmes, and this led Vind's theory of mean groupoids. The work had already taken shape as a draft for a research monograph around 1970, but its final publication was considerably delayed, partly for practical reasons and partly due to the emergence of new results from Vind himself and others. Some of these had to do with the extension of the expected utility hypothesis to preferences that are not necessarily complete, one of Karl Vind's later research projects.

As a researcher, Karl Vind remained active after retirement as an organizer of and participant in scientific meetings and seminars. His influence on the mathematical economics profession goes beyond his published work, since he took great pleasure in following the work of other researchers, in particular young ones, who received valuable suggestions from a person genuinely interested in their work. Due to this aspect of his scientific activity, he has had a lasting influence on the development of the field.

Article

Jacob Viner, the economic theorist and historian of economic thought, was born and raised in Montreal, the son of immigrant parents from eastern Europe. As an undergraduate he attended McGill University, where he was taught economics by Stephen Leacock, the famous humorist. Leacock used texts by Mill and Walker, Milk and Water, as the students referred to them, showing ‘good judgment’ according to an account that Viner gave later in life. For graduate work he went to Harvard, where he earned a Ph.D. in 1922. He was a student and eventually became a close friend of Frank W. Taussig, the well-known authority on economic theory and international economics. At that time and during the earlier part of Viner's career he and Taussig were rare specimens in what was, except for a very few others, essentially a ‘wasp’ establishment. But in other respects their background was quite different. Viner was a self-made man who had emancipated himself from the immigrant quarter of Montreal, while Taussig was born into a patrician family with wealth and native culture.

Taussig's specialities were the fields to which Viner himself was drawn and in which he earned great distinction, in addition to his perhaps even more distinguished work in the history of economics, where his accomplishments were almost without rival.

During the two world wars, during the Great Depression, and on and off at other times, Viner did consulting and other work in Washington, but he was foremost an academic, who taught at the University of Chicago in 1916–17 and from 1919 to 1946, when he went to Princeton and taught there until his retirement in 1960. Viner advanced rapidly at Chicago, where the department then was headed by J.M. Clark, and he became a full professor at age 32. A few decades earlier, in the same department, Veblen had risen to the rank of assistant professor only at age 43. But Veblen had defied convention
Viner's tenure at Chicago coincided in part with his editorship of the *Journal of Political Economy* for a period of 18 years. Most of the time the post was held jointly with Frank H. Knight, who, after having earlier spent two years at Chicago, returned to it in 1927. Both men imprinted on the journal the mark of their own great gifts.

Viner's contributions to economic theory and the history of economic thought are embodied in periodical articles that were reprinted in book form in 1958 under the title *The Long View and the Short*. His contributions to general theory consist principally of two remarkable articles, one published in 1921 and the other ten years later. Of the two, the second on ‘Cost Curves and Supply Curves’ (Viner, 1958, pp. 50–78) made an immediate and powerful impact on the profession. Written, as it was, by a then well-established scholar, it contained virtually the whole of the modern exposition, graphic and otherwise, of the theory of cost, including the envelope curve, about which Viner had a legendary dispute with his mathematically more proficient Chinese draftsman. It also contained, perhaps for the first time in print, the words ‘marginal revenue’. All this matter eventually entered into the elementary textbooks. Viner's accomplishment paralleled that of Knight, whose graphic portrayal of the theory of production in *Risk, Uncertainty and Profit* (1921) likewise entered into the mainstream of economic theory and became the basis for the textbook treatment of the matter. Among the two great scholars there was forged a substantial portion of partial equilibrium analysis as it evolved during the first half of the 20th century.

Viner's earlier article, ‘Price Policies: The Determination of Market Price’, published in 1921 and covering barely five pages in the reprint of 1958, was in some respects an even more dazzling achievement than the later and much better-known one. Five years ahead of Sraffa, six years ahead of the publication of Joan Robinson's and Chamberlin's books on the subject, Viner developed here, in a short paragraph, the outlines of the theory of monopolistic competition. He writes of inflexible prices, ‘differentiation’ of products, advertising, non-price competition and other characteristics of markets that are neither fully competitive nor completely monopolistic. In such markets producers may succeed in creating a special demand for their products. They can then to some extent determine prices independently of the prices charged by their competitors and still maintain their sales (Viner, 1958, pp. 5–6). In the same context Viner also developed, in a few sentences, the theory of what became later known as the kinky demand curve, 18 years ahead of Sweezy's article on the subject.

These were indeed path-breaking contributions, but their existence was virtually ignored until Viner's article was reprinted in 1958. The place of the original contribution – L.C. Marshall, ed., *Business Administration*, University of Chicago Press, 1921 – was not exactly obscure but elusive nevertheless from the standpoint of a reader looking for innovations in economic theory. Chamberlin did not mention Viner in the bibliographies that he appended to successive editions of his book and which eventually listed around 1,500 items. As regards the kinky demand curve, there is no reference to Viner in Sweezy's article in the *Journal of Political Economy* for 1939, of which Viner then was the co-editor, nor in Stigler's critique published in the same journal in 1947. All this is an unresolved puzzle. No one knows why Viner never developed more fully the ideas sketched in his brief article of 1921 and why he, who in other contexts did not shy away from announcing his priority, remained silent about this one. The ideas surely were his own and not derived from an oral tradition at Harvard, whose only potential fount, Allyn Young, came to Harvard only in 1920, when Viner was already teaching at Chicago. He could not very well have anticipated unfriendly criticism, because the Chicago of the 1920s, where J.M. Clark had a senior position, was not the Chicago of the later so-called Chicago School, all of whose leaders,
beginning in the mid-1940s, voiced disapproval of the theory of monopolistic competition. Viner not only had an analytical mind that was stocked with original ideas, but combined with this a stupendous book learning that within the scope of the humanities and social sciences, and especially their history, was virtually universal and gave special depth to his studies in the history of economics. He was perhaps not as scintillating a writer as Schumpeter, nor did he turn out, as did Schumpeter, a comprehensive treatise on the subject, but his work, scattered in periodical articles, contains far more reliable and judicious interpretations of such matters as utilitarianism, and classical and Marshallian economics. The most important of Viner's articles on the history of economics were reprinted in Part II of the collection published in 1958. Their coverage extends all the way from the mercantilists to Marshall and Schumpeter. The essay on mercantilist thought shows the mercantilists in pursuit both of power and wealth as ultimate ends of national policy. Another on Adam Smith demonstrates, among other matters, that Smith was not a doctrinaire advocate of laissez-faire, a quality that he shares with Viner. Smith was a favoured subject of Viner's studies, and in 1965 he contributed an introduction of 145 pages to a new edition of Rae's Life of Adam Smith, the standard biography. An essay about the utility concept in value theory defends the concept against its critics. Writing about Bentham and J.S. Mill (1949), Viner clarifies the meaning of the former's hedonic calculus and by restricting it to comparisons between pain and pleasure contributes to the rehabilitation of this concept, for which, he believes, an idea of Benjamin Franklin's may have been the inspiration. Mill and Marshall are both viewed in their Victorian setting. The former's Principles, a combination of 'hard-headed rules and utopian aspirations', was 'exactly the doctrine that Victorians of goodwill yearned for'. Marshall fitted into the Victorian age that was complacent about the present and optimistic with respect to future progress. Except for the collection of his articles published in 1958 and two posthumous publications, all of Viner's books are about international economics, with a collection of his articles in this field, titled International Economics, published in 1951. His work in international economics covers virtually all its phases – theory, history of thought, and policy – with occasional use of empirical material. His earliest book, Dumping (1923), contained the first comprehensive and systematic study of this subject. It was followed a year later by Viner's doctoral dissertation on Canada's Balance of International Indebtedness, 1900–1913, which was written on the suggestion of Taussig, who directed a number of related empirical studies designed to demonstrate the operation of the balance-of-payments adjustment process. In 1937 there was published Viner's masterwork, Studies in the Theory of International Trade, which blends in an inimitable manner theoretical analysis and erudite doctrinal history. Its aim was to trace the evolution of the modern theory of international trade. It starts out with the mercantilists and continues with the bullionist controversies, the currency school–banking school controversy, the international mechanism of adjustment, and the doctrine of the gains from trade. In Viner's view, the comparative-cost doctrine is dependent on a real-cost theory of value rather than on opportunity cost. While this view was not in tune with the time, there are many forward-looking sections in the book, including references to a lecture given by Viner in 1931 in which later models of Lerner, Leontief and Hicks were anticipated. In 1950 Viner published The Customs Union Issue, which contained the distinction between trade creation and trade diversion, the starting point of later discussions of the matter. Viner's articles on International Economics, collected in 1951, start with one on the most-favoured-nation clause and end with an essay on the economic foundations of international organizations. Many of the articles are
indispensable for the study of the policy issues of the time. In 1952 Viner made his contribution to the emerging field of economic development in a book on *International Trade and Economic Development*. In this work he took a far less favourable view of a number of public policies designed to accelerate economic development than was commonly held at that time. He refused to identify agriculture with poverty, stressed that industrialization was more often a consequence than a cause of prosperity, and placed the main burden of promoting development on the underdeveloped country itself.

Viner had for long been interested in theological ideas, especially of the more remote past, and after his retirement he started out on a project designed to explore the relationship between religious and economic thought. This great project proved open-ended. After Viner's death only two fragments were published, one on *The Role of Providence in the Social Order* (1972), and the other on *Religious Thought and Economic Society* (1978). The first of these works is an original accomplishment that traces the derivation of a number of economic ideas from theological precedents, for example, the theory of international trade that is grounded in differences in factor endowments, Smith's invisible hand, and the providential origin of social inequality that was claimed in the past. The second work is written along more conventional lines and reviews the economic doctrines of the Fathers of the Church, of the Scholastics, secularizing tendencies in later Catholic social thought, and Protestantism and the rise of capitalism. This last chapter contains a critical analysis of the Weber–Tawney thesis of the Calvinist origin of capitalism.

To place Viner's work into its proper historical setting, a word is in order about his relation to the Chicago School. A common conception takes his membership or leadership in this school for granted, but this view is mistaken. Viner himself said that much in a remarkable letter to Patinkin written shortly before his death (Patinkin, 1981, p. 266; the letter is also reproduced by Reder, 1982, p. 7). It must be remembered that at the time when Viner taught at Chicago, the designation ‘Chicago School’ was not yet a commonly used term. To be sure, Viner's views about laissez-faire, Keynesian economics and government intervention had something in common with the views held by representatives of the Chicago School, but on the whole he was a more pragmatic thinker and more aware of the need for qualification and consideration of circumstances of time and place. Moreover, Viner, from whom stems the definition ‘economics is what economists do’, would not have felt comfortable within the confines of a school, especially of one that at times has come close to defining economics as the study of competitive markets. The early leaders of what later became known as the Chicago School were Henry Simons and Knight, not Viner. Like no one else, Knight had a charismatic appeal that yielded conversions to libertarianism in his classroom – James Buchanan has testified to this – and that made him the more likely founder of a school. It is significant also that Viner, and, for that matter, Knight too, urged deficit spending during the Great Depression. Viner called the plea for an annual balanced budget a mouldy fallacy (Viner, 1933, p. 129). He was critical of Hayek's libertarianism (Viner, 1961). He denied that competition was both a norm and normal, pointing out instead that monopoly is so prevalent in the markets of the western world today that discussions of the merits of the free competitive market as if that were what we are living with or were at all likely to have the good fortune to live with in the future seem to me academic in the only pejorative sense of that adjective.

He also insisted that ‘no modern people will have zeal for the free market unless it operates in a setting
of “distributive justice” with which they are tolerably content’ (Viner, 1960, pp. 66, 68). (The article in which Viner developed these ideas was ostensibly an exposition on the rhetoric of laissez-faire, an early exercise in an approach that D.N. McCloskey was to apply on a wider scale more than a quarter century later.) Against Friedman Viner supported discretionary monetary management rather than conduct in conformity with a ‘rule’ (Viner, 1962). And, last but not least, it was Viner who created the substance of the theory of monopolistic competition, which in a peculiar dialectic was later to become the target of the Chicago School.

vintage capital

Raouf Boucekkine, David de la Croix and Omar Licandro
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews the early vintage capital literature of the 1960s, and identifies the factors behind the revival of topic from the 1990s. The fundamental properties of the seminal vintage capital growth models are disentangled, and the origins of the associated controversy on the importance of embodied technical progress are evoked. The recent revival of this literature is analysed with special emphasis on the rising support for the Solowian view of investment following Gordon's 1990 fundamental work on the price of durable goods, and the emergence of a new vintage human capital literature devoted to some fundamental economic growth issues.

Keywords
capital–labour substitution; Cobb–Douglas technology; cohort size; consumption smoothing; demographic transition; demography; Denison, E.; depreciation; diffusion of technology; embodiment hypothesis; fertility; human capital; inequality (explanations); information technology revolution; innovation; investment cycles; Leontief technology; life expectancy; neoclassical growth theory; neoclassical production functions; obsolescence; overlapping generations models; Phelps, E.; population growth; productivity slowdown; quasi-rent; replacement echoes; Solow, R.; technical progress; transition dynamics; vintage capital; vintage human capital

Article

In neoclassical growth theory capital is assumed to be homogeneous and technical progress disembodied, meaning that all capital units benefit equally from any technological improvement. The disembodied nature of technical progress looks unrealistic, as acknowledged by Solow (1960, p. 91):

This conflicts with the casual observation that many if not most innovations need to be embodied in new kinds of durable equipment before they can be made effective.
Accounting for the age distribution of capital is a way to cope with this criticism. It actually inspired an important stream of the growth literature of the 1950s and 1960s, giving birth to vintage capital theory. An economy is said to have a vintage capital structure if machines and equipment belonging to separate generations have different productivity, or face different depreciation schedules as in Benhabib and Rustichini (1991). Let us denote by $I(v)$ the number of machines of vintage $v$. With zero physical depreciation, vintage technology $v$ is

$$Y(v, t) = F(I(v), L(v, t), e^{Y(t)}),$$

where $Y(v, t)$ is the output of vintage $v$ at time $t \geq v$ and $L(v, t)$ is the amount of labour assigned to this vintage. Parameter $\gamma > 0$ designates the rate of technical progress, which is said to be embodied since it benefits only vintage $v$. $F(.)$ has the properties of a neoclassical production function. Vintages produce the same final good

$$Y(t) = \int_{t - T(t)}^{t} Y(v, t) \, dv,$$

where $Y(t)$ is total production and $T(t)$ is the lifetime of the oldest operative vintage.

Besides realism, vintage capital models were initially thought to be able to generate quite different long-run properties and short-term dynamics from neoclassical growth models. Because the productivity gap between new and old vintages is increasing over time, the latter need not be operated for ever, and, contrary to the neoclassical growth theory, the lifetime of capital goods might well be finite (Johansen, 1959). Such a property was thought to involve non-monotonic transition dynamics governed by the replacement of scrapped goods, known as the replacement echoes principle, which again sharply departs from neoclassical growth models.

On more general ground, vintage capital models were at the heart of the embodiment controversy, which opposed Solow to some leading growth theorists and empiricists, among them Phelps (1962) and Denison (1964). While the former argued that accounting for the fraction of technological progress which is exclusively conveyed by capital accumulation (that is, embodied technical progress) is important to accounting for growth, Phelps argued that the decomposition of technical progress is irrelevant in the long run. Recent studies notably by Gordon (1990) have resuscitated this controversy, as we shall see. Before developing all these themes, it should be noted that, whereas early vintage capital
theory primarily focused on physical capital accumulation, recent contributions have taken the same view of human capital accumulation (see Chari and Hopenhayn, 1991). Vintage human capital is generated either by successive vintages of technologies which induce specific skills or by demographic conditions. Such contributions have brought out a new and quite appealing understanding of the mechanisms behind technology diffusion and demographic transitions, for example. We briefly review them also.

The lifetime of capital

In Johansen (1959), technology is ‘putty-clay’, meaning that capital–labour substitution is permitted \textit{ex ante} but not once capital is installed. Technological progress is assumed to be labour-saving. Because factor proportions are fixed \textit{ex post},

\[ \gamma(v, t) = F\left( I(v), e^{\gamma} L(v, t) \right) = g(\lambda(v)) \cdot I(v), \]

where the labour–capital ratio \( \lambda(v) \) and the size of the capital stock \( I(v) \) are both decided at the time of installation, and employment is \( L(v, t) = \lambda(v) \cdot e^{\gamma} I(v) \). In Johansen, \textit{obsolescence} determines the range of active vintages. Quasi-rents of vintage \( v \) at date \( t \) are proportional to \( g(\lambda(v)) - \lambda(v) \cdot e^{\gamma} w(t) \), where \( w(t) \) is the equilibrium wage. Since wages are permanently growing as a direct consequence of technical progress, quasi-rents are decreasing. Machines of vintage \( v \) are operated as long as their quasi-rents remain positive. Consequently, the scrapping age is defined by \( T = t^* - v \) where \( g(\lambda(v)) = \lambda(v) \cdot e^{\gamma} w\left(t^*\right) \). Therefore, Johansen's framework leads to an endogenous, finite lifetime of capital.

Replacement echoes

If capital lifetime is finite, there might be a room for replacement echoes, as mentioned above. Solow et al. (1966) examine this question in the simpler case of a Leontief technology, when factor substitution is not allowed either \textit{ex ante} or \textit{ex post}. In such a case, \( \gamma(v, t) = \gamma(v) = I(v) = e^{\gamma} L(v) \), for all \( t \geq v \). One unit of vintage capital \( v \) produces one unit of output once combined with \( e^{-\gamma} v \) units of labour. Technical progress is embodied and takes the form of a decreasing labour requirement. For the same reasons as in Johansen, capital goods are scrapped in finite time. Using in addition a constant saving rate, and some technical assumptions, Solow et al. show convergence to a unique balanced growth path, delivering the same qualitative asymptotic behaviour as the neoclassical growth model. This was quite disappointing, since under finite lifetime one would have expected an investment burst from time to time, giving rise to replacement echoes.
Let us normalize the labour supply to unity. From labour market clearing, \( \int_{t-\tau}^t T(v) L(v) \, dv = 1 \). Under constant lifetime, time differentiation of the equilibrium condition yields \( L(t) = L(t - \tau) \), implying that investment is mainly driven by replacement activities. When obsolete capital is destroyed, new investments are needed to replace the scrapped machines, creating enough jobs to clear the labour market. As a direct consequence, job creation and investment have a periodic behaviour, implying that investment cycles are reproduced again and again in the future.

Solow et al. (1966) did not find echoes because of the constant saving rate assumption, which completely decouples investment from replacement. In an optimal growth model with linear utility and the same technological assumptions, Boucekkine, Germain and Licandro (1997) show (finite time) convergence to a constant lifetime, letting replacement echoes operate and generate everlasting fluctuations in investment, output and consumption. Under strictly concave preferences, fluctuations do arise in the short run but get dampened in the long run by consumption smoothing (see Boucekkine et al., 1998). Therefore, the short-run dynamics of vintage capital models differ strikingly from the neoclassical growth model, provided capital and labour are to some extent complementary, consistently with the observed dynamics of investment at both the plant level (Doms and Dunne, 1998) and the aggregate level (Cooper, Haltiwanger and Power, 1999). Non-monotonic behaviour has also been shown by Benhabib and Rustichini (1991) for vintage models with non-geometric depreciation.

The embodiment hypothesis

A crucial property of vintage capital models is the embodied nature of technological progress: the incorporation of innovations into the production process cannot be achieved without the acquisition of the new vintages which are their exclusive material support. According to Solow (1960), embodiment can have crucial implications for growth accounting. To make the point, he considers a Cobb–Douglas vintage technology

\[
Y(v, t) = \left[ e^{Y(v)} \right]^{1-\alpha} L(v, t)^\alpha,
\]

and the capital–labour ratio adjusts continuously. The embodiment hypothesis takes the form of quality adjustments, with capital's quality growing at rate \( \gamma \). In sharp contrast to Johansen, capital lifetime needs not be finite, since under Cobb–Douglas technology any wage cost could be covered by assigning arbitrarily small amounts of labour.

A striking outcome of Solow's model is its aggregation properties. Denote by \( L(t) \) the total labour supply, and define quality adjusted capital as

\[
K(t) = \int_{-\infty}^t e^{Y(v)} \, dv.
\]
Since marginal labour productivity equalizes across vintages, aggregate output becomes

$$\gamma(t) = \kappa(t)^{1 - \alpha} L(t)^{\alpha}.$$ (1)

Aggregate vintage technology in Solow (1960) degenerates into a neoclassical production function. However, by differentiating (1), the motion law for capital is slightly different

$$K'(t) = e^{Y(t)} L(t),$$

reflecting embodied technical change. Since $e^{-Y} t$ measures the relative price of investment goods at equilibrium, the value of capital is by definition $A(t) = e^{-Y} \kappa(t)$, and evolves following

$$A'(t) = l(t) - \gamma A(t).$$

Technological progress operates as a steady improvement in equipment quality, which in turn implies obsolescence of the previously installed capital. In Solow, obsolescence does not show up through finite time scrapping but through labour reallocation reflecting a declining value of capital. This important point has been at the heart of recent literature on the productivity slowdown and the information technology revolution (see Whelan, 2002). Indeed, the potential implications for growth of embodied technical progress were tremendously controversial in the 1960s. In a famous statement, Denison (1964) claimed ‘the embodied question is unimportant’. His argument was merely quantitative and restricted embodiment to changes in the average age of capital in a one-sector growth accounting exercise. In particular, his reasoning omits de facto the relative price of capital channel. Greenwood, Hercowitz and Krusell (1997), by using Gordon's (1990) estimates of the relative price of equipment, quantitatively evaluate the two-sector Solow model, claiming that around 60 per cent of US per-capita growth is due to embodied technical change. As pointed out by Hercowitz (1998), Gordon's series have been good news for the Solowian view.

**Vintage human capital**

http://www.dictionaryofeconomics.com/library/lemoyne.edu/article?id=pde2008_V000072&goto=5&result_number=1836
The vintage capital growth literature typically considers labour as a homogenous good. However, just as physical capital is heterogenous, so too is the labour force. The concept of vintage human capital was explicitly used in the 1990s to treat some specific issues related to technology diffusion, inequality and economic demography.

In a world with a continuous pace of innovations, a representative individual faces the typical question of whether to stick to an established technology or to move to a new and better one. The trade-off is the following: switching to the new technique would allow him to employ a more advanced technology but he would lose the expertise, the specific human capital, accumulated on the old technique. In Chari and Hopenhayn (1991) and Parente (1994), individuals face exactly this dilemma. In such frameworks the generated vintage human capital distributions essentially mimic the vintage distribution of technologies, the time sequence of innovations being generally exogenously given. Chari and Hopenhayn (1991) consider a two-period overlapping generations model where different vintage technologies, operated by skilled and unskilled workers, coexist. Old workers are experts in the specific vintage technology they have run when young. The degree of complementary between skilled and unskilled labour affects negatively the velocity of technological diffusion, since young individuals have strong incentives to invest in old technologies when their unskilled labour endowment is highly complementary to the skilled labour of the old.

Jovanovic (1998) argues that vintage capital models are particularly well suited to explain income disparities across individuals and across countries. The main mechanism behind them is the following. Under the assumption that machines’ quality and labour’s skill are complementary, the best machines are assigned to the best-skilled individuals, exacerbating inequality. If reassignment is frictionless, then the best-skilled workers are immediately assigned to the frontier technology, the second-best go to the machines just below the frontier, and so on. Even though it is at odds with Chari and Hopenhayn, where adoption costs induce a much slower switching of technologies, frictionless reassignment has the virtue, consistent with cross-country evidence, of implying persistent inequality, in contrast to Parente (1994), which bears leapfrogging.

On the theoretical side, Jovanovic makes an important contribution to the vintage capital literature to the extent that he addresses the hard problem of combining vintage physical capital and vintage human capital in a framework where the vintage distributions of both assets are endogenous. Jovanovic uses an assignment model à la Sattinger (1975) to solve this difficult problem. Firms combine machines and workers in fixed proportions, say one machine for one worker, at every instant. Because labour resources are fixed, the latter fixed-proportions assumption implies that old machines become unprofitable at a finite time, as in Johansen. Vintage human capital comes from human capital accumulation à la Lucas (1988): the growth of the stock of human capital determines the maximal quality of human capital available: if the worker has human capital, \( h \), and works a fraction of time \( u \) (in production), then her skill is given by \( s = u h \). The typical assignment problem of a firm having acquired capital of a given vintage is to find the optimal vintage human capital or skill of the associated worker (via profit maximization), which makes it possible to achieve the pairing of skills and machines on the basis of the persistent inequality mechanism outlined above.

Demographics
One likely channel through which demographics affect growth is the size, quality and composition of the workforce. From this perspective, generations of workers can be understood as being vintages of human capital. In a continuous-time overlapping generations framework, Boucekkine, de la Croix and Licandro (2002) model the vintage specificity of human capital from schooling decisions. Individuals optimally decide how many years to spend at school as well as their retirement age; life expectancy has a positive effect on both because of its beneficial impact on the return to education. In such a framework, the vintage specificity of human capital depends, not on technological vintages as in Chari and Hopenhayn (1991), but on cohort-specific demographic characteristics, including education.

The observed relation between demographic variables, such as mortality, fertility and cohort sizes, and growth is anything but linear. Since a key element is between-generation differences in human capital, these nonlinearities may be modelled by the mean of a vintage structure of population. Boucekkine et al. (1998) generate nonlinear relationships between economic growth and both population growth and life expectancy. A longer life, for example, has several conflicting effects. On the one hand it increases the incentives to acquire education and reduces the depreciation rate of aggregate human capital. But on the other, an older population, which finished its schooling a long time ago, is harmful for economic growth.

Conclusion

After a relatively long stagnation, the vintage capital literature, which was a fundamental growth area in the 1960s, has been experiencing a revival since the early 1990s. This revival is due to several factors, among them the rising support for the Solowian view of investment following Gordon's fundamental work on the price of durable goods, the emergence of a new vintage capital growth theory led by Benhabib and Rustichini (1991) relying on a novel and appropriate mathematical set-up, and notably the increasingly common view that some fundamental economic growth issues (like technology diffusion, for example) do require the vintage structure to be better appraised. Of course, many tasks within this new literature remain to be addressed. In particular, much work is needed to bring the vintage models closer to the data. The work of Gilchrist and Williams (2000) is fundamental in this respect.

Vintages are durable goods acquired at different points of time. The acquisition prices for capital goods of each vintage at each point of time together with investments of all vintages at each point of time constitute the basic data on quantities and prices. These data can be employed in generating the complete vintage accounting system.

Keywords
capital measurement; capital services; depreciation; durable goods model of production; investment; Jorgenson, D. W.; price–quantity duality; production functions; rate of return; vintage accounting; vintages

Article
Investment represents the acquisition of capital goods at a given point of time. The quantity of investment is measured in the same way as the durable goods themselves. For example, investment in equipment is the number of machines of a given specification and investment in structures is the number of buildings of a particular description. The price of acquisition of a durable good is the unit cost of acquiring a piece of equipment or a structure.

By contrast with investment, capital services are measured in terms of the use of a durable good for a stipulated period of time. For example, a building can be leased for a period of years, an automobile can be rented for a number of days or weeks, and computer time can be purchased in seconds or minutes. The prices of the services of a durable good is the unit cost of using the good for a specified period.

Aggregation over vintages

We can refer to durable goods acquired at different points of time as different vintages of capital. The
flow of capital services is a quantity index of capital inputs from durable goods of different vintages. Under perfect substitutability among the services of durable goods of different vintages, the flow of capital services is a weighted sum of past investments. The weights correspond to the relative efficiencies of the different vintages of capital.

The durable goods model of production is characterized by price-quantity duality. The rental price of capital input is a price index corresponding to the quantity index given by the flow of capital services. The rental prices for all vintages of capital are proportional to the price index for capital input. The constants of proportionality are given by the relative efficiencies of the different vintages of capital.

We develop notation appropriate for the intertemporal theory of production by attaching time subscripts to the variables that occur in the theory. We can denote the quantity of output at time \( t \) by \( y_t \) and the quantities of \( J \) inputs at time \( t \) by \( x_{jt} (j = 1, 2, \ldots, J) \). Similarly, we can denote the price of output at time \( t \) by \( q_t \) and the prices of the \( J \) inputs at time \( t \) by \( p_{jt} (j = 1, 2, \ldots, J) \).

In order to characterize capital as a factor of production, we require the following additional notation:

- \( A_t \) – quantity of capital goods acquired at time \( t \).
- \( K_{t,\tau} \) – quantity of capital services from capital goods of age \( \tau \) at time \( t \).
- \( p_{A,t} \) – price of acquisition of new capital goods at time \( t \).
- \( p_{K,t}\tau \) – rental price of capital services from capital goods of age \( \tau \) at time \( t \).

To present the durable goods model of production we first assume that the production function, say \( F \), is homothetically separable in the services of different vintages of capital:

\[
\forall \tau = F[G(K_{t,0}, K_{t,1}, \ldots K_{t,\tau}, \ldots), x_{2t} \ldots x_{jt}].
\]  

(1)

Where \( K_t \) is the flow of capital services, we can represent this quantity index of capital input as follows:

\[
K_t = G,
\]

where the function \( G \) is homogeneous of degree one in the services from capital goods of different ages. If we assume that the quantity index of capital input \( K_t \) is characterized by perfect substitutability among the services of different vintages of capital, we can write this index as the sum of these services:
Under the additional assumption that the services provided by a durable good are proportional to initial investment in this good, we can express the quantity index of capital input in the form:

\[ K_t = \sum_{\tau=0}^{\infty} K_{t, \tau}. \]  

The flow of capital services is a weighted sum of past investments with weights given by the relative efficiencies \( \{ d_{\tau} \} \) of capital goods at different ages.

Under constant returns to scale we can express the price of output as a function, say \( Q \), of the prices of all inputs. The price function \( Q \) is homothetically separable in the rental prices of different vintages of capital:

\[ q_t = Q[p_{K, t, 0}, p_{K, t, 1}, \ldots, p_{K, t, \tau}, \ldots, p_{2t}, \ldots, p_{Jt}]. \]  

Where \( p_{K, t} \) is a price index of capital services, we can represent this index as follows:

\[ p_{K, t} = P, \]

where the function \( P \) is homogeneous of degree one in the rental prices of capital goods of different ages. Under perfect substitutability among the services of different vintages of capital, we can write the price index of capital input \( P \) as the price of the services of a new capital good:

\[ P_{K, t} = P_{K, t, 0}. \]
Under the additional assumption that the services provided by a durable good are proportional to the initial investment, we can express the rental prices of capital goods of different ages in the form:

\[ p_{K,t,T} = d_T p_{K,t} \ (\tau = 0, 1, \ldots). \] (4)

The rental prices are proportional to the rental price of capital input with constants of proportionality given by the relative efficiencies \( \{d_\tau\} \) of capital goods of different ages. Given the quantity of capital input \( K_t \), representing the flow of capital services, and the price of capital inputs \( p_{K,t} \), representing the rental price, capital input plays the same role in production as any other input. We next derive the prices and quantities of capital inputs from the prices and quantities for acquisition of durable goods \( p_{A,t} \) and \( A_t \).

**Vintage accounting**

We begin our description of the measurement of capital input with the quantities estimated by the perpetual inventory method. Taking the first difference of the expression for capital stock in terms of past investments (2), we obtain:

\[ K_t - K_{t-1} = A_t + \sum_{\tau=1}^{\infty} (d_\tau - d_{\tau-1}) A_{t-\tau}, \]

where \( R_t \) is the level of replacement requirements in period \( t \). The change in capital stock from period to period is equal to the acquisition of investment goods less replacement requirements.

We turn next to a description of the price data required for the measurement of the price of capital input. There is a one-to-one correspondence between the vintage quantities that appear in the perpetual inventory method and the prices that appear in our vintage price accounts. To bring out this correspondence we use a system of present or discounted prices. Taking the present as time zero, the discounted price of a commodity, say \( q_t \), multiplied by a discount factor:

\[ q_t = \prod_{s=1}^{t} \frac{1}{1 + r_s} p_t. \]
The notational convenience of present or discounted prices results from dispensing with explicit discount factors in expressing prices for different time periods. In the correspondence between the perpetual inventory method and its dual or price counterpart the price of acquisition of a capital good is analogous to capital stock. The price of acquisition, say \( q_{A,t} \), is the sum of future rental prices of capital services, say \( q_{K,t} \), weighted by the relative efficiencies of capital goods in all future periods:

\[
q_{A,t} = \sum_{\tau=0}^{\infty} d_{\tau} q_{K,t+\tau+1}
\] (5)

This expression may be compared with the corresponding expression (2) giving capital stock as a weighted sum of past investments. Taking the first difference of the expression for the acquisition price of capital goods in terms of future rentals (5), we obtain:

\[
a_{A,t} - q_{A,t-1} = -q_{K,t} - \sum_{\tau=1}^{\infty} (d_{\tau} - d_{\tau-1}) q_{K,t+\tau} = -q_{K,t} + q_{D,t}
\]

where \( q_{D,t} \) is depreciation on a capital good in period \( t \). The period-to-period change in the price of acquisition of a capital good is equal to depreciation less the rental price of capital. Postponing the purchase of a capital good makes it necessary to forgo one period's rental and makes it possible to avoid one period's depreciation. In the correspondence between the perpetual inventory method and its price counterpart, investment corresponds to the rental price of capital and replacement corresponds to depreciation. We can rewrite the expression for the first difference of the acquisition price of capital goods in terms of undiscounted prices and the period-to-period discount rate:

\[
p_{K,t} = p_{A,t-1} r_{t} + p_{D,t} - (p_{A,t} - p_{A,t-1})
\] (6)

where \( p_{A,t} \) is the undiscounted price of acquisition of capital goods, \( p_{K,t} \) the price of capital services, \( p_{D,t} \)
depreciation, and \( r_t \) the rate of return, all in period \( t \). The price of capital services \( p_{K,t} \) is the sum of return per unit of capital \( p_{A,t-1,t} \), depreciation \( p_{D,t} \), and the negative of revaluation, \( p_{A,t} - p_{A,t-1} \). To apply this formula we require a series of undiscounted acquisition prices for capital goods \( p_{A,t} \), rates of return \( r_t \), depreciation on new capital goods, \( p_{D,t} \), and revaluation of existing capital goods \( p_{A,t} - p_{A,t-1} \).

To calculate the rate of return in each period we set the formula for the rental price \( p_{K,t} \) times the quantity of capital \( K_{t-1} \) equal to property compensation. All of the variables entering this equation – current and past acquisition prices for capital goods, depreciation, revaluation, capital stock and property compensation – except for the rate of return, are directly observable. Replacing these variables by the corresponding data we solve this equation for the rate of return. To obtain the capital service price itself we substitute the rate of return into the original formula along with the other data. This completes the calculation of the service price.

In the perpetual inventory method data on the quantity of investment goods of every vintage are used to estimate capital formation, replacement requirements and capital stock. In the price counterpart of the perpetual inventory method data on the acquisition prices of investment goods of every vintage is required. In the full price–quantity duality that characterizes the vintage accounts, capital stock corresponds to the acquisition price of durable goods and investment corresponds to the rental price of capital services.

**Conclusion**

The distinguishing feature of capital as a factor of production is that durable goods contribute capital services to production at different points of time. The services provided by a given durable good are proportional to the initial investment. In addition, the services provided by different durable goods at the same point of time are perfect substitutes. The weights correspond to the relative efficiencies of the different vintages of capital. The durable goods model of production was originated by Walras (1954) and is discussed in greater detail by Jorgenson (1973) and Diewert (1980).

The durable goods model is characterized by price–quantity duality. The rental price of capital input is a price index corresponding to the quantity index given by the flow of capital services. The rental prices for all vintages of capital are proportional to the price index for capital input. The constants of proportionality are given by the relative efficiencies of the different vintages of capital. The dual to the durable good model of production was introduced by Hotelling (1925) and Haavelmo (1960). The dual to this model has been further developed by Arrow (1964) and Hall (1968).

The acquisition prices for capital goods of each vintage at each point of time together with investments of all vintages at each point of time constitute the basic data on quantities and prices. These data can be employed in generating the complete vintage accounting system originated by Christensen and Jorgenson (1973) and described by Jorgenson (1980). Price and quantity data that we have described for a single durable good are required for each durable good in the system. These data are used to derive price and quantity indexes for capital input in the theory of production presented in the entry on production functions.

virtual economy

Clifford G. Gaddy
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The virtual economy was the system of informal rent distribution that arose in post-Soviet Russia in the 1990s as nonviable Soviet-era manufacturing industries sought to protect themselves from the discipline of the market. Enterprise directors and their allies throughout the economy (including government officials) colluded to use nonmarket prices and various forms of nonmonetary exchange such as barter to transfer value from resource sectors to manufacturing industry. The article discusses the system's historical roots, describes some of its characteristic phenomena, and outlines a model for behaviour of enterprises.

Article

The virtual economy was the name given to the system of informal rent sharing or value distribution that prevailed in Russia in the 1990s. Featuring widespread use of nonmonetary exchange and nonmarket prices to conceal transfers of value, especially from resource sectors to manufacturing industry, the virtual economy reached a peak in the run-up to the country's financial crisis in August 1998. The strategies used by enterprise directors to participate in this nonmonetary economy fundamentally changed the behaviour of hundreds and thousands of noncompetitive manufacturing enterprises in Russia during the transition process. The behavioural adaptation permitted enterprises to survive in the transition environment where they ought to have failed. The expectation had been that when the old Soviet industrial structure was shocked by the sudden collapse of central planning and the subsequent launching of radical market reforms – including mass privatization and elimination of overt subsidies – economic agents would be forced to change their behaviour to become competitive in a market economy. The transition was thus intended as a Darwinian process whereby only those enterprises that
could transform themselves into competitive operations would survive. But in the case of Russia, the
dinosaurs survived – without restructuring. They did change, but instead of adapting to the market, they
changed to protect themselves from the market.

In essence the virtual economy was a peculiar system of rent distribution in which the primary vehicle
through which agents laid claim to rents was production. The virtual economy was the set of informal
institutions that facilitated the production of goods that were value-subtracting, that is, worth less than
the value of the inputs used to produce them. Enterprises were able to engage in such production
because they had recipients who were willing to accept fictitious (nonmarket) pricing of the goods at
levels that masked their lack of profitability. Buyers and sellers colluded to hide the fictitious nature of
the pricing. In the classic form of the virtual economy, they did so by avoiding money, instead using
barter and other forms of nonmonetary exchange, as well as even more intricate subterfuges.

Since value was being destroyed as the system operated, there had to be a source of value. The ultimate
‘value pump’ in Russia was the fuel and energy sector, above all one single company, Gazprom –
Russia’s natural gas monopoly. In exchange for the rights to keep what it earned from exports, Gazprom
pumped value into the system by supplying gas without being paid for it (or, more generally, at a cost
that was low enough to keep enterprises operating). Gazprom subsidies, which then led to arrears to the
government, were the primary way in which unprofitable activity was supported in Russia.

The virtual economy evolved and persisted because it met the needs of so many actors in the economy.
Workers and managers at industrial dinosaurs benefited because the virtual economy postponed the
ultimate reckoning for loss-making firms. Government, especially at the sub-national level, where much
of the important action took place, benefited because the virtual economy system maintained
employment and the provision of social services. Gazprom also benefited, since the value transfers it
made to the virtual economy were the price it paid to appropriate the massive rents from exports.

The roots of the virtual economy mechanisms lay in the Soviet system, especially the production
relationships that had developed under the Soviet command economy. These relationships represented a
peculiar type of asset, ‘relational capital’, which supplemented the enterprise’s conventional physical and
human capital. Thanks to relational capital, market reform policies did not necessarily compel the
enterprise to restructure in order to be able to compete in the market environment. Enterprises chose
between whether to become more competitive in the market, by investing in physical and human capital,
or to be better protected from the market, by investing in relational capital.

The term ‘virtual economy’ was coined in 1998 by Gaddy and Ickes, building on terminology in a
Russian government report from 1997. In early 1996, alarmed by the extent of tax delinquency in the
country, President Boris Yeltsin appointed a special blue-ribbon panel to investigate the low rate of
collection of taxes in Russia. Presenting its findings after an 18-month investigation, the panel reported
that the country’s largest companies conducted 73 per cent of all their business in the form of barter and
other nonmonetary forms of settlement. Especially alarming was the extent of nonmonetary payments of
taxes. During the period of review, these large enterprises paid less than eight per cent of their tax bills
in actual cash. They simply failed to meet 29 per cent of their obligations at all, while ‘paying’ the
remaining 63 per cent in the form of offsets and barter goods. The market value of the goods delivered
was far below the nominal price used in the offsets, leaving the government with substantially less in
virtual economy: The New Palgrave Dictionary of Economics

real revenues than officially accounted for. In summing up their own conclusions about the contemporary Russian economy, the investigatory commission wrote:

An economy is emerging where prices are charged which no one pays in cash; where no one pays anything on time; where huge mutual debts are created that also can't be paid off in reasonable periods of time; where wages are declared and not paid; and so on. … [This creates] illusory, or virtual earnings, which in turn lead to unpaid, or virtual fiscal obligations, [with business conducted at] nonmarket, or virtual prices. (Karpov, 1997)

Gaddy and Ickes (1998) suggested that the entire system be called a virtual economy ‘because it [was] based on illusion, or pretense, about almost every important parameter of the economy: prices, sales, wages, taxes, and budgets’. The pretense that had become the norm was as characteristic of the virtual economy as were the colourful forms of nonmonetary exchange.

The nonmonetary economy

The nonmonetary means of payment that characterized the virtual economy spanned a wide range. They included direct exchanges of goods (true barter), either bilaterally or through ‘chains’ with multiple participants, offsets (where debts accrued by one party were later paid off not in money but in goods), and promissory notes called veksels. Veksels – the name is derived from the German Wechsel (‘promissory note’) – were a widespread nonmonetary payment mechanism that ranged from being a substitute for money to essentially a form of barter.

There were several key nodes in the barter chains, above all the major natural monopolies known popularly as the ‘three fat boys’ (tri tolstyaka) – Gazprom (the natural gas monopoly), RAO UES (the electricity monopoly), and MPS (the state railways). All three frequently complained that they collected as little as ten per cent of their revenues in cash. Almost all enterprises in Russia were consumers of the output of these three companies, rail freight transport, gas and electricity. The three monopolies also accounted for about 25 per cent of taxes due to the federal budget. The fact that everyone needed to purchase services from the ‘fat boys’ meant that there was a ready demand for the veksels (IOUs) of these companies. It was this special position that put them at the core of the non-payments system in Russia.

The other key player in the barter economy was the government, or rather, governments at all levels. Here again was an agent to whom nearly everyone had an obligation. The volume of accrued unpaid taxes, plus the huge fines and penalties levied for nonpayment, presented governments with an almost inexhaustible supply of debts. And, in turn, governments themselves owed many others. They were, like the natural monopolies, a key node for barter.

One particularly important phenomenon was tax offsets. An enterprise owed taxes to the government, and concluded an agreement whereby those tax obligations were settled by delivering goods or performing services for the government. Of all the forms of nonmonetary transactions observed in Russia in the 1990s, the mechanism of tax offsets was the most characteristic of the virtual economy. Russian governments at all levels grew increasingly willing to offset enterprises’ tax obligations against goods or services delivered to the government. By the end of 1997, the accumulated tax debt was

http://www.dictionaryofeconomics.com/library/lemoyne.edu/article?id=pde2008_V000067&goto=S&result_number=18380
enormous. Industrial enterprises were particularly egregious delinquents. The sum owed by the enterprises at the end of 1997 was equal to 46 per cent of the amount they actually remitted in taxes for the whole of 1997. These enormous debts gave impetus to the practice of tax offsets.

Consider, for example, an enterprise that was able to supply the local government with services in lieu of taxes. The enterprise could have paid its tax liability in money, but that would have required selling its output for cash. Alternatively, the enterprise could negotiate with the government to supply some service as an offset for taxes. If the enterprise had resources that were not fully utilized, the latter alternative was likely to reduce the effective tax burden on the enterprise. Moreover, once the government showed itself to be willing to engage in tax offsets, the options open to enterprises expanded. The enterprise could now potentially pay its taxes not only with its own products but also with products it received in barter deals from other enterprises. This greatly reduced the cost to the seller of accepting goods rather than cash.

The motivation for governments to join in the barter economy was simple. They reasoned that if they could not get cash, it was better to reach some sort of settlement than receive nothing at all. In some cases, especially at the local level, an enterprise could offer to deliver goods or services to the city or regional government in lieu of taxes. At the federal level, it was more common for the government to cancel tax arrears or taxes due by writing off the government's own debt to the enterprise in question for state orders. Once the practice was established with respect to past arrears, there was an anticipatory factor: enterprises began to feel confident that they could henceforth ship off products to the government, knowing that later they would be allowed to offset their taxes in an equivalent amount. Less than 60 per cent of all federal taxes collected in 1997 were paid in cash; the rest were in the form of offsets.

The federal government was particularly victimized by these schemes. Enterprises frequently colluded with regional and local officials to hide income and hence keep revenues away from the federal government for taxes whose revenues were split between local and national authorities. In other cases, local governments demanded that enterprises pay their taxes in the form of goods and services that could be used only locally and not be shared with the federal government (for instance, by providing road construction or repairs of buildings). Often, if the federal government received anything at all in these schemes, it was only what the regional governments did not want.

In one notorious case reported in the Russian press in the spring of 1998, the oblast (province) government of Samara had permitted enterprises to pay their regional taxes in the form of goods. One of the items offered turned out to be ten tons of toxic chemicals from a local chemical plant. Although the plant claimed (and was given) credit for 400 million rubles (80,000 dollars) in taxes, auditors later determined that the chemicals were worthless (and indeed dangerous). The Samara government never suffered from this curious deal, however, since it had previously sought and received permission from the federal ministry of labour to fulfil its obligations to the federal unemployment compensation fund by delivering goods instead of money. Among the goods it offered were the ten tons of toxic chemicals (Gaddy and Ickes, 2002, p. 176).

As a result of these practices, the Russian budget ran massive deficits. Even using the inflated prices used in the offset deals, federal revenues plummeted – from 16.2 per cent of GDP in 1995 to 12.4 per cent in 1998. To finance its deficits, the government had resorted to extensive borrowing outside and inside Russia at increasing and unsustainably high costs, thus digging itself even deeper in debt. Finally, on 17 August 1998, the government defaulted on about 40 billion dollars’ worth of its own ruble-
denominated debt instruments (so-called GKO$s), some 17 billion dollars of which were held by foreigners.

**The Soviet roots**

The roots of the virtual economy lay in the structure and institutions bequeathed to Russia by its Soviet predecessor. Some parts of the economy, notably the resource industries, were value-adding. But most of the vast manufacturing sector that Russia had inherited could not compete in a market setting. In fact, by the final years of the Soviet era, the manufacturing sector was in poor condition even on the terms of the planned economy. By official Soviet standards, more than one-third of equipment in Russian industry was physically obsolete. Soviet planning practice, which emphasized output over costs, set physical, rather than economic, obsolescence as the criterion for removing a machine from the factory. As long as the machine could produce anything at all, it was kept in production. The result was very low replacement rates for capital equipment.

The location of industry in the Soviet economy was another problem. Not only did Soviet location policy ignore transport costs but it also failed to take into account the costs associated with the cold Russian climate – in terms of energy use, health maintenance and many other factors. By being placed in some of Russia’s coldest and most remote regions, the manufacturing enterprises were rendered even less competitive and less attractive for foreign investment.

Equally important as the structure of the Soviet economy and its lack of competitiveness was the fact that this reality was hidden. As the market transition began, past history and performance gave no information about which sectors, or enterprises, were value-adding and which were value-destroying. The culprit was distorted Soviet pricing.

**Soviet pricing and the ‘circus mirror’ effect**

Soviet prices were not based on opportunity cost, or value; rather, they were simply an accounting instrument to measure plan fulfilment. Although Soviet prices were set arbitrarily, they were not set randomly. They were determined by specific rules of the system, which produced some systematic biases. First, the planners underpriced raw material inputs, especially energy. They based raw materials prices only on the operating costs of extraction, while ignoring rent. In so doing, they disregarded the opportunity cost of using the resources now rather than in the future. The planners’ overriding goal was to increase today’s output. Scarcity pricing might have induced more conservation, but it would have militated against maximizing current production. This bias in raw materials prices fed into the system of industrial prices. Heavy consumers of energy were, in effect, subsidized. So, too, were heavy users of capital, thanks to the absence of interest charges. In short, costs of production were calculated on the basis of an incomplete enumeration of costs. This led to lower prices for inputs, especially resource inputs, than for final uses and thus an understatement of the share of gross output used in production and, hence, an overstatement of net output.

In addition to incomplete cost-based pricing, the Soviet system was explicitly biased towards certain users. The Soviet leadership assigned priority in the economy to heavy industry, especially the defence industry, and it was important that it appear that these sectors were producing value. This non-scarcity-based pricing was like a distorting mirror at the carnival. It created the illusion that many enterprises
were value-producing when in fact they were value-destroying.

The ‘loot chain’

A further factor contributing to the opaqueness of the Soviet economy and its post-Soviet successor was the way in which income from control of assets was passed down as payoffs through what Gregory Grossman (1998) referred to as the loot chain. In the USSR, wealth diverted from the official state economy into private hands was shared among networks of individuals in the form of payoffs, bribes, and other schemes. Over time an ever greater proportion of people's incomes depended on the chain of corruption and side payments. The virtual economy perpetuated the loot chain in post-Soviet Russia. The living standards of a huge number of people depended on the chain of production and distribution of goods and services in the virtual economy system, where value redistribution, in contrast to looting pure and simple, occurred in a form that paralleled and was intertwined with actual productive economic activity. This made it especially difficult for agents to discern what their own value and the value of their assets would have been in a well-developed and transparent economy. Basic ideas of a market economy, such as the relationship between individual effort and reward, became almost impossibly obscure. One's static position in the production process – for instance, membership in the workforce of a particular enterprise – was more important for success than individual skills and abilities. The Soviet system separated 'what you get' from 'what you do'. The reality was that the effort–reward nexus was random. Instead of 'from each according to his ability, to each according to his needs (or ability)', it was 'to each according to some unknowable, random criterion'. The durability of the misperception depended on its opaqueness. There was no alternative, competing information about the real relationship. This meant that the loot chain was also a constraint on the future evolution of the economy. Individuals were dependent on the prevailing system and they could not know what an alternative system would offer. The uncertainty caused them to resist abandoning the prevailing system.

Impermissibility of true reform

While there was no accurate information about the economic importance of the large Soviet manufacturing sector, its social and political importance was unavoidable. Many of the least competitive enterprises – the so-called dinosaurs of Soviet industry – were socially the most important. They employed millions of workers and provided for tens of millions of their family members. Entire cities depended on them. The sheer size of this sector – as shown by employment – operated to maintain its social and political importance, and the illusion of its economic performance. In a sense, then, the importance of the manufacturing sector in Russia was an illusion economically but continued to be a political and social reality. This latter reality constrained serious market reform policies. Russia did not formally reject the policies themselves; instead, it continued with a pretence of market reform. Policymakers launched one measure after another in their attempt to transform Russia into a market economy. But very few of those measures were allowed to play themselves out to their full extent. The consequences of complete and proper implementation would have been politically intolerable. Thus, while the nation's leadership
proclaimed reform policies, enterprises and other agents continued to behave in ways that rendered the policies ineffective.

The behavioural implications

The range of behavioural options in the virtual economy was broad. The ability to use nonmonetary mechanisms to pay taxes to governments and bills to the natural monopolies fundamentally changed the range of opportunities for action available to Russian enterprise directors. By allowing enterprises to settle their obligations by delivering goods for which there was no effective demand, the governments and the monopolies offered an incentive to avoid restructuring. For many enterprises it was easier to produce such goods than to restructure and earn additional monetary income to pay bills in cash. Producing those goods allowed for the use of idle capital and labour. In short, offsets and barter permitted some enterprises to survive without restructuring. To represent the full range of choice, not only market-oriented activity but also behaviour characteristic of the virtual economy, Gaddy and Ickes (2002) employed the notion of a two-dimensional space, called $r-d$ space. The following sections outline their model.

Market distance, $d$

The impact of liberalization on the Soviet economy can be expressed with a spatial metaphor: liberalization revealed the distance that a Russian enterprise would have to travel to compete in the world economy. Let $d$ designate the enterprise's ‘distance to the market’ at the start of transition. Clearly, $d$ depends on the enterprise's initial endowments of the things that matter for market viability – physical and human capital, as well as the enterprise's marketing structure and organizational behaviour, but also the characteristics of the good that the enterprise produces (its quality and cost of production). Formally, define an enterprise's $d$ as the amount of capital expenditure needed to enable the enterprise to produce a product that is competitive in the market. The fundamental reason for measuring $d$ in terms of the investment cost is that transition causes a divergence between the value of existing (inherited) capital and that of newly installed capital.

One may begin to grasp this point by recalling what happened to traditional models of investment in market economies during the energy crisis of the 1970s. Those models predicted that investment would decline, given the tremendous increase in the price of energy. In fact, however, spending on new equipment and buildings soared. The reason for this discrepancy between model and reality was the divergence between the value of installed capital that was energy intensive and new capital that was energy saving. The conventional model ignored the sharp decline in the economic value of the existing capital stock as a result of the 1973 energy crisis. Installed capital had been the result of investment decisions based on low energy prices; hence, its value fell dramatically once energy prices quadrupled. This in turn only increased the demand for new investment in energy-saving equipment. The result was a divergence between the value of installed capital (which lost value) and that of new capital (which had full economic value). In the Russian context, measuring market distance $d$ by the need for new capital investment is a way of capturing the cost of filling the gap between the value of inherited (Soviet) capital and new (market) capital.
Distribution of $d$

The level of $d$ differs widely among enterprises in the economy. An enterprise that already produces a product it can sell in world markets at a price above cost will have a value of $d$ equal to 0. A completely noncompetitive enterprise will have an enormously large $d$. Everyone else will be somewhere between. For example, an oil-producing enterprise will have a very low $d$. Its product is already right for the market. It may need only relatively small investments in marketing, and so on. A Soviet-style machine tool producer, in contrast, is likely to have a long distance to travel.

The distribution of $d$'s in transition economies differs in two respects from that in market economies. In transition economies the range of $d$'s is greater and the distribution is more skewed. Both differences stem from the dissimilarity in the process of entry and exit in market and planned economies. In a market economy, whether or not a new firm attempts to enter an industry depends on the founders’ expectations about the new firm’s competitiveness. They will enter if they expect the firm’s potential costs to be lower (its productivity to be higher) than those of existing firms. No firm enters an industry in which it expects it will be noncompetitive. Over time the competitiveness of some firms declines, so $d$ increases. But if a firm in a market economy has too high a level of $d$, it will be forced to close. Competition and hard budget constraints cause high-$d$ enterprises to shut down.

In a transition economy, by contrast, some enterprises have very high $d$'s that would not be observed in a market economy. There are several reasons for these high-$d$ enterprises. First, in socialist economies entry was not determined by expectations of profitability or competitiveness but rather by the need to fulfil plan targets. Second, insulation from the world economy meant that enterprises were created that produced goods for which the country might not have had a comparative advantage. Third, especially in the case of Russia, the priority given to defence production led to a proliferation of enterprises that produced goods whose market collapsed with the end of the Soviet Union. Fourth, since the geographic location of industry in the Soviet period was based on ignoring transport costs (as well as the costs associated with extraordinarily cold temperatures), the location of enterprises was also a factor in increasing the $d$ in many cases. For all these reasons, the distribution of the $d$'s in Russia at the onset of the transition had a much higher mean and was more skewed to the right than in a mature market economy. This extra mass of high-$d$ enterprises was the burden of the Soviet legacy. And it was this burden that was the essence of the restructuring problem: so many enterprises had to radically reduce their distance to the market at the same time.

One way to think of the purpose of economic reform is to reduce the average distance in the economy. This occurs through three means: (1) exit of high-$d$ enterprises; (2) entry of new low-$d$ enterprises; (3) and reduction of the $d$ of surviving enterprises. In an ideal market world, market distance would be the only condition that characterized the state of an enterprise. If the only important difference in enterprises were their initial level of $d$, then policies that put pressure on existing high-$d$ enterprises and encourage creation of new low-$d$ enterprises would have the effect of pushing the distribution in the direction of the market.

Relational capital

The conventional view of restructuring, whereby reform means reducing $d$, assumes that each enterprise...
virtual economy: The New Palgrave Dictionary of Economics

has one set of resources – its physical and human capital – which it must use ever more efficiently in order to survive. The virtual economy view, by contrast, posits that some enterprises have another resource, relational capital, which they can draw on to enhance their chances for survival. Relational capital is the stock of goodwill that an enterprise can use to avoid the strictures of the budget constraint. An enterprise that has high relational capital can undertake transactions (bartering, using tax offsets, delaying payment) that other enterprises, with low amounts of relational capital, cannot get away with. To put it another way, relational capital is goodwill that can be translated into the ability to continue to engage in production and exchange without reducing the distance to the market. It is therefore the existence of this second dimension that can explain the persistent survival of high-d enterprises in the Russia of the 1990s.

At the onset of transition enterprises differed in their inherited relational capital – call it r – just as they differed in their d. Some enterprises (or their directors) had very good relations with local and/or federal officials. Relations with other enterprises also varied.

Origins of relational capital

The relational capital of Russian enterprises was initially accumulated in the Soviet system. Enterprise directors relied heavily on the accumulation and use of personal connections. Relational capital was passed forward to the post-Soviet system in a deceptively simple manner: it was spontaneously privatized. And here lies an important aspect of economic transition in Russia. As Hewett (1988) described, plan fulfilment in the Soviet economy required enterprise directors to use informal skills. Their ability to accomplish this, and their position in the economic hierarchy, was critical to their incomes. While directors earned income from these positions, they did not legally own the source of these incomes. The demise of the planning system, which had already begun with Mikhail Gorbachev's reforms in the late perestroika period, had the effect of increasing the autonomy of enterprise directors. With the start of economic reform and privatization, the role of the enterprise director increased; other mediating actors (planners, party officials) played less and less of a formal role in economic allocation. Directors used this opportunity to appropriate the returns to the relationships they had developed and cultivated under the previous system. However, in order for directors to appropriate these returns, the enterprises had to continue to operate. Much of the relational capital was both enterprise-specific and person-specific. To the extent that it was enterprise-specific, the director could not cash out the relational capital. The primary form of these connections was relationships with directors of other enterprises, often in related lines of activity, and with ministerial officials and local government officials. The relational capital was worthless to the incumbent director unless he remained in that particular enterprise. He could not leave the enterprise and take the relational capital with him. Furthermore, because it was person-specific, he could not sell it to someone else. Instead, in order to appropriate the rents accruing to his relational capital, he had to remain in the enterprise and keep it operating. The privatization of relational capital is thus an important part of the explanation of why directors fought to keep open enterprises that had few prospects in the market economy.

r–d space

The concept of relational capital can be used to revise the spatial representation of the Russian transition
Virtual economy: The New Palgrave Dictionary of Economics

There are now two state variables that describe the nature of an enterprise. In addition to the dimension of market distance, enterprises can be arrayed in terms of their level of relational capital. The initial conditions of an enterprise can thus be described by a two-dimensional space, \( r-d \) space, in which each enterprise has its own location.

Whether one views the enterprise sector in a single (\( d \)) dimension or in the two dimensions of \( r-d \) space is critical for how reform policy is understood. The conventional, one-dimensional view assumes that economic reform measures will have the greatest impact on those enterprises that have the highest level of \( d \). According to this assumption, for example, if budget constraints are tightened, enterprises that are farthest from the market will be under greatest competitive pressure. Similarly, it is assumed that if the economy is opened to international competition, the greatest impact will be on those enterprises that are most in need of restructuring. In the two-dimensional \( r-d \) space environment, the effects of market-type reforms need not have this property at all. Tightening the budget constraint will not necessarily put the most pressure on the enterprise that is most inefficient (with the highest \( d \)). If the enterprise has been endowed with high \( r \), it may be insulated against the impact of this policy; it can use relations to evade the budget constraint. And if tight budget constraints are enforced against enterprises that are lower in \( r \), then the policy may, in fact, have greater impact on low-\( d \) enterprises than high-\( d \) enterprises.

It is not just the initial levels of either \( r \) or \( d \) that matter, of course. An enterprise's location in \( r-d \) space is not the immutable relic of its past; it depends on the path of enterprise investment decisions. If the enterprise has invested in \( r \), it will improve its resistance to policies of tight budget constraints. The enterprise director's problem is to decide how much to invest in reducing distance and how much to invest in relational capital.

voluntary contribution model of public goods

Richard Cornes
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article surveys the literature on the model of voluntary contributions to public goods that has developed since the early 1980s. This literature draws explicitly on noncooperative game theory. We present a recent novel statement of the problem, based on ‘replacement functions’, which is both more powerful and more transparent than the traditional formulation that uses players' best response functions. We survey existence, uniqueness and comparative static properties of the basic model, and also sketch some of the extensions of that model – impure public goods, weakest link and best shot – that have been proposed and applied to such problems as global public goods and the global commons. We also draw attention to recent attempts to dynamize the model.

Keywords

pure public goods; impure public goods; noncooperative games; neutrality; free riding; underprovision; weakest and weaker links; best and better shots; replacement functions; lotteries and public good provision

Article
Two classic papers by Samuelson (1954, 1955) played a major role in provoking interest in the problem of public good provision. However, they did not provide an explicit model of decentralized provision. His formal analysis focused on necessary conditions for their optimal provision. Elements of a positive model of decentralized provision – hereafter the standard model – were gradually developed during the following decades, and more complete formal analyses were provided by Cornes and Sandler (1985) and by Bergstrom, Blume and Varian (1986).

1 Introduction

Consider a community with an exogenous number, \( n \), of members. They have preferences over a private good and a public good. Player \( i \)'s consumption of the private good is \( y_i \), and the total provision of the public good is \( G \).

Preferences, resource constraints, and the technology that converts individual contributions into the total available public good are summarized, respectively, by the following assumptions:

- **Preferences** Player \( i \)'s preferences are represented by a utility function, \( u_i(y_i, G) \), which is strictly increasing in both arguments and quasiconcave. Both goods are normal.

- **Resource constraint** \( y_i + c_i g_i \leq m_i \), where player \( i \)'s unit cost as a contributor \( c_i \), and money income \( m_i \), are exogenously given. \( g_i \) is player \( i \)'s contribution to the public good.

- **Technology of public good provision** \( G = \sum_{j=1}^{n} g_j \).

The model considers the Nash equilibrium of the static noncooperative game containing these elements when each player is choosing her best response, \( \hat{g}_i \), to the choices made by all others, \( G_{-i} = \sum_{j=1, j \neq i}^{n} g_j \). This formulation slightly generalizes the standard model in that we allow unit costs to differ across contributors. This extension, initially explored by Ihori (1996), has interesting implications.

2 A graphical treatment
Analyses typically derive a best response function for each player. This determines the player's most preferred choice of contribution as a function of the choices made by all other players: \( \hat{\theta}_i = b_i(G_{-i}) \), where \( \hat{\theta}_i \) is player \( i \) 's utility-maximizing response. A Nash noncooperative equilibrium is an allocation at which every player chooses her best response. Formally, it is a solution to the \( n \) equations provided by the individual best response functions in the \( n \) unknowns, \( g_1, g_2, \ldots, g_n \). Questions about existence, uniqueness and other properties of equilibrium become questions about the existence, uniqueness and other properties of solutions to this set of equations. Such an approach, though naturally suggested by noncooperative game theory, is not the most helpful or transparent method of tackling these issues. We shall briefly sketch an alternative approach, suggested by Cornes and Hartley (2007a), which provides both a rigorous and powerful tool of analysis, and a simple and transparent geometric representation.

Individual behaviour

Figure 1(a) shows player \( i \)'s preferences, constraints and choices. Suppose her income is \( m_i \). If the sum of all other players' contributions is \( C_{-i} \), player \( i \) can devote all her money income to private goods consumption and enjoy the public good provided by others. This allocation is the point \( E' \). Each unit of private good consumption given up by \( i \) augments total public good provision by the amount \( 1/c_i \). Thus her budget constraint is the line \( E'F' \). Her most preferred choice is the point of tangency, \( P' \). By varying \( G_{-i} \) parametrically, we can trace out the income expansion path \( II' \), which summarizes the player's behaviour. The locus \( II \) is everywhere continuous, and slopes upwards at all points at which player \( i \) is at an interior point, choosing strictly positive values of both \( y_i \) and \( g_i \). If there is a finite value of \( G_{-i} \) at which \( \hat{\theta}_i = m_i \), at that point the locus become horizontal.
Note that, for any given value of $G$, the vertical distance between the income expansion path and the locus of the income constraint $mm$ measures the implied value of expenditure by $i$ on the public good, $c_i\hat{\vartheta}_i = m_i - \hat{\psi}_i$. If $c_i = 1$, this same distance measures the quantity of the public good. If $c_i \neq 1$, then a simple scaling up or down of the vertical axis in panel (b) allows us to depict the quantity $g_i$. In any event, under our assumptions, to any given level of total public good provision $G$ above a certain value there corresponds a unique level of contribution by player $i$, $\hat{\vartheta}_i$, that is consistent with that observed level, in the sense that $\hat{\vartheta}_i$ is a best response to the quantity $G - \hat{\vartheta}_i$. We write the implied functional relationship as $\hat{\vartheta}_i = r_i(G)$ and call this player $i$'s replacement function. The figure suggests that every player has a replacement function that is continuous, everywhere non-increasing, and strictly decreasing in $G$ wherever the replacement value itself is positive.

One further property of an individual's replacement function is significant. Suppose that, at a given level of $G$, player $i$ is a strictly positive contributor. Consider the consequence of an increase of $\Delta m_i$ in $i$'s money income. At that given level of $G$, Figure 1 panel (a) shows that her chosen allocation is unchanged. She consumes an unchanged quantity of the private good. Thus, her contribution to the public good changes by the amount

$$\Delta\hat{\vartheta}_i = \frac{\Delta m_i}{c_i}.$$ 

Geometrically, the graph of (the positive section of) her replacement function rises vertically by an amount that, appropriately deflated by the cost parameter, equals the income change. This property plays a crucial role in comparative static analysis.

**Nash equilibrium**

Figure 2 shows the graphs of players' replacement functions in a three-player game. Equilibrium is an allocation at
which the aggregate quantity of the public good is consistent with the replacement values to which it gives rise. In an $n$-player voluntary contribution game, it is an allocation at which

$$R(G) \equiv \sum_{j=1}^{n} r_j(G) = G.$$  

The ‘aggregate replacement function’ $R(G)$ is shown as the thick line in Figure 2. It is simply the vertical sum of the individual graphs. A Nash equilibrium may be depicted graphically as a point where the graph of $R(G)$ intersects the $45^\circ$ ray through the origin in Figure 2. This relationship describes a Nash equilibrium in the form of a single equation in a single unknown, $G$, regardless of how many players there are, and how they differ with respect to preferences, unit costs and money incomes. Armed with the properties already sketched above of the individual replacement functions, scrutiny of this equation is sufficient to provide a complete positive analysis of the model. First, however, note the following simple points. First, the sum of two continuous functions is continuous. Second, the sum of two monotonic functions is itself monotonic.

Figure 2
Nash equilibrium
3 Properties of the equilibrium

We now have all the ingredients for a rigorous analysis of the equilibrium properties of the model, which we now investigate.

Existence of equilibrium

Consider the player whose replacement graph reaches the 45° ray furthest from the origin in \((G, R(G))\) space. It is possible that, at that level of \(G\), all other players are choosing to contribute zero. In this case, we have found an equilibrium, at which the chosen player is the sole contributor. Alternatively, there may be other players whose replacement values are positive. In this case, we have found a value of \(G\) at which \(R(G) > C\). Then monotonicity implies that, as \(G\) rises, the left-hand side of this inequality falls, while the right-hand side rises. Continuity implies that there must be a finite value of \(G\) at which the equilibrium condition holds. Either way, an equilibrium certainly exists. In Figure 2, this is the point \(G^N\), at which the sum of all players' contribution levels that are individually consistent with \(G^N\) is also collectively consistent.

Uniqueness of equilibrium

Monotonicity implies that \(R(G)\) is everywhere nonincreasing. Clearly, \(G\) is a strictly increasing function of itself. Thus, there can only be one value of \(G\) at which \(R(G)=G\).

Presumptive inefficiency of equilibrium

In the basic model, in which a common unit cost is assumed across players, there is a general presumption that too little of the public good is provided at equilibrium, in the sense that Pareto-superior allocations can be obtained by increasing the level of public good provision. This may be confirmed by a simple envelope argument. Suppose that, at an equilibrium, players \(j\) and \(k\) are both positive contributors. Starting from the equilibrium, a small increase in player \(j\)'s contribution imposes a second-order cost on player \(j\), but generates a first-order benefit for
player $k$. Similarly, a small increase in player $k$’s contribution imposes a second-order cost for player $k$ and a first-order utility gain for player $j$. Thus it is possible for both to be made better off if both raise their contributions slightly above their equilibrium levels. Furthermore, such a move will not hurt other players, and will generally benefit them. Thus it is Pareto-improving.

In the current model, in which unit costs are allowed to differ across players, this remains true. There is also, however, a second source of inefficiency. This arises from the fact that the ‘wrong’ people contribute at equilibrium. Consider an equilibrium at which both a high-cost and a low-cost contributor are making positive contributions. An initial transfer of income from the high to the low-cost player shifts the replacement function of the high-cost player down, and that of the low-cost player up, in the neighbourhood of the equilibrium value of $G$. But the latter shift is quantitatively greater, so that the aggregate replacement function shifts upwards. The equilibrium provision therefore must rise, and contemplation of Figure 1(a) makes it clear that all players are better off in the new equilibrium.

Note that we talk of presumptive, not necessary, underprovision. This is for two reasons. First, as Cornes and Sandler (1996, p. 160) point out, if every player prefers to consume the private and public good in fixed proportions, so that their indifference curves are L-shaped, then the equilibrium is Pareto efficient. This possibility disappears if we allow some substitutability between the private and public goods. A second possibility, which certainly needs to be taken more seriously in policy discussions of public good provision than is sometimes done, is that the equilibrium involves zero total provision and that, even when provision is zero, the sum of all player’s marginal valuations is less than the minimum cost of producing an increment of the public good. In this case, the public good neither is, nor should be, provided.

Neutrality

Suppose that two players – say $i$ and $j$ – have the same value for the cost parameter. Consider an equilibrium, $G^*$, at which both are strictly positive contributors. Now transfer an amount of income, $\Delta m$, from one to the other. In the neighborhood of $G^*$, the recipient's replacement graph shifts upwards by the amount $\Delta m$. The donor's graph shifts downwards by the amount $\Delta m$. Thus, if both remain positive contributors at $G^*$, that value remains the sole
equilibrium public good provision level. Nothing real has changed – equilibrium levels of private good consumption and of total public good provision, and therefore equilibrium utility levels, are unaffected by the income transfer. This is the famous neutrality property of the standard model, which assumes a common value of the cost parameter for all players. Often attributed to Warr (1983), it was foreshadowed in earlier work by Shibata (1971).

Non-neutrality

The reasoning that led to the neutrality result allows us to understand easily the circumstances under which neutrality fails to hold. First, suppose that the source of the income transfer is initially choosing to contribute zero. Then, at the initial level of $G$, the reduction in her income cannot shift the relevant portion of her replacement function downwards – she is already contributing zero. The recipient's replacement graph shifts upwards. Therefore the aggregate replacement graph shifts upwards, and the equilibrium provision of the public good must now be higher. Transfers between existing contributors and noncontributors will have real consequences, leading to changes in both the equilibrium total public good provision and also in individual equilibrium utility levels. It is even possible, as Cornes and Sandler (2000) point out, that transfers from each of several noncontributors to contributors leads to a Pareto-superior allocation.

Second, our discussion of the presumptive inefficiency of equilibrium has already shown that an income transfer from a high-unit-cost contributor to a low-unit-cost contributor will lead to a higher level of equilibrium provision and to a Pareto improvement.

Implications of a cost change

Suppose that player $i$ is initially a positive contributor, and that she enjoys an exogenous reduction in her unit cost. Consideration of Figure 1 shows that the level of her preferred contribution that is associated with the initial equilibrium value of $G$ must now be higher. In the absence of any other shocks, the equilibrium level of total provision must rise. Thus, every player except for $i$ enjoys a higher equilibrium utility. However, player $i$ herself may be either better or worse off – on the one hand, total provision is higher, but on the other hand she is now
contributing a higher share of that total, since her fellow contributors have reduced their contributions.

Limiting behaviour as \( n \) gets large

The implications of adding players to the community are very easy to trace using our suggested approach. Suppose a fourth player joins the group of three depicted in Figure 2. To identify the new equilibrium, we merely add the new player's replacement graph to the existing ones. There are two possibilities. It is possible that, at the equilibrium of the three-player community the fourth player would choose to contribute zero. This will be the case if the extra player's replacement graph hits the horizontal axis in Figure 2 at a point to the left of \( G^N \). The equilibrium level of total provision, and the choices and utilities of the three initial players, are unchanged. The fourth player chooses to contribute nothing, and enjoys the existing level of public good, while allocating all of his money income to private good consumption. Alternatively, the replacement value of the new player is positive at the existing equilibrium. In this case, the graph of the aggregate replacement function shifts upwards in the neighborhood of the initial equilibrium. The new equilibrium involves a higher total provision level. Existing contributors will reduce their individual contributions, and all are advantaged by the addition of the extra player.

In the presence of a large number of potential contributors who may differ in terms of incomes, preferences or unit costs, the diagram strongly suggests the conclusion reached by Andreoni (1988) – namely, that when \( n \) is large, the proportion of players who make strictly positive equilibrium contributions may be vanishingly small. Almost all players choose zero contributions.

4 Extensions

Early attempts to apply the voluntary contributions model – for example, to charitable giving, in which the aggregate \( G \) is the total quantity subscribed to some good cause – suggest that the very strong implications of the simple model – neutrality when unit costs are the same across contributors, and its implication that, when \( n \) is large, the number of strictly positive contributors will be a very small fraction of \( n \) – are difficult to square with empirical evidence. In addition, recent concerns with global and regional public goods have led to an interest in situations that naturally seem to involve public good technologies other than the summation one described above.
We now briefly review some of the recent extensions and modifications of the model.

**Technology of public good provision**

Hirshleifer (1983) suggested two types of public good which are not captured by the summation technology and which, he argued, may be of empirical significance. They are characterized by different public good provision technologies. Best-shot and weakest-link public goods are captured, respectively by the following technologies:

\[
\text{Best-shot: } G = \max\{g_1, g_2, \ldots, g_n\}
\]

\[
\text{Weakest-link: } G = \min\{g_1, g_2, \ldots, g_n\}.
\]

Hirshleifer's example of a best-shot public good involves defensive guns ringing a city, each trying to shoot down an approaching missile. What matters to the city's inhabitants is the accuracy of the single most accurate shot. His example of a weakest-link involves a group of farmers, each owning a pie-shaped slice of land within a circular area surrounded by sea. Each is responsible for the maintenance of his part of the perimeter dyke. In the event of a storm that threatens to breach the dyke, it is the level of maintenance of the least well-maintained stretch of wall that determines the level of security enjoyed by all. Sandler (2004) suggests a wide range of situations involving regional or global public goods that are better captured by one or other of these formulations than by the standard summation formulation. These formulations have very distinctive equilibrium properties. For example, consider a two-player model with
the weakest link technology in which there is an equilibrium at which both contribute, say, ten units to the public good. Then any allocation at which each is contributing $x$ units, where $x$ lies between zero and ten, is also an equilibrium. After all, if the other player is contributing $x$ units, it does not pay you to contribute any more than $x$, since the total provision is defined by the smaller individual contribution. This game there can have a continuum of equilibria. Hirshleifer himself suggested that the players may be expected to choose the Pareto-dominant equilibrium. However, experimental evidence suggests that players find it surprisingly hard to coordinate on the Pareto dominant equilibrium.

Cornes (1993) and Cornes and Hartley (2007b) consider the class of games in which the total level of a public good is generated by individual contributions according to a constant returns to scale CES production process:

$$C = \left[ \sum_{i=1}^{n} g_i^\nu \right]^{\frac{1}{\nu}}.$$ The summation model is obtained by putting $\nu=1$: $\nu \to +\infty$ generates the best shot, and $\nu \to -\infty$ generates the weakest link. They show that, if $-\infty < \nu < 1$, the resulting weaker link model has a unique equilibrium. It is only at the limit, when the isoquants associated with the production technology are L-shaped, that Hirshleifer's problem of multiple equilibria arises. Moreover, if player $i$ is contributing less than player $j$ at an equilibrium – perhaps because her income is lower, or because she has less interest in the public good – then player $i$ has a higher marginal product as a contributor. Hence, neutrality with respect to income transfers breaks down, and a transfer from player $j$ to player $i$ may lead to a higher equilibrium level of public good provision and may be Pareto improving.

Situations involving $\nu > 1$ are better-shot games. Here, the production technology is inherently nonconvex, and again multiple equilibria may arise. For finite values of $\nu$, an equilibrium may involve positive contributions by each of a team of positive contributors, while the rest make zero contributions. However, there may be many such equilibria, each involving a different team of contributors. In Hirshleifer's best-shot case, if there are $n$ players, there may be $n$ equilibria, each of which involves a single 'champion', or 'dragon-slayer', who is the sole positive contributor, while all others make zero contributions. Again, achieving an equilibrium requires the players to resolve a tricky coordination problem.

**Preferences**
Cornes and Sandler (1984, 1994) extend the basic model by modifying the individual preferences. They included player $i$'s own contribution as an argument of her own utility function, in addition to the aggregate quantity $G$:

$$u_i(\cdot) = u_i(y_i, g_i, G).$$

They suggest this formulation as a model of charitable giving, a suggestion explored by Andreoni (1988). Donor $i$ not only cares about the total amount given to the charitable giving, $G$, but also experiences a ‘warm glow’ of satisfaction from her own contribution, $g_i$. If the standard resource constraint and public good technology are retained, this modification is sufficient to produce very rich comparative static possibilities: neutrality does not generally hold, and an increase in player $i$'s money income alone may either increase or reduce the equilibrium level of $G$. Finally, note that if the utility function is assumed to take the Cobb-Douglas form – then at any equilibrium every player will make a positive contribution to the public good. A proliferation of noncontributors as the number of players increases is no longer implied.

This extension significantly broadens the range of potential applications of the model. First, there is nothing to stop us from considering situations in which player $i$ regards $G$ as a public bad – then at any equilibrium every player will make a positive contribution to the public good. A proliferation of noncontributors as the number of players increases is no longer implied. Kotchen (2006) and Ruebbelke (2002) have explored such models. Morgan (2000) and Duncan (2002) have used a slight modification of this model to investigate the potential role that lotteries, or raffles, may play in raising the public good level above that implied by the voluntary contribution model. The basic idea is simple. The presence of the public good by itself involves a positive externality, and will tend to be underprovided. If individuals buy lottery tickets, each of which partially contributes to the public good and also gives its purchaser a probability of winning a money prize, a negative externality is thereby added – by
buying a ticket, and increasing my chance of winning the prize, I inflict a negative externality on other ticket holders. There are two externalities, one beneficial and one harmful. The resulting equilibrium, at which these externalities tend to counteract each other, may involve a higher level of public good provision than if it were provided simply by individual contributions in the absence of the lottery.

**Dynamic models**

Up to this point, our discussion has remained firmly within the context of a one-shot static game. It is natural to wonder how the properties of equilibrium – in particular its presumptive inefficiency – are affected if we allow the contribution game to be played over many time periods. Schelling (1960, p. 45) suggested that such a setting may allow each player to make a small contribution, then wait to see whether others follow suit, before deciding whether to make a further small contribution. His suggestion has been analysed more formally by others, notably by Admati and Perry (1991) and Marx and Matthews (2000).

The last-named authors, whose analysis includes a useful discussion of the difference between their model and that of Admati and Perry, allow every player to choose a contribution level in each time period – any non-negative contribution, however large or small, is admissible. The properties of equilibria depend on (i) the degree of heterogeneity of players' valuations of the public good, (ii) the rate at which future costs and benefits are discounted, and (iii) whether or not there is a significant step in the benefit function – for example, a bridge generates no benefits until it is completed, thus representing an extreme example of a benefit function with a discrete step. They provide good news and bad news. The good news is that, if contributions can be made in small increments over time, equilibria can be attained that are more efficient than the equilibrium associated with the one-shot game. They argue that, if players' valuations are similar, and the rate of discount low, then nearly efficient equilibria exist. Furthermore, the presence of a significant benefit jump helps the prospects of successful completion of a project. An efficient equilibrium of the dynamic game may exist even in situations in which the only equilibrium of the static game involves zero contributions. The bad news is that, in common with many other dynamic games, there also exist other equilibria involving zero contributions.

Duffy, Ochs and Vesterlund (2007) have investigated the properties of such dynamic models experimentally.
They confirm that contributions do indeed tend to be higher in dynamic games of the kind proposed by Marx and Matthews, but their results cast doubt on the claimed importance of jumps in the benefit function.

Jancsi (John) von Neumann was born to Max and Margaret Neumann on 28 December 1903 in Budapest, Hungary. He showed an early talent for mental calculation, reading and languages. In 1914, at the age of ten, he entered the Lutheran Gymnasium for boys. Although his great intellectual (especially mathematical) abilities were recognized early, he never skipped a grade and instead stayed with his peers. An early teacher, Laslo Ratz, recommended that he be given advanced mathematics tutoring, and a young mathematician Michael Fekete was employed for this purpose. One of the results of these lessons was von Neumann's first mathematical publication (joint with Fekete) when he was 18.

Besides his native Hungarian, Jancsi (or Johnny, as he was universally known in his later life) spoke German with his parents and a nurse and learned Latin and Greek as well as French and English in school. In 1921 he enrolled in mathematics at the University of Budapest but promptly left for Berlin, where he studied with Erhard Schmidt. Each semester he returned to Budapest to take examinations without ever having attended classes. While in Berlin he frequently took a three-hour train trip to Göttingen, where he spent considerable time talking to David Hilbert, who was then the most outstanding mathematician of Germany. One of Hilbert's main goals at that time was the axiomatization of all of mathematics so that it could be mechanized and solved in a routine manner. This interested Johnny and led to his famous 1928 paper on the axiomatization of set theory. The goal of Hilbert was later shown to be impossible by Kurt Gödel's work, based on an axiom system similar to von Neumann's, which resulted in a theorem, published in 1930, to the effect that every axiomatic system sufficiently rich to contain the positive integers must necessarily contain undecidable propositions.

After leaving Berlin in 1923 at the age of 20, von Neumann studied at the Eidgenossische Technische Hochschule in Zurich, Switzerland, while continuing to maintain his enrolment at the University of Budapest. In Zurich he came into contact with the famous German mathematician, Hermann Weyl, and also the equally famous Hungarian mathematician, George Polya. He obtained a degree in Chemical Engineering from the Hochschule in Zurich in 1925, and completed his doctorate in mathematics from the University of Budapest in 1926. In 1927 he became a privatdozent at the University of Berlin and in

1929 transferred to the same position at the University of Hamburg. His first trip to America was in 1930 to visit as a lecturer at Princeton University, which turned into a visiting professorship, and in 1931 a professorship. In 1933 he was invited to join the Institute for Advanced Study in Princeton as a professor, the youngest permanent member of that institution, at which Albert Einstein was also a permanent professor. Von Neumann held this position until he took a leave of absence in 1954 to become a member of the Atomic Energy Commission.

Von Neumann was married in 1930 to Marietta Kovesi, and his daughter Marina (who became a vice-president of General Motors) was born in 1935. The marriage ended in a divorce in 1937. Johnny's second marriage in 1938 was to Klara Dan, whom he met on a trip to Hungary. They maintained a very hospitable home in Princeton and entertained, on an almost weekly basis, numerous local and visiting scientists. Klara later became one of the first programmers of mathematical problems for electronic computers, during the time that von Neumann was its principal designer.

In 1938 Oskar Morgenstern came to Princeton University. His previous work had included books and papers on economic forecasting and competition. He had heard of von Neumann's 1928 paper on the theory of games and was eager to talk to him about connections between game theory and economics. In 1940 they started work on a joint paper which grew into their monumental book, *Theory of Games and Economic Behavior* published in 1944. Their collaboration is described in Morgenstern (1976).

Von Neumann became heavily involved in defence-related consulting activities for the United States and Britain during World War II. In 1944 he became a consultant to the group developing the first electronic computer, the ENIAC, at the University of Pennsylvania. Here he was associated with John Eckert, John Mauchly, Arthur Burks and Herman Goldstine. These five were instrumental in making the logical design decisions for the computer, for example, that it be a binary machine, that it have only a limited set of instructions that are performed by the hardware, and most important of all, that it run an internally stored program. It was acknowledged by the others in the group that the most important design ideas came from von Neumann. The best account of these years is Goldstine (1972). After the war von Neumann and Goldstine worked at the Institute of Advanced study where they developed (with others) the JONIAC computer, a successor to the ENIAC, which used principles some of which are still being used in current computer designs.

In 1943 von Neumann became a consultant to the Manhattan Project which was developing the atomic bomb in Los Alamos, New Mexico. This work is still classified but it is known that Johnny performed superbly as a mathematician, an applied physicist, and an expert in computations. His work continued after the war on the hydrogen bomb, with Edward Teller and others. Because of this work he received a presidential appointment to the Atomic Energy Commission in 1955. He took leave from the Institute for Advanced Study and moved to Washington. In the summer of 1955 he fell and hurt his left shoulder. Examination of that injury led to a diagnosis of bone cancer which was already very advanced. He continued to work very hard at his AEC job, and prepared the Silliman lectures (von Neumann, 1958), but was unable to deliver them. He died on 8 February 1957 at the age of 53 in the Walter Reed Hospital, Washington, DC.

**The theory of games**

Without question one of von Neumann's most original contributions was the theory of games, with which it is possible to formulate and solve complex situations involving psychological, economic,
strategic and mathematical questions. Before his great paper on this subject in 1928 there had been only a handful of predecessors: a paper by Zermelo in 1912 on the solution in pure strategies of chess; and three short notes by the famous French mathematician E. Borel. Borel had formulated some simple symmetric two-person games in these notes, but was not able to provide a method of solution for the general case, and in fact conjectured that there was no solution concept applicable to the general case. For a commentary on the priorities involved in these two men's work see the notes by Maurice Frechet, translations (by L.J. Savage) of the three Borel papers, and a commentary by von Neumann, all of which appeared with von Neumann (1953a).

The three main results of von Neumann's 1928 paper were: the formulation of a restricted version of the extensive form of a game in which each player either knows nothing or everything about previous moves of other players; the proof of the minimax theorem for two-person zero-sum games; and the definition of the characteristic function for and the solution of three-person zero-sum games in normal form. Von Neumann also carried out an extensive study of simplified versions of poker during this time, but they were not published until later.

The extensive form of a game is the definition of a game by stating its rules, that is, listing all of the possible legal moves that a player can make for each possible situation he can find himself in during a play of the game. A pure strategy in a game is a much more complicated idea – a listing of a complete set of decisions for each possible situation in which the player can find himself. A complete enumeration of all possible strategies shows that the number of such strategies is equal to the product of the number of legal moves for each situation, which implies that there is an astronomical number of possible strategies for any non-trivial game such as chess. Most of these are bad, and would never be used by a skillful player, but they must be considered to find its solution. The normalized form of a game is obtained by replacing the definition of a game as a statement of its rules, as is done in its extensive form, by a listing of all of the possible pure strategies for each player. To complete the normalized form of the game, imagine that each player has made a choice of one of his pure strategies. When pitted against another a unique (expected) outcome of the game will result. For the moment we will imagine that the outcome of the game is monetary, and therefore each player gets a ‘payoff’ at the end of the game which is actually money. (Later we will replace money by ‘utility’.) If the sum of the payments to all players is zero the game is said to be zero-sum; otherwise it is a non-zero-sum game.

The normalized form of a game is also called a matrix game, and any real \( m \times n \) matrix can be considered a two-person zero-sum game. The row player has \( m \) pure strategies, \( i=1, \ldots, m \), and the column player has \( n \) pure strategies, \( j=1, \ldots, n \). If the row player chooses \( i \) and the column player chooses \( j \) then the payoff \( a(i,j) \) is exchanged between them, where \( a(i,j)>0 \) means that the row player receives \( a(i,j) \) from the column player, while a negative payoff means that the column player receives the absolute value of that amount from the row player.

The importance of the careful analysis of the extensive and normalized forms of a game is that it separates out the concept of strategy and psychology in any discussion of a game. As an example, in poker bidding high when having a weak hand is commonly called ‘bluffing’, and considered an aggressive form of play. As a result of this formulation, and the solution of simplified versions of the game von Neumann showed that in order to play poker ‘optimally’ it is necessary to bluff part of the time, i.e., it is a required part of the strategy of any good poker player. A similar analysis for simplified bridge shows that a required part of an optimal bridge strategy is to signal, via the way one discards low cards in a suit, whether the player holds higher cards in that suit.
The analysis of special kinds of games shows that some of them can be solved by using pure strategies. This class includes the games of ‘perfect information’ such as the board games of chess and checkers. However, even such a simple game as matching pennies shows that an additional strategic concept is needed, namely, that of a ‘mixed strategy’. This concept appeared first in the context of symmetric two-person games in Borel's 1921 paper. Briefly, a mixed strategy for either player is a finite probability function on his set of pure strategies. For matching pennies the common strategy of flipping the penny to choose whether to play heads or tails is a mixed strategy that chooses both alternatives with equal probability (1/2), and is, in fact, an optimal strategy for that game.

We now discuss the way that von Neumann made precise the definition of a solution to a matrix game.

Let $A$ be an arbitrary $m \times n$ matrix with real number entries. Let $x$ be an $m$-component row vector, and let $f$ be an $m$-component column vector all of whose components are ones. Then $x$ is a mixed strategy vector for the row player in the matrix game $A$ if it satisfies: $xf = 1$ and $x \succeq 0$. Similarly, let $y$ be an $n$-component column vector, and let $e$ be an $n$-component row vector of all whose components are ones. Then $y$ is a mixed strategy vector for the column player in the matrix game $A$ if it satisfies: $ey = 1$ and $y \succeq 0$. Mixed strategy vectors are also called probability vectors because they have non-negative components that sum to one, and hence could be used to make a random choice of a pure strategy by spinning a pointer, choosing a random number, etc. To complete the definition of the solution to a game, we need a real number $v$, called the value of the game. The solution to the matrix game $A$ is now a triple, a mixed strategy $x$ for the row player, a mixed strategy $y$ for the column player, and a value $v$ for the game: these quantities must solve the following pair of (vector) inequalities:

$$xA \succeq v e \text{ and } Ay \preceq v f.$$  

Because these are linear inequalities, one might suspect (and would be correct) that the optimal $x$, $y$ and $v$ can be found by using a linear programming code and a computer.

However, in the 1920s it was not clear that such a solution existed. In fact, Borel conjectured that it did not. The most decisive result of von Neumann's 1928 paper was to establish, using an argument involving a fixed point theorem, his famous minimax theorem to the effect that for an arbitrary real matrix $A$ there exists a real number $v$ and probability vectors $x$ and $y$ such that

$$\min_{x} \max_{y} Ax = \max_{y} \min_{x} Ax \equiv v.$$  

This theorem became the keystone not only for the theory of two-person matrix games, but also for $n$-persons games via the characteristic function (to be discussed later).

We now discuss the major differences between von Neumann and Morgenstern (1944) and von Neumann's 1928 paper. The information available to each player was assumed, in the 1928 paper, to be the following: when required to move, each player knows either everything about the previous moves of
his opponents (as in chess), or nothing (as in matching pennies). By using information trees, and partitioning the nodes of such trees into information sets, in 1944 this concept was extended to games in which players have only partial information about previous moves when they are required to make a move. This was a difficult but major extension, which has not been substantially improved upon since its exposition in the 1944 treatise.

A second major change in the basic theory of games was in the treatment of payoff functions. In the 1928 paper payoffs were treated as if they were monetary, and it was implicitly assumed that money was regarded as equally important by each of the players. In order to take into account the well-known objections, such as those of Daniel Bernoulli, to the assumption that a dollar is equally important to a poor man as a rich man, a monetary outcome to a player was replaced by the utility of the outcome. Although Bernoulli had suggested that the utility of \(x\) dollars should be the natural logarithm of \(x\), so that the addition of a dollar to a rich man's fortune would be valued less than the addition of a dollar to a poor man's fortune, this specific utility concept was never universally accepted by economists. So utility remained a fuzzy, intuitive concept. Von Neumann and Morgenstern made the absolutely decisive step of axiomatizing utility theory, making it unambiguous and they can properly be said to have started the modern theory of utility, not only for game theory, but for all of economics and the social sciences. Almost two-thirds of the 1944 treatise consists of the theory of \(n\)-person constant-sum games, of which only a small part, the three person zero-sum case, appears in the 1928 paper. When \(n > 2\), there are opportunities for cooperation and collusion as well as competition among the players, so that there arises the problem of finding a way to evaluate numerically the position of each player in the game. In 1928 von Neumann handled this problem for the zero-sum case by introducing the idea of the characteristic function of a game defined as follows: For each coalition, that is, subset \(S\) of players, let \(v(S)\) be the minimax value that \(S\) is assured in a zero-sum two-person game played between \(S\) and its complementary set of players. To describe the possible division of the total gain available among the players the concept of an imputation, which is a vector \((x(1), \ldots, x(n))\) where \(x(i)\) represents the amount the player \(i\) obtains, was introduced. For a coalition \(C\) in a constant-sum game \(v(C)\) is the minimum amount that the coalition \(C\) should be willing to accept in any imputation, since by playing alone against all the other players, \(C\) can achieve that amount for itself. Except for this restriction there is no other constraint on the possible imputations that can become part of a solution. An imputation vector \(x\) is said to dominate imputation vector \(y\) if there exists a coalition \(C\) such that (1) \(x(i) \geq y(i)\) for all \(i\) in \(C\), and (2) the sum of \(x(i)\) for \(i\) in \(C\) does not exceed \(v(C)\). The idea is that that the coalition \(C\) can ‘enforce’ the imputation \(x\) by simply threatening to ‘go it alone’, since it can do no worse by itself.

One might think, or hope, that a single imputation could be taken as the definition of a solution to an \(n\)-person constant-sum game. However, a more complicated concept is needed. By a von Neumann–Morgenstern solution to an \(n\)-person game is meant a set \(S\) of imputations such that (1) if \(x\) and \(y\) are two imputations in \(S\) then neither dominates the other; and (2) if \(z\) is an imputation not in \(S\), then there exists an imputation \(x\) in \(S\) that dominates \(z\). Von Neumann and Morgenstern were unable (for good reasons, see below) to prove that every \(n\)-person game had a solution, even though they were able to solve every specific game they considered, frequently finding a huge number of solutions. At the very end of the 1944 book there appears a chapter of about 80 pages on general non-zero-sum games. These were formally reduced to the zero-sum case by the technique of introducing a fictitious player, who was entirely neutral in terms of the game's strategic play, but who either consumed any
excess, or supplied any deficiency so that the resulting $n+1$ person game was zero-sum. This artifice helped but did not suffice for a completely adequate treatment of the non-zero-sum case. This is unfortunate because such games are the most likely to be found useful in practice.

About 25 years after the treatise appeared, William Lucas (1969) provided as a counter-example, a general sum game that did not have a von Neumann–Morgenstern solution. Other solution concepts have been considered since, such as the Shapley value, and the core of a game.

One of the most interesting non zero-sum games considered in that chapter was the so-called market game. The first example of a market game (though it was not called that) was the famous horse auction of Böhm-Bawerk, published in 1881. The horses had identical characteristics, each of 10 buyers had a maximum price he was willing to bid, and each of 8 sellers had a minimum price he was willing to accept. Böhm-Bawerk's solution was to find the 'marginal pairs' of prices, which turned out to be included in the von Neumann–Morgenstern solution to this kind of game. Later work on this problem was done by Shapley and Shubik (1972) and Thompson (1980, 1981).

The expanding economy model

Another of von Neumann's original contribution to economics was von Neumann (1937), which contained an expanding economy model unlike any other economic model that preceded it. When von Neumann gave a seminar to the Princeton economics department in 1932 on the model, which was stated in terms of linear inequalities not equations, and whose existence proof depended upon a fixed point theorem more sophisticated than any published in the mathematics literature of the time, it is little wonder that he made no impression on that group. He repeated his talk on the subject at Karl Menger's mathematical seminar in Vienna in 1936, and published his paper in German in 1937 in the seminar proceedings. The paper became more widely known after it was translated into English and published in The Review of Economic Studies in 1945 together with a commentary by Champernowne.

Von Neumann's model consists of a closed production economy in which there are $m$ processes and $n$ goods. In order to describe it we use the vectors $e$ and $f$ previously defined together with the following notation:

- $x$ is the $m \times 1$ intensity vector with $x_f = 1$ and $x \geq 0$.
- $y$ is the $1 \times 1$ price vector with $e_y = 1$ and $y \geq 0$.
- $\alpha = 1 + a/100$ is the expansion factor, where $a$ is the expansion rate.
- $\beta = 1 + b/100$ is the interest factor, where $b$ is the interest rate. The model satisfies the following axioms:
  1. $x_B \geq \alpha \cdot x_A$ or $x(B - \alpha \cdot A) \geq 0$.
  2. $B_y \leq \beta \cdot y$ or $(B - \beta \cdot A)y \leq 0$.
  3. $x(B - \alpha \cdot A)y = 0$.
  4. $x(B - \beta \cdot A)y = 0$.
  5. $xBy > 0$.

Axiom 1 makes the model closed, i.e., the inputs for a given period are the outputs of the previous.
Axiom 2 makes the interest rate be such that the economy is profitless. Axiom 3 requires that...
overproduced goods be free. Axiom 4 forces inefficient processes not to be used. And Axiom 5 requires the total value of all goods produced to be positive.

In order to demonstrate that for any pair of nonnegative matrices $A$ and $B$, solutions consisting of vectors $x$ and $y$ and numbers $\alpha$ and $\beta$ exist, an additional assumption was needed:

$$\text{Assumption V. } A + B > 0.$$ 

This assumption means that every process requires as an input or produces as an output some amount, no matter how small, of every good. With this assumption, and the assumption that natural resources needed for expansion were available in unlimited quantities, von Neumann showed that necessarily $\alpha = \beta$, that is, that the expansion and interest factors were equal. In his paper, von Neumann proved a sophisticated fixed point theorem and used it to prove the existence theorem for the EEM.

D.G. Champernowne (1945) provided the first acknowledgement that the economics profession had seen the article, and also provided its first criticisms. We mention three:

1. (1) Assumption V which requires that every process must have positive inputs or outputs of every other good was economically unrealistic.
2. (2) The fact that the model has no consumption, so that labour could receive only subsistence amounts of goods as necessary inputs for production processes, also seems unrealistic.
3. (3) The consequence of Axiom 3 that overproduced good should be free is too unrealistic.

Criticisms 1 and 2 were removed by Kemeny, Morgenstern, and Thompson (1956), who replace Assumption V by:

Assumption KMT-1. Every row of $A$ has at least one positive entry.
Assumption KMT-2. Every column of $B$ has at least one positive entry. The interpretation of KMT-1 is that every process must use at least one good as an input. And the interpretation of KMT-2 is that every good must be produced by some process. With these assumptions they were able to show that there were a finite number of possible expansion factors for which intensity and price vectors existed satisfying the axioms. They also showed how consumption could be added into the model, which responded to criticism 2.

An alternative way of handling these criticisms appears in Gale (1956).

In Morgenstern and Thompson (1969, 1976), the third criticism above was answered by generalizing the model to become an ‘open economy’. In such an economy the price of an overproduced good cannot fall below its export price, and it cannot rise above its import price. Generalizations of the open model have been made by Los (1974) and Moeschlin (1974).

**Von Neumann's influence on economics**

Although von Neumann has only three publications that can directly be called contributions to

economics, namely, his 1928 paper on the theory of games, his 1937 paper (translated in 1945) on the expanding economy model and his 1944 treatise (with Morgenstern) on the theory of games, he had enormous influence on the subject. The small number of contributions is deceptive because each one consists of several different topics, each being important. We discuss these separately.

The expanding economy model, von Neumann (1937) consisted of two parts: the first input–output equilibrium model that permits expansion; and second the fixed point theorem. The linear input–output model is a precursor of the Leontief model, of linear programming as developed by Kantorovich and Dantzig, and of Koopman's activity analysis. This paper, together with A. Wald (1935) raised the level of mathematical sophistication used in economics enormously. Many current younger economists are high-powered applied mathematicians, in part, because of the stimulus of von Neumann's work.

The theory of games, von Neumann (1928) and von Neumann and Morgenstern (1944), was an enormous contribution consisting of several different parts: (1) the axiomatic theory of utility; (2) the careful treatment of the extensive form of games; (3) the minimax theorem; (4) the concept of a solution to a constant-sum n-person game; (5) the foundations of non-zero-sum games; (6) market games. Each of these topics could have been broken into a series of papers, had von Neumann taken the time to do so. And he could have forged a brilliant career in economics by publishing them. However, he found that making an exposition of the results that he had worked out in notes or in his head was less interesting to him than investigating still other new ideas.

Von Neumann's indirect contributions, such as the theory of duality in linear programming, computational methods for matrix games and linear programming, combinatorial solution methods for the assignment problem, the logical design of electronic computers, contributions to statistical theory, etc. are equally, important to the future of economics. Each of his contributions, direct or indirect, was monumental and decisive. We should be grateful that he was able to do so much in his short life. His influence will persist for decades and even centuries in economics.

Nikolay Vorob'ev is commonly regarded as the founder and the leader of game-theoretic school in the former Soviet Union. Vorob'ev was born on 18 September 1925 in Leningrad (now St Petersburg). His father was a lawyer and his mother a surgeon. Beginning his education at technical institutes in Izhevsk and Moscow, he returned to Leningrad in 1944 and became a student at the Leningrad Shipbuilding Institute. In 1946 he began study at the Faculty of Mathematics and Mechanics of the Leningrad State University. In 1948 he left the Shipbuilding Institute and graduated from the university. In 1947 Vorob'ev published his first paper in semigroup theory.

In 1948 Vorob'ev started a postgraduate programme at the Leningrad branch of the Steklov Mathematical Institute. His supervisor was Professor A.A. Markov, under whose influence he studied constructive mathematical logic, which was rapidly developing at that time. His Candidate of Science thesis in mathematics was devoted to logical deduction rules in systems with strong negation. He received his Candidate of Science degree in 1952. In the same year he joined the Steklov Mathematical Institute as a junior research associate. Here he once more changed his scientific interests and started research concerned with both algebra and probability theory.

Axiomatic training in algebra and logic, along with studies in probability theory, permitted Vorobe'ev to make a transition to the study of game theory. His paper ‘Controlled Processes and Game Theory’ (1955) was the first paper in game theory published in the former Soviet Union. His 1959 review article ‘Finite Noncooperative Games’ served for many years as a primary Russian language source for understanding game theory. In the next five years Vorob'ev made an attempt to develop the theory of coalitional games, that is, games in which players belonging to one coalition are acting as one player, and therefore mixed strategies have to be defined as correlated families of measures. To prove
the existence of stable outcomes in such games, he solved some non-standard problems from combinatorial topology and probability theory, thus combining ideas and methods from various branches of mathematics. At that time he also made interesting generalizations of H. Kuhn's equivalence theorem about behaviour strategies in extensive games with perfect recall, proposed an algorithm on enumerating equilibrium points in bimatrix games and studied games with forbidden situations. These results constituted the basis of his Doctor of Science thesis, which he defended in 1961. In the same year he organized the Soviet Union's first laboratory for game theory and operations research at the Steklov Mathematical Institute of the Academy of Sciences. Under his supervision more than 30 students obtained candidate and doctoral degrees in game theory. In 1968 Vorob'ev organized the first all-Union game theory conference in Erevan (Armenia) and the second in 1971 in Vilnius (Lithuania). He was the main speaker at both conferences, which each attracted more than 100 participants. His addresses focused on methodological and philosophical aspects of game theory as well as areas of applications. He forecast the application of game theory in economics, military affairs, biology, law, ethics, sociology, medicine and literature.

In 1975 his laboratory moved to the Institute for Socio-Economic Problems. Unfortunately, the administration of the institute considered any application of mathematical methods in social sciences as inconsistent with prevailing Marxist-Leninist dogmas. Game theory was no exception, which was why the laboratory was forced to concentrate on mathematical problems arising in game theory. Vorob'ev wrote an interesting monograph *Foundations of Game Theory: Noncooperative Games* (published in English translation in 1994) and considered it the first volume in a planned series of books on game theory. The second volume, ‘Cooperative Games’ was not completed. He also wanted to write a volume titled ‘Dynamic Games’.

Vorob'ev was a brilliant lecturer. He taught part-time at the Leningrad State University and many other universities in Russia and elsewhere, delivering courses in game theory, algebra, probability theory and number theory. He wrote many textbooks, the most popular among which is *Game Theory for Economists and System Scientists* (published in English translation in 1977). He edited most of the translations of the principal Western scientific monographs into Russian, including the famous *Theory of Games and Economic Behavior* by J. von Neumann and O. Morgenstern (1944). He also edited two bibliographic indices on game theory literature up to 1974. They contain about 5,000 summaries of game-theory books and papers from all over the world.

voting paradoxes

Donald G. Saari
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

After using an example to motivate why voting theory is so central to the social sciences, this survey describes some of the more recent (and, surprisingly, benign) interpretations of Arrow's Impossibility Theorem as well as explanations of the wide selection of voting paradoxes that drive this academic area. As described, it now is possible to explain all positional voting paradoxes while creating any number of illustrating examples.

Keywords

anti-plurality system; approval voting; Arrow, K.; axiomatic approach to decision rule choice; Borda Count; Condorcet, M.; cumulative voting; elections; Gibbard–Satterthwaite theorem; impossibility theorem; independence of irrelevant alternatives; Kruskal–Wallis test; Luce, D.; plurality vote; Sonnenshein–Mantel–Debreu theorem; transitivity; voting paradoxes; voting rules; Walras's Law

Article

Almost daily, news articles describe important elections being held somewhere in the world. The newsworthiness of these events is obvious: election outcomes can change the political, societal and economic directions of a city, a state, or even a country. Elections, in fact, are everywhere; their use ranges from legislative bodies busily determining laws to a kindergarten class selecting a recess treat ‘with a show of hands’. As elections are important, we impose safeguards such as the secret ballot. But a strong message coming from voting theory is that the choice of a voting rule can do more to frustrate the ‘will of the voters’ than any scheming, cigar-smoking political boss.

To illustrate this comment, consider the following three-candidate example where A>B>C means a voter prefers A to B to C. Let four voters prefer A>B>C, three prefer A>C>B, two prefer C>A>B, two prefer C>B>A, and six prefer B>C>A. With the:
Voting paradoxes: The New Palgrave Dictionary of Economics

- **plurality vote**, or ‘vote for one’, *A wins* with the A>B>C ranking;
- **Borda Count**, where 2, 1, 0 points are assigned, respectively, to a voter's first, second and third ranked candidate, *B wins* with the B>C>A ranking;
- **anti-plurality**, or ‘vote for two’, system, which is equivalent to voting against a candidate, *C wins* where its C>B>A ranking happens to reverse the plurality ranking.

Not all candidates reflect the ‘will of these voters’, yet each ‘wins’ by selecting an appropriate voting rule. Pairwise majority votes offer no help with their A>B, B>C, C>A cycle. The message is that, rather than capturing the views of the voters, an election outcome may more accurately reflect the *choice of the voting rule*.

More general rules include *n*-candidate positional methods defined by *n* weights \( w_1, w_2, \ldots, w_n = 0; w_1 > 0 \) and \( w_j \geq w_j + 1 \) where \( w_j \) points are assigned to a voter's *j*th ranked candidate; candidates are ranked by the sums of assigned points. While \((1, 0, 0), (2, 1, 0)\) and \((1, 1, 0)\) represent the above rules, \((8, 3, 0)\) is still another choice. Different weights, however, may generate other election outcomes. Indeed, the above example allows *seven* different positional election rankings. For instance, the \((8, 3, 0)\) outcome is a fourth strict ranking B>A>C; the three remaining rankings involve ties.

One probable reason for the many different election rules is that inventing new ones is limited only by one's imagination; for example, positional methods define run-off rules whereby, after the bottom-ranked candidates are dropped, the remaining two are reordered. With our example, the plurality, Borda, and anti-plurality run-offs elect, respectively, A, B and B. Other approaches allow each *voter* to select a positional method to tally his ballot. With *cumulative voting*, for instance, a voter splits, say, three points in any integer manner; for example, she may use \((3, 0, 0)\), or \((2, 1, 0)\). *Approval voting* (AV) allows a voter to vote for (approve) any number of candidates; for example, he could select \((1, 0, 0)\) or \((1, 1, 0)\).

But, whenever voters can determine how to tally their own ballots, we must anticipate that a single profile (that is, listing of voters’ preferences) can admit many different outcomes. Indeed, while changing positional methods generates seven different rankings for our example, *all 13* ways to rank three candidates are admissible cumulative or AV outcomes. Some theorists view this flexibility as a virtue (for example, Brams, Fishburn and Merrill, 1988); others treat this extreme indeterminacy as a serious failing (for example, Saari and Van Newenhizen, 1988).

As our example demonstrates, selecting an inappropriate voting or decision rule could inadvertently cause inferior outcomes – with negative concomitant consequences. This is not an isolated phenomenon: with conservative assumptions, about 69 per cent of contested three-candidate elections allow election rankings to change with different positional methods (Saari and Tataru, 1999). The percentage significantly increases with more candidates.

Further underscoring the complexity is Arrow's (1951) seminal impossibility theorem. He first requires voters to have complete (all pairs are ranked), transitive (a voter preferring A>B and B>C prefers A>C) preferences without restrictions, and the societal outcomes to be complete transitive rankings. Then Arrow characterizes all rules satisfying two basic properties. The first (Pareto) is a unanimity condition whereby, if everyone ranks a pair of candidates in the same manner, that is the societal ranking. To motivate the second, ‘independence of irrelevant alternatives’ (IIA), condition with a reoccurring phenomenon in the judging of figure-skating, suppose a committee's ranking is Susan>Barb>Jeannie. Imagine Barb's anguish if, told that had more judges liked Jeannie, Barb would have ranked over Susan.
Why should the judges' opinion of Jeannie affect the (Susan, Barb) ranking? Arrow's 'independence of irrelevant alternatives' (IIA) condition prohibits this difficulty. Essentially, IIA requires each pair's ranking to depend only on each voter's relative ranking of this pair.

With these minimal conditions, Arrow proves that, for three or more candidates, the only admissible rule is a dictator – a specified voter whereby the societal outcome always agrees with her preferences independent of what other voters want. Understandably, Arrow's result is often interpreted to mean 'no voting rule is fair'. An alternative, significantly more benign explanation is given below.

The overpowering message is that the choice of a decision rule is crucial. Indeed, determining which rules are 'optimal' is the primary concern of voting theory, where finding axiomatic characterizations of rules, or discovering paradoxical examples, seems to dominate. Another approach (Luce, 1959) imposes structure on the outcomes; this structure determines what voting rules are admitted and what restrictions must be imposed on voter choices. A third, recent emphasis examines the data structure – voter preferences – to determine what the voters want and then which voting rules deliver the appropriate outcome (Saari, 2000).

For a template, treat a voting rule as a mapping from the domain (space of individual preferences) to the range (space of societal outcomes). The axiomatic approach emphasizes properties of the mapping, Luce's approach emphasizes the structure of the range, and my recent approach emphasizes the structure of the domain. All three approaches are briefly described.

### Axiomatic approach and paradoxes

Borrowed from mathematics, a standard justification for the ‘axiomatic approach’ is that ‘it tells us what we are getting’. After all, axioms are intended to form the fundamental building blocks of a theory, so axiomatic characterizations should specify what to expect from different voting rules. But this expectation requires the conditions to be true axioms; most often they are not. Instead, many results uniquely identify a rule in terms of special, perhaps idiosyncratic, properties rather than characterizing the rule. As an analogy, it is easy to envision settings where certain properties uniquely identify ‘John’ as a studious, well-behaved student, while different properties uniquely identify ‘John’ as a street-wise juvenile delinquent. By concentrating on particular traits, both sets of properties uniquely identify John, but neither completely describes nor characterizes him.

Similarly, many so-called ‘axiomatic characterizations’ of voting rules are, in reality, properties that inadvertently emphasize special profiles, so while they uniquely identify certain rules, they do not characterize them. As an example, certain technical assumptions plus the condition ‘a candidate top-ranked by most voters wins’ uniquely identifies the plurality vote. Alternatively, the same technical conditions accompanied with the ‘with \( n \)-candidates, a candidate may win even if bottom-ranked by all but one more than \( 1/n \) of the voters’ property also uniquely identifies the plurality vote. Neither is an axiomatic characterization: by depending on special profiles, neither really ‘tells us what we are getting’.

This literature, however, identifies valued voting rule properties. Another widely used approach with the same objective is to find ‘voting paradoxes’, that is, unexpected outcomes. Indeed, the origin of this field derives from a 1770 example (published in Borda, 1781) that Borda constructed to question the plurality vote: with his example the C>B>A plurality outcome conflicts with the pairwise rankings that are consistent with A>B>C; his (2, 1, 0) Borda Count conclusion agrees with the pairwise rankings.
In contrast, Condorcet (1785) believed we should decide via pairwise comparisons: a Condorcet winner (loser) is the candidate who beats (loses to) all other candidates in majority pairwise votes. To distinguish his approach from Borda’s, he constructed an example whereby the Condorcet winner is not top-ranked by the Borda Count – or any positional rule. The controversy over whether Borda’s or Condorcet’s method is superior continues: comments on this debate are given below.

With examples, Condorcet illustrated that his method can fail; for example, the Condorcet triplet A>B>C, B>C>A, C>A>B defines the pairwise cycle A>B, B>C, C>A where neither a Condorcet winner nor loser exists. Later I explain why Condorcet’s example remains central to voting theory.

Others continuing Condorcet’s philosophy explored ways to handle cyclic outcomes; for example, Dodgson’s (1876) (Lewis Carroll from ‘Alice in Wonderland’) method finds the ‘closest’ Condorcet winner (that is, over all possible lists of pairwise rankings, find the list with a Condorcet winner that is ‘closest’ to the actual election tallies), while Kemeny’s Rule finds the ‘closest’ transitive ranking. Surprisingly, as Ratliff (2001) proved, the Dodgson winner need not be Kemeny top-ranked; it can be anywhere within the Kemeny ranking. As Ratliff (2003) also proved with examples, if Dodgson's method is extended to select the top two, or top three, candidates, the outcomes need not be consistent; that is, examples exist where the Dodgson winner is not a Dodgson top-two candidate, and none of them is in the Dodgson top three. Voting behaviour is very complex.

‘Paradoxes’, then, identify new properties of voting rules. Nurmi (1999; 2002), for instance, creates several examples illustrating how major voting rules disagree over a wide selection of desirable properties. His work suggests it may be futile to select voting rules based on specified properties because no rule may satisfy all of them, and most surely there are other valued properties that we have yet to recognize. Fishburn creates many fascinating examples; one (1981) has a plurality ranking of A>B>C>D, but, if D drops out, the same voters have the plurality ranking of C>B>A; Fishburn’s example illustrates an unexpected reversal property of the plurality vote.

Examples disclose subtle properties of voting rules, so a way to find all such properties is to find everything that can happen: that is, a profile defines a list – an election ranking for each possible subset of candidates. The goal is to find all lists that can be created with all possible choices of positional rules and all possible profiles. Call this collection of lists a ‘dictionary’. Entries in a dictionary, then, describe all possible ranking properties for all positional rules and even for methods, such as AV and run-offs, based on positional and pairwise rules. Even entries outside the dictionary describe properties; for example, lists of the (A>B>C, B>A, C>A, C>B) type, where some profile allows the pairwise rankings to reverse the positional ranking, never are in the Borda Dictionary, so, by being a missing listing, it describes a Borda consistency property.

Such dictionaries exist (for example, Saari, 1989; Saari and Merlin, 2000) showing, for instance, that most positional rules allow anything to happen. For instance, rank seven candidates in any desired manner. Next, re-rank the seven six-candidate subsets (created by dropping someone) in any desired manner; for example, if you wish, reverse the original ranking, or select them randomly. Continue doing so with each subset of five, four, three and two candidates. While the choices could be chaotic, a profile exists where the voters’ plurality ranking for each subset is the selected one. (The same conclusion holds for most choices of positional rules over the different subsets.) What provides hope from these dictionaries is that the Borda Count – defined by \((n-1, n-2, \ldots, 1, 0)\) – is the unique rule (when used with every subset of candidates) that significantly minimizes the number and kinds of allowed...
voting paradoxes. Thus, the Borda Count enjoys the maximum number of positive properties; for example, only Borda always ranks a Condorcet winner over a Condorcet loser.

A related ‘dictionary’ result (Saari, 1992a) proves that a ten-candidate profile exists where $9(9!)$ (recall, $9! = (9)(8)(7)...(2)(1)$, so $9(9!)$ is over three million) different election rankings without ties result from changing the positional method; each candidate is top ranked with some rules and bottom ranked with others. (For $n$-candidates, up to $(n-1)[(n-1)!]$ different strict election rankings can emerge from changes in positional methods.)

**Luce's approach**

Arrow (1951) proved that with three or more candidates no voting rule satisfying his conditions always has transitive outcomes. Luce (1959) adopted a different approach; he imposed constraints on admissible election outcomes. His conditions, which are described in terms of probabilities to reflect his interest in individual decisions, are stricter than Arrow's. Expressed in terms of voting, Luce requires a candidate's vote percentage to remain consistent over all subsets of candidates. For instance, if A, B, and C receive, respectively, $1/3$, $1/2$, and $1/6$ of the vote, then in a pairwise comparison B beats A by receiving $(1/2) / [(1/3) + (1/2)] = 3/5$ of the vote. Luce's conditions, then, capture settings where a candidate's support is intrinsic; relative to other candidates, the support remains fixed over all sets of candidates even should new ones join.

The accompanying voting rule and admissible profiles are not specified; they are selected to be consistent with Luce's conditions. But, even with his strong conditions, the accompanying profile restriction with the plurality vote is surprisingly relaxed. Only limited extensions of this approach have been explored for voting theory, but more is possible for settings where candidates have intrinsic support.

**Emphasizing the data**

So far I have sampled ways to analyse voting rules through properties of the rules and by imposing restrictions on admissible election outcomes. It remains to explore how the domain structure – the individual preferences – sheds light on these rules. The approach mimics how we might determine whether an election outcome reflects the ‘will of the voters’: one way is to compare the outcome with what the voters say they want. To develop methodology, reverse the order: first determine what the voters want, and then determine which voting rules respect these outcomes.

To indicate how to determine what the voters want, consider tallying an Alice>Barb ‘22:20’ election outcome. One tallying approach combines an Alice and a Barb vote – a tie. After counting the 20 ties, Alice breaks the tie as she has two extra supporters. For more candidates, the approach is to determine configurations of preferences that arguably constitute ties. This provides a filter; if a voting rule fails to deliver a tie, expect it to introduce a bias in election outcomes. While this is the motivation, the technical objective is to find a coordinate system for the space of profiles. Different coordinates represent how portions of profiles influence different voting rules.

Such a coordinate system for profiles has been established for any number of candidates (Saari, 1999; 2000). For intuition about how this is done and the kinds of available results, the three-alternative setting (Saari, 1999) is outlined. The space of profiles is divided into three distinct coordinates, or subspaces,
voting paradoxes: The New Palgrave Dictionary of Economics

 profiles that cause all possible positional method problems, but with no effect on pairwise rankings;

 profiles that cause all problems with pairwise majority votes, but with no effect on positional rankings; and

 profiles where no problems arise with any positional or majority vote rule.

The power of such a coordinate decomposition is apparent. As a sample:

 The coordinates allow us to explain properties of election rules. For instance, positional rules failing to have a tie for the first class of profiles can seriously disagree with pairwise majority vote outcomes.

 The second class of profiles explains problems dating to the 1780s about conflicts between pairwise and positional methods as well as agendas, tournaments and so forth.

 Conflicts associated with any profile, such as our initial one, can be explained; for example, finding the portions of a profile in each of these directions identifies why different rules have different election outcomes.

 Examples illustrating any possible paradox can be constructed. Start with a profile in the last class where there is complete agreement among all rules. To introduce a conflict with positional methods, add a profile portion from the first class; to create conflict with pairwise outcomes, add a profile portion from the second class.

To determine the first coordinate direction, we must find all profiles affecting only positional outcomes. While this is done mathematically, for an intuitive explanation combine a ranking with its reversal, for example, (A>B>C, C>B>A): it is arguable that the outcome should be a tie. It is a tie for majority votes over pairs. But with positional rules (w₁, w₂, 0), the A:B:C tallies are w₁:2w₂:w₁, where a tie occurs if and only if (iff) \( w₁ = \frac{2}{3} w₂ \); that is, the desired tie occurs iff the Borda Count is used. If this configuration is used as a filter, then beware of a non-Borda rule. This is because, instead of a tie, rules with \( w₁>2w₂ \) (for example, the plurality vote) have an \( A = C > B \) outcome, while rules with \( w₁<2w₂ \) (for example, the anti-plurality vote) have a \( B > A = C \) outcome. Consequently, profiles exist where non-Borda positional rankings must differ from majority vote outcomes.

Surprisingly, all possible differences among three-candidate positional election rankings reflect how different rules handle these reversal profile components. Indeed, to create the initial example, I started with one voter with the B>C>A preference. To generate differences in positional outcomes, add \( x \) reversal units of (A>B>C, C>B>A) and \( y \) of (A>C>B, B>C>A). As the plurality and anti-plurality tallies for A:B:C are, respectively, \( x+y:y:x \) and \( x+y:2x+y:x+2y \), algebra yields my \( x = 2, y = 3 \) choices creating the desired positional outcomes – and conflicts. (Borda is not affected by reversal terms, so its ranking remains the starting B>C>A.) As all possible positional differences are generated by reversal terms, any justification for one positional rule (for example, properties that uniquely identify one rule over others) must reduce to analysing the reversal component (A>B>C, C>B>A) tally.

The second coordinate direction, capturing all conflict among pairwise majority votes, is the Condorcet
voting paradoxes: The New Palgrave Dictionary of Economics

triplet with its resulting cycle. This component is responsible for all pairwise voting mysteries, including
the majority vote cycles, differences in Dodgson's and Kemeny's methods, problems with agendas,
tournaments and so forth. This assertion holds for any number of candidates. To create a Condorcet $n$-
tuple, start with an $n$-candidate ranking, say A>B>C>D>E. For the next ranking, place the top candidate
on the bottom, creating B>C>D>E>A. Continue until each candidate is in first, second, ..., last place
precisely once. This configuration should define a tie, and it does for all positional methods. But the
profile also creates majority vote cycles. Surprisingly, these profile coordinate components cause all
possible pairwise problems.

To illustrate with our initial example, start with the B>C>A preference. Adding $z$ units of (A>B>C,
B>C>A, C>B>A) results in A:B, B:C, C:A pairwise votes of, respectively, $2z:1+z$, $2z+1:z$, $2z:1+z$. So
$z = 2$ creates the desired cycle. Adding these reversal and Condorcet terms to the starting ranking
yields the initial example.

The remaining coordinate directions, where nothing goes wrong, are called Basic directions. For
candidate A, it consists of two preferring A>B>C, two preferring A>C>B, one preferring B>A>C, one
preferring C>A>B; that is, two for each ranking where A is top-ranked, one for each where A is second-
ranked. More generally with $n$-candidates, candidate X's Basic direction has $(n-j)$ voters with each
ranking where X is $j$th ranked. While not intuitive, these coordinate directions come from mathematics.
The important point is that no conflict occurs in this profile space; for example, the tallies for any voting
rule for all candidates identifies the tally for all voting rules over any subset of candidates. Nothing goes
wrong. These three kinds of directions span the six dimensions of profile space, so they complete the
three-alternative analysis. (A profile, of course, normally has only parts in each direction.)

Explaining all differences

All possible differences among three-candidate standard voting rules, then, reflect how voting rules react
to reversal and Condorcet profile components. The many desirable properties of the Borda Count, for
instance, arise because it is the only rule based on positional and majority votes that always delivers a tie
for these components.

I indicated how all positional differences reflect how positional rules treat reversal terms, so it remains
to describe the Condorcet components. For motivation, suppose three voters must vote for one of two
candidates from each of three schools. Suppose the candidates are [Anne, Bob], [Connie, Dave], [Ellen,
Fred]. Does a [Bob, Dave, Fred] outcome, each by 2:1, reflect the voters’ views? To answer this
question without knowing the actual preferences, all supporting preferences must be listed.

Four of the five profiles have two voters selecting different candidates from each school; this causes a
tie. Breaking the tie is the last voter's [Bob, Dave, Fred] preference. The fifth profile has the preferences
[Anne, Dave, Fred], [Bob, Connie, Fred], [Bob, Dave, Ellen]. It is difficult to argue against the outcome
for the first four profiles as a tie is broken. At least statistically, then, the outcome respects most
supporting profiles. But it is difficult to justify the fifth ‘outlier’ profile other than pointing to the 2:1
votes.

While most profiles justify the conclusion, suppose the fifth ‘outlier’ profile is the actual one where each
voter wanted to elect a woman and a man. The profile reflects their wishes; the outcome does not. The
reason is clear: the majority vote strictly emphasizes information about specific pairs; it ignores
information – even intended relationships – among pairs. Consequently, rather than recognizing the
added ‘balanced gender’ condition, the majority vote must ignore it.

To connect this example with the Condorcet triplet, identify \( \text{Anne} = B > A, \text{Bob} = A > B; \)
\( \text{Connie} = C > B, \text{Dave} = B > C; \text{Ellen} = A > C, \text{Fred} = C > A: \) the Condorcet triplet becomes the outlier
‘fifth profile’, and the ‘balanced gender condition’ is equivalent to ‘transitivity’. Because any argument
applied to one setting transfers to the other, it follows that the cyclic outcome for the Condorcet triplet
(the ‘paradox of voting’) occurs because (a) this outcome reflects most supporting profiles (even though,
by involving cyclic preferences, they are not admitted), and (b) the majority vote strips all connecting
information, *including transitivity*, from the profile. (c) While majority pairwise voting may suffice if
candidates have ‘intrinsic support’, it can distort outcomes for usual cases.

In general:

- Pairwise outcomes reflect the average over *all possible* supporting profiles; paradoxes, such as
  with the Condorcet triplet, indicate that the actual profile is an outlier relative to the average.
- Majority votes strip away all intended relationships, including transitivity, from the profile.
- Whenever intended relations are dropped, they come from profile portions based on Condorcet *n*-tuples.

**Explaining mysteries**

The above structure explains several mysteries. The ones described here compare the Borda and
Condorcet rules, briefly discuss all rules based on pairwise outcomes, and explain Arrow’s Impossibility
Theorem.

As indicated, for any number of candidates all possible differences between the Borda and pairwise
rankings manifest the majority vote's reaction to Condorcet *n*-tuples, which introduce cyclic affects. As
an illustrating example, with two preferring \( A > B > C, \) and one preferring \( B > A > C, \) both the Borda and
pairwise rankings reflect \( A > B > C. \) Adding \( x \) units of the Condorcet [\( B > A > C, A > C > B, C > B > A \)] never
affects the Borda ranking, but its cyclic effect changes the A:B, B:C, C:A pairwise tallies to \( 2 + x: 2 x + 1, 2 x + 3 : 2 x, 2 x + 3 : 2 x + 3 \) where \( x = 2 \) makes B the Condorcet winner, \( x \geq 4 \) creates a cycle.

*Any* difference between the Borda and Condorcet winners, then, reflects Condorcet profile components.
Thus, any argument supporting Condorcet over Borda must justify something other than a tie for a
Condorcet triplet or *n*-tuple.

Voting rules relying on majority vote pairwise rankings, such as Kemeny's and Dodgson's rules, inherit
the majority vote difficulties caused by Condorcet *n*-tuples. As these rules are primarily intended to
handle cyclic behaviour, their value presumably emerges when the Condorcet component is dominant.
But the stripping action of the majority vote over these components means that, unexpectedly, the rule
cannot use information about the voters’ transitive preferences. Consequently, if the transitivity of voter
preferences is valued, such rules should not be used. If transitivity is not valued, we must question using
rules that impose transitivity on the outcomes.

A similar analysis holds for Arrow’s Theorem (Saari, 2001). An unexpected feature of IIA, as with the
majority vote, is to strip from the decision rule all information that individuals have transitive
preferences. But, if the rule cannot use the transitivity of individual preferences, then transitive societal
outcomes cannot be expected unless profiles are severely restricted; that is, the societal outcome reflects
the imposed data structure rather than properties of the rule. One severe restriction is to use the
preferences of a single voter; this explains Arrow's dictator.
As Arrow's negative result is strictly caused by IIA unintentionally stripping away valued information about individual preferences, resolutions must modify IIA to allow the rule to use this information. To illustrate, a transitive ranking, say $A > B > C$, separates some alternatives from others. Listing these separations as \([A > B, 0], [B > C, 0], [A > C, 1]\) provides information about the transitive individual preferences. Let IIIA (Intensity IIA) be where a pair's societal ranking is determined by how each voter ranks the pair and the number of separating alternatives. By replacing IIA with IIIA in Arrow's conditions, Arrow's dictator is replaced with the Borda Count, and rules based on the Borda Count.

**Strategic behaviour**

Beyond the above ‘single-profile’ problems, multiple-profile concerns catalogue interesting changes in outcomes by changing a profile. They include the seminal Gibbard (1973)–Satterthwaite (1975) theorem asserting that, with three or more alternatives, no decision rule is immune from strategic behaviour: that is, with any rule, situations exist where some voter ensures a personally better outcome by voting according to other than her true preferences. There is, in fact, a host of related behaviour; see, for example, Nurmi (1999; 2002). Some rules, for instance, can cause a winning candidate to lose by attracting more supporting voters. Similarly, Fishburn and Brams (1983) discovered the ‘no-show’ paradox where, with the plurality run-off, a voter obtains a personally better outcome by not voting.

These results reflect the higher dimensionality of profiles that accompanies added alternatives. With two candidates, a voter can vote for, or against, her favorite. With more alternatives, beyond her top and bottom choice, a voter can consider intermediate options. As suggested by the ‘don't waste your vote’ cry for strategic voting, situations exist where, by voting strategically, some voters can block personally lower-ranked candidates from winning. The Gibbard–Satterthwaite result proves this happens for all realistic rules.

A common source of problems, such as the no-show paradox, or where two subcommittees elect ‘A’ but the combined committee does not, and so forth, is when the rule loses monotonicity. Positional methods are monotonic; that is, with added support a candidate has higher tallies. But difficulties occur with rules involving several subsets of candidates; for example, a run-off involves \{all \(n\)-candidates\} and \{top two\}. What causes problems is that the first election determines who is advanced to the second. Consequently, added support for a winning candidate could also advance a stronger opponent to the run-off.

**Implications for economics**

Voting rules are aggregation methods: voters’ preference rankings are aggregated into a societal ranking. But as much of economics, and the social sciences, also involves aggregation rules, we must anticipate that the behaviour of voting rules predicts behaviour elsewhere in economics and other disciplines. This happens. As illustrations, the above result allowing \(9(9!)\) different positional election rankings for a single ten-candidate profile, where almost any specified outcome can occur, has a parallel with the Sonnenshein (1972)–Mantel (1972)–Debreu (1974) Theorem asserting that any continuous function satisfying Walras's Laws can be (up to minor technical conditions on prices) the aggregate excess.
demand function for some exchange economy. As another example, recall the voting result stating that, even if the rankings for the different subsets of candidates are selected in an arbitrary manner, a supporting profile can be found. The same behaviour arises in economics. The voting result allowing a ranking to be selected for each subset of candidates, and a profile can be found so that the selected ranking is the actual election ranking also has an economic parallel: that is, the Sonnenshein–Mantel–Debreu Theorem extends to where a different function can be selected for each subset of commodities, and an economy (initial endowment and utility function for each agent) can be found so that (with the same technical condition) the aggregate excess demand for each subset is the selected one (Saari, 1992b).

Voting results have parallels in non-parametric statistics, namely, select rankings for each subset of alternatives: for most non-parametric rules, a data-set can be found so that each set's actual ranking is the selected one. In voting, the positional rule most immune from the ‘anything can happen’ difficulty is the Borda Count. In nonparametric statistics, the Kruskal–Wallis test has similar properties (Haunsperger, 1992).

Wade, John (1788–1875)

Daniele Besomi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

John Wade was born in London to working class parents. He worked for more than a decade as a journeyman wool sorter, then he ‘wrote his way out of obscurity’ (Harling, 2004). He was encouraged by Francis Place to engage in journalism: his first venture was a penny newspaper, The Gorgon, published in 1818–19 on money lent by Bentham and Henry Bickersteth (later Baron Langdale). Wade's articles are reputed to be well informed and detailed, so that The Gorgon's influence surpassed its limited circulation. It attempted to find a junction point between, on the one hand, radical reformers and trade unionists, to which group Wade belonged, and, on the other hand, moderate reformers, with particular reference to the possible use of utilitarian doctrines to improve the condition of the labouring classes.

Keywords

Bentham, J.; capital–labour relations; cobweb theorem; Place, F.; speculation; technological progress; utilitarianism; Wade, J.

Article

In 1819 Wade published anonymously in two-penny sheets The Black Book, where he documented in detail the revenues and privileges of the ‘parasitic’ classes: clergy, aristocracy, and anyone connected with the government. The book (1820), later qualified as a handbook of radical agitators, was very successful, with over 50,000 copies sold in its various editions. In 1828 Wade joined the staff of the newly founded Spectator, and in the course of his life he wrote several inquiries and a number of compendia on such topics as Manchester Massacre (1819), A Political Dictionary ... Chiefly Designed for the Use of Members Of Parliament ... (1821), A Popular Digest of the Laws of England (1826, 24th edition in 1869), Digest of Facts and Principles on Banking (1826), British History, Chronologically Arranged (1839), Principles of Money, with their Application to the Reform of the Currency and of Banking (1842), the last book on Harlotry and Concubinage being dated 1859. His juvenile positions
became more widely accepted in later years, and in 1862 he was granted a £50 annual pension by Lord Palmerston. He died in Chelsea in 1875.

Wade's *History of the Middle and Working Classes* (1833) offers interesting insights into the nature of capital and its relation to labour, but especially on periodic fluctuations in prices and activity. While most of Wade's contemporaries focused on crises, conceived either as accidental events or, more rarely, as periodically returning, Wade offered one of the earliest, if not the earliest, dynamic models of endogenous cycles in individual industries. Having recognized the existence of a ‘commercial cycle’ showing some ‘periodic regularity’ and recurring every five to seven years (Wade, 1833, pp. 211, 255), he offered an explanation consisting essentially in a cobweb-like mechanism. Price movements trigger changes in both demand and production, which in turn react against the original movement. When prices rise, demand falls while production increases. Supply thus outpaces demand, and prices fall, setting off the opposite movement (1833, p. 254). The cycle results from the system's tendency to correct price fluctuations. The assumption, implicit in this part of the argument, that reactions are either slow or lagged was made explicit a few pages later where Wade observed that the introduction of new machinery takes some time to fully develop its consequences on production and prices (1833, p. 257).

On top of this mechanism, Wade considered a number of relieving or aggravating circumstances, including foreign competition, changes in fashion or technological progress. Notably, he saw ‘illusive speculation’ of an ‘epidemic character’, addressed ‘to the passion and not to the reason of mankind’, as the generator of crises. This argument was common at the time, but while his contemporaries saw in this the root of the problem, Wade was adamant that this was an aggravating cause only, superimposing onto the main mechanism.

wage curve

David G. Blanchflower and Andrew J. Oswald
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article summarizes evidence for the existence of a wage curve – a downward-sloping relationship between the level of pay and the local unemployment rate – in modern micro data. At the time of writing, the curve has been found in 40 nations. Its elasticity is approximately –0.1.

Keywords

labour economics; microfoundations; Phillips curve; Phillips, A. W.; power laws; unemployment; wage curve

Article

The wage curve is a statistical regularity or empirical ‘law’ of economics. It traces out, as in Figure 1, a downward-sloping relationship between wages and local unemployment. Its elasticity is approximately –0.1. Although this kind of downward-sloping shape has since been replicated in many other nations and by many other authors, Figure 1 here is reproduced from work on US data by Blanchflower and Oswald (1994, p. 134). The y axis, here labelled ‘antilog’, is a measure of the level of pay.

Figure 1
As an example, consider two regions within a country. Assume Region A’s unemployment rate is double that in Region B. The wage-curve finding states that a worker’s wage will then be ten per cent lower in Region A than the wage of an identical worker in Region B.

To understand the wage curve’s place in intellectual history, it is useful to go back to one of the oldest questions in economics, namely, that of how the price of labour is affected by the unemployment rate. Following an empirical tradition begun by the New Zealand economist A.W. Phillips (1958), this issue has traditionally been studied with aggregate time-series methods. Although its robustness is still questioned, the Phillips curve, which is a relationship between wage growth and unemployment, has become part of the bedrock of macroeconomics textbooks. Sargan (1964) pointed out that it was possible to view the Phillips curve as being consistent with a steady-state solution where the level of pay depends on the level of unemployment.
The wage curve is a robust empirical phenomenon ... but there is ... evidence of publication bias. There is indeed an uncorrected mean estimate of about −0.1 for the elasticity. After controlling for publication bias by means of two different methods, we estimate that the ‘true’ wage curve elasticity at the means of study characteristics is about −0.07.

Why the wage curve exists, however, is not so well understood. One way to rationalize such a pattern is to appeal to non-competitive theories of the labour market – for example, to the idea of a no-shirking condition or a Nash bargaining-power locus. According to this kind of analytical framework, high local unemployment makes life tougher for workers (because, for example, they will find it harder to obtain work if laid off by their current employer), and therefore it is not necessary for employers to remunerate them so generously. The wage curve is then potentially an important element of a theory of equilibrium in the labour market such as in Shapiro and Stiglitz (1984) or Pissarides (2000).

The wage curve seems relevant beyond its implications for labour economics. First, macroeconomic analysis has for some decades stressed the need for microeconomic foundations. Second, some macroeconomics textbooks make extensive theoretical use of a wage curve (at the aggregate level), but do not provide evidence for it. Wage curves have been reported for Argentina, Australia, Austria, Belarus, Belgium, Brazil, Bulgaria, Burkina Faso, Canada, Chile, China, Côte d’Ivoire, Czech Republic, Denmark, East Germany, Estonia, Finland, France, Great Britain/UK, Holland, Hungary, India, Ireland, Italy, Japan, Latvia, New Zealand, Norway, Poland, Portugal, Romania, Russia, Slovakia, Slovenia, South Africa, South Korea, Spain, Sweden, Switzerland, Taiwan, Turkey, USA and West Germany. These studies are summarized in Blanchflower and Oswald (2005). A meta-analysis – on a sample of 208 wage–unemployment wage curve elasticities from the literature – by Nijkamp and Poot (2005, p. 445) concludes that...

**How to cite this article**

Wage indexation is a mechanism designed to adjust wages to information that cannot be foreseen when the wage contract is negotiated. A wage contract with indexation clauses will specify the wage base (that is, the money wage applicable in the absence of new information), the indexation formula that will be used to update wages, and how often updating will occur. Most traditional discussion has focused on wage indexation to the price level as a mechanism to stabilize real wages in the presence of inflation. More recently, however, attention has shifted to indexation to a wider set of indicators. These indicators include both richer price information (such as the value added price deflator and the terms of trade) and rules designed to index wages to indicators measuring the level of nominal activity (such as nominal GNP). Concurrently, growing attention has been given to the potential role of wage indexation in affecting the will and ability to reduce inflation.

The economic evaluation of the role and desirability of wage indexation is inherently tied to the assessment of the functioning of the labour market and the role of wage contracts. If labour markets are cleared continuously, as in an auction market (that is, if wages are adjusted continuously to equate the demand and the supply of labour), wage contracts serve no purpose and indexation clauses are either redundant or diminish welfare. On the other hand, the potential role of various wage indexation schemes grows the further we move away from an auction labour market. Consequently, an analysis regarding the role of wage indexation invites a specification of the nature of the deviations from an auction labour market and of the disequilibrium mechanism applied in that market. Indeed, challengers of the usefulness and relevance of wage indexation have remarked on the lack of rigorous understanding of the postulated deviations from auction market behaviour (see Barro, 1977). At the same time, a growing body of research has proceeded on the assumption that the existence of nominal contracts with limited degrees of indexation provides enough evidence to reject an auction labour-market clearing hypothesis.
wage indexation: The New Palgrave Dictionary of Economics

(see Fischer, 1977b). This assumption has justified studies of the economics of wage indexation in models that lack a rigorous general equilibrium framework, but still provide insights into complicated economic environments. We start with a review of analytical studies on wage indexation, continue with overview of experience with wage indexation in various countries, and close with some interpretative remarks.

Analytical aspects of wage indexation

The usefulness of indexing wages to the price level has been the subject of considerable research, and perceptive comments on the topic can be found in publications going back to Keynes's *General Theory of Employment, Interest and Money* (1936). A renewed interest in the question was generated by Gray (1976; 1978) and Fischer (1977a), who integrated the rational expectation hypothesis with nominal contracts. They considered an economy where nominal contracts preset the contract wage before the realization of stochastic shocks. The rational expectation hypothesis is invoked to determine the contract wage, which is set at a level that is expected to clear the labour market. The contract agreement also specifies the degree of wage indexation to unanticipated inflation. A complete indexation implies real wage rigidity, whereas the absence of indexation entails nominal wage rigidity in which changes in the price level directly affect the real wage. The contract specifies also the determination of employment rule, which is assumed to be demand determined. Consequently, in general employment will deviate from the flexible equilibrium level (that is, from the employment level that will prevail in an economy where the wage is set as to clear the labour market continuously). The optimal degree of indexation is designed so as to minimize the expected squared output deviations from its market clearing level. This can be shown to be equivalent to minimizing the deadweight loss in the labour market for risk-neutral agents (see Aizenman and Frenkel, 1985). The optimal degree of wage indexation is a compromise between two opposing forces: the wish to neutralize the potential output consequences of monetary (nominal) shocks by keeping real wages stable, and the wish to reduce real wages in the presence of adverse real shocks. The first goal is accomplished by complete wage indexation to prices, and the second by partial indexation. Optimal indexation balances between these two forces, implying that greater importance of monetary relative to real shocks will be associated with higher indexation. Such an indexation scheme implies that the real sector is not insulated from monetary variability (see Gray, 1976; Fischer, 1977a). As a result, optimal indexation will tend to stabilize output around its full equilibrium level while it will tend to increase the volatility of prices.

Subsequent research had raised several important questions, for instance why wages are contingent only on prices and not on other relevant information. As Barro (1977) and Karni (1983) have pointed out, optimal contingencies will allow wages to adjust to all relevant information, thereby clearing the labour market continuously and eliminating the output effects of monetary policy. The fact that we find no contracts with rich sets of contingencies suggests, however, that it will be very costly to collect and process all the information needed to write and enforce full contingency contracts (see Fischer, 1977b; Blanchard, 1979). Another related question is the underlying justification of the disequilibrium hypothesis. As demonstrated by Cukierman (1980), the indexation derived by Gray is affected by the disequilibrium hypothesis. It can be shown, however, that this issue becomes inconsequential once we approach a full contingency contract because such a contract will clear the market independently of the
disequilibrium hypothesis (see Aizenman and Frenkel, 1985).

Further developments regarding wage indexation have extended the analysis to open economies. Flood and Marion (1982) showed that optimal indexation is determined by the exchange rate regime, whereas Aizenman and Frenkel (1985) demonstrated that optimal indexation is only one among many potential policies, and that there is a close linkage between wage indexation, monetary policy and exchange rate policies.

A relevant consideration in these discussions is the set of indicators to which the wage is indexed. Most of the above studies derived optimal indexation rules in terms of the underlying structural parameters (like the elasticities of demand in the money and labour market). While these results are informative, their usefulness is limited by the degree of availability of information regarding the underlying structure. In an environment with limited and costly information, indexation rules that use easily available data, without relying on the structural parameters, should have natural advantage. Such rules were studied by Marston and Turnovsky (1985) who investigated the usefulness of wage indexation to the GNP price deflator and to the GNP in the context of energy shocks. Aizenman and Frenkel (1986) pursued related research, showing that if the elasticity of demand for labour exceeds the elasticity of supply, then indexing nominal wages to nominal GNP is preferable to indexing to the value added price index, and this, in turn, is preferable to indexation to the CPI (this ranking is reversed when the elasticity of the supply of labour exceeds the elasticity of demand). Similar results are applicable for ranking the usefulness of targeting monetary policy to the above indicators. Taking another research direction, Fethke and Policano (1984) addressed the usefulness of coordinating the timing of wage negotiations in a multisectoral economy. They concluded that when disturbances are driven primarily by relative shocks (that is, shocks that hit the two sectors differentially) staggered negotiation is optimal.

Once we place wage indexation in its proper perspective as a macroeconomic policy instrument, a natural question arises regarding the linkages between wage indexation and other policies such as taxes and assets indexation (see Friedman, 1974), the risk-sharing effects of indexation (see Azariadis, 1978) and wage renegotiation (see Gray, 1978 and Aizenman, 1984). Further analysis and references regarding these important topics can be found in a useful conference volume (Dornbusch and Simonsen, 1983).

Experience with wage indexation

The experience with indexation of the last decades has been mostly with various degrees of wage indexation to the CPI. The precise indexation policy differs across countries considerably, depending on the centralization of the wage negotiation process and the degree to which wage indexation is viewed as income policy instead of as an instrument to enhance the efficiency of the labour market. For example, in the United States wage indexation is allowed, but there are no guidelines and the details of the indexation schemes are left for the contract negotiation. In Europe, Latin America and Israel labour negotiation tends to be more centralized, and the indexation provisions tend to be dictated by a centralized policymaker. Some countries (for instance, Italy and Brazil) have applied wage indexation as an implicit income policy. This was done by imposing a rigid base wage and a high degree of wage indexation (and in some cases with a cap at high income levels). Such a policy is a poor substitute for direct income policy because it generates distortions in the labour market. These distortive effects increase in periods associated with real shocks, such as changes in input prices and in aggregate demand.
Other countries have attempted to design partial indexation as a device to allow real wage flexibility in the presence of terms of trade shocks (see Brenner and Patinkin, 1977). While experience with indexation differs across countries, several observations appear to be common to them all. *First*, the degree of indexation to the price level and the frequency of wage adjustment tend to go up with the level and volatility of inflation (see Ehrenberg, Danziger and San, 1983, and Kleiman, 1977). *Second*, a higher indexation rate tends to reduce linkages between excess demand forces in the labour market and wages (see Sachs, 1983). *Third*, limited indexation seems not to be a controversial issue for countries with stable and relatively low inflation rates. For countries with high and volatile inflation the desirability of wage indexation is an important policy issue when attention shifts to curbing that inflation. In various countries in the last decades we have observed the adoption of indexation at low and moderate inflation rates. Once inflation has risen to intolerable levels, however, the policymaker has tended to couple abrupt disinflationary policies with disindexation policies (for example in Iceland in 1983 and in Israel in 1985). This tendency is related to the fact that a typical indexation scheme adjusts wages to lagged inflation, implying that it builds in inertia, thereby a policy of disinflation will tend to raise real wages during the transition, generating unemployment (see Simonsen, 1983, and Fischer, 1984).

**Concluding remarks**

The role of nominal contracts and the potential role of wage indexation and macro policies are major research topics in macroeconomics. In recent years we have witnessed considerable development in this area, achieved by integrating the rational expectation hypothesis into models where transaction costs prevent continuous auction market clearing. The present state of theoretical research is, however, far from satisfactory. On the one hand, the theoretical papers reviewed above do not offer a framework that will satisfy ‘purists’, although they allow assessment of important policy issues in the presence of realistic contracts. On the other hand, ‘purists’ have not so far been able to explain the existence of nominal contracts of the type observed in various segments of the labour market. Interesting research directions that may provide further clues are frameworks that will recognize and model economic environments where decisions are costly. These costs stem from the observation that data gathering and screening are not free, and that resources are lost in the negotiation process. Such a framework will put a premium on simpler decision rules requiring less frequent negotiation, and nominal wage contracts may be one important example of such rules. The research into nominal contracts reviewed above is, we may hope, a step in that challenging direction.

The experience with wage indexation to prices suggests that greater attention should be given to the design of tractable indexation rules that will generate real wage flexibility in the presence of real shocks while retaining the purchasing power of wages in the presence of nominal disturbances. Such rules should be based upon widely available information. A candidate that deserves further exploration is wage indexation to nominal GNP. Simple-minded rules for indexation to the CPI have several potential disadvantages. They prevent real wage and employment adjustment in the presence of real shocks, thereby causing suboptimal employment. In the presence of nominal shocks and inflation, indexation to prices can generate dynamic inconsistencies – in the short and intermediate run it mitigates the losses associated with unanticipated inflation, but it thereby reduces the will to follow policies that are prudent
wage indexation: The New Palgrave Dictionary of Economics

with regard to inflation, causing higher inflation in the long run. Once the policymaker attempts to
disinflate, the indexation scheme may exacerbate the welfare costs associated with the transition to
lower inflation. Thus, a policy device that is viewed as useful in the short run can be harmful in the long
run. Consequently, indexation rules are not a substitute for prudent macro-policies. Rules that index wages to
nominal income or to the GDP deflator can serve a useful role as part of macro-policies that recognize
the need to undergo real adjustment in the presence of real shocks. At the same time, they are deceptive
and harmful if they are used as income policy tools in an attempt to maintain the purchasing power of
wages in economies exposed to productivity and terms-of-trade shocks.

Abstract

We examine trends in wage inequality in the United States and other countries since the 1960s. We show that there has been a secular increase in the 90–50 wage differential in the United States and the United Kingdom since the late 1970s. By contrast the 50–10 wage differential rose mainly in the 1980s and flattened or fell in the 1990s and 2000s. We conclude that a version of the skill-biased technical change hypothesis combined with institutional changes (the decline in the minimum wage and trade unions) continues to offer the best explanation for the observed patterns of change.

Article

1 Introduction

Study of the structure of wages has been a preoccupation of economists for a long time and dates back at least as far as Adam Smith. Until the early 1990s economists commented on the remarkable stability of the wage structure in the post-war period. But then many empirical studies (for example, Bound and Johnson, 1992) noticed that wage inequality in America had risen dramatically since the late 1970s. Related empirical research (notably by Goldin and Katz, 1999; 2001) went back further in time uncovering other periods of changing wage structures in American history. Other countries, notably the United Kingdom, also saw a significant increase in wage inequality at about the same time as the recent US changes (Machin, 1996). These observations kick-started what has become a huge empirical and theoretical literature seeking to measure and explain changes in wage inequality (see the survey of Katz and Autor, 1999). Since wages are a major part of people's income and economic well-being, the increase in wage inequality feeds through to income, consumption and poverty rates. So understanding the patterns of wage inequality is important from a normative as well as a positive perspective.

In this article we examine what has happened to the wage distribution since the 1960s, looking principally at the United States, where the bulk of the economic research has focused, but where possible also examining other countries. Section 2 describes the observed changes in the structure of wages (although we fully acknowledge there are some contentious, and as of yet unresolved, issues about the observed patterns of change). Section 3 looks at the main explanations of the observed changes that have emerged from the large body of work in this area. Section 4 offers some conclusions.

2 What has happened to the wage distribution?

2.1 Overall trends in US wage inequality
To set the scene, Figure 1 plots out the salient features of the US full-time weekly wage distribution from 1963 through to 2003. At least three things stand out from Figure 1. First, educational wage differentials – measured as the gap in pay between college and high school educated workers – have risen consistently since 1979 (after falling somewhat in the 1970s and rising somewhat in the 1960s). The rate of increase was more rapid in the 1980s than after 1992. (This ongoing secular rise in educational wage premia is also seen in the hourly wage series from March outgoing rotation group of the Current Population Survey, CPS; see Lemieux, 2006.) Second, the 90–10 wage differential – defined as the difference in weekly pay for those at the 90th and 10th percentiles of the overall wage distribution – has been rising since 1976 (and maybe even earlier). Third, the ‘residual’ 90–10 wage differential – the difference between those at the 90th and 10th percentiles of the overall wage distribution after controlling for education, experience and gender – has risen consistently since 1967, especially after the mid-1970s (see Juhn, Murphy and Pierce, 1993). This increase in ‘within group’ wage inequality has also generated much excitement and interest from theorists, but is particularly hard to interpret in the light of compositional changes (Lemieux, 2006).

Figure 1
Even though different data-sets show some differences and there are some variations in inequality measures across data sources, the overall picture is one of a dramatic increase in American wage inequality since 1979.

### 2.2 Comparing the United Kingdom with the United States

The United Kingdom is another country where wage inequality has risen dramatically. Comparison of the United States and United Kingdom is useful to pin down certain issues to do with the rise in wage inequality. One important point is that since 1980 there are marked decadal differences in the opening up of the wage structure. Analysis of US and UK micro-data uncovers a clear picture for the 1980s in both countries: wage growth was more pronounced at higher points of the distribution, and faster wage growth higher up the distribution is almost monotonic in both countries, leading to large increases in wage inequality. An important difference, however, is that in the United Kingdom there was positive wage growth throughout the distribution whereas in the United States workers in the bottom quartile actually experienced zero or negative wage growth.

The picture becomes more complex post-1990. In both countries the 90–50 continues to diverge (‘upper tail inequality’) whereas the 50–10 (‘lower tail inequality’) in the United States actually shrinks, indicating some wage compression. In the United Kingdom the 50–10 is stable (increasing a bit in the 1990s and shrinking a bit in the 2000s). Overall then, the increase in wage inequality has been stronger in the upper tail than the lower tail taking the period as a whole, and has been more pronounced in the 1980s than post-1990.

A marked and important similarity between the two countries is the continuous and rapid growth of wages at the very top of the distribution. In the United Kingdom, wage growth at the 95th percentile (and above) is greater than at other percentiles of the wage distribution in the 1980s, 1990s and 2000s. This is also true for the United States (except for the 10th percentile in the 1990s). So within the picture of overall rising inequality the very rich have done particularly well.

The other key feature of the changing wage distributions in the United Kingdom and the United States (and elsewhere) has been the polarization of work into ‘good jobs’ and ‘bad jobs’ (defined as high-wage and low-wage jobs). While there has been significant growth in well-paid ‘good jobs’ at the upper tail of the distribution (like lawyers, senior managers and consultants) there has been an increase in low-paid ‘bad jobs’ in the lower tail of the distribution (like cleaners, hairdressers, shop assistants and burger flippers). In the 1990s especially it seems that the middle of the distribution seemed to do somewhat worse than those at the top or bottom. These findings have been reported on in the United States (Autor, Katz and Kearney, 2006), United Kingdom (Goos and Manning, 2007) and Germany (Spitz-Oener, 2006).

### 2.3 The experience of other countries

There is less systematic evidence for the evolution of the wage distribution outside of the United States and the United Kingdom, especially for more recent years. Table 1 uses OECD data to show 90–10 male wage ratio for a range of countries between 1980 and 2000. Broadly speaking, the 1980s rise in inequality was seen only in the United Kingdom and the United States and in specific countries where particular episodes to move to a much more market-oriented economy occurred (notably New Zealand). Elsewhere wage inequality did not alter much. The 1990s is a little different, with evidence of widening wage structures starting to occur in places previously characterized by stable wage structures – Germany is a very good example of this. Moreover, as we discuss below, the Continental European countries did experience a larger increase in unemployment, which may be due to the same underlying forces that have pushed up wage inequality in Britain and America.
### 3. Explanations of changes in wage inequality

A natural place to begin to analyse the observed changes in the wage structure is to consider a model of changes in supply and demand. We then need to incorporate institutional features (such as minimum wages and trade unions) into the model.

#### 3.1 Sources of skill premia: supply and demand

Rising wage inequality has been accompanied by an increase in the relative demand for skilled or educated workers. This is evident since, despite the increase in the relative supply of more skilled workers in many countries, their relative wage has also gone up, suggesting that relative demand for skilled workers has been rising faster than relative supply. In Table 2, for example, the proportion of graduates grew from 20.8 per cent of the population in 1980 to 34.2 per cent in 2004 in the United States. (In the United States the graduate measure is having a bachelor's degree or higher – that is, excluding people with some college who do not get a degree.) The equivalent figures from the United Kingdom were even more dramatic – the growth in graduates was from 5 per cent to 21 per cent over the same time period. However, at the same time the relative wages of graduates compared with those of non-graduates increased. In a competitive model of the labour market with skilled and unskilled workers, these facts can be reconciled by an increase in the relative demand for skilled workers.

Notes: Sample is all people aged 18–64 in work and earning, except for relative wages, which are defined for full-time workers. The relative wage ratios are derived from coefficient estimates on a graduate dummy variable in semi-log earnings equations controlling for age, age squared and gender (they are the exponent of the coefficient on the graduate dummy).

A simple way to formalize this, following Katz and Murphy (1992), is in the context of a constant elasticity of substitution (CES) production function with two labour inputs:

\[
Q_t = \left[ a_t (a_t N_s) + (1 - a_t) (b_t N_u) \right]^2 / \rho
\]  

In eq. (1) aggregate output is \( Q \) and is produced with college educated-equivalent skilled labour \( N_s \) and high school-educated equivalent unskilled labour \( N_u \) in period \( t \). The parameters \( a \) and \( b \) represent skilled and unskilled augmenting technical change, \( \alpha \) indexes the share of work activities of skilled labour and \( \rho \) is a parameter that determines the elasticity of substitution between skilled and unskilled labour \( \sigma = \frac{1}{1-\rho} \). Skill-biased technological changes involve increases in \( a/b \) or \( \alpha \).

Assuming college and high school equivalents are paid their marginal product we can use eq. (1) to solve for the ratio of marginal products of the two types of labour, \( W_s / W_u \), and relative supplies of labour, \( N_s / N_u \), in year \( t \) as:

\[
\ln(W_s / W_u)_t = (1 / \sigma) \left[ D_t - \ln(N_s / N_u)_t \right]
\]

where

\[
D_t = \sigma \left[ \ln(a_t / (1 - a_t)) + \rho \ln(a / b)_t \right]
\]

is a relative demand index of shifts favouring college equivalents and is measured in log quantity units. The impact of changes in relative skill supplies \( N_s / N_u \) depends on the elasticity of substitution, \( \sigma \). The larger this parameter is, the bigger will be the effects of supply changes on relative wages. Equation (3) shows that changes in \( D \) can arise from (disembodied) skill-biased technical change, non-neutral changes in relative prices or quantities of non-labour inputs and shifts in product demand.

Katz and Murphy (1992) implemented an empirical version of eq. (2), replacing \( D \) with a linear time trend (‘trend’) for US data between 1963 and 1987. They estimate:

\[
\ln(W_s / W_u)_t = \gamma_0 + \gamma_1 \text{trend} + \gamma_2 \ln(N_s / N_u)_t + \nu_t
\]
finding $\gamma_2$ to be significantly negative (equal to $-0.709$), implying an elasticity of substitution of about 1.4 ($\sigma = -1 / \gamma_2 = 1.41$), with a significant trend increase in the college premium of 3.3 per cent per annum ($\gamma_1 = 0.333$). In the literature that has followed the estimates of the elasticity of substitution are typically in the 1.4 to 1.6 range (see, for example, the study of Autor, Katz and Kearney, 2005). The main point to take away from these estimates is that there appears to be a systematic demand shift towards more skilled workers throughout the last four decades of the 20th century. This is not to suggest that supply side changes are unimportant. Deviations of relative skill supplies from the trend are negatively associated with deviations of the relative wage from trend as suggested by $\gamma_2 < 0$. The slowdown of the growth of education in more recent cohorts is certainly one factor accounting for the increase in inequality as shown by Card and Lemieux (2001). But the most important factor over the longer run in accounting for the growth in educational wage differentials appears to be the trend demand shift towards the more skilled. The critical question then becomes: what could account for this change?

3.2 The cause of relative demand shifts: technology or trade?

To date, the two main explanations for the demand shift towards the more skilled are skill-biased technological change (SBTC) and increased international trade. We examine each of these in turn.

3.2.1 Skill-biased technological change

Equation (3) above directly relates the change in the skill premia to SBTC. The idea is that new technologies such as information and communication technologies (ICTs) are complementary with the skills of more-educated workers. More-educated workers may find it easier to cope with the uncertainty surrounding new technologies in general, or may have a particular advantage in using ICT effectively. Rapid falls in the quality-adjusted prices of ICT or a more rapid investment in new technologies (for example, from higher R&D intensities) could therefore have shifted demand towards more-skilled workers. There is now abundant empirical evidence that suggests that SBTC is an important and international phenomenon (for example, see the survey in Bond and Van Reenen, 2007). A typical analysis estimates the following cost share equation (usually for industries or workplaces):

$$\Delta \text{SHARE} = \beta_1 \text{TECH} + \beta_2 \Delta \ln \left( \frac{K}{Y} \right) + \beta_3 \ln \left( \frac{W_s}{W_u} \right) + \varepsilon$$  \hspace{1cm} (5)$$

where \text{SHARE} is the wage bill share of skilled workers, \text{TECH} is a measure of technical change, \text{K} is the capital stock, \text{Y} is value added, \text{W}_s/\text{W}_u is relative wages, $\Delta$ the difference operator and $\varepsilon$ an error term. This relationship can be derived from the stochastic form of a translog short-run variable cost function with labour as the two variables and physical capital and technological capital as the two fixed factors (for example, Berman, Bound and Griliches, 1994). The test of skill-biased technical change is whether $\beta_1 > 0$, and the overwhelming preponderance of econometric evidence supports this finding. An example of the genre is Machin and Van Reenen (1998), who examine this relationship using manufacturing data across many industries in seven OECD countries (the United States, the United Kingdom, France, Japan, Germany, Denmark and Sweden) in the 1970s and 1980s. In all of the countries examined they found that demand was shifting more quickly towards skilled workers in the more technologically advanced industries (that is, $\beta_1 > 0$ in eq (5)). This was robust to using either occupation or education as a measure of skills, using either R&D intensity or computer use as a measure of technology, and instrumenting own R&D with frontier (US) R&D. In most countries they also found evidence of capital–skill complementarity ($\beta_2 > 0$). Estimating versions of eq. (5) in other countries, in non-manufacturing sectors (for example, Autor, Katz and Krueger, 1998) and on more disaggregated plant-level data (for example, Doms, Dunne and Troske, 1997) also appears to uncover evidence of SBTC.

There are several other sources of evidence on SBTC. Berman, Bound and Machin (1998) report evidence of faster skill demand shifts occurring in the same sorts of industries in different countries, and one may view this as informing the SBTC hypothesis (to the extent that similar industries in different countries utilize similar technologies). A less-used alternative to test for SBTC is to regress the adoption of technologies on skill prices (that is, when skilled workers’ wages rise relative to those of unskilled workers this should
3.2.2 Increased international trade

At first glance, the simple Heckscher–Ohlin model of trade offers a seemingly cogent explanation of why unskilled workers have fared badly in recent decades. Less-developed countries such as China and India have become integrated into the global economy as trade barriers and transportation and communication costs have fallen. Unskilled workers in the OECD counties now have to compete not only with workers at home but also with a large number of workers overseas. The influx of cheap goods produced with low-skill labour puts downward pressure on the wages and employment opportunities of unskilled workers in the West, and is responsible for the observed shifts in relative labour demand. To model this we explicitly consider two regions: ‘North,’ which is skill-abundant and ‘South’ which is unskilled-abundant. There are four industries: tradable high-skill intensive, tradable low-skill intensive, non-tradable high-skill intensive and non-tradable low-skill intensive. The Stolper–Samuelson theorem establishes that relative wages in each country will depend on relative output prices of the tradable industries: the higher the relative price of the skill-intensive good, the higher the relative wage of the skilled workers. What happens when a small open economy in the North moves from autarky to free trade? The removal of trade barriers increases the relative price of the skill-intensive good and this means the skill premium rises in the North. Although this model is coherent, it also offers several other predictions which turn out to be at odds with the data (see Desjouqueres, Machin and Van Reenen, 1999, for extensive discussion of these predictions). First, the increasing specialization of the North in skill-intensive goods under free trade means that employment should shift between industries to skill-intensive industries. But because relative skill prices have risen we should expect to see that employment within industries shifts towards (the cheaper) unskilled workers. Decompositions of the increase in the aggregate employment share of skilled workers, however, almost all show that within industries there has been a strong shift towards skilled workers. This might be because the level of aggregation of industries is too high, but more disaggregated industries and even firm-level studies suggest that a sizable proportion is ‘within’. Even more convincingly, Desjouqueres, Machin and Van Reenen (1999) show that non-traded sectors – such as hotels and wholesale outlets – also show a shift towards skilled workers (and an increase in the educational wage premium). This pattern of within-industry shifts is consistent with general SBTC, but inconsistent with the basic trade theory. Second, we should observe that relative prices of the unskilled-intensive sectors should fall rapidly in the North. There is some evidence for this in the United States but there is no significant relationship for any other country (at least until the mid-1990s). Even in the United States the evidence from Krueger (1996) suggests that this relationship was only apparent after 1989, when wage inequality grew slowly. Finally, naive regressions that include import penetration and other trade variables in eq. (5) generally find no role for these trade variables (for example, Machin and Van Reenen, 1998). This does not take into account the general equilibrium effects underlying the Heckscher–Ohlin model, of course. Overall there is little support for the trade-based explanation of demand shifts. There are two caveats to this conclusion. First, most of these studies were based on data prior to the early 1990s when China started to become more of a major exporter. Second, trade might induce some of the skill biased technological change discussed in the previous section as suggested by Acs (2002).
Research trying to reconcile cross-country differences in change in wage inequality has emphasized the role of labour market institutions that affect wages differently in different places. There are several features of this work, ranging from studies that look in detail across countries to those that focus on the role played by particular labour market institutions like minimum wages or trade unions.

3.3.1 Cross-country evidence

As discussed in Section 2, there has been considerable heterogeneity in the evolution of relative wages across OECD countries since the 1970s. The rise in inequality was much stronger in the Anglo–Saxon countries (for example, the United States and the United Kingdom) than elsewhere (for example, France, Germany and Japan). Although the technology and/or trade shocks discussed in the previous subsections should be global events, the Continental European and Japanese economies have experienced a much greater increase in unemployment than the United States since the late 1970s. One view is that European unemployment and American inequality are ‘two sides of the same coin’ – institutional rigidities (and perhaps generous welfare benefits) placed a floor under the wages of unskilled workers in Continental Europe, resulting in increased unemployment rather than greater inequality. (There is also a new, growing body of work arguing that tastes and social norms are important for explaining cross-country patterns of change; see, amongst others, Bénabou and Tirole, 2006.)

This is probably too crude. Nickell and Bell (1995) have shown that relative unemployment rates between skilled and unskilled workers did not rise by as much as would be expected in this simple model. Similarly, the cross-country correlation between the growth in unemployment and earnings inequality is not very strong (for example, Burniaux, Padrini and Brandt, 2006). Finally, European countries may have been better at keeping up the growth of supply of the quantity and quality of skills than in the United States and United Kingdom (although Table 2 shows that skill expansion in the United Kingdom was very rapid).

At the very least, the fact that wage inequality has not risen in the countries where minimum wages and/or union power remained strong suggests that institutions do have an important role to play.

3.3.2 Minimum wages

There is much evidence that minimum wages compress wage differentials (DiNardo, Fortin and Lemieux, 1996). In the United States the real value of the Federal minimum wage fell significantly during the 1980s, and some authors argue that this can account for all of the change in wage inequality (for example, Lee, 1999). By the same token the uprating of the minimum wage in the 1990s helps explain the slowdown in wage inequality. As Card and DiNardo (2002) emphasize, the time series pattern is very strong – see Figure 2.

wage inequality, changes in: The New Palgrave Dictionary of Economics

Log 90/10 hourly earnings inequality and real minimum wage
A problem with the “purely institutional” argument, however, is that it seems highly unlikely that the minimum wage can explain what is happening in the top half of the wage distribution. Analysis of the minimum wage suggests that the impact on workers above median wages is close to zero. Nevertheless, the most striking finding of the analysis in Section 2 was that there appeared to be a secular increase in the 90–50 wage ratio since the late 1970s in the United States (and the United Kingdom). It is hard to reconcile these facts with the minimum wage-explains-all story. Similarly, when Autor, Katz and Kearney (2005) add the minimum wage to eq. (4), although it has the expected negative sign it does little to reduce the long-run unexplained relative demand shift towards higher education wage differentials.

Where the institutional story does better is in accounting for the dramatic increase in residual wage inequality in the bottom half of the wage distribution in the 1980s. This residual wage change was more episodic, and most of the change is plausibly accounted for by the minimum wage (and compositional effects – see below).

Another problem with the pure minimum wage explanation is that wage floors changed much less in other countries where wage inequality also rose. For example in the United Kingdom, the minimum wage system that operated at the time when wage inequality rose (the ‘Wage Councils’) only covered a relatively small proportion of the workforce (around 12 per cent at the time of abolition in 1993). Furthermore, during the 1993–9 time period when all non-agricultural minimum wages were abolished in the United Kingdom, wage inequality at the lower end actually started to stabilize (Dickens, Machin and Manning, 1999; Machin and Manning, 1994).

3.3.3 Trade unions and imperfect competition

As with minimum wages there is robust evidence that unions act to compress wage differentials (for example, Freeman, 1980; Card, 1996). Since unions have declined in the United States and the United Kingdom, this may be another institutional mechanism putting upwards pressure on wage inequality. Unionization rates fell from 25 per cent to 15 per cent between 1979 and 1998 in the United States, and from 53 per cent to 31 per cent in the United Kingdom over the same period. Gosling and Lemieux (2004) argue that union decline can account for over a third of the increase in male wage inequality in both countries over the 1983–98 period.

As with the minimum wage explanation, it is rather difficult to evaluate these statistical decompositions as they are not based on an underlying economic model. But it does seem rather implausible that unions could be the major explanation in the United Kingdom, the minimum wage system that operated at the time when wage inequality rose (the ‘Wage Councils’) only covered a relatively small proportion of the workforce (around 12 per cent at the time of abolition in 1993). Furthermore, during the 1993–9 time period when all non-agricultural minimum wages were abolished in the United Kingdom, wage inequality at the lower end actually started to stabilize (Dickens, Machin and Manning, 1999; Machin and Manning, 1994).

An alternative set of theories has emerged that emphasizes rents derived from imperfect competition (albeit from a different source from unions). This approach has frictions in the labour market that generate heterogeneous wages even for identical workers. Some more productive or technologically advanced firms may share quasi-rents to workers who are matched with them (for example, Van Reenen, 1996). If the dispersion of these wage premia has increased over time, this could lie behind the increased wage inequality. For example, in Caselli (1999) firms experiment with the uncertain new technology, and some of those that are successful obtain higher productivity, resulting in higher wages for the workers with whom they are matched. To date, there is little hard empirical evidence on these theories, although Faggio, Van Reenen and Salvanes (2006) offer some evidence that firm productivity heterogeneity has increased and this is linked to firm wage inequality as Caselli’s model would suggest.
There has been a dramatic increase in wage inequality since the late 1970s in the United States, the United Kingdom and other anglophone countries. A significant part of this is due to the growth of wage differentials between educational groups. We have argued that the fundamental reason for this is a long-run growth in the relative demand for skills driven by technology change (rather than trade). Changes in skill supply and institutional changes have affected the timing of how skill-biased technical change impacts upon the wage structure. The increase in inequality in the United States and the United Kingdom slowed down after 1990, but has continued to grow in the upper tail of the wage distribution, and wage inequality has started to rise in places previously characterized by stable wage structures (like Germany), indicating that explaining changing patterns of wage inequality remains high on the research agenda of empirical economists.

wages fund

John Vint
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The wages fund doctrine was an important element in the classical analysis of the labour market – elements of the wages fund doctrine are to be found in the Wealth of Nations (1776) – and articles attempting to defend it were still being produced over a hundred years later. Its longevity was due to its success in generating a wide range of economic predictions. It is noted for John Stuart Mill's recantation in 1869 – a rare case of an important doctrine being explicitly rejected by a major political economist.

Article

The wages fund doctrine was an important element in the classical analysis of the labour market – elements of the wages fund doctrine are to be found in the Wealth of Nations in 1776 – and articles attempting to defend it were still being produced over a hundred years later. The wages fund doctrine began to take shape in the work of the early classical writers and became more rigid later. On the one hand, it was popularized by Marct (1816) and Martineau (1832) among others, and employed in more vulgar forms in political debates; on the other, it was used much more carefully and technically by the classical economists to produce a wide range of economic predictions. It is noted for John Stuart Mill's recantation in 1869 – a rare case of an important doctrine being explicitly rejected by a major political economist.

The approach to the wages fund doctrine adopted by the classical writers varied over the period but by the middle of the 19th century there was a generally accepted analysis, from which Mill dissented. In this article I will begin by examining this recantation view of the doctrine and then outline the various phases in its development and decline.
In his book *On Labour*, which appeared in 1869, W.T. Thornton presented a critique of supply and demand analysis and the wages fund doctrine. John Stuart Mill reviewed the book in the *Fortnightly Review* for May and June 1869, and in this review he made his famous recantation from the wages fund doctrine. Mill sketched what he understood the accepted doctrine to be:

There is supposed to be, at any given instant, a sum of wealth, which is unconditionally devoted to the payment of wages of labour. This sum is not regarded as unalterable, for it is augmented by saving, and increases with the progress of wealth; but it is reasoned upon as at any given moment a predetermined amount. More than that amount it is assumed that the wages-receiving class cannot possibly divide among them; that amount, and no less, they cannot but obtain. So that, the sum to be divided being fixed, the wages of each depend solely on the divisor, the number of participants. In this doctrine it is by implication affirmed, that the demand for labour not only increases with cheapness, but increases in exact proportion to it, the same aggregate sum being paid for labour whatever its price may be. (1869, p. 515)

The predetermined fund is usually conceived of as a stock of wage goods or necessaries, and if this stock is changed from one production period to the next, while the labour force remains constant, the real wage rate would also change. Some classical economists discussed the consequences of a change in the money fund under circumstances where the fund of wage goods remained the same. One line of argument was that the workers could consume only wage goods and not luxuries, and that therefore the increased expenditure on the fixed stock of goods would lead to an increase in prices, leaving the real wage rate unchanged. This can be regarded as the ‘rigid’ version of the theory. The fact that not all classical writers subscribed to this version all the time was ultimately an important feature in its demise. The origins of the doctrine in British political economy are to be found in the work of Adam Smith, although he was heavily influenced by the Physiocrats’ notion of *avances*. In the *Wealth of Nations* Smith clearly proposed the notion that wages are advanced to workers by capitalists from capital, although there is nothing to suggest that these advances are predetermined or fixed. Moreover, while the wages fund theory presents a competitive solution to the determination of the wage rate, Smith argued for an uncompetitive solution ‘upon all ordinary occasions’ (1776, p. 82) due to the superior bargaining position of the employers.

In the first edition of the *Essay on the Principles of Population* 1798, Malthus put forward all the elements of the wages fund doctrine, including the argument that increased money payments would be offset by increased prices, leaving the real wage rate unchanged. However, in the first edition of the Malthus's *Principles of Political Economy* (1820), the wages fund was not well developed. Labour demand was loosely related to growth in capital or resources. By contrast, in the second edition of the *Principles of Political Economy* (1836), Malthus's discussion of wages is much fuller and much closer to a wages fund approach.

There is no simple, consistent statement of the wages fund doctrine as outlined above to be found in Ricardo's *Principles of Political Economy* (1817), or any of his other published works or correspondence. In the chapter on machinery, Ricardo does present an example which makes use of the logic of the wages fund, but there are other passages in the *Principles* and in his correspondence where
Ricardo's approach to wages runs directly counter to the doctrine. For example, in correspondence with Trower, Ricardo (1951, VIII, p. 258) argued that under certain circumstances workers can consume luxuries.

The mature phase, when the accepted version fully emerged, is associated with the work of Marcet and McCulloch, and the doctrine was applied to a range of economic issues by Torrens, Senior and J.S. Mill. McCulloch has been regarded by prominent historians of economic thought such as Bonar (1885, p. 272) and Cannan (1893, p. 263) as the author of the analysis which had originated in Marcet's Conversations on Political Economy (1816), although it had, in fact, been originally expounded by Malthus in 1798 (see Vint, 1994, pp. 77–88).

McCulloch argues in the Principles of Political Economy (1825) that a country's ability to employ workers depended on the existence of an ‘amount of the accumulated produce of previous labour’. The wage rate depended on the ‘proportion which the whole capital bears to the whole amount of the labouring population’ (1825, p.173). He argued that wages do not depend on the amount of money allocated to labourers – if the mount of money halved but the quantity of wage goods remained the same the labourer ‘would carry a smaller quantity of pieces of gold and silver to market than formerly; but he would obtain the same quantity of commodities in exchange for them’ (1825, p. 174). This was the rigid fund of Malthus.

It was the Malthus–McCulloch rigid version of the wages fund doctrine which underpinned some of the later popularizations used to argue against the efficacy of strikes and the role of trades unions. But as Taussig pointed out (1896, pp. 239–40), the classical economists themselves, up until Mill's Principles in 1848, did not use the doctrine in this way. McCulloch himself, for example, eschewing the wages fund doctrine in this context, made a powerful case for trades unions in 1824; Torrens (1834) made use of the wages fund analysis to show that unions could act to raise wages. Mill did use the wages fund doctrine to deny the effectiveness of union action in 1848 but his case was heavily qualified.

Among the popularisers, Harriet Martineau made use of the rigid fund in ‘Manchester Strike’, one of the tales from the Illustrations of Political Economy (1832), to argue that strikes were futile; William Ellis argued that in a combination to raise wages ‘success is impossible’ because ‘the capital out of which the increased wages are to be drawn does not exist’ (1854, p. 224).

There were clearly potential weaknesses in the rigid version of the doctrine – were wages actually paid from capital; was the fund predetermined; could workers consume only wage goods? Despite these potential flaws the doctrine lasted for almost a century, and from the mid-1820s was an accepted part of classical theory. One potential explanation for its longevity is that it was used successfully by the major political economists such as Senior (1830) and J.S. Mill to produce a wide range of predictions relating, for example, to the effects of the introduction of machinery on the wage rate, the impact of various kinds of war loans on wages and the effects of landlord absenteeism (see Vint, 1994, pp. 124–75).

Mill's recantation came at the end of a decade of change for the British trade union movement. Events on the ground were important – there was an intense political debate concerning the legal status and role of trades unions, culminating in the appointment of Royal Commission of Inquiry in 1867. Alongside these events there was an important theoretical discussion concerning the wages fund doctrine in the work of Fawcett (1860), Longe (1866) and most importantly Thornton (1869). Longe argued that wages were not paid from capital, and both he and Thornton argued that the wages fund was not predetermined. In the ‘recantation’ Mill attacked the theory, arguing that the demand for labour does not increase with
cheapness, that the wages fund is not predetermined and that the money funds in the hands of employers were flexible and could be bargained for by workers. He then went on to produce his famous recantation statement:

The doctrine hitherto taught by all or most economists [including myself], which denied it to be possible that trade combinations can raise wages, or which limited their operation in that respect to the somewhat earlier attainment of a rise which the competition of the market would have produced without them, – this doctrine is deprived of its scientific foundation, and must be thrown aside. The right and wrong of the proceedings of Trades’ Unions becomes a common question of prudence and social duty, not one which is peremptorily decided by unbending necessities of political economy. (1869, pp. 517–18)

Thus in a few short paragraphs Mill apparently disposed of a central tenet of classical economics and one which had a long history. There were attempts to revive the doctrine by Cairnes (1874) and others, but these failed. Cairnes's arguments were thoroughly demolished by F.A. Walker (1875) in the first comprehensive review of the debate. In 1879 Sidgwick also reconsidered the controversy in the *Fortnightly Review*. After agreeing that ‘Professor Walker's argument gives a *coup de grâce* to the old wages-fund theory’, Sidgwick threw out a challenge to Walker and other economists to put something in its place (1879, p. 411). This challenge and the response of Walker and others to it generated what Gordon referred to as the ‘second round debate’ (1973, pp. 23–31) and which resulted in the eventual development of marginal productivity theory. Until Sidgwick's watershed contribution, the point of reference for the discussion of wage theory was the debate which began in the 1860s, but thereafter subsequent writers made fewer references to the earlier controversy. There continued to be defences of the doctrine, but often the focal point was Walker's work, and none of these efforts succeeded in undoing the damage done earlier.

Wakefield was born in London on 20 March 1796, the eldest son of Edward Wakefield, a radical Quaker philanthropist, statistician, and author of a standard work on Ireland which was highly regarded by Ricardo, James Mill and other members of the philosophic radical circle. His son was to become one of the more colourful characters to inhabit the margins of the history of economic debate, and can be variously described as a publicist, politician and author. Apart from his practical and frequently controversial contributions to the development of Australia, Canada and New Zealand, he left a distinctive mark in the annals of classical political economy during the middle third of the 19th century. After a chequered education at Westminster School and Edinburgh High School, from which he was expelled in 1811, Wakefield first read for the Bar and later served as secretary to the British envoy to the Court of Turin (1814–20). In 1816 he successfully eloped with a 16-year-old Ward-in-Chancery who died in childbirth in 1820. From 1820 to 1825 he served with the British legation in Paris and entertained ambitions of entering Parliament. In 1826 he made an attempt to acquire a rich wife by the most direct means available: he abducted the daughter of a wealthy family from her school and married her at Gretna Green. He was apprehended by her family at Calais and subsequently given a three-year sentence, which he spent studying capital punishment and transportation, writing a powerful pamphlet condemning the former, and turning the latter into what was to become a lifetime's preoccupation with colonization. His first work on the subject, A Letter from Sydney (1829), purporting to be the reflections of a disillusioned settler on the poor prospects for Australian social and economic development, was actually written from Newgate prison. After his release Wakefield produced a spate of books, articles and prospectuses on the subject of colonization which led to the formation of the National Colonization Society in 1830 – a society which obtained the support of a number of Members of Parliament and of the youthful John Stuart Mill. Although most of his writings dealt with colonization in one form or another, his work on England and America: A Comparison of the Social and Political State of Both Nations
Wakefield's views on colonization were based on a dual analysis of Britain's need for an outlet for its surplus capital and population and a diagnosis of the causes of weak economic development in colonies of new settlement enjoying access to abundant land. His own schemes for 'systematic colonization' were intended as an almost self-regulating solution to both of these problems. Making use of ideas derived from the work of Robert Gourlay, Wakefield advanced a theory of growth in new countries which was designed to support a plan of optimal development. Contrary to the received view, he maintained that access to free or cheap land was responsible for population dispersion, scarcity of labour for hire, and consequent inability to reap the benefits of economies of scale through market concentration and the combined efforts of capital and labour. Under these circumstances the 'natural' pattern of development led to stagnation. Convict labour in Australia and slavery in the American South were both unsatisfactory expedients adopted to deal with a problem that could only be overcome by charging a 'sufficient price' for public or waste land which would deter premature dispersion, stabilize a revolving wage-labour force, and create a fund that could be used to subsidize immigration. The price was defined as one that was high enough to delay land acquisition by newly arrived immigrants without capital of their own, and low enough not to discourage voluntary immigration by reducing real wages and the return on capital.

Colonization on this plan required a new beginning in a colony that was not contaminated by convict labour; and for this purpose Wakefield initially chose South Australia, forming an association for this purpose in 1834. When his proposals were diluted in operation by the founders of the colony (among them another political economist, Robert Torrens), Wakefield turned his attention to New Zealand, serving as the Director of the New Zealand Colonization Company from 1839 to 1846. In 1838 he accompanied Lord Durham on his mission to Canada and wrote the appendix on land disposal to the resulting Durham report.

Wakefield's ideas are of interest for a number of reasons. He belongs to the non-Ricardian underworld by virtue of his attack on Say's Law, the wage-fund doctrine, and the associated idea that capital and labour could never be in surplus together – a mirror image of the problem in colonies where both were scarce. Yet his success in convincing John Stuart Mill and other economists of the correctness of his diagnosis of British and colonial problems gave new significance to the export of capital and labour to colonies and hence to the whole subject of colonization and the development of new countries as a topic within orthodox political economy.

Wakefield also plays a part in the Marxian tradition, or rather its demonology, as a result of Marx's decision to devote a chapter of Capital (vol. 1, ch. 23) to showing how Wakefield, under colonial conditions of labour scarcity, had been forced to reveal the underlying logic of capitalist exploitation. What could be achieved quite naturally under European conditions had to be created artificially in new colonies, with the additional subtlety that having served a term of exploitation, the wage-labourer had to pay for his replacement. One could also claim that Wakefield, less unwittingly, anticipated Hobson and Lenin in providing an economic interpretation of imperialism as a necessary response to stagnation in mature capitalist economies.

In 1853 Wakefield finally practised what he had been preaching by emigrating to New Zealand, where he died in 1862.

Wald, Abraham (1902- 1950)

E. Roy Weintraub
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Cassel, G.; general equilibrium; Menger, K.; Schlesinger, K.; sequential analysis; statistical decision theory; Wald, A.

Article

Born in Cluj, Rumania, Wald came to Vienna in 1927 to study mathematics with Karl Menger, the geometer and son of the economist Carl Menger. Menger introduced Wald to the active mathematical group in Vienna, and secured for him a position as mathematical tutor to the economist Karl Schlesinger. This led to Wald's producing the first proofs of existence for models of general equilibrium; his analysis was based on Cassel's restatement of the Walrasian model, as modified by Schlesinger's treatment of free goods. These works were published in the proceedings of Menger's mathematical colloquium, and a summary was published in the Zeitschrift für Nationalökonomie in 1936. These papers were remarkable for their time and, with von Neumann's paper on equilibrium in a model of an expanding economy, are the first significant contributions to the mathematical analysis of general equilibrium models in economics. Wald is the link between the early work by Walras and the later work by Kenneth Arrow, Gerard Debreu and Lionel McKenzie on the existence of competitive equilibria.

A fine mathematician, Wald was nevertheless prevented from gaining a regular academic position because of Viennese anti-Semitism. Menger helped Wald secure a consultancy position with Oskar Morgenstern who directed the Institut für Konjunkturforschung, where Wald took an interest in the statistical problems that were associated with the analysis of business cycles. Wald's book on seasonal adjustment of time series was a result of his work at Morgenstern's Institut.

Wald was able to escape from Vienna when the Nazis arrived, and made his way to the United States where he initially secured a fellowship, in 1938, at the Cowles Commission which was then at Colorado Springs. When the Commission moved to Chicago, Wald obtained a position, on a Carnegie grant, as Harold Hotelling's assistant at Columbia University. He moved to a faculty post at Columbia in 1941, and was promoted to Associate Professor in 1943 and Professor in 1944.

Wald's contributions to statistics are immense. His most significant paper appeared in 1939 in the Annals

of Mathematical Statistics as ‘Contributions to the Theory of Statistical Estimation and Testing Hypotheses’ (in Wald, 1955). This paper, written before modern decision theory was developed, contained notions of decision space, weight and risk functions, and minimax solution (based on von Neumann's 1928 paper on game theory). Wald's paper was not appreciated at the time, much as was the case with his papers on general equilibrium theory. He did not return to statistical decision theory until 1946, after von Neumann and Morgenstern had presented the theory of games.

During the Second World War, Wald worked with the Statistical Research Group and developed much of the theory of sequential analysis. Although he did not create the idea of taking observations sequentially, Wald did invent the sequential probability ratio test. This original material was published in 1947 after wartime restrictions were lifted.

In 1950, at the height of his powers, Wald and his wife died in a plane crash in India.

Internationally the most widely known and esteemed American economist of his generation, Walker had a varied and distinguished public career. After obtaining his AB at Amherst in 1860, he studied law for one year before joining the Northern army and was successively a Civil War general, deputy to David A. Wells in the Budget Office, chief of the US Treasury's Bureau of Statistics, Superintendent of the Census of 1870 and 1880, Professor of Political Economy and History at Yale's Sheffield Scientific School, and also occasionally at Johns Hopkins, and President of the Massachusetts Institute of Technology, 1881–97. At home Walker was primarily known as an outstanding educational administrator and statistician, for he permanently raised the standards of government statistics, helped to create a permanent Bureau of the Census, and served as President of the American Statistical Association from 1882–97. Abroad, he was recognized more as an economic theorist, especially for his work on wages, money and currency policy.

His attack on the wages fund and formulation of a residual claimant theory of wages attracted widespread attention, though it gained few adherents. His writings on money, and a textbook on political economy, were also well regarded, and his support for bimetallism, which involved the monetization of silver, represented an important contribution to a highly controversial current policy debate. In 1878 Walker was appointed US Commissioner to the Paris International Monetary Conference, but in later years he refused comparable invitations as he became disenchanted with the slow progress of international negotiations.

A moderate critic of the ruling classical laissez-faire orthodoxy, Walker responded sympathetically to the rising young generation of German-trained American economists, hence he was both an obvious and in practice ideal choice as first President of the American Economic Association, from 1885 to 1892. His presidential addresses provide revealing insights into the condition of the subject and the emerging economics profession during those critical years. Walker was an open-minded man, forthright in
expression but fair in controversy. He believed in competition while recognizing its imperfections. An
undoctinaire free trader, he was concerned about the growth of immigration and the decline in the
native birth rate. An advocate of moderate reductions in hours of work, he was one of the first American
economists to recognize entrepreneurial gains as rents of ability. Fifty years after his death, Walker's
eminence was acknowledged when the American Economic Association selected his name for its most
distinguished award, the Walker Medal.

land nationalization; numeraire; property rights; scarcity; Walras, A. A.; Walras, L.

Article

Amateur economist whose writings have received some limited attention, chiefly because some of his views and economic concepts influenced his son, Léon. Auguste Walras was born in Montpellier, France, on 1 February 1801, and died in Pau on 18 April 1866. He studied at the Ecole Normale of Paris (1820–23); was a tutor in Paris (1823–31); a secondary school teacher (1823, 1831–5); a professor of philosophy first at the Royal College in Lille (1839) and then at the Royal College in Caen (1840–47); and a regional school superintendent (1847–62).
Believing that an understanding of property requires a sound theory of value, Auguste Walras developed the unoriginal and unsatisfactory thesis, primarily on the basis of admittedly metaphysical considerations, that economic value depends upon scarcity (rareté). This he defined as the relation between the quantity of a commodity and the number of people that have need for it. He concluded that only scarce things are appropriated and constitute property (Walras, 1831). He then argued that natural law dictates that the state, like the individual, has the right to own property, and that land in particular should belong exclusively to society as a whole. Developing an explanation of the current ownership of land, he pointed out that it is a consequence of social institutions and historical events. During the feudal era, it was placed by the king under the suzerainty of individuals in return for their military services, and their descendants subsequently ruled it as public officials. Since the need for their feudal functions has disappeared, so also has their right to the use of land, and they have become parasites who benefit from economic growth without contributing to it. The class struggle is therefore between landowners and the rest of society, and social justice requires that it be resolved in favour of society as a whole. Believing in conciliation and rejecting revolutionary action, he argued that the state should acquire all land by purchasing it, and should rent it to private users. During the period before complete nationalization the increments in pure land rent arising from the progress of society should be taxed away, and there should be heavy taxes on transfers of land. Since individuals have the right to own what they make, taxation of
produced wealth, as distinct from rent, is unjust. It is therefore an advantage of land nationalization that the state would be supported by the rent it earns and taxation could be eliminated (Walras, 1848). He regarded this proposal as being founded upon scientific analysis and described himself as a socialist, but it is clear that his interpretation and solution of 'the social problem' – the problem of the poverty of the working class during the 19th century – was highly coloured by his normative views and was bourgeois in character.

Auguste Walras also studied the function of precious metals in the growth of social wealth, in the measurement of value, and in exchange; argued that the increase of wealth is the object of economic science; made a distinction between capital and income, and between the market for services and the market for products; introduced the entrepreneur as a person who buys factors of production and sells products; and devised the concept of a numéraire (Walras, 1849). He did not fully develop these ideas nor integrate them into a theory of economic behaviour. His main concern in all his work was to buttress his theory of property and his solution to the social problem.

Walras, Léon (1834–1910)

Donald A. Walker

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Léon Walras was the initiator of models of purely competitive general economic equilibration and equilibrium, of mathematical treatments of them, and of many aspects of microeconomic theory. In his period of maturity as a theoretician, he developed a comprehensive model that includes exchange, production of non-durable goods, production of capital goods, and monetary behaviour. That model features irrevocable disequilibrium behaviour and capital accumulation, and its equilibrium is therefore path dependent. His last theoretical effort, which was a failure but nevertheless very influential, was to try to develop a virtual and therefore path-independent model that would justify his static equation system.

Léon Walras was the founder of models of general economic equilibrium.

1 Biography

Walras was born on 16 December 1834 in Evreux, which is in the Department of Eure in France, and christened Marie Esprit Léon. His father was Antoine Auguste Walras, a secondary school administrator and an amateur economist; his mother was Louise Aline de Sainte Beuve, the daughter of an Evreux notary. After studying at the College of Caen from 1844 to 1850, he entered the Lycée of Douai, where he received the bachelier-ès-lettres in 1851 and the bachelier-ès-sciences in 1853. He entered the School of Mines of Paris in 1854, but, finding the course of preparation of an engineer not to his liking, he gradually abandoned his academic studies in order to cultivate literature, philosophy and social science. Although those efforts resulted in a short story and a novel, Francis Sauveur (1858), it rapidly became apparent to him that his true interests lay with social science. Accordingly, in 1858 he agreed to his father's request to devote himself to economics and promised to continue his father's investigations (1965, vol. 1, pp. 1–2).

During his youth in Paris, Walras became a journalist for the Journal des Economistes and La Presse from 1859 to 1862, the author of a refutation on philosophical grounds of the normative economic doctrines of P.-J. Proudhon (Walras, 1860), an employee of the directors of the Northern Railway in 1862, and managing director of a cooperative association bank in 1865. He gave public lectures on cooperative associations in 1865; was co-editor and publisher with Léon Say of the journal Le Travail, a review devoted largely to the cooperative movement, from 1866 to 1868; and, during those years, gave public lectures on social topics (Walras, 1868) in which he advocated Victor Cousin's doctrine of compromise between economic classes. After the failure of the association bank in 1868, he found employment with a private bank until 1870 (1965, vol. 1, pp. 3–4). During the 1860s he tried intermittently to obtain an academic appointment in France, but he lacked the necessary educational credentials, and the 11 economics positions in higher education in France were monopolized by orthodox economists who, he complained, passed their chairs on to their relatives (1965, vol. 1, p. 3).

His fortunes ultimately changed as a result of his participation in 1860 in an international congress on taxation in Lausanne, for that drew him to the attention of Louis Ruchonnet, a Swiss politician who secured his appointment in 1870 to an untenured professorship of economics at the Academy (subsequently University) of Lausanne in Switzerland. He was made a tenured professor there in 1871, and held that position throughout his teaching career.

Walras's personal life was initially unconventional. He and Célestine Aline Ferbach (1834–79) formed a common law union in the late 1850s. She had a son, Georges, by a previous liaison, and she and Walras...
had twin daughters in 1863, one of whom died in infancy. In 1869 he married Célestine, thereby legitimizing their daughter, Marie Aline, and adopted Célestine's son. A long illness of Célestine's and the meagreness of Walras's salary made life very difficult for him for several years. His time and energy were sorely taxed not only by the need to care for his wife but by the need to supplement his salary by teaching extra classes, contributing to the Gazette de Lausanne and the Bibliothèque Universelle, and working as a consultant for La Suisse insurance company. Five years after Célestine's death in 1879, Walras married Léonide Désirée Mailly (1826–1900). The marriage was a happy one. Her annuity relieved his financial distress, and his situation was further improved in 1892 by an inheritance of 100,000 francs from his mother, which enabled him to pay debts incurred in publishing and disseminating his works, and to buy an annuity of 800 francs.

2 Influences upon his thought

Walras's professional life was devoted to research and teaching. He frequently asserted that his research was a development of his father's and that was true in some respects. It was under the influence of his father's classification of economic studies that Léon, as early as 1862, planned the division of his life's work into the study of pure theory, economic policies and normative goals (Walras to Jules du Mesnil Marigny, 23 December 1862, L 81; the ‘L’ stands for ‘letter’, and, like all correspondence cited in this article, the letter is in Walras, 1965), the areas of study that were ultimately set forth respectively in the Eléments d'économie politique pure (1874; 1877b; 1889; 1896a; 1900; 1926; 1954), the Etudes d'économie social (1896b) and the Etudes d'économie politique appliquée (1898). Léon adopted his father's classification of the factors of production into the services of labour, land and capital goods, regarding the source of each service as a type of capital. He adopted his father's definitions of capital as wealth that can be used more than once and of income as wealth that can be used only once, and modified his father's vague term ‘extensive utility’, clarifying it by defining it as the quantity-axis intercept of a market demand curve. The topic of utility had been treated in French thought by writers such as F. Galiani (a Neapolitan diplomat at Versailles) and E.B. de Condillac, and it was given further development under the name rareté by Auguste Walras, who thus bequeathed to Léon an interest in the concept of utility in relation to the value of goods and an awareness of its dependence upon scarcity, an interest that ultimately led him to define rareté as marginal utility. Auguste used the word ‘numéraire’ to mean an abstract unit of account, and Léon adapted the meaning of the word to his purposes. Auguste's philosophy of social justice and his belief in the desirability of nationalizing land were advocated by Léon throughout his adult life. Léon's major economic theories, however, were derived from his own original inspiration and from sources other than his father. Auguste's greatest contributions to Léon's development as an economist were to encourage him to study economics, to suggest that it should be a mathematical science (A.A. Walras, 1831, ch. 18; Walras, 1965, vol. 1, p. 493), and to give him access to a library of books on economics.

In that library was A.A. Cournot's Recherches sur les principes mathématiques de la théorie des richesses (1838), which Léon Walras credited with having demonstrated that economics could and should be expressed in mathematical form (Walras to Cournot, 20 March 1874, L 253; Walras to H.L. Moore, 2 January 1906, L 1614; Walras, 1905a). Cournot's work introduced Walras to the mathematical formulation of exchange between two locations, the theory of monopoly and the associated conditions
for profit maximization, the analysis of how prices are repeatedly changed in a search for equilibrium in a purely competitive market, and the demonstration of the effect of large numbers of traders upon the determinacy of price, all topics that Walras developed in his own work (1954, pp. 370–72, 434–40, 443). The first demand curve that Walras beheld was Cournot's and he found it immensely suggestive. He was critical of it, however, because he perceived that Cournot's postulate that the quantity demanded of a good is a function only of its own price is inaccurate if more than two goods are exchanged, and that Cournot did not provide a theoretical rationale for the demand function. Those perceptions, Walras observed, were the starting point for his own inquiries (1965, vol. 1, p. 5; 1905a).

Other ingredients that went into the composition of Walras's theories were provided by Adam Smith, John Stuart Mill, François Quesnay, A.R.J. Turgot and Jean-Baptiste Say. Smith had revealed many of the consequences of unfettered competition and had formulated the concept of normal value. Mill had provided a supplement to and reinforcement of Cournot's and Smith's analyses of competitive pricing (Walras to Ladislaus von Bortkiewicz, 27 February 1891, L 999), and also an extension and grand synthesis of classical doctrines that served Walras as a catalyst for critical studies (Walras, 1954, pp. 404–5, 411, 419, 423). Quesnay, in his *Tableau économique*, had expressed the concept of a circular flow of income and of the interdependence of the various parts of the economy. Turgot had clearly delineated the idea of the simultaneous and mutually determined general equilibrium of those parts. Say (1836) had suggested the distinction between the capitalist and the entrepreneur had portrayed the entrepreneur as an intermediary between the market for productive services and the market for outputs, and, in that analysis and in his law of markets, had adumbrated the interdependence between the incomes of the factors of production and the demand for goods. Walras sharpened those ideas and made them a fundamental part of his general equilibrium model.

A.N. Isnard's *Traité des richesses* (1781), a book that Léon owned and that may have been in his father's library, was probably an important source of some of Walras's constructions (Jaffé, 1969; Klotz, 1994). Like Walras, Isnard was interested in determining equilibrium price ratios, set up a system of simultaneous equations of exchange showing the dependence of the value of each good upon the values of the others, stressed the necessity of having as many independent equations as unknowns, and perceived that the use of a numeraire rendered his system determinate. Anticipating Walras's treatment of production, Isnard assumed given ratios of the inputs in a mathematical model and expressed the costs of production in equation form. Also like Walras, Isnard studied the allocation of capital among different uses, coming to the conclusion, as did Walras, that in equilibrium the net rate of income of different capital goods is the same.

Finally, Louis Poinsot's *Eléments de statique* (1803) exerted a powerful influence upon Walras. He first read that book when he was 19 years old and kept it at his bedside for decades (Walras to Melle Dick May, 23 May 1901, L 1483). Poinsot painted a picture of the mutual interdependence of a vast number of variables, of how the dynamic forces in physical systems eventuate in an equilibrium in which each object is sustained in its path and relative position. Electrified by the implications of Poinsot's work, Walras conceived a magnificent project. He would emulate Poinsot's vision and analysis in reference to the general equilibrium of the economic universe! That he carried out that plan can be inferred from the striking similarity of the form of his work to Poinsot's, with its careful delineation of functional dependences and parameters, its sets of simultaneous equations and its equilibrium conditions. Equipped, therefore, with ideas that he could take as building blocks and points of departure, with enough geometry and algebra to put together mathematical statements of economic relationships and
conditions – his use of calculus in the *Eléments* came after the first edition – and with the explicit objective of developing a mathematical theory of general equilibrium, Walras began his scholarly activity in Lausanne in 1870. In a period of great creativity that lasted until 1878, he developed most of the foundations of the theory of general equilibrium that appeared in the first edition of the *Eléments*. Walras insisted to his publisher that the first part appear in 1874, before the second part (1877b) was completed, because he learned in May of that year that W.S. Jevons had published a mathematical theory of utility and exchange that was similar to his own (J. d'Aulnis de Bourouill to Walras, 4 May, 1874, L 267), and he was anxious to establish the independence of his discoveries and his priority in respect to most of them. For those same reasons, he published four brilliantly original memoirs containing the heart of his theory of general equilibrium during 1874, 1875 and 1876 (Walras, 1877a), paid for the costs of publication of his books, and sent copies of them and of his articles to his many correspondents. From 1878 to 1889, Walras significantly extended and refined his theory of general equilibrium (Section 3).

Walras was an extremely conscientious teacher, but he was an uninspiring lecturer (Walras, 1965, vol. 2, p. 560), and the students at Lausanne were interested in careers in law, not in economics, so he failed to develop disciples among them. Moreover, he was with increasing frequency afflicted by bouts of mental exhaustion and irritability that made it difficult for him to lecture and to read and write (see Walker, 2006a, pp. 183–7). In 1892 he took a leave of absence to regenerate his strength in order to be able to continue teaching, but soon realized he would find the strain of returning to his tasks insupportable and retired in that year, being at that time 58 years of age. Subsequently Walras's powers waned rapidly. In 1899 and 1900, he tried unsuccessfully to develop a virtual model of general equilibration and equilibrium (Section 4). After 1900 he completely ceased theoretical construction (Walker, 2006a, p. 191), but he wrote a few articles in which he restated earlier ideas. In late 1901 and 1902, he made some inconsequential changes to the *Eléments* which were ultimately put into the text of the fourth edition (1900) to produce the 1926 edition, both of them unfortunately called the ‘definitive edition’ (1900, p. v; 1926, title page). The latter was chosen for translation by William Jaffé (Walras, 1954) and thus became the edition that is known in the anglophone world. Walras died on 5 January 1910 in Clarens, Switzerland.

3 The mature comprehensive model of general economic equilibrium

Walras's subject matter

Walras recognized that there were imperfectly competitive market structures and developed a theory of monopoly to take account of an important class of such phenomena (1954, lesson 41). Realizing, however, that the incorporation of non-competitive elements into his general equilibrium model was beyond his powers (1954, p. 256) and believing that a high degree of competition was ‘almost universal’ and deserved to be treated as the general case (Walras to Ladislaus von Bortkiewicz, 27 February 1891, L999), he devoted most of his energies to working out a comprehensive model of interrelated ‘freely competitive’ markets, the aspect of his theoretical work with which this entry is concerned. Competition is most effective, he noted, in organized markets, and he assumed that markets are of that type (1954, pp. 83–4), but he also regarded his analysis as applicable in a general way to less highly organized

competitive markets (1954, p. 84).

During his period of maturity as a theoretician, Walras modified and extended the model of competitive general equilibrium that he had presented in the first edition of the *Eléments*, constructing what will be called his mature comprehensive model. He presented it in 1889 in the second and greatest edition (and in the third, (1896a), identical to it in regard to the main body of the text). In the following exposition of that model, all the references to Walras (1954) are to passages that appeared in the 1889 edition.

The model is comprehensive in the sense that it deals with exchange, production, capital formation and credit, and monetary behaviour. It is non-virtual: it deals with irrevocable exchange at prices that are disequilibrium ones from the point of view of the state of the entire set of markets, and with the non-virtual dynamics of production, consumption, saving and investment. Those irrevocable economic activities occur during the course of the equilibrating process and are part of it (1889, pp. 235, 280). The sub-models included in the comprehensive model, such as the models of consumer demand, of the firm, of the entrepreneur, of exchange, of production, and so on, will sometimes be called theories, because Walras had reference to the behaviour of the real economy rather than purely hypothetical schemes. Each major sub-model has four parts: structure, equilibration, equilibrium conditions and comparative statics.

Regarding the structure of each market, Walras assumed that preferences, the number of economically active individuals, the amounts of natural resources and technology are constant. He identified consumers, workers, landlords, capitalists and entrepreneurs, their economic characteristics, and their objectives and how they try to achieve them. He specified the types of goods that are traded, the institutional features and rules of the market, and the individual and market supply and demand functions for goods (material and immaterial).

Regarding the dynamic equilibrating processes by which the markets undergo adjustments when in disequilibrium, Walras called them ‘tatonnements’, which means ‘gropings’, to emphasize that the equilibrium magnitudes of prices and quantities are not known by the participants during the disequilibrium phase but are found by repeated trial and error experiments. Walras considered the exposition of tatonnement to be ‘the object and proper goal of pure economics’ because he believed that the real economy is stable (Walras to Bortkiewicz, 17 October 1889, L 927; Walras to Charles Gide, 3 November 1889, L 933). Walras gave a verbal demonstration of the stability of his model. He recognized that the dynamic functioning of markets depends on the economic agents, institutions and conditions identified in the first part of each model, and in order to portray the disequilibrium behaviour that he perceived in the real economy he accordingly discussed the activities and interactions among diverse economic agents in trade and production, the generation and elimination of profits and losses, the operation of the stock market and many other details of behaviour drawn from economic life. Most of his presentation of the model is concerned with its stability, that is, its behaviour in disequilibrium. Thus the allegation, perpetuated by generations of commentators (for example, Jaffé, 1971, p. 281; 1981, pp. 252–61), that Walras devoted his attention almost exclusively to the conditions of static equilibrium in an abstract model devoid of institutional detail, economic facts and dynamic behaviour is a misrepresentation of his work.

Walras was partially responsible for that misrepresentation, because in 1900 he referred to his general equilibrium model as ‘static’ without qualification, and contrasted it with what he called ‘the dynamic point of view’, by which he sometimes meant the view taken in considering economic growth (Walras, 1954, p. 318). On the other hand, he also stated on many occasions that a dynamic theory is contained in
his mature comprehensive model, and his usage will be followed in this article. The 'static theory of exchange', he wrote, 'may be defined as the exposition of the equilibrium formula'. The 'dynamic theory', in contrast, which Walras claimed to have been the first to explore, is 'the demonstration of the attainment of that equilibrium through the play of the raising and lowering of prices' (1895, in 1965, vol. 2, p. 630). Similarly, in responding to Irving Fisher's criticism that he had not considered time, Walras pointed out that that was true only of his exposition of the conditions of static equilibrium, and that he gave a dynamic treatment of production in lesson 20 (1889) of the *Eléments* (Walras to Fisher, 28 July 1892, L 1064).

**Theory of exchange**

Walras was concerned in this theory with the determination of the equilibrium prices of goods and the quantities of goods exchanged. Setting forth the structure of exchange markets, he assumed that the preferences of the traders and the aggregate amounts of the goods they hold in each market are given. He first assumed that goods (including services) are exchanged directly for each other and then that they are exchanged for money. The participants include brokers, professional traders, retailers, wholesalers, the owners of the factors of production in their capacities as demanders of consumer goods and capital goods properly speaking, and entrepreneurs, who supply and demand goods. The supply and demand functions are reciprocally related (Walras, 1954, pp. 96–7). Given a trader's demand curve for A, its price times the related number of units he wants to buy is his supply of B expressed as a function of the price of A in terms of B. Observing what happens to the areas of the rectangles under the demand curve for A as its price rises, Walras deduced that the quantity supplied of B initially rises and then falls. In the same way, a trader's supply of A can be derived from his demand for B. Walras summed the individual demand and supply curves respectively in the market for A to obtain the market curves, and similarly for B. It will be seen that he adapted and extended this analysis of the dependence of the supply of one good upon the demand for another when he took up the question of multi-good exchange. Walras also assumed that in each market the rule is enforced that disequilibrium transactions are not allowed (1880a, p. 461; 1880b, p. 78; 1954, p. 85). He described that as being true of the 19th-century Paris bourse, but in fact disequilibrium transactions occurred there most of the time (Walker, 2000; 2001), in recognition of which he allowed late in his career that his description is in actuality 'a hypothesis that no scientific spirit would hesitate to concede to the theoretician' (Walras, 1895, in 1965, vol. 2, p. 630).

To explain demand and infuse his early model of exchange (1869–70) with purposive action, Walras developed a theory of preferences shortly before 1872 in which he assumed that traders want to maximize utility, that utilities are independent and additive, and that the marginal utility of a good is a decreasing function of the quantity acquired or consumed. Nevertheless, he was floundering in his attempts to relate utility to market behaviour, so he appealed for help to Antoine Paul Piccard, a professor of industrial mechanics at the Academy of Lausanne, who responded in 1872 by developing a model of utility maximization and deriving the individual demand function within it (1965, vol. 1, pp. 308–11), thus meriting a part of the credit that has previously been given exclusively to Walras for that achievement. Everything then fell into place for Walras, and he proceeded to develop the view of economizing and maximizing behaviour that he imprinted on Continental neoclassical economics. He extended the technique shown in Piccard's model, making utility maximization the driving force in each of his models, and obtaining the equilibrium conditions of the participants in a multi-good system (1954,
The dynamic behaviour of Walras's exchange model is a tatonnement process in the sense that the path of the price in each market is the unplanned outcome of market forces. The process depends upon human nature (see Walker, 2006a, pp. 114–39) and on the rules, institutions and conditions devised and enforced by market authorities and by government (Walras, 1880a; 1880b; 1895 in 1965, vol. 2, p. 632; and see 1954, p. 474). A price is initially cried at random (1877b, p. 127; 1954, p. 169) by any of the traders, and the suppliers and demanders subsequently follow the Walrasian pricing rule: that is, they change the price in the same direction as the sign of the market excess demand for the good. Suppliers call out progressively lower prices if it is negative, and demanders call out progressively higher prices if it is positive. Preferences are constant, and the rule against disequilibrium transactions ensures that the asset distribution remains unchanged during the equilibrating process. Therefore, the initial supply and demand functions and, consequently, the particular-equilibrium price on any given day in the temporarily isolated market, are not affected by the disequilibrium behaviour of the traders. That price equates the supply and demand quantities; it is quoted sooner or later, and the equilibrium amounts of the good are exchanged (1954, p. 106, lessons 6, 9).

Markets are not isolated, however, so Walras introduced the central feature of his contribution to economic science, namely an account, in his theory of exchange and in the other parts of his mature comprehensive model, of the interrelationships among the markets for different goods (including services). If a trader has a good that he wants to trade for several others, the amount that he offers in any market is related to the amounts that he offers in the other markets, so the amount that he wishes to purchase or sell of any good is seen to be a function not only of his preferences, his income and the price of that good but also of the prices of other goods. Consequently, the market supply and demand quantities and the price in any market are dependent in part upon the prices in other markets (1954, lesson 12).

Moreover, Walras explained that the sum of the values of a trader's quantities demanded must equal the sum of the values of his quantities supplied. That relation is one way of stating the individual budget equation, and it is a version, on the individual level (1954, p. 165), of what has come to be known as Walras's Law, a fundamental statement of the way that markets are interrelated. Walras was able to identify the law in part by reasoning an individual cannot demand any commodity without offering in return commodities (or money) having the same total value, so, if some of his excess demands are positive, others of them must be negative, and in part because of the device of the numeraire. The latter, a good in terms of which the values of all goods are expressed (1954, p. 161), made clear to him, as it had to Isnard, that there is exactly the right number of excess demands: in a system with n goods, there are only n–1 independent market equations involving n–1 price ratios, but also only n–1 unknowns, inasmuch as the price of the numeraire, the nth good, in terms of itself is unity (1954, pp. 161–2, 241).

With reference to the market level in multi-commodity exchange, Walras affirmed that the sum of the positive or negative market excess demand quantities for each good multiplied by its price is zero (1954, p. 170), and he stated a version of Walras's Law for the market excess demand quantities of productive services (1954, p. 248). In a Walrasian equilibrium, supply equals demand for every good, so each excess demand quantity is zero. Each excess demand quantity, multiplied by the price of the good, must therefore be zero, so the sum of the excess demands each multiplied by the price must be zero. In the case of an individual, Walras stated only, regarding the variables, that ‘there will be between them all’ the relationship that indicates that their sum is equal to zero, without addressing explicitly whether the...
equation is true in disequilibrium as well as in equilibrium (1889, p. 143, which differs from Walras, 1954, p. 165). In the case of multi-commodity exchange, he probably implied that it is always true even though in disequilibrium the market supply and demand quantities of every commodity are not simultaneously equal (1954, pp. 169–70). In the productive services formulation, he indicated explicitly in the Eléments that it is true only in equilibrium; the functioning of the market mechanism is necessary when the economy is not in equilibrium, he stated, to drive the excess demands to zero and thus solve the equation (1954, pp. 248–9; 1889, pp. 242–6). He later declared, however, that it holds in both disequilibrium as well as in equilibrium (1898, pp. 277–8; Walker, 2006a, pp. 152–4). His implicit reasoning appears to be that the sum of the excess demand quantities, each multiplied by its price, is zero in disequilibrium even though some or all excess demand quantities are not zero, thus implying that the law is an identity.

Walras asserted regarding his mature comprehensive model (and hence regarding its sub-models) that equilibrium exists, on the grounds that the number of independent equations equals the number of unknowns (prices and quantities). He was, of course, mistaken in that belief. Wilhelm Lexis had pointed out in 1881 that Walras's equations might nevertheless not have real positive solutions or any solution at all (see Walras, 1965, vol. 1, p. 747), a fact that only since the late 1920s and early 1930s became well-known (see Weintraub, 1983; Van Daal, Henderiks and Vorst, 1985).

The interdependence of markets, Walras explained, gives rise to the major problem of general equilibrium analysis, which is the question of the stability of the model, implicitly containing the question of the existence of equilibrium. Will a system of freely competitive markets that is initially in disequilibrium converge to a position of equilibrium? After any market reaches temporary equilibrium through the exchange of the equalized market supply and demand quantities, the traders note what has happened to the prices in other markets. Their reaction is manifested in a shift of the market demand curve, which puts the market once more into disequilibrium and initiates another series of quoted prices leading to a new market-day equilibrium. Will its readjustment aid or impede the equilibrating process taking place in other markets? Does the series of market-day prices in the set of markets move closer to an equilibrium of the entire system or further from it? Walras claimed that he had shown that the answer to those questions is that the market system converges to general equilibrium as a result of the ways that markets are interrelated and of the operation of the Walrasian pricing rule in each market (Walras, 1954, pp. 172, 179–80).

Walras then specified the conditions that prevail in the static equilibrium of exchange of a multi-market system. The ratio of the raretés, or marginal utilities, of any two goods is equal to the ratio of their prices, and the price of any good in terms of another good is equal to the ratio of the prices of those two goods in terms of any third good (1954, p. 157). Those conditions are satisfied when the quantities supplied and demanded of each good are equal (1954, p. 172).

Finally, Walras briefly examined some features of the comparative statics of the exchange model (1954, pp. 147–9). He shifted the utility curves for a good and determined that its equilibrium price changes in the same direction as the shift in the curves. He then successively increased and decreased the traders' endowments of a good and determined that its equilibrium price successively decreases and increases.
In his model of production, Walras was concerned with the determination of the equilibrium prices of productive services and the equilibrium rates of output of the quantities of non-durable goods. Walras did not present this model directly and without modifications as part of his mature comprehensive model. The latter deals with durable goods as well as non-durables and therefore contains a wider model of production. Nevertheless, Walras carried over the processes of pricing and aspects of the tatonnement in the non-durables model into the comprehensive model.

Setting forth the structure of the production model, Walras first identified the markets for productive services, in which he assumed that the amounts of economic resources and therefore the maximum possible amounts of their services are given. The demanders of productive services are the entrepreneurs. Their ultimate aim is to maximize utility, which they achieve through maximizing profits. In their capacities as entrepreneurs, they combine productive services and materials in proportions that are determined by what Walras called the technical coefficients of production. The coefficients, which he assumed to be fixed in much of his general equilibrium theorization, indicate the amount of each of the inputs that is used to make a unit of output. With fixed coefficients and given prices of the productive services, the average cost is constant as the firm's output varies. If any of those prices change, the average cost curve shifts in the same direction.

The suppliers of productive services are workers, who own personal faculties; landlords, who own natural resources; and capitalists, who own capital goods or provide capital funds (Walras, 1877b, p. 218; 1954, pp. 214–15). Their aim is to maximize utility, which motivates them to offer services to the entrepreneurs in exchange for income.

Walras then identified the market for consumer goods (material and immaterial). These goods (in the production model) are consumed immediately after being produced; they are used only once and are used up in that process. The suppliers of them are the entrepreneurs. The demanders are the workers, landlords, and capitalists acting in their roles as consumers, motivated in their purchases by the desire to maximize utility. They pay for them with the incomes that they have been paid by the entrepreneurs. The only type of capital goods produced in the model is non-durables, that is, variable capital goods like raw materials. Those goods, like consumer goods, are used up in a single application as soon as they are purchased. Of course, that is true of the services of all types of economic resources. In the model, there is no saving. The durable capital goods that are used in production do not depreciate or become obsolete, nor are they subject to accidents. There are no markets for them or for land.

The tatonnement in the production sub-model, and in the capital goods and monetary sub-models, and in the comprehensive model as a whole, is in considerable measure the outcome of the actions of entrepreneurs. Walras assumed that all resources are highly mobile. Entrepreneurs have good knowledge (but not perfect foresight) of the profitability or unprofitability of producing any particular good and accordingly enter or leave an industry. The tatonnement that occurs in the markets for inputs is a process of groping for the equilibrium amounts of resources employed in different industries. The entrepreneurs hire the factors of production, combining them in technologically determined proportions or experimenting to find optimum proportions if the coefficients are variable (1896a, pp. 490–1), and sell services and finished goods to consumers (1954, lesson 21, and pp. 426–7; Walker, 1996, ch. 13). The entrepreneurs hire and use disequilibrium quantities of productive services during the tatonnement, and produce disequilibrium quantities of goods (1889, pp. 234–5, 240–1, 249–50). The payment that the entrepreneurs receive in disequilibrium for their entrepreneurial activity is profit, which Walras defined on a per unit basis as the price of output minus its average cost, with the latter including the wages of...
management. An entrepreneur may undertake the functions of other factors of production – he may also, for example, be a capitalist or a manager of the firm – and ordinarily he has to do so, but his multifaceted role as entrepreneur is a distinct one (1954, p. 222).

The tatonnements in the markets for productive services and for consumer goods are interrelated. If the consumers’ demand for a good increases, the price is bid up in accordance with the Walrasian pricing rule. The quantities demanded and supplied become equal at a high price because the supply function does not initially change. The price of the product then exceeds its cost of production, so the entrepreneurs in the industry make profits. Attracted by the prospect of doing the same, other entrepreneurs enter it, and existing firms increase their output. As the market supply of output function changes so that more output would be offered at each possible price, the price in the exchange market for the good is lowered by the entrepreneurs in an effort to dispose of the entire flow of output. As the demands for productive services increase, their prices are bid up, which raises the average cost of production. Thus the price falls and the average cost rises (1954, p. 253). If demand for a good decreases, its price falls below the average cost of production, so the entrepreneurs make losses. This leads some of them to leave the industry and some of them to diminish the output of their firms. The prices of the productive services fall as the demand for them decreases, which lowers the average cost of production. As less of a good is offered, its price is forced up. Thus the average cost falls and the price rises (1954, p. 253). It will be noted that these are all non-virtual processes in the model. Walras concluded that the average cost of production and the price of the good become equal, whereupon equilibrium is reached and the tatonnement ends. It follows that in equilibrium the entrepreneur obtains neither profit nor loss (1877b, p. 232; 1954, p. 225).

Pursuing still further the question of the stability of the model, Walras reasoned that the interactions of traders in different markets aid the equilibrating process. The change in the output of a product, he argued, has an effect on its price that is unidirectional, whereas the unidirectional changes that it induces in the outputs of other products have only indirect repercussions on its price, and the latter more or less cancel each other because some of them change in one direction and some in another (1954, p. 246). In the non-virtual adjustment, ‘The [resulting] system of new quantities of manufactured products and of new selling prices is thus closer to equilibrium than the old one; and we have only to continue the process of groping to approach still more closely to equilibrium’ (1954, pp. 246–7). In other words, once again, ultimately the tatonnement leads to the simultaneous equalization of supply and demand in every market.

The equilibrium, Walras stressed, is the normal state of the market in the sense that it is the one to which the variables in disequilibrium perpetually and automatically tend in a regime of free competition (1954, p. 224). Since it contains the equilibrium of exchange (1954, p. 224), it is characterized by the conditions that the quantities supplied and demanded are simultaneously equal regarding each consumer good, each productive service, and each primary material. A stable circular flow is established in which the total cost equals the total revenue in each firm, the incomes received from the entrepreneurs by the owners of the factors of production equal the revenues earned by the firms, and those incomes are spent on consumer goods by the owners of the factors of production. Walras's theory of production therefore showed ways in which input and output markets for non-durable goods are linked together. Sales at a disequilibrium price of the items that are produced do not alter the assets held by the participants because the quantities exchanged do not have an existence after the exchange; they are used up immediately. The equilibrium of the production model is therefore not path dependent. That is of no
significance, however, because the model is a hypothetical special case. It does not take account of the production of capital goods or of consumer durables which occurs in the real economy and in Walras's mature comprehensive model.

Walras then considered variations in some of the parameters of the production model. If the marginal utility curves for a good shift up, he reasoned, its price in terms of the numeraire increases. If the marginal utility curves shift down, the opposite occurs. If the quantity of a product or service possessed by the holders changes, its price changes in the opposite direction (1954, p. 260).

**Theory of capital formation and credit**

Walras referred to the three sources of services (labour, land, and capital) as different types of capital because they all endure through time and produce a flow of services, but in this article the unqualified word ‘capital’ or the term ‘capital goods’ will mean durable, man-made, inanimate instruments of production. Walras first examined the determination of the prices of land and personal faculties, as distinct from the prices of their services. The aggregate supply of land, a given condition, is perfectly inelastic, and its price is its gross income divided by the rate of net income (1954, pp. 270, 309). The number of workers is also a given condition. The price of a worker is equal to his gross income minus the cost of replacing and insuring him, divided by the rate of net income. Workers are not bought and sold, however, so their prices are virtual (1954, pp. 271, 311).

Walras’s theory of capital is concerned with the determination of the amounts and prices of capital goods, as distinct from their services, and the determination of their rate of net income. Capital goods are specific items of real capital; capital funds, raised by the sale of shares on the bourse, constitute fluid and mobile purchasing power which can be used to acquire economic resources to construct different kinds of physical capital (1954, pp. 270, 311). Capital is formed by capitalists saving money and, most commonly, lending it to entrepreneurs (1954, p. 270). The net saving of the capitalists as a group equals aggregate income minus aggregate consumption, minus the depreciation and insurance costs of capital goods. The entrepreneurs purchase or rent capital goods, earn revenue from their use, and repay any sums they have borrowed (1954, p. 290, §§ 190, 235). Walras’s identification of that process explains why he inserted the word ‘credit’ (1954, p. 270) into the name of his capital-goods model, but he did not develop a general theory of credit within it, because he did not introduce loans made by banks. Some capitalists prefer to own capital goods, so Walras assumed occasionally that they acquire them directly in physical form (1954, p. 289), and assumed frequently that they acquire them through buying stock certificates (for example, 1954, p. 289). In each case, the physical capital is used by entrepreneurs, so ‘the demand for new capital goods comes from entrepreneurs who manufacture products and not from capitalists who create savings’ (1954, p. 270). The entrepreneurs purchase the particular kinds of capital goods that are profitable, with the result that the kinds that are produced and used reflect the structure of demands for consumer goods (1954, pp. 225, 303).

Describing the tatonnement regarding both non-durable products and durable goods, that is, summing up the non-virtual character of the tatonnement in the mature comprehensive model, Walras explained that after a certain rate of net income and certain prices of services have been cried and after certain quantities of products and new capital goods have been manufactured, if this rate, these prices and these quantities do not satisfy the conditions of general equilibrium, it
One aspect of the tatonnement takes place in the stock market and another in the course of the production of capital goods. In the stock market, which is the market for new capital goods, each capitalist attempts to maximize utility by saving and acquiring more stocks that have relatively high yields and less of those with lower yields (1954, p. 289), with the result that the total value of new capital goods and the excess of income over consumption both move in the same direction as all prices. It follows, Walras maintained, that the tendency of the change in prices to destroy the equality between the total value of new capital goods and the excess of income over consumption is weaker than the tendency of the change in the rate of net income to bring the total value of new capital goods and the excess of income over consumption into equality with each other. Moreover, ‘in these conditions, it is evident that the price and the average cost of the capital good (K) will have been little altered from equality by the increases in the quantities produced of the capital goods (K′), (K″)…’ (1889, pp. 292–3). ‘Thus the system involving the new rate of net income and the new prices will be closer to equilibrium than the old system; and it is only necessary to continue the process of groping for the system to move still more closely to equilibrium’ (1954, p. 288).

In the course of the production of capital goods proper, entrepreneurs acquire more capital goods that yield relatively high returns, and diminish their use of capital goods that yield lower returns. As a consequence, the rate of net income from each capital good proper tends toward the same value (1954, p. 309). If profits are being made from the production of capital goods in an industry, new entrepreneurs enter it, and those already in it increase their rate of production. That drives up the prices of productive services, which causes the average cost to rise towards equality with the price of the capital good. If losses are incurred, entrepreneurs diminish production. That drives down the prices of productive services, which causes the average cost to fall towards equality with the price of the capital good (1889, p. 293). It is ‘probable’, or, ‘it is to be presumed’, Walras maintained, that the effects of changes in the output of a new capital good that tend to cause equality between its average cost and its price will be stronger than the contrary effect of interrelated changes in the output of other capital goods, so the process converges to equilibrium (1954, p. 293). Referring again to the non-virtual character of the tatonnement, Walras explained that ‘The new system of revised quantities manufactured and of revised costs of production and selling prices of new capital goods is thus nearer equilibrium than the original system’, and it is only necessary to continue the tatonnement to approach it more and more closely (1889, p. 293; 1954, p. 293).

The tatonnement in the mature comprehensive model involving both non-durable and durable goods represents and explains what happens in the real economy:

Now, this tatonnement is precisely that which occurs by its own forces on the market for products [non-durables], under the regime of free competition, while the entrepreneurs who produce new capital goods, just like the entrepreneurs who produce products, increase their production or diminish it according to whether profits or losses are made. (1889, p. 294; 1954, p. 294)
Walras expressed the equilibrium conditions in the formation of new capital goods in the lengthy analysis that he called the theorem of the maximum utility of new capital goods, which he described as crowning and confirming his entire theoretical system (Walras to H.S. Foxwell, 16 December 1888, L 859; Walker, 1984b). Although he assumed initially that new capital goods do not require amortization or insurance, Walras then made the realistic assumption that capital goods wear out and are subject to accidents. The rate of net income generated by a particular capital good is then given by the gross income it earns minus amortization and insurance costs, divided by the price of the capital good. In equilibrium each trader maximizes utility by holding the quantities of capital goods that make the ratio of the marginal utility of each capital good to its price equal for all his capital goods. Because of the adjustment of yields and capital good prices, the rate of net income derived from every type of capital good is the same (1954, p. 281). There is a single price for each type of capital good, equal to its average cost (1954, p. 280). Furthermore, the price of any given type of well-maintained old capital goods is equal to the price of the same kind of new capital goods, so the equilibrium prices of all capital goods ‘are equal to the ratios of their net incomes to the rate of net income’ (1954, p. 309). The latter is the rate of interest. Its equilibrium value equates aggregate saving and investment (1954, p. 276).

Walras believed that through this analysis he had seen behind the veil of money or numeraire and discovered the real determinants of that rate. It is manifested in the banking system, he argued, but it is determined in the stock market. It is the ratio of net profit to the price of a share of stock, which in equilibrium equals the common ratio of the net price of capital services to the price of the good that yields them (1954, p. 290).

Walras then turned to the comparative statics of the capital goods market. If the price that has to be paid for the services of a capital good increases or decreases as a result of a parametric change, the price of the capital good itself increases or decreases. Its price also varies inversely with the rate of depreciation and with the rate of the insurance premium. If the rate of net income changes, the prices of all capital goods change in the same direction (1954, pp. 309–12).

Theory of money and circulating capital

Walras wanted to reduce the monetary mechanism ‘to its essential elements’ (1889, p. 379). He therefore carefully specified the structural and behavioural features of his mature fiat money model, drawing upon his direct experience as a young man with real financial matters and his extensive knowledge, accumulated throughout his career, of empirical monetary arrangements and problems. He explained that fiat money, like pieces of paper with an engraved image, has no utility of its own. Economic agents hold it because it enables them to purchase goods that have utility (1889, p. 378). Entrepreneurs and some consumers have net demands for cash balances because of the non-synchronization of payments and receipts (1886, pp. 40–4). The size of a consumer’s desired cash balance depends upon desires to consume and save, which depend upon his character and habits, income, the value of the commodities he wants to buy, and the rate of interest (1889, pp. 377, 268–71). The size of an entrepreneur’s desired cash balance depends upon the nature and state of his business, and on his character, habits, and the rate of interest (1889, p. 377). These are desired real balances because they represent the demand for a specific bundle of goods. The aggregate real desired cash balance is the nominal one divided by the price level, which is the inverse of the price of money. That aggregate is the demand for future consumer and capital goods (1889, pp. 378–9).
Walras incorporated a market for loans into his model. First, there are the demanders. They are consumers, entrepreneurs and savers, who go to the market and borrow. The first two groups buy the goods and services they need. A curious temporary assumption is that savers, the third group, borrow to obtain the funds they lend. Thus ‘we have the daily demand for money which is exercised on the market for money capital’ (1889, p. 381). What is happening behind the veil of money, Walras explained, is that the consumers and entrepreneurs are actually borrowing the fixed and circulating capital on which they spend the money, and the interest borrowers pay is generated by the fixed and circulating capital that the borrowed money finances. Second, there are the suppliers of funds in the loan market. In one group of them are entrepreneurs who have receipts from the previous day from sales to consumers and from sales of new fixed and circulating capital good to other entrepreneurs, and in the other group are landlords, workers and capitalists who have receipts from the previous day from sales of services (1889, p. 381).

Walras then specified how the mechanism of free competition operates in regard to monetary circulation in disequilibrium of the money market. It will be noted that the entire behaviour relating to money in the mature comprehensive model is non-virtual. Mainly explicitly, he indicated the tatonnement that was presented later by the Cambridge cash balances theorists. He created the temporal framework for the period analysis in his model by assuming first that production and consumption ‘extend over all the moments of the entire year’ (1889, p. 316). Workers, capital goods, and money are used up and are simultaneously reproduced and replaced. He then assumed that markets function every day and that different types of related behaviour occur sequentially on a series of days (1889, pp. 381–3). Thus he developed a continuous-production and periodic-market model.

A change, say a decrease, in the quantity of money causes disequilibrium. The Walrasian period analysis then indicates that the process of equilibration takes three ‘days’. On the day that the decrease occurs, the old rate of interest still rules and the quantity of cash balances demanded exceeds the quantity supplied. The immediate result is that the rate of interest increases. On ‘the next day on the market’, a temporary equilibrium is reached, ‘at a new higher rate of interest at which the desired cash balance would be reduced’ (1889, p. 383). During that day, the prices of all goods fall proportionately to the decrease in the quantity of money and the aggregate nominal desired cash balance remains lower, but the real balance is ‘able to become what it was before’ as a result of the fall of prices. Then, ‘on the day after that’, the third day, permanent equilibrium is attained, the rate of interest falling back to its old level, which is equality with the rate of net income from capital goods (1889, p. 383). The same sequence occurs if the aggregate desired cash balance function increases. If the parameters change in the opposite direction, the opposite sequence of adjustments occurs. There are many more details, situations and variations of assumptions that Walras considered regarding the model. He was able to sum up what he had done in this way: if the quantity of money increases or the desired cash balance decreases, prices rise proportionately, and the reverse. ‘This law extends to money the principle by virtue of which value increases with utility and decreases with the quantity’ and therefore integrates the determination of the value of money into his mature comprehensive model and therefore into his general theory of value (1889, p. 383).

When there is monetary equilibrium, that model is in equilibrium in all respects. Walras summarized its aspects in the following way. There is ‘the equilibrium of exchange’ in which prices are proportional to marginal utilities and consumer satisfaction is maximized; there is ‘the equilibrium of production’ with prices equal to average costs and zero profits; there is ‘the equilibrium of capital formation’ with prices of land, human faculties and capital goods proper proportional to the prices of their services; and finally...

there is ‘the equilibrium of circulation, in view of the fact that the exchangers would have the cash balances that they desire at the announced rate of interest’ (1889, p. 379).

Walras therefore made significant theoretical innovations in his mature theory of money. In it, he raised basic questions about the nature of a true money, its role, the valuation of money, its place in preference functions and hence in demand and supply functions, the sequence of adjustments that occur after a change in its quantity, and the impact upon equilibrium prices and the rate of interest. His modelling of cash balance behaviour and dynamic period analysis anticipated some of the theoretical techniques used during the 1920s and 1930s by J.M. Keynes, D.H. Robertson, and J.R. Hicks, none of whom acknowledged his contributions. That was probably because the insightful analysis and potentially fruitful constructions that Walras put into the mature money model are in the forgotten 1889 edition.

Economic growth

Walras did not develop a complete model of economic growth, but he examined some aspects of the topic in connection with his mature comprehensive model. One was endogenous variations in its parameters. He was led to speculate about that subject by the consideration that the equilibrium conditions identified in the mature comprehensive model are never reached in the real economy because tatonnement takes time, and consequently parameters such as preferences and the amount of labour change before equilibrium is reached (1954, p. 380). In order to take account of this situation, ‘we shall now suppose that the annual production and consumption, which we had hitherto represented as a constant magnitude for every moment of the year under consideration, change from instant to instant along with the basic data of the problem’ (1954, p. 380). Services and goods are used up and are produced. Net new capital goods come into existence and are put to use, and circulating capital is borrowed by entrepreneurs from the capitalists in the form of money loans (1954, p. 379). Walras did not analyse in any further detail that moving equilibrium or ‘continuous market’ economy.

A second aspect of growth that he examined was ‘the laws of the variation of prices in a progressive economy’ (1954, p. 382), that is, some of the features of alternatives paths of economic growth. For this task he first defined economic progress as the substitution of capital services in place of land services in given production functions (1954, p. 383). The substitution implies variable coefficients of production, and to introduce these Walras used the theory of marginal productivity. He did not claim to have originated that theory although he anticipated some of its features. In fact, Hermann Amstein, a mathematician at Lausanne, worked out its major principles in 1877 (Amstein to Walras, 6 January 1877, L 364; translated in Jaffé, 1983, pp. 205–6). Walras did not understand or use Amstein's work, however, and the major credit for the theory of marginal productivity that first appeared in the Eléments in 1896 (Appendix III) must be given to Enrico Barone (1895).

Walras defined technical progress as changes in production functions, including the introduction of entirely new processes, but he did not analyse it, beyond concluding that it contributes, along with economic progress, to ensuring that output increases without limit in a progressive economy (Walras, 1954, p. 387). He also discussed, in a highly general way, how the prices of products and services vary with different amounts of capital and sizes of the population (1954, pp. 389–91). His principal conclusion was that the rate of net income falls as the stock of capital grows, the proximate causes of the process being rising rents and falling prices of capital services.

Walras was well aware that capital accumulation means economic growth and requires a different
characterization of equilibrium, noting that ‘In order to have a supply, a demand, and prices of capital goods, it is necessary to substitute for the conception of a stationary economic state that of a progressive economic state’ (1889, p. 264). His way of dealing with this problem in 1889 was to assume that new capital goods are not used until what he represented to be the end of the tatonnement, thinking that would preserve the static equilibrium. That did not, however, remedy the problem, as will now be shown. Walras attempted to give a mathematical proof of the stability of the tatonnement of the mature comprehensive model, spread throughout the pages of his treatise. He believed that he showed that the model is stable by working with his system of static equations of general equilibrium. He posited a disequilibrium state and then varied the prices in the equations in accordance with the Walrasian pricing rule, and claimed that equilibrium is the result of the tatonnement. That claim is logically flawed, for two reasons.

The first is that the tatonnement in the mature comprehensive model, unlike the model of the production of non-durable goods and services, is path dependent even though the new capital goods are not used during any of the phases of adjustment before equilibrium is ostensibly reached. Positive net investment has the result that individual holdings of capital goods and many of the other nominal parameters and all the variables of the model are altered. Each different disequilibrium rate of production and sales of capital goods occurring within each phase of the tatonnement changes their prices and average costs, profits, and the rate of net income. Consequently, Walras's attempted proof was not rigorous and could not have been valid, given the static equations that he used. They have the endowments of assets in the initial disequilibrium as parameters. Their solutions therefore depend on those constants. The model, however, is not a virtual system, so the individual holdings of assets and their total amounts vary during the course of the tatonnement. The result is that the variables of the model do not converge to the solutions of Walras's static equation system. Any equilibrium to which the prices and quantities converge cannot be the one indicated by his equations because they do not describe his model.

The second reason is that the ‘equilibrium’ that Walras asserted exists at the end of the tatonnement is factitious and cannot materialize, even if there were no problem of path dependency. The supposed equilibrium could exist only transitorily while the model is held in a state of arbitrarily suspended animation by the postulate that the additions to the capital stock are not used – a deus ex machina that interrupts the incomplete workings of its endogenous processes. The instant that Walras removed the postulate, that is, the instant that the net new capital goods are put into use, the ‘equilibrium’ is ruptured, and through dynamic processes many of the nominal parameters and all the variables of the model change, in the way just indicated in the discussion of the consequences of the use of net new capital goods. If they continue to be produced, as Walras assumed, the system follows a path of growth. The equilibrium path and any stationary equilibrium that the system may eventually reach is quite unlike the solutions to the static equations of general equilibrium that he presented in the 1889 edition of the Eléments and subsequently.

4 Walras’s last theoretical work

The written pledges sketch

In 1899 Walras changed his work in two major ways, and put the changes into the Eléments in 1900. One was to devise a new model of money and circulating capital (see below). The other was to try to
construct a virtual model. The motive for the latter was that Walras had come to realize by 1899 that his equation system is compatible only with such a model. Instead of trying to develop a different equation system, however, one that would represent the non-virtual mature comprehensive model, he chose to abandon the latter, to retain his static equations, and to try to construct a virtual model that would serve as their foundation and justification. In the 1900 revision, he eliminated much of each of two forceful and lengthy statement of the non-virtual tatonnement (Walras, 1889, pp. 234–5, 280), which consequently appear in Jaffé’s translation only in very abbreviated form (1954, pp. 242, 282). He retained, however, crucial parts of those statements and retained elsewhere throughout the revision most of the other language describing the non-virtual behaviour of the economy and of the mature comprehensive model. That explains why the reference ‘Walras, 1954’ can be cited to document many the features of the 1889 mature comprehensive model. It is also one of the principal causes of the 1900 and 1926 editions (and therefore Jaffé’s translation of the latter) being a chaotic mixture of incompatible language and sub-models.

To construct a virtual model, Walras conceived the device of written pledges (engagements écrits, as they were and are called in the Paris bourse). He asserted that the model has three phases, made identifiable, he believed, ‘by means of the hypothesis of written pledges’. First, there is ‘the phase of preliminary gropings towards the establishment of equilibrium in principle’, the purely virtual phase (1954, p. 319). When a price is cried in any market, suppliers of goods and services write out the amounts that they pledge to produce and sell at that price, but only if it turns out to be the equilibrium value, that is, the one that is part of the set of prices that equates the market supply and demand quantities simultaneously in every market (1899, p. 103; 1900, pp. 215, 260; 1954, pp. 242, 282). Thus Walras adopted the device in order to eliminate changes in the holdings of assets before the entire system of markets has reached equilibrium, changes which would otherwise occur as a result of trade occurring in a market when it reaches market-day equilibrium while other markets are still in disequilibrium, or as a result of disequilibrium production, which changes the aggregate amounts of goods held before general equilibrium has been reached.

In the first phase, entrepreneurs are supposed to plan to move from unprofitable to profitable industries and to plan to create firms or to expand or contract their existing firms, and to predict accurately the financial results of their plans, without actually moving or creating or hiring or spending or producing at all. Owners of productive services are imagined to offer their services repeatedly at disequilibrium prices without actually earning any income or consuming any goods or services. The entire system of interrelated markets is imagined to go through complex costless processes of information acquisition, price changes and changes in the supply quantities that are pledged, all without anyone being allowed to agree to a single actual transaction or undertake any production or consumption, until the equilibrium set of prices has been found.

It is symptomatic of Walras's significantly diminished ability to concentrate and pursue lengthy chains of reasoning after 1898 that his words ‘the hypothesis of written pledges’, although followed by dozens of pages of modelling and theorization, including his immediately following account of the three phases which he introduced into the fourth edition of the Eléments at the same time as writing those words, is the last sentence in which Walras mentioned them in any of his writings. His references to written pledges had become fewer and fewer in the successive pages of the 1900 revision. Finally he either forgot about them or decided they were not an idea worth pursuing any further, abandoned his attempts to change the older constructions in his treatise to accord with their use, and introduced new sub-models.
Second, there is ‘the static phase in which equilibrium is effectively established *ab ovo* as regards the quantity of productive services and products made available during the period considered, under the stipulated conditions, and without any changes in the data of the problem’ (1954, p. 319). This means that the economy ‘remains [for the time being] *static* because of the fact that the new capital goods play no part in the economy until later in a period subsequent to the one under consideration’ (1954, p. 283).

In this postulated static equilibrium, services and non-durable consumer commodities are produced, sold and used. Walras was asserting that the result of the tatonnement in the sketch is that the market supply and demand quantities are equated in every market simultaneously, whereupon the non-virtual activities of exchange, production, consumption, saving and investment take place. He therefore believed that none of the parameters (‘the data of the problem’) of his system of equations of general equilibrium undergoes endogenously induced changes during the tatonnement. He believed that a static equilibrium is consequently the one given by the solutions to his static equation system, and that his new version of tatonnement converges to that equilibrium for the same general reasons as he had adduced in 1889.

Third, continuing to write as though the sketch were a complete functioning system, Walras indicated that it undergoes ‘a dynamic phase in which equilibrium is constantly being disturbed by changes in the data and is constantly being re-established’ (1954, p. 319; 1900, p. 302). The new capital goods, both fixed and circulating, Walras wrote, ‘are made available during the second phase’ but ‘are not put to use until the third phase’. When they are used, however, ‘the first change in the data of our problem’ occurs (1954, p. 319). The result of changes in the data is that the ‘fixed equilibrium will then be transformed into a *variable* or *moving* equilibrium, which re-establishes itself automatically as soon as it is disturbed’ (1954, p. 318). The use of the new capital goods generates economic growth.

Of course, Walras asserted that the three phases and all the behaviours and outcomes that he wanted the sketch to have, such as the equalization of supply and demand, do in fact occur in it, but in actuality the sketch does not support his claims. Those accounts are not descriptions of the sketch. They are simply postulates; they cannot be deduced from its structure and procedures, which is why Walras’s work on virtuality is properly described as a sketch rather than a model. He made the mistake of assuming that potential demanders, whether consumers or entrepreneurs, do not write pledges to buy, so they have no way of making their desired demands known. For that reason alone (although there are many others; Walker, 1996, section I), the sketch cannot function. There are no individual or market demand functions, Walrasian pricing, transactions or production. Equilibrium does not exist because the number of unknowns (prices, the quantities of goods and services) exceeds the number of independent equations (the market supply functions). Moreover, the device of written pledges is so inherently flawed that there are no conceivable revisions that can transform it into a functioning system (Walker, 1996, section I).

Finally, it is evident that the sketch has no explanatory value in reference to the real economy. Despite the sketch's shortcomings, its aim of excluding irrevocable disequilibrium behaviour from a general equilibrium model, achieved simply as a postulate, nevertheless became a central and indispensable part of Walras’s intellectual legacy for certain of his successors, including Gustav Cassel, Abraham Wald, John von Neumann, Kenneth Arrow, Frank Hahn and Gérard Debreu (Walker, 2006a, pp. 288–312). It is a pity that they adopted his virtual notion and were unaware of or disregarded his robust and more realistic mature comprehensive model, for through the development of many of its characteristics lies the way to a more useful general equilibrium theory, as recent research has shown (Walker, 2006a, pp. 334–6; 2006b).
Commodity E in the last model of the production and pricing of capital goods

In 1900 Walras invented a fictional good (E) constituted of perpetual annuity shares, another example of the deterioration of the quality of his modelling after 1899. It was by means of that concept that he chose to deal with a positive, zero or negative excess of aggregate income over aggregate consumption in his capital-goods model. It appears that he wished to express aggregate savings as a single homogenous quantity – the demand for E. Each perpetual share pays one unit of numeraire per year, and its price, determined by supply and demand, is the reciprocal of the rate of interest (Walras, 1954, pp. 274–6, 308–9). If people want an additional amount of interest income, they provide savings through purchasing new perpetual shares. The numeraire-capital that capitalists pay for units of E is used by entrepreneurs to buy productive services and materials that are transformed into new capital goods. Walras viewed the capital-goods markets as reaching equilibrium through adjustments of the goods’ rates of return (1954, pp. 275–6, 308).

Walras's device of the E commodity, which he frankly described as imaginary (1954, p. 274), has not been adopted by economists who succeeded him, because of its remoteness from the realities of capital accumulation and the distortions that it creates in a model of that process. He did not realize that it is incompatible with the written pledges procedure. If the latter is assumed to occur, the capitalists have no way of expressing their demand for E. Moreover, as it happens, Walras retained his references to the purchasing of stock certificates and private and government bonds which appear in the mature capital goods model (for example, 1954, §§ 255, 270), and he introduced short-term loans into his new money model, although the incompatibility of E with those financial instruments increases the incoherence of the last two editions of the Eléments. His treatment of saving, investment and the capital goods market in the mature comprehensive model is superior to his final thoughts on the subject.

Walras's last model of money and circulating capital

In his revision of the Eléments in 1900, Walras stated that he wanted to design the structure of this model on 'exactly the same terms and in precisely the same way' as in the 1900 models of exchange, production and capital formation (1900, p. 42). He did not in fact do that because he mentioned written pledges only twice in the first half of the exposition of the model and not at all in the second half of it. In fact, he constructed the new model of money and real circulating capital before he thought of written pledges. He first presented it in an article in 1899. After the last page of the article, he added an afterthought, a note of 37 lines introducing the device of written pledges (1899, p. 103). He subsequently inserted most of the note into the text of the article, and inserted the result almost verbatim into the 1900 edition of the Eléments (1954, lessons 29, 30), completely eliminating the treatment of money that he had presented in the mature comprehensive model.

In contrast with his mature comprehensive model, Walras described the functions of money and the formation of money prices in his last model of general equilibrium on the assumption that there is no uncertainty in equilibrium, and consequently that the dates and monetary value of future purchases and sales are known (1954, pp. 317–18). Money is one type of circulating capital, he explained; the other is circulating physical capital. Replacing his formulation of an equation of exchange that had anticipated Irving Fisher's (1877b, pp. 180–81), Walras asserted that circulating physical capital yields utility from
its ‘service of availability’ – that is, by being readily available – and money provides, by proxy, the same service of availability as the good that it is destined to purchase and yields the same utility as that service. All economic agents try to hold utility-maximizing amounts of money and circulating physical capital (1954, pp. 320–1). The latter, held by consumers and entrepreneurs, is acquired with money, so the essential concern of Walras’s model of circulating capital reduces to the question of the demand for and supply of money and its price.

Savers make some of their balances available as loans through buying or perpetual annuity shares (1954, pp. 318–20). The aggregate gross supply of money is the total stock issued by the monetary authority in the case of a fiat money economy, and is the amount of circulating coin in the case of a commodity-money economy (1954, pp. 321–4). The price of money, the numeraire, is unity and the price of its service is the rate of interest (1954, pp. 320, 327). Given the flows of receipts and purchases, the individual gross and net demand for cash balances and the individual net supply of them are functions of the rate of interest. The sum of the individual net demands for money is the aggregate demand function, and the sum of the individual net supplies of money is the aggregate supply function (1954, pp. 320–1).

The tatonnement in the money market, Walras contended, explains how the rate of interest and the equilibrium aggregate net quantities of cash balances supplied and demanded are determined (1954, pp. 325, 327). The rate of interest changes according to the Walrasian pricing rule. When the excess quantity demanded of cash balances is positive, the rise in the rate decreases the quantity demanded of cash balances by consumers and entrepreneurs by increasing the cost of the service of availability that money provides, and also decreases the quantity demanded by entrepreneurs by causing a fall in profits and hence in the desired rate of production. The rise in the rate of interest also causes the net quantity of cash balances that savers want to supply to increase. If the desired supply of cash exceeds the desired demand at the current rate of interest, the opposite effects occur (1954, p. 333). The tatonnement continues until the equilibrium price of the service of availability of money is found – namely, the price that equates the net and therefore the gross quantities supplied and demanded of cash balances – whereupon the money market reaches equilibrium (1899, p. 96; 1900, pp. 297–319; 1954, pp. 315–33).

The equilibrium prices of all goods in terms of money are given by its role as the numeraire and by the workings of the entire model that determine the ratio of exchange between each good and the numeraire. In general equilibrium, the price of the service of all money held by different individuals for different purposes is the same (1954, p. 326). Moreover, because an underlying influence upon the rate of interest on money is the value productivity of physical capital, an influence exerted through variations in the volume of funds invested, the equilibrium rate on money is the same as the equilibrium rate of net income determined in the market for capital. There is therefore equality in the rate of net income from all capital goods and real and monetary circulating capital (1954, p. 323).

Walras then considered the comparative statics of the model. He changed the utility functions for the service of money and deduced that the marginal utility and value of the service of money changes in the same direction. He changed the quantity of money and deduced that the marginal utility and value of the service of money changes in the opposite direction, and that all prices change in the same direction without any alterations in relative prices (1954, p. 333). He noted that, if the utility curves for net income shift up or down, the rate of net income changes in the opposite direction. If the quantity of net income varies, the rate of net income varies in the same direction. If utility functions and the quantity of net income both vary in such a way that the marginal utilities remain unchanged, the rate of net income also remains unchanged (1954, p. 307).
An aura of unreality is imparted to Walras’s 1900 edition of the *Eléments* by his abstracting from money through much of his exposition of exchange, production and capital formation, and then by introducing it in such a way that it does not change their characteristics (1954, pp. 319–24). In particular, by postulating that there is no uncertainty in his last model of money and circulating capital, without the slightest explanation of how that would be possible, he eliminated consideration of much of the behaviour associated with money in the real economy. Money does, however, influence a great deal of real economic behaviour in special ways associated with uncertainty, a fact of which Walras’s extensive writings on real monetary arrangements, problems and policies reveal him to have been perfectly cognizant. Moreover, his concept of fictional perpetual annuity shares is a superfluity that further detracts from the verisimilitude of his models of capital formation and money. He should instead have retained his mature model of the money market in which he dealt with the behaviour related to some of the major financial assets in which people actually invest.

5 Economic policies

Walras developed all his policy proposals during the years prior to his last theoretical efforts. He never mentioned the latter formulations in connection with real empirical matters. In particular, the written pledges sketch did not influence him to modify or innovate policy proposals, necessarily so because the functioning and hence the problems of the economy are not virtual. Walras was greatly interested in the economic problems of his day and in socio-economic reform, guided in his major policy proposals by his normative convictions, which were derived from his father's philosophy of society and justice. Those convictions were a mixture of conventional 19th-century liberalism and notions of the rightness and efficacy of state interventionism (1896b). Like many scholars, each with different views, Walras bestowed the title of ‘natural law’ upon the principles of justice that he considered desirable, and so he might be called a natural-law philosopher or casuist. Nevertheless, he was not a natural-law economist. He did not believe that there is, behind observable facts, a structure of economic laws that are divinely ordained, or that are peculiarly in tune with the structure of the universe and human aspirations, or are ceaselessly at work so that violations of them can only result in chaos or frictions. Nor did he construct his economic model with the conscious intention of expressing his normative views. Sharply distinguishing normative and positive economics, he stated that he designed his theories for the purpose of understanding economic reality (Walker, 1984a; 2006a) and presented his normative work explicitly as such and carefully segregated it (Walras, 1896b) from the publications presenting his economic theories.

Walras’s policy recommendations ranged over natural monopolies, which he believed should be nationalized; prices, which he believed should be stabilized by a monetary authority; bimetallism, which he believed had both advantages and disadvantages; the stock market, which he believed should be regulated by the state in order to improve its organization and ensure its integrity; taxes, which he believed were unjust and confiscatory and should be abolished; and land, which he believed should be purchased by the state and rented to private users, thereby providing it with revenue (1905b, pp. 272–3). Arguing that his advocacy of nationalization of land and natural monopolies was based upon a scientific understanding of the functioning of the economy, Walras called himself a ‘scientific socialist’.

6 Contributions
Criticisms of Walras’s work cannot obscure the greatness of his contributions. When he began his investigations in 1868, economics on the Continent was hardly a scientific pursuit but rather a mixture of normative prescriptions, classical theories expressed alongside protectionist doctrines, and commercial law. In England it was in the state exemplified by the work of J.S. Mill – with much that could be used as a basis for future investigations, but also without a clear view of the relationships of distribution and production, limited by a cost-of-production theory of value, and lacking a theory of supply and demand in multiple markets. The attitude of most of Walras’s contemporaries was that, since economic behaviour involves preferences and the human will, it cannot be expressed in a rigid and deterministic set of algebraic relations. Walras changed all that, transforming economics and propelling it forward in a gigantic intellectual leap.

His contribution can be divided into two interrelated parts. One is that, in his mature comprehensive model, he constructed or refined or adapted to his purposes many of what became the fundamental building blocks of modern economic theory. In this effort he accomplished an enormous amount of highly creative economic analysis, brilliantly analysing the structure of economic reality to bring many of its essential features into clear relief, in eight major original contributions. First, he went far beyond the work of the other developers of the marginal utility theory by using it to analyse the disequilibrium and equilibrium behaviour of a variety of participants undertaking different economic functions in multiple markets, rather than confining the theory to the investigation of consumer demand and of exchange in an isolated market. Second, he had clear priority in constructing the theory of exchange in multiple competitive markets. In that regard, his work was greatly in advance of his predecessors’ and was replete with fruitful constructions, theorems and postulates, like the reciprocal relation of supply and demand, the device of a numéraire, the individual budget equation, Walras’s Law, the theorem of equivalent distributions, and the laws of change of prices. Third, he constructed a theory of the firm and of market supply in which he appears to have developed independently the modern idea of a firm’s production function, derived the equation for a firm’s average cost, expressed the firm’s offer of output mathematically, and aggregated the firm’s supply functions to obtain the market supply in a particular industry. Fourth, he was the first to examine the question of the existence of equilibrium in a competitive multi-market system of exchange and production. Fifth, in his work on tatonnement he initiated the study of the stability of competitive general equilibrium and contributed significantly to its understanding, with his most successful theorizing on the topic relating to his mature comprehensive model. There is nothing in the literature before Walras’s time or until the time that his work was used by others that is even remotely like or on the level of his reasoning regarding the process of convergence to equilibrium of a non-virtual competitive multi-market system. Sixth, he developed a theory of the entrepreneur, of profits, and of the allocation of resources that became the basis of Continental work on those topics (Pareto, 1896–7, passim; Pareto, 1906, passim; Barone, 1896, p. 145; Schumpeter, 1912/1926, p. 76; Schumpeter, 1954, p. 893; Walker, 1986). Seventh, Walras created a fruitful theory of capital, achieving an early formulation of the conditions for a Pareto optimum in capital markets. As in a number of his other investigations, his characteristic contribution in that regard was not to be the first to think of the problem but to be the first to offer an account of those markets’ disequilibrium interrelationships and equilibrium conditions in a model of the general equilibrium of an economy. Eighth, he developed a cash-balances theory of money in his period of maturity as a theoretician which had great originality and has stimulated much valuable research (Marget, 1931; 1935; and see Walker,

1970, p. 696; 1996, pp. 235–55). Those eight areas of analysis were the core of neoclassical microeconomic theory and thus constituted much of the structure of knowledge that was the starting place for 20th-century economics.

The second part of Walras's contribution was not the idea of the general equilibrium of a freely competitive economic system, which other economists had suggested; it was his implementation of that idea. Other economists had helped in fashioning the building blocks that Walras used. His achievement, however, was not only to develop them but also, through incisive analysis and constructive thought, to weave them into an account of the equilibrating processes of a complex, non-virtual, multi-market economy. Those building blocks dealt with real economic behaviour, and it is his use of building blocks with that essential quality that gives his work its richness, robustness and relevance. Walras was also the first economist to try to set up a system of equations to describe the conditions of static equilibrium of a general equilibrium model.

Walras thus accomplished by the mid-1870s far more than any other economist had done in regard to constructing a model of an economic system as a whole, and more single-handedly in that regard than any other economist in the history of the discipline.

7 Influence

Walras's work was not given the recognition that it merited in France during the 25 years after 1874, and his centennial, in 1934, elicited no conference on his work there. By the 1950s, however, the French attitude toward Walras had changed, as was ultimately symbolized by the creation in 1984 of the Centre Auguste et Léon Walras (but no longer symbolized in that way, for the research group has a new name; it is now a part of the organization known as ‘TRIANGLE, Unité mixte de Recherche 5206 du Centre national de la Recherche scientifique’) at the université Lumière Lyon 2. With the English, Walras's experience was also disappointing. His initial cordiality towards W.S. Jevons, as a fellow pioneer in mathematical economics, was dissipated by Jevons's failure to recognize Walras's contributions to the theory of exchange and to the construction of a relatively complete model of a competitive economy, and eventually Walras, quite unreasonably, came to regard Jevons as a plagiarist of his work (Walras to M. Pantaleoni, 17 August 1889, L 909). Similarly, Walras's relations with P.H. Wicksteed began well (Wicksteed to Walras, 1 December 1884, L 619) but deteriorated sharply when Wicksteed failed to give credit to those whom Walras considered to be the true originators of the theory of marginal productivity (Walras, 1965, L 1220, n. 3; 1896a, pp. 490–2). Walras justly felt neglected by Alfred Marshall, who mentioned him only thrice in the briefest of comments in the Principles (Marshall, 1890; 1920) and wrote not a word about Walras's development of general equilibrium theory. Walras also came to dislike Edgeworth for criticizing his theories of tatonnement, capital goods and the entrepreneur (Walras to Gide, 3 November 1889, L 933, and 11 April 1891, L 1000; Walras to Pantaleoni, 5 January 1890, L 953). In general, Walras believed, the English had closed their minds to his theories and had become spiteful in their treatment of them (see Walker, 1970, pp. 699–70).

The extremity of the language with which Walras characterized the English was unjustified, because, although he had reason for disappointment with their neglect of his general equilibrium theory, Jevons (1879, preface) and Edgeworth (1889) had recognized valuable elements in his work, and he was the only living economist included in the first edition of Palgrave's Dictionary of Political Economy.
Walras, Léon (1834–1910) \( \rightarrow \) The New Palgrave Dictionary of Economics (Sanger, 1899). The fact is that Walras grew hypersensitive about the motives of his critics, the failure of the majority of economists to recognize the value and priority of his contributions, and the possibility of plagiarism of his ideas during the 1880s and 1890s. There had been two periods in his life, he complained, ‘one during which I was a madman, and one during which everyone made my discoveries before me’ (Walras, undated, in Jaffé, 1983, p. 203, n.54).

This account of Walras's disappointments should be balanced by a realization that his scientific labours had afforded him ‘up to a certain point, pleasures and joys like those that religion provides to the faithful’ (Walras to Marie de Sainte Beuve, 15 December 1899, L 1432), and a recognition of the professional satisfactions that he increasingly experienced in the last two decades of his life. Maffeo Pantaleoni (1889), Enrico Barone (1895, in Jaffé, 1983, p. 186; 1896), and Vilfredo Pareto (Pareto to Walras, 15 October 1892, L 1077) contributed greatly toward giving Walras's work a secure place in Continental economics and thus ultimately in economics everywhere. In 1895 Pareto's appointment as Walras's successor to the chair of economics at Lausanne assured Walras that his doctrines, expressed in his treatment of a non-virtual competitive economy, would be perpetuated and developed, and the accessible literary presentations of Walras's ideas in Pareto's books (1896–7; 1906) began their widespread dissemination. Pareto borrowed most of the ideas of Walras that have been mentioned in this article, using them as the basis for his contributions to the theories of non-virtual general equilibrium, the monopolistic entrepreneur, and welfare economics. Wilhelm Lexis, Ladislaus von Bortkiewicz and Eugen von Böhm-Bawerk gave Walras's models serious attention. Knut Wicksell based his theory of price determination squarely upon Walras's work (Wicksell to Walras, 6 November 1893, L 1168), and Karl Gustav Cassel was inspired in the construction of his models (1903; 1918) by Walras's equation system and idea of virtuality expressed in the written pledges sketch. Walras was given recognition in the United States: in 1892 he was made an honorary member of the American Economic Association, Irving Fisher praised his work (Fisher, 1892, p. 45; 1896), H.L. Moore became his avowed disciple and explicator (Moore to Walras, 19 May 1909, enclosure to L 1747; Moore, 1929), and Henry Schultz taught Walras's economics and, like Moore, undertook theoretical and econometric studies of general equilibrium relationships (for example, Schultz, 1929; 1932; 1933). His mature comprehensive model was the starting point for the work of Joseph Schumpeter, who, throughout his entire career, devoted himself to the study of disequilibrium and general equilibration of non-virtual economic phenomena.

The manifestations of acceptance led Walras to believe he would ultimately triumph, and that enabled him to achieve a mental calmness (Walras to Marie de Sainte Beuve, 15 December 1899, L 1432; Walras to A. Aupetit, 28 May 1901, L 1485). ‘Be assured of my serenity’, he wrote to old friends in 1904, ‘I have not the least doubt about the future of my method and even of my doctrine; but I know that success of this sort does not become clearly apparent until after the death of the author’ (Walras to G. and L. Renard, 4 June 1904, L 1574). Walras's prediction of great success was accurate. An indication of what the future would hold for his theories was given by the celebration of his jubilee in 1909 by the University of Lausanne, in the course of which he was honoured as the first economist to establish the conditions of general equilibrium, thus founding the School of Lausanne (Walras, 1965, L 1696, n. 5). His achievements were praised in a statement signed by 15 leading French scholars, including Charles Gide, Charles Rist, Georges Renard, Alfred Bonnet, Albert Aupetit and François Simiand (Walras, 1965, enclosure to L 1747), and in communications from many others (Pareto to the Dean of the Faculty of Law of the University of Lausanne, 6 June 1909, L 1755; Schumpeter to Walras, 7 June 1909, L 1756).
Walras's contributions inspired and provided a substantial beginning for the branches of general equilibrium theory and applications as they have developed since the 19th century. Indeed, the filiations of his ideas have become so numerous and dense as to be an integral and central part of the mainstream of modern economics. His achievement of developing particular theories and binding them together in a model of an entire economic system has given his work an influence on the verbal, mathematical and econometric study of the interrelationships of all parts of economic systems that has been durable and immense. For sheer genius and intuitive power in penetrating the veil of the chaos of immediately perceived experience and divining the underlying structure of fundamental economic relationships and their extensive interdependencies and consequences, Walras has been surpassed by no one.

Walras's Law

Don Patinkin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Walras's Law is an expression of the interdependence among the excess-demand equations of a general-equilibrium system that stems from the budget constraint. It is so called because Walras made use of this interdependence from the first edition of his *Éléments d'économie politique pure* through the fourth, which for all practical purposes is identical with the definitive edition. Walras presents the argument for an exchange economy and extends his analysis to deal first with a simple production economy and then with one in which capital formation also takes place. Here, Walras's Law is derived in a more general way than usual.

Article

Walras's Law (so named by Lange, 1942) is an expression of the interdependence among the excess-demand equations of a general-equilibrium system that stems from the budget constraint. Its name reflects the fact that Walras, the father of general-equilibrium economics, himself made use of this interdependence from the first edition of his *Éléments d'économie politique pure* (1874, §122) through the fourth (1900, §116), which edition is for all practical purposes identical with the definitive one (1926). I have cited §116 of this edition because it is the one cited by Lange (1942, p. 51, n. 2), though in a broader context than Walras's own discussion there (see below). In this section, Walras presents the argument for an exchange economy. In accordance with his usual expository technique (cf. his treatment of the *tâtonnement*), he repeats the argument as he successively extends his analysis to deal first with a simple production economy and then with one in which capital formation also takes place (ibid., §§206 and 250, respectively).

For reasons that will become clear later, I shall derive Walras's Law in a more general – and more cumbersome – way than it usually has been. Basically, however, the derivation follows that of Arrow and Hahn (1971, pp. 17–21), with an admixture of Lange (1942) and Patinkin (1956, chs I–III and Mathematical Appendix 3:a).

Let $x_i^h$ be the decision of household $h$ with respect to good $i$ (i.e., a product-output); $x_i^h < 0$, it is a good purchased by the household; if $x_i^h > 0$, it is a good (mainly, labour or some other factor-service) sold. Similarly, let $y_j^f$ be the decision of firm $f$ with respect to good $i$; $y_j^f > 0$, it is a good produced and sold by the firm (i.e., a product-output); if $y_j^f < 0$, it is a factor-input.
For $y_i \geq 0$, this is a supply function; for $y_i < 0$, it is a demand function for the services of factors of production. Profits (positive or negative) of firm $f$ are then

$$R_f = \sum_i p_i y_i (v, k^f).$$

Let $d^{hf}$ represent the proportion of the profits of firm $f$ received by the household $h$. Its total profits received are then $\sum_f d^{hf} R_f$ and its budget constraint is accordingly

$$\sum_i p_i x_i^h = \sum_f d^{hf} R_f,$$

which assumes that households correctly estimate the profits of firms (cf. Buiter, 1980, p. 7; I shall return to this point below). As with the firm, let us, *mutatis mutandis*, conduct individual-experiments with household $h$ (with its given tastes), subject to its budget constraint (3) by varying the elements of $v$, while keeping its initial endowment (represented by the vector $e^h$ constant. This yields the behaviour functions

$$x_i^h = x_i^h (v, e^h) (i = 1, \ldots, n).$$

For $x_i \geq 0$, this is a demand function for goods; for $x_i < 0$, it is a supply function (e.g., of factor-services). Substituting from (2) and (4) into (3) then yields

$$\sum_i p_i x_i^h (v, e^h) = \sum_f d^{hf} \sum_i p_i y_i (v, k^f).$$

which holds identically for all \( v, e, k \) and \( p_i \). Summing up over all households then yields

\[
\sum_h \sum_i p_i x_i^h (v; e^h) = \sum_h \sum_f d^{hf} \sum_j p_j y_j^f (v; k^f).
\]

(6)

which we rewrite as

\[
\sum_i p_i \sum_h x_i^h (v; e^h) - \sum_i p_i \sum_h \left( \sum_f d^{hf} \right) y_j^f (v; k^f).
\]

(7)

On the assumption that firm \( f \) distributes all its profits,

\[
\sum_h d^{hf} = 1 \text{for all } f,
\]

(8)

so that (7) reduces to

\[
\sum_i p_i [X_i (v; E) - Y_i (v; K)] = 0
\]

(9)

identically in all \( v, E, K \) and \( p_i \), where

\[
X_i (v; E) = \sum_h x_i^h (v; e^h) \text{ and } Y_i (v; K) = \sum_f y_j^f (v; k^f)
\]

(10)

represent the aggregate demand and supply functions, respectively, for good \( i \); \( E \) is a vector containing all the \( e^h \); and \( K \) a vector containing all the \( k^f \). If \( X_i (v; E) - Y_i (v; K) > 0 \), an
excess demand is said to exist in the market; if \( \lambda_y(v, k) < 0 \), an excess supply; and if \( \lambda_y(v, k) = 0 \), equilibrium.

Equation (9) is a general statement of Walras's Law. Its most frequent application in the literature has been (as in Walras's *Eléments* itself) to the general-equilibrium analysis of a system of perfect competition, in which the behaviour functions of firms are derived from the assumption that they maximize profits subject to their production function; and those of households are derived from the assumption that they maximize utility subject to their budget constraint. In this context, the vector \( v \) is the price vector \( (p_1, \ldots, p_{n-1}) \), with the \( n \)th good being money and serving as numéraire (i.e., \( p_n = 1 \)), so that there are only \( n - 1 \) prices to be determined. Ignoring for simplicity vectors \( E \) and \( K \), which remain constant in the conceptual market-experiment, equation (9) then becomes

\[
\sum_{i=1}^{n} p_i \{ x_i(p_1, \ldots, p_{n-1}) - y_i(p_1, \ldots, p_{n-1}) \} = 0 \text{ identically in the } p_i
\]

(11)

(Though it does not bear on the present subject, I should note that under the foregoing assumptions, and in the absence of money illusion, each of the demand and supply functions is homogeneous of degree zero in \( p_1, \ldots, p_{n-1} \) and in whatever nominal financial assets are included in \( E \) and \( K \) (e.g., initial money holdings).) Thus Walras's Law states that no matter what the \( p_i \), the aggregate value of excess demands in the system equals the aggregate value of excess supplies. This is the statement implicit in Lange's presentation (1942, p. 50).

Walras himself, however, sufficed with a particular and narrower application of this statement, and was followed in this by, *inter alia*, Hicks (1939, chs. IV: 3 and XII: 4–5), Modigliani (1944, pp. 215–16) and Patinkin (1956, ch. III: 1–3). Assume that it has been shown that a certain price vector \( (p_0^1, \ldots, p_0^{n-1}) \) equilibrates all markets but the \( j \)th. Since (11) holds identically in the \( p_i \), it must hold for this price vector too. Hence substituting the \( n - 1 \) equilibrium conditions into (11) reduces it to

\[
p_j^0 \{ x_j(p_1^0, \ldots, p_{n-1}^0) - y_j(p_1^0, \ldots, p_{n-1}^0) \} = 0.
\]

(12)

Thus if \( p_j^0 > 0 \), the price vector \( (p_1^0, \ldots, p_{n-1}^0) \) must also equilibrate the \( j \)th market, which means that only \( n - 1 \) of the equilibrium equations are independent. In this way Walras (and those who followed him) established the equality between the number of independent equations and the number of price-variables to be determined. (Though such an equality is not a sufficient condition for the existence of a unique solution with positive prices, it is a necessary – though not sufficient –condition for the peace-of-mind of those of us who do not aspire to the rigour of mathematical economists.)

It should however be noted that at the end of §126 of Walras's *Eléments* (1926), there is a hint of Lange's broader statement of the Law: for there Walras states that if at a certain set of prices 'the total demand for some commodities is greater (or smaller) than their offer, then the offer of some of the other commodities must be greater (or smaller) than the demand for them'; what is missing here is the quantitative statement that the respective aggregate values of these excesses must be equal.

Since the contrary impression might be gained from some of the earlier literature (cf., e.g., Modigliani, 1944, pp. 215–16), it should be emphasized that no substantive difference can arise from the choice of the equation to be 'dropped' or 'eliminated' from a general-equilibrium system by virtue of Walras's Law. For identity (11) can be rewritten as

\[
x_j(p_1, \ldots, p_{n-1}) - y_j(p_1, \ldots, p_{n-1}) = - \frac{1}{p_j} \sum_{i=1 \atop i \neq j}^{n} p_j \{ x_i(p_1, \ldots, p_{n-1}) - y_i(p_1, \ldots, p_{n-1}) \} \text{ identically in the } p_i
\]
Thus the properties of the 'eliminated' equation are completely reflected in the remaining ones. Correspondingly, no matter what equation is 'eliminated', the solution for the equilibrium set of prices obtained from the remaining equations must be the same. (From this it is also clear that the heated 'loanable-funds versus liquidity-preference' debate that occupied the profession for many years after the appearance of the *General Theory*, was largely misguided; see Hicks, 1939, pp. 157–62; see also Patinkin, 1956, ch. XV: 3, and 1958, pp. 300–302, 316–17.)

In his influential article, Lange (1942, pp. 52–53) also distinguished between Walras's Law and what he called Say's Law, and I digress briefly to discuss this. As before, let the first $n - 1$ goods represent commodities and the $n$th good money. Then Say's Law according to Lange is

$$\sum_{i=1}^{n-1} p_i X_i(p_1, \ldots, p_{n-1}) = \sum_{i=1}^{n-1} \bar{p}_i \bar{X}_i(p_1, \ldots, p_{n-1})$$

identically in the $p_i$.

That is, the aggregate value of commodities supplied at any price vector $(p_1, \ldots, p_{n-1})$ must equal the aggregate value demanded: supply always creates its own demand.

On both theoretical and doctrinal grounds, however, I must reject Lange's treatment of Say's Law. First of all, Lange himself demonstrates (ibid., p. 62) that identity (14) implies that money prices are indeterminate. In particular, subtracting (14) from (11) yields

$$X_n(p_1, \ldots, p_{n-1}) = \gamma_n(p_1, \ldots, p_{n-1})$$

for all $p_i$.

That is, no matter what the price vector, the excess-demand equation for money must be satisfied, which in turn implies that money prices cannot be determined by market forces. But it is not very meaningful to speak of a money economy whose money prices are indeterminate even for fixed initial conditions as represented by the vectors $E$ and $K$. So if we rule out this possibility, we can say that Say's Law in Lange's sense implies the existence of a barter economy. Conversely, in a barter economy (i.e., one in which there exist only the $n - 1$ commodities) Say's Law is simply a statement of Walras's Law. Thus from the above viewpoint, a necessary and sufficient condition for the existence of Say's Law in Lange's sense is that the economy in question be a barter economy: it has no place in a money economy (Patinkin, 1956, ch. VIII: 7).

Insofar as the doctrinal aspect is concerned, identity (14) cannot be accepted as a representation of Say's actual contention. For Say's concern was (in today's terminology) not the short-run viewpoint implicit in this identity, but the viewpoint which denied that in the long run inadequacy of demand would set a limit to the expansion of output. In brief, and again in today's terminology, Say's concern was to deny the possibility of secular stagnation, not that of cyclical depression and unemployment. Thus, writing in the first quarter of the 19th century, Say (1821a, p. 137) adduces evidence in support of his thesis from the fact 'that there should now be bought and sold in France five or six times as many commodities, as in the miserable reign of Charles VI – four centuries earlier. Again, in his *Letters to Malthus* (1821b, pp. 4–5) Say argues that the enactment of the Elizabethan Poor Laws (codified at the end of the 16th century) proves that 'there was no employ in a country which since then has been able to furnish enough for a double and triple number of labourers' (italics in original). Similarly, Ricardo, the leading contemporary advocate of Say's *loi des débouchés*, discusses this law in chapter 21 of his *Principles* (1821), entitled 'Effects of Accumulation of Profits and Interest'; on the other hand, he clearly recognizes the short-run 'distress' that can be generated by 'Sudden Changes in the Channels of Trade' (title of ch. 19 of his *Principles*. For further discussion see Patinkin, 1956, Supplementary Note L.)

Let me return now to the general statement of Walras's Law presented in equation (9) above. This statement holds for any vector $\mathbf{v}$ and not only for that appropriate to perfect competition. In particular, Walras's Law holds also for the case in which households and/or firms are subject to quantity constraints. In order to bring this out, consider the analysis of a disequilibrium economy presented in chapter XIII:2 of Patinkin (1956) and illustrated by Figure 1. In this figure, $w$ is the money wage-rate, $p$ the price level, $N$ the quantity of labour, $Q(w/p, K_0)$ the firms' demand curve for labour as derived from profit-maximization as of a given stock of physical capital $K_0$; and $R(w/p)$ is the supply curve of labour as derived from utility maximization subject to the budget constraint (these perfect-competition curves are what Clower (1965, p. 119) subsequently denoted as 'notional curves'). Assume that because of the firms' awareness that at the real wage rate $(w/p)_1$ they face a quantity constraint and will not be able to sell all of the output corresponding to...
their profit-maximizing input of labour $N_1$, they demand only $N_2$ units of labour, represented by point $P$ in Figure 1. This constraint also operates on workers, who can sell only the foregoing quantity of labour instead of their optimal one $N_3$, represented by point $H$. In brief, at point $P$, both firms and workers are off their notional curves. In order to depict this situation, the notional curves must accordingly be replaced by quantity-constrained ones; namely, the kinked demand curve $TAN_2$ and kinked supply curve $OUE$. Note that for levels of employment before they become kinked, the curves coincide respectively with the notional ones (but see Patinkin, 1956, ch. XIII: 2, n. 9, for a basic analytical problem that arises with respect to the kinked demand curve $TAN_2$).

Figure 1

The obverse side of these constraints in the labour market are corresponding constraints in the commodity market. In particular, as Clower (1965, pp. 118–21) has emphasized, the demands of workers in this market are determined by their constrained incomes. Clower also emphasizes that it is this quantity constraint which rationalizes the consumption function of Keynes's *General Theory*, in which income appears as an independent variable. For in the absence of such a constraint, the individual's income is also a dependent variable, determined by the optimum quantity of labour he decides to sell at the given real wage rate in accordance with the labour-supply function \( N^s = R(w/p) \) in Figure 1; and he makes this decision simultaneously with the one with respect to the optimum quantities of commodities to buy. If, however, his income is determined by a quantity constraint which prevents him from selling his optimum quantity of labour, the individual can decide on his demands for commodities only after his income is first determined. This is the so-called 'dual decision hypothesis' (Clower, ibid.). To this I would add (and its significance will become clear below) that the quantity constraint also rationalizes the form of Keynes's liquidity preference function, for this too depends on income (*General Theory*, p. 199). Furthermore, if the behaviour functions in the markets for labour, commodities and money balances are thus quantity-constrained, so too (by the budget constraint) will be that for bonds – the fourth market implicitly (and frequently explicitly) present in the Keynesian system. (The theory of the determination of equilibrium under quantity constraints – in brief, disequilibrium theory – has been the subject of a growing literature, most of it highly technical; for critical surveys of this literature, see Grandmont, 1977; Drazen, 1980; Fitoussi, 1983; and Gale, 1983, ch. 1.)

In the *General Theory* (ch. 2), Keynes accepted the ‘first classical postulate’ that the real wage is equal to the marginal product of labour, but rejected the second one, that it always also measures the marginal disutility of labour. In terms of Figure 1 this means that while firms are always on their demand curve \( N^d = Q(w/p, K_0) \), workers are not always on their supply curve \( N^s = R(w/p) \). Thus, for example, at the level of employment \( N_2 \), the labour market will be at point A on the labour-demand curve, corresponding to the real wage rate \( (w/p)_2 \); but the marginal utility of the quantity of commodities that workers then buy with their real-income \( (w/p)_2 \). \( N_2 \) is greater than the marginal disutility of that level of employment. And Keynes emphasizes that only in a situation of full-employment equilibrium – represented by intersection point \( M \) in Figure 1 – will both classical postulates be satisfied.

Consider now the commodity market as depicted in the usual Keynesian-cross diagram (Figure 2). The 45° line represents the amounts of commodities which firms produce and supply as they move along their labour-demand curve from point \( T \) to \( M \). Thus \( Y \) represents the output (in real terms) of \( N_0 \) units of labour. Note too that the negative slope of the labour-demand curve implies that the real wage declines as we move rightwards along the 45° line.
Walras's Law

Consider now the consumption function of workers. The income which they have at their disposal is their constrained income as determined by the labour-demand curve in Figure 1.

What must now be emphasized is that Walras's Law holds in this situation too – provided we relate this Law to excess-demand functions of the same type. Thus if within our four-good Keynesian model we consistently consider notional behaviour functions, the excess supply of labour described in Figure 1 corresponds to an excess demand for commodities which is generated by workers' planned consumption expenditures at the real wage rate (w/p)1 and (w/p)2, respectively. On the assumption that the elasticity of demand for labour is greater than unity, the higher the level of employment the greater the income of workers and hence their consumption expenditures. From Figure 2 we see that at income Y2 there is an excess demand for commodities. This causes firms to expand their output to, say, Y1, and hence their labour-input to, say, N1, thus causing the constrained labour-supply curve to shift to the right to the kinked curve OUVLF. By construction, Y1 is the equilibrium level of output.

Curve E represents the aggregate demand curve, which is the vertical sum of the consumption function of workers (E1) and capitalists (E2), respectively, and of the investment function (I). For simplicity, these last two are assumed to be constant. The fact that curve E does not coincide with the 45° line reflects Keynes's assumption that in a monetary economy, Say's Law (in Keynes's sense, which is the macroeconomic counterpart of Lange's subsequent formulation) does not hold (ibid., pp. 25–6).

Consider now the consumption function of workers. The income which they have at their disposal is their constrained income as determined by the labour-demand curve in Figure 1. Thus assume that Y1 and Y2 in Figure 2 are the outputs corresponding to the levels of employment N1 and N2, respectively. The corresponding incomes of workers at these levels are (w/p)1•·•N1 and (w/p)2•·•N2. On the assumption that the elasticity of demand for labour is greater than unity, the higher the level of employment the greater the income of workers and hence their consumption expenditures. From Figure 2 we see that at income Y2 there is an excess demand for commodities. This causes firms to expand their output to, say, Y1, and hence their labour-input to, say, N1, thus causing the constrained labour-supply curve to shift to the right to the kinked curve OUVLF. By construction, Y1 is the equilibrium level of output.

What must now be emphasized is that Walras's Law holds in this situation too – provided we relate this Law to excess-demand functions of the same type. Thus if within our four-good Keynesian model we consistently consider notional behaviour functions, the excess supply of labour describes in Figure 1 corresponds to an excess demand for commodities which is generated by workers' planned consumption expenditures at the real wage rate (w/p)1 and level of employment N3 as compared with firms' planned output at that wage rate and lower level of employment N2; and there will generally also exist a net excess planned demand for bonds and money. Alternatively, if we consistently consider constrained functions, then constrained equilibria exist in the labour market (point L), the commodity market (point L'), the bond market and the money market. Similarly, the broader form of Walras's Law states that a constrained (say) excess supply in the commodity market corresponds to a constrained net excess demand in the bond and money markets, while the labour market is in constrained equilibrium. In brief, a sufficient condition for the validity of Walras's Law is the individual's demand and supply functions on which it is ultimately based are all derived from the same budget constraint, whether quantity-constrained or not. (This is the implicit assumption of Patinkin's (1956, p. 229; 1958, pp. 314–16) application of Walras's Law to a disequilibrium economy with unemployment, and the same is true for Grossman (1971) and Barro and Grossman (1971; 1976, p. 58).)

I must admit that the validity of Walras's Law in this Keynesian model depends on our regarding the kinked curve OUVLF as a labour-supply curve, and that this is not completely consistent with the usual meaning of a supply curve or function. For such a function usually describes the behaviour of an agent under constraints which leave him some degree of freedom to choose an optimum, whereas no such freedom exists in the vertical part of OUVLF. However, I prefer this inconsistency to what I would consider to be the logical – and hence more serious – inconsistency that lies at the base of the rejection of Walras's Law, and which consists of lumping together behaviour functions derived from different budget constraints.

It is thus clear that the foregoing constrained equilibrium in the labour market is not an equilibrium in the literal sense of representing a balance of opposing market forces, but simply the reflection of the passive adjustment by workers of the amount of labour they supply to the amount demanded by firms (cf. Patinkin, 1958, pp. 314–15). From this viewpoint, the constrained equilibrium in the labour market always exists and simply expresses the fact that, by definition, every ex post purchase is also an ex post sale. In contrast, as we have seen in the discussion of Figure 2 above, the corresponding constrained equilibrium in the commodity market is a true one; for, in accordance with the usual Keynesian analysis, were the level of Y to deviate from Y1, automatic market forces of excess demand or supply would be generated that would return it to Y1. And a similar statement holds, mutatis mutandis, for the constrained equilibria in the bond and money markets.

Note, however, that in the commodity market too there is an ex post element. This element is a basic, if inadequately recognized, aspect of the household behaviour implied by Clower's 'dual decision hypothesis': namely, that households' constrained decisions on the amount of money to spend on commodities is based on their ex post knowledge of the amount of money received from the constrained sale of their factor services. And to this I again add that a similar statement holds for their constrained decisions with reference to the amounts of bonds and money balances, respectively, that they will want to hold. (Note that an analysis in terms of constrained decisions can also be applied to the case in which households do not correctly estimate firms' profits in equation (3) above, and are thus forced to base their effective (say) consumption decisions on the ex post knowledge of these profits.)
In this treatment of an economy with constrained functions, Clower (1965, pp. 122–3) has claimed that under these conditions Walras's Law does not hold. This is not true for the Law as hitherto discussed. What Clower seems to have in mind, however, is that though the excess supply of labour LH in Figure 1 is notional, it nevertheless exerts pressure on workers to reduce their money wages; in contrast, the notional excess demand for commodities corresponding to LH (see above) cannot – because of their constrained incomes – lead households to exert expansionary pressures on the commodity market. Thus there exists no effective excess demand for commodities to match the effective excess supply of labour. Accordingly, no 'signal' to the market is generated that will lead to the expansion of output and consequent reduction of unemployment (cf. also Leijonhufvud, 1968, pp. 81–91). And it is the absence of such a 'signal' that Leijonhufvud (1981, ch. 6) subsequently denoted as 'effective demand failure'.

This 'failure', however – and correspondingly the failure of Walras's Law to hold in Clower's sense – is not an absolute one: for though there is no direct signal to the commodity market, an indirect one may well be generated. In particular, the very fact that the constrained equilibrium in the labour market does not represent a balancing of market forces means that the unemployed workers in this market will be a potential source of a downward pressure on the money wage rate. And if this pressure is to some extent effective, the resulting decline in money wages will generate an increase in the real quantity of money, hence a decrease in the rate of interest, hence an increase in investment and consequently in aggregate demand – and this process may be reinforced by a positive real-balance effect (see chapter 19 of the General Theory, which, however, also emphasizes how many weak – and possibly perverse – links are in this causal chain). Thus a sufficient condition for absolute 'effective demand failure' is the traditional classical one of absolute rigidity of money wages and prices.

An analogy (though from a completely different field) may be of help in clarifying the nature of the foregoing equilibrium in the labour market. Consider a cartel of (say) oil-producing firms, operating by means of a Central Executive for the Production of Oil (CEPO) which sets production quotas for each firm. The total quantity-constrained supply so determined, in conjunction with the demand conditions in the market, will then determine the equilibrium price for crude oil, and that equilibrium position is the relevant one for Walras's law. But this will not be an equilibrium in the full sense of the term, for it coexists with market pressures to disturb it. In particular, the monopolistic price resulting from CEPO's policy is necessarily higher than the marginal cost of any individual member of the cartel. Hence it is to he interest of every firm in the cartel that all other firms adhere to their respective quotas and thus 'hold an umbrella' over the price, while it itself surreptitiously exceeds the quantity constraint imposed by its quota and thus moves closer to its notional supply curve as represented by its marginal-cost curve. And since in the course of time there will be some firms who will succumb to this temptation, a temptation that increases inversely with the ratio of its quota to the total set by CEPO, actual industry output will exceed this total, with a consequent decline in the price of oil. Indeed, if such violations of cartel discipline should become widespread, its very existence would be threatened.

This analogy is, of course, not perfect. First of all, unlike workers in the labour market, the member-firms of CEPO have themselves had a voice in determining the quantity constraints. Second, and more important, any individual firm knows that by ‘chiselling’ and offering to sell even slightly below the cartel price, it can readily increase its sales. But analogies are never perfect: that is why they remain only analogies.

A final observation: the discussion until now has implicitly dealt with models with discrete time periods. In models with continuous time, there are two Walras's Laws: one for stocks and one for flows: one for the instantaneous planned (or constrained) purchases and sales of assets (primarily financial assets) and one for the planned (or constrained) purchases and sales of commodity flows (cf. May, 1970; Foley and Sidrauski, 1971, pp. 89–91; Sargent, 1979, pp. 67–69; Buiter, 1980). On the other hand, in a discrete-time intertemporal model, in which there exists a market for each period, there is only one Walras's Law: for in such a model, all variables have the time-dimension of a stock (see Patinkin, 1972, ch. 1).

war and economics

Craufurd D. Goodwin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

War has always intrigued economic thinkers: how economic interdependence affects the likelihood of conflict, the costs and benefits of aggression, how to fight a successful war and achieve a stable peace. Many prominent early economists had useful things to say, for example Smith, J.B. Clark, Pigou, Veblen and J.M. Keynes. Economists came into their element in the Second World War and the Cold War; welcomed into government, they distinguished themselves as macroeconomists, microeconomists, broad-based advisers, public administrators, and public figures. By the 1990s economists concerned with war and peace had established their own sub-discipline, with journals, textbooks and college courses.

Article

Prehistory

Political economy emerged from moral philosophy as a distinct field of study in the 18th century. Before that economic ideas were part of a continuum developing from the speculation of Greek philosophers about how to achieve the good life, the advice from medieval schoolmen about how to achieve salvation, and the recommendations of 17th century merchants and public administrators about how to strengthen the emerging nation-states. In this early literature economic ideas were entwined with concerns about
communal security. No matter whether the unit of concern was a nation, a city-state, or a manor, conquest by an external enemy was seen as a catastrophe. Conversely, great economic benefit was seen to come from military victory.

Hesiod in eighth-century BC Greece suggested that economic isolation and self-sufficiency might be the best protection against war because for voracious enemies out-of-sight was out-of-mind. Indeed, the ideal communities imagined by Plato in Atlantis, Sir Thomas More in Utopia, and Francis Bacon in New Atlantis were all remote from their neighbours (Lowry, 1991, p. 6). Security, they implied, lay in isolation and economic autarky. In economic interdependence there was danger. Economic interchange requires human interaction and from such contacts emerge frictions, cupidity, and ultimately physical violence. The state dealt with domestic violence through the police and the courts. Correspondingly international trade and flows of resources across borders should be constrained by the state to reduce tensions that could lead to war. The ancients recognized that, if war should begin, the structure of the economy could profoundly affect the capacity of a state to defend itself. The early Greeks appreciated that the highly efficient hoplite military formation, as well as other military tactics, depended upon the strength and high morale of their small-scale farming population. As an effective fighting machine a labour force of docile day labourers just would not do. Similarly, the citizen-based merchant marine of Athens was the foundation upon which her powerful navy rested (Lowry, 1991, p. 7).

Warfare was treated by the Greek philosophers and their admirers in the Middle Ages as simply one among many possible economic activities. Trade, colonization and conquest of one's neighbours were alternative uses of national resources. The task of leaders was to identify the best among them. This calculation required the kind of hardheaded cost–benefit analysis that became the hallmark of later economics. Erasmus wrote in 1516 in a tract for the future Charles V of Spain: ‘when the prince has put away all personal feelings, let him take a rational estimate long enough to reckon what the war will cost and whether the final end to be gained is worth that much – even if victory is certain’ (Lowry, 1991, p. 17). Erasmus warned that any responsible leader must guard against the self-interested advice of private persons who might gain from war while the community at large would lose. ‘It too often happens that nobles, who are more lavish than their means allow, when the opportunity is presented stir up war in order to replenish their resources even at home by the plunder of their peoples’ (1991, p. 17). This advice sounds like an early warning against a military–industrial complex!

War and classical political economy

To a degree, the classical political economy that appeared in the 18th century was an extension of the earlier ‘mirror for princes’ literature to which Erasmus contributed. It, too, was intended to guide statesmen in the preparation and implementation of public policy. An important difference, however, was that the political economists thought that they brought much greater impartiality and detachment to their work. Policy implications, they believed, emerged ineluctably from their theory, and ad hoc reasoning could be replaced by principle (Silberner, 1946). Adam Smith took the same cost–benefit stance towards warfare as Erasmus, but he developed its implications more fully, and he drew from them optimistic prospects for the future (Smith, 1776, pp. 689–708; and Goodwin, 1991, pp. 24–8). In the tradition of Enlightenment thinking, Smith presumed good political leaders would be rational, and the challenge, therefore, was to construct circumstances in which they would select peace over war.
Happily, Smith observed, conditions were likely to emerge from growth in ‘the necessaries, comforts and conveniences of life’ that would make nations ever more peaceful. A consequence of economic growth was that, over time, the opportunity costs of warfare rose – reflecting both the direct costs of munitions and supplies and the production forgone from military servicemen in the prime of their productive lives. On the other hand, the value of potential spoils of war to an advancing country would no more than remain constant. As the costs rose and the potential gains remained fixed, the likelihood of benefiting from aggression declined, and the warlike tendencies of rational nations fell steadily as they grew economically. The military preparedness of a prosperous nation, therefore, would seldom be for offence. However, preparedness remained critical for defence, especially against less prosperous neighbours whose cost–benefit calculations of aggression against them might for some time remain positive. The main task of the military establishment in any prosperous nation was to make the costs of aggression against it higher than any plausible gain. In this way the notion of rational deterrence was given a precise exposition by Smith.

An intriguing yet minor Enlightenment thinker who proposed an economic doctrine while applying it also to military strategy and tactics was the Welshman Henry Lloyd, a major-general and professional mercenary in the wars of the 18th century, parodied by Gilbert and Sullivan in *Pirates of Penzance* for his commitment to social theory (Speelman, 2002).

Thomas Robert Malthus among the classical economists provided a reason rooted in demographic growth to explain why the costs of conflict should always be kept clearly before potential aggressors (Malthus, 1826, p. 47; and Goodwin, 1991, p. 26). When an increasing population pressed hard upon natural resources a suffering nation was likely to look abroad for relief and conflict would ensue. Indeed, the slaughter of warfare became one of the powerful ‘positive’ checks to population growth. Deterrence costs should always be kept sufficient to make certain that aggression would be carried out by overpopulated countries against someone else. John Stuart Mill concluded in 1848 that deterrence had by that date been so successful that war had become likely only in colonies where ‘savages’ prepared unreasonable cost-benefit calculations (Mill, 1848, p. 707).

Economists, beginning with Smith, were quick to see an analogy between the security needs of all nations taken together and those of small communities that formed themselves into nation-states to benefit from the rule of law. Costs of protection could be reduced globally through international agreements. Smith favoured for Britain a kind of ‘commonwealth’ that would include former colonies. Later economists were enthusiastic supporters of such institutions of world government as the International Court of Justice at The Hague, the League of Nations and the United Nations.

Economic thinkers have often puzzled about just what is required to fight a successful war. Some pamphleteers in the 17th century thought that a stock of ‘treasure’ was needed. Smith thought, to the contrary, that a satisfactory flow of product was necessary; a vibrant and robust economy would allow the state to ‘draw from their subjects extraordinary aids upon extraordinary occasions’ (Smith, 1776, p. 446). Costs to the economy, he thought, were necessarily different in a small war from a large one. For example, soldiers who were not seriously challenged by the prospect of a slight skirmish in a minor war might be persuaded to volunteer at wages below market rates, led on by their ‘youthful fancies’ and ‘romantic lapses’. The taxpayers in this situation, moreover, might not complain about modest levies because ‘this amusement compensates the small difference between the taxes which they pay on account of the war, and those which they are accustomed to pay in time of peace’ (1776, p. 920). In a full-scale war, on the other hand, soldiers fearing personal injury demanded payment at top market rates, taxpayers
balked at the levies upon them, and it became necessary to issue public debt as the only way to raise revenue. Happily the net costs of war usually were low because productive capital was seldom damaged and, as the classical economist John Rae observed, the turmoil of conflict seemed to stimulate the powers of invention (Rae, 1834, pp. 222–3).

**Marginal economics applied to war**

An important turn in the evolution of modern economics occurred in the 1870s when the mainstream accepted utility maximization as its norm and incremental analysis as its method (Black, Coats and Goodwin, 1973, p. 19). This shift took place in the middle of the Pax Britannica, one of the most peaceful periods in European history, and the new analytical tools had seldom to be used to explain warfare. Under the marginal paradigm all destructive conflict was treated as socially irrational and contributing to net social disutility. War was mentioned in relation to public finance where it was usually categorized as a ‘bad’, like crime and disease, the opposite of a ‘good’. The main questions were how many public resources should be allocated to deterrence and how should these resources be deployed. Two writers who epitomized the marginalist approach to conflict in the years leading up to the First World War were the English economist/journalist Norman Angell, and the pioneering American price theorist John Bates Clark (Barber, 1991a, pp. 61–84). Angell used economic reasoning in a book on war entitled *The Great Illusion* (1910), which reached a large and influential readership. He claimed that because of widespread international economic integration war had become everywhere futile and irrational. No one could gain from a fight. The economic dependence of virtually all countries on their neighbours for markets, products and materials made it impossible for them to achieve a net gain through conquest. This was not to say that war was impossible, only that it was unlikely by the economist's logic. This position, of course, was the exact opposite of the venerable idea developed by Plato that economic integration was dangerous and economic autarky could be the road to world peace. In Angell's view, Adam Smith's desired condition for deterrence had been achieved in which all powerful nations that made a disinterested study must conclude that the costs of war exceeded the benefits. Even indemnity payments to winners – if they could be enforced, as they had been after the Franco–Prussian War – were likely to cause serious market dislocations in the recipient nation as well as in the payer and were of little net gain to anyone.

John Bates Clark of Columbia University, the most prominent American marginal economist, studied war as part-time Director of the Division of Economics and History of the Carnegie Endowment for International Peace, founded by Andrew Carnegie in 1910. In 1911 Clark mobilized in Bern most of the celebrated economists of the time from around the world to explore how economics could help achieve permanent world peace. Those in attendance were conscious of the current threat of war and agreed to turn their talents to how it could be avoided. Clark's hope was to identify adjustments that might be made to incentives and rewards in the global economy to reduce the likelihood of conflict. There was a prevailing sense among the economists that tensions grew out of structural errors and misunderstandings, and in this Clark saw an analogy with industrial relations. Mediation and arbitration that worked in one sphere might work also in the other. One task for economists could be to propose equitable middle ground between potential combatants.
Despite Clark's and Angell's optimism about the capacity of economics to show the way to a stable world peace, heterodox economists in the socialist, historical and emerging American Institutionalist traditions continued to worry that economic forces within the industrial nations would lead inevitably to conflict. Thorstein Veblen, John A. Hobson and others warned of tensions based on class division and the proclivity of one social group to exploit another (Biddle and Samuels, 1991; and Davis, 1991). When these tensions spread overseas through colonial expansion and an aggressive search for profits the possibility of international conflict became serious.

No matter whether economists writing about conflict in the years before the First World War were in the respectable mainstream or in the professional underworld, their reflections were mainly those of outsiders. War was a subject about which their theory seemed to have something to say, and so they said it. But there is little evidence that their observations had a measurable impact on the thought or actions of those who decided upon peace and war.

The First World War threw many prominent economists nearly into despair: the war was so costly, so barbarous, and so irrational! It seemed even to cast doubt on the controlling force of reason in society. Francis Hirst, editor of The Economist, in a personal manifesto in 1915 entitled ‘The Political Economy of War’ saw ahead only ‘social and economic ruin’ (Barber 1991a, p. 72). Gustav Cassel in Sweden and the young John Maynard Keynes in Britain were deeply discouraged to find that despite the global integration that Angell and others had described the belligerents seemed able and willing to continue the conflict for a prolonged period, far after any rational leaders would have been expected to make peace (Barber, 1991a, pp. 76–9). After the war finally came to a close Keynes wrote in his celebrated polemic against the peace treaty, The Economic Consequences of the Peace (1920), that sheer vindictiveness had overcome good sense. Later, Keynes, John Bates Clark, and other economists were outraged that the American Senate refused to ratify American participation in the League of Nations. It seemed to them that once again, prejudice and political opportunism had overwhelmed reason on vital matters related to peace and war. So what use was economics in the search for peace? After a century of giving positive answers to this question economists had now to admit ‘perhaps not very much’!

Economists in the years between the two world wars, apparently humbled by the seeming irrelevancy of their efforts in the years surrounding the first war, were generally reluctant to engage with subjects related to peace, war and national security. They had lost their self-confidence and they responded by withdrawing from the field. War for most economists simply was no longer a respectable area for attention. It became, instead, a condition exogenous to their models and left to be analysed by other disciplines. Symbolically, the Carnegie Endowment for International Peace restructured its efforts in search of peace away from the abortive multi-national study of the economics of war to a 132-volume economic and social history of the First World War under the direction of the distinguished Columbia historian James T. Shotwell. The clear message of the Carnegie switch was that since the deductive methods of the marginal economists had not shown the way to peace it was time to give inductive historians a chance.

One of the few exceptions to the interwar inattention by economists to peace and war came from an unlikely source, the Cambridge theorist and successor to Alfred Marshall, A.C. Pigou. In his Political Economy of War (1921) Pigou set out to shed light on ‘the anatomy and physiology’ of ‘a strained and
stressed economy’ (Barber, 1991b, p. 131). Another exception was John Maurice Clark who, with his father John Bates Clark, attempted to estimate the full economic cost of the First World War, including the value of lost human as well as physical capital (Clark, 1931).

It appeared to many professional economists in the years between the wars that the dragon they had to slay in order to achieve peace was not in fact war itself but rather the conditions that led to war – at that time, economic depression and unemployment. So long as workers could not find jobs, and bankruptcies destroyed entrepreneurs, civil insurrection was likely. And when economic distress led to the rise of demagogues then world peace was truly at risk. Enquiry into the root causes of macroeconomic crisis proceeded at several levels. In Europe, business cycle institutes looked for disturbing patterns in worldwide economic activity and for means of coping cooperatively with distress (De Marchi, 1991). In the United States, economists inside and out of the Roosevelt administration experimented with a variety of new stimulative and regulatory mechanisms. In Britain, Keynes and his students at the University of Cambridge developed and propagated a new macroeconomics focused on the adequacy of aggregate effective demand, and they pointed to fiscal policy as the means to achieve economic stability. Keynes recalled T.R. Malthus's observation that wars of aggression could emerge from nations that had been unsuccessful in solving their internal economic problems, but the crucial short-run internal challenge now, he noted, was unemployment rather than overpopulation. The causal sequence, nevertheless, was the same. The route to world peace lay in internal macroeconomic reform and in international economic cooperation.

Victory for the economists in the Second World War

The economics discipline entered the Second World War without having thought deeply over the prior two decades about how to respond to conflict. Certainly it had no sub-discipline, as it does today, concerned with the economics of war, peace, defence and security. Moreover, economics was held in relatively low repute, at least among those in power. It was perceived, correctly, as an eclectic multi-paradigmatic field that spoke still with many voices: marginalist, Institutionalist, Keynesian, socialist, historical and others. Moreover, several of these voices were to a degree threatening to the established order. They came in America from advisers to US President Franklin D. Roosevelt, friends of organized labour and farmers, from architects of a welfare state – and worse. On the American campus in the 1930s academic freedom cases frequently involved economists, the result of the authorities attempting to silence troublemakers (Hofstadter and Metzger, 1955). It was ironic that by 1945 the Second World War had given to economics a much improved reputation and a perception among outsiders of a social value that had not been recognized before. Arguably, it gave as much to economics as economics gave to it. Even though few economists had made a study of war before 1939 they seemed to know what to do when the war began. Undoubtedly the memory of poor administrative performance during the First World War caused governments to welcome economists with relatively open arms 25 years later. In the first war resources and finished goods had been squandered by the bureaucrats and business persons recruited for the occasion. War finance had stumbled, prices had risen unacceptably, and profiteering occurred to a scandalous degree. Now, the economists claimed, they could do it all better.

It turned out that in the Second World War economists of all stripes could find useful work. Moreover, they got along rather well with the public servants and a new set of volunteers from the private sector.
Institutionalists like John Kenneth Galbraith supervised price control and war mobilization (Galbraith, 1981). Keynesians like Lauchlin Currie and Gerhard Colm designed non-inflationary monetary and fiscal policy (Sandilands, 1990; and Stein, 1969). Microeconomists like Charles Kindleberger (Kindleberger, 1991) demonstrated the use of optimizing techniques in selecting bombing targets, and economic historians like Walt Rostow helped to create the first high-powered intelligence service (Lodewijks, 1991). Even smart young Marxists like Paul Baran and Paul Sweezy found useful roles. A consequence of the impressive wartime performance by economists was that, when the war ended, the discipline had gained new respect. Indeed, politicians and bureaucrats alike found the economist's perspective so useful that they searched for ways to embed the discipline in government in peacetime. The Council of Economic Advisers, set up in the White House, and the semi-public RAND Corporation were both established with this objective in mind. After the war economists were sprinkled liberally throughout both the executive and legislative branches and the Federal Reserve, and the economist's approach was seen in the consideration of problems both of peace and war. The placement by Secretary of Defense McNamara of ‘whiz kids’ – economists and ‘systems analysts’ – firmly by his side when he entered the Kennedy administration in 1960 was only the latest step in the infiltration by economists that had started 20 years before.

When the National Science Foundation was created after the Second World War in response to Vannevar Bush's persuasive picture, *Science, the Endless Frontier* (1945) it was symbolic that the case for inclusion of economics was made not on the basis of its theoretical innovations or contributions over two centuries to human welfare; instead, a list was presented of the contributions to the recent war effort. The sociologist/economist Talcott Parsons, who was charged by the Social Science Research Council to prepare a lobbying document for use with Congress, described the participation of economists in such new agencies as the Office of Strategic Services and the Foreign Economic Administration, as well as the strengthening of older ones such as the Bureau of Agricultural Economics and the Treasury. The most impressive contribution of economists, Parsons concluded, came in the application of the Keynesian theory of income determination, primarily by Simon Kuznets, to achieve wartime full employment without inflation (Klausner and Lidz, 1986, p. 100).

The discussion in this entry thus far has been mainly about how economics has addressed war throughout its history, but after 1945 the relationship ran in both directions. Economics was itself changed fundamentally by its involvement with war though contacts with new people, new problems, new professional circumstances and new funding sources such as the Office of Naval Research. The most revolutionary new tool brought into economic analysis during the war was game theory, emerging from the collaboration of the mathematician John Von Neumann with the economist Oscar Morgenstern (Weintraub, 1992). Used originally to model parties in conflict it was extended to models of interactions between all kinds of actors, including those in cooperation. Operations research was another field with deep military roots to which economics contributed, and from which it brought back tools to the discipline (Mirowski, 2002).

New global breadth was the third contribution of war to economics. Not only were conventional issues of international trade and finance given new urgency by the challenge of rebuilding the world economy, but for both economic and strategic reasons it became necessary to understand friends and foes more thoroughly. This gave rise to new fields called ‘comparative economic systems’ and ‘Soviet studies’. When it became necessary to organize recovery from the Second World War and construct strong
nations as bulwarks against Communism, ‘development economics’ appeared as a new sub-discipline, with generous funding from government and private foundations.

The triumph of economics in the Cold War

The rise to prominence of economics in the study of war began during the Second World War. The discipline had shown that it could be useful in many ways during full mobilization. But the complete edifice of modern defence economics was constructed only later, during the Cold War (1946–89). There were three reasons. Perhaps of greatest significance was the steadily increasing cost of weapons systems. More items than just nuclear weapons and space exploration bore big price tags – such things as carrier battle groups, strategic bombers and foreign basing of forces. Clearly, hard choices had to be made among alternatives. Yet the questions remained: who should make the choices and how should they be made? Conflict of interest might become rampant. Decision-making by politicians was not appealing, since they were likely to put the prospect of re-election ahead of the public interest, and maybe even of human survival. Military forces protected the republic, but from the perspective of a legislator they also resembled pork. The military contractors in the private sector were just as problematic: profit rather than national interest usually dominated their incentive structures, even when on leave in government. Despite legislation that established a unified command under the Joint Chiefs of Staff, leaders of the separate forces still engaged in wasteful competition for resources and resisted cost-saving cooperation. When the warrior president Dwight Eisenhower echoed Erasmus and warned of the dangers from a rising ‘military–industrial complex’ there was an unassailable cause for concern.

So enter the economists. They announced that optimization subject to constraints was their specialty. Scarcity was their stock in trade. Pure reason was their method – and they were incorruptible. They accepted neither ideology nor any sentimental appeals to service loyalty or norms other than the public welfare. They were trained to look for rent seekers under every bed. Voters accepted the necessity of an adequate defence in the Cold War but they wanted as little of it as possible to get the job done, and they wanted it at the lowest cost. Economists made a plausible case that they were best equipped to get the job done that way.

A second reason for the rise to power of economists during the Cold War was their evident command of analytical techniques critical to the management of nuclear confrontation. The skills of the economist in minimizing the costs of defence were certainly comforting, but their avowed capacity to manage weapons of mass destruction was valued even more. The essential consideration was that if nuclear weapons were ever used again this would constitute profound policy failure. Bluff, restraint, and an absolute reluctance to engage simply had to be the main characteristics of nuclear policy. But surely these were not the characteristics that were ingrained in the professional soldier, who was trained to fight – precisely the action that could not be countenanced when the weapons employed would kill friend and foe alike? Indeed, the Cold War was the economist's war par excellence, fought at last with the condition wished for by Adam Smith 200 years before that the powerful nations of the world would reach a stage when conflict of any kind would be ‘irrational’ and the role of strategy was exclusively to arrange for war never to occur. Deterrence had to be on a massive scale and every step taken to see that there could not be a miscalculation. The first mistake could be fatal. The memory of Sarajevo, and world war by accident, was very vivid still. Economists made a strong case for their role in military strategy and operations because, above all, they seemed to recognize the absolute necessity of peace during the Cold
The third reason for the rise to prominence of economists in the Cold War, and for their fingers rather than those of more conventional warriors to be on the trigger, was the alternatives. In the post-war years an image emerged of high-placed military commanders that was deeply troubling; in important cases they seemed arrogant, vain, and sometimes out of control. As events unfolded and memoirs were published, Generals Patton, De Gaulle, MacArthur, Montgomery and others all appeared to be in varying degrees emotional prima donnas, insubordinate to civilian control. These men might be much beloved of their troops, and they might have tactical skills and ‘leadership qualities’ necessary to triumph in conventional battle, but could they be trusted with the ticket to Armageddon? Many voters said emphatically ‘No!’ Closer in time, by the 1950s, than the mythic warriors of the Second World War was General Curtis Lemay, chief of the United States Strategic Air Command, who talked of bombing the enemy back to the Stone Age. Worried citizens might be pardoned for wondering whether, if ever he took such action the enemy might not find the means to bring everyone else along with them. The fictional extrapolation of General Lemay, represented in the film Dr Strangelove, sent many a shiver down American spines. The Cuban missile crisis in 1962 also provided a real-life example of why the fate of the world should rest on cool heads and calculating minds. Rightly or wrongly, as early as the 1950s many inside and outside of government had concluded that military affairs had become too dangerous to be left to the military. But who else was there? The political leaders did not seem able to rise to the challenge. The brass might grumble at the prospect of military decision-making falling into the hands of bloodless civilians, but to others this location promised relief. Among the civilians the economists, appreciated now for their dispassion and detachment, seemed the most attractive candidates. In constructing policy toward Cuba the rumpled game theorist and Harvard professor Thomas Schelling (Nobel Prize 2005) seemed a much preferred alternative to Dr Strangelove. Economists entered the highest reaches of military strategy by several routes. After the National Security Act of 1948 in the United States provided for establishment of a National Security Council, economists began to take important positions on the Council staff. The Harvard economist Carl Kaysen became Deputy National Security Adviser in the Kennedy administration and Walt Rostow from the Massachusetts Institute of Technology (MIT) became National Security Adviser to President Johnson. Robert McNamara, Secretary of Defense under both Kennedy and Johnson, while not a professional economist himself had a high regard for the economist's approach. He set up a systems analysis unit in the Pentagon under the economist Alain Enthoven that was intended to carry the economist's way of thinking throughout the military. The RAND Corporation was an important Cold War resource with advice flowing at the highest levels from such well-known economists as Henry Rowen, James Schlesinger, Stephen Enke and Charles Wolf. The academic discipline of the time also contributed a galaxy of stars who served as consultants and informal advisors to various parts of the legislative and executive branches. Thomas Schelling, Charles Hitch, Roland McKean and Martin Shubik are only a few of the most prominent. None of these considered himself a specialist exclusively on war but rather a general economist who could turn his attention, and his tools, to the particular problems presented by war. The appointments of James Schlesinger as Secretary of Defense and director of the Central Intelligence Agency, both in 1973, signalled the zenith of economics in the US defence establishment. An intriguing characteristic of the economists involved with the Cold War was their unwillingness to hive off into a regularized subsection of the economics discipline, such as health or agricultural economics. Indeed, they often led a life of glamour and glory unknown to other economists before or
War and Economics: The New Palgrave Dictionary of Economics

They operated near the apex of power, were cleared at the highest level of security, and dealt directly with urgent matters of life and death to the nation. Moreover, they were compelled to become multidisciplinary if they were to operate effectively and to become part of the informal community that contained government officials of all kinds, business leaders, scientists, and members of the other disciplines concerned with war, including history, law, philosophy, political science, sociology and others. They had to keep abreast of arcane technological developments and new weapons, learn about treaties, and comprehend the relations of the armed forces with society. They became part of the field known as ‘strategic studies’ (served by the London-based International Institute of Strategic Studies), students of international relations, and regular contributors to the mass media. They might see more of leaders in other defence-related fields, such as Bernard Brodie, Alistair Buchan, Hedley Bull, Harold Brown, Richard Garwin and Albert Wohlstetter, than they did of their disciplinary kin.

While some economists rose to positions of great influence within the defence and foreign policy establishment during the Cold War, others became involved in what was known sometimes as peace and conflict studies, or peace science. Prominent economists in this movement included Kenneth Boulding and Walter Isard. Their focus was particularly on costs of defence, causes of conflict, arms races, and arms control and disarmament. Their influence seems to have been confined mainly to their own community.

The landmark study in the defence economics literature of the cold war is The Economics of Defense in the Nuclear Age (1960) by C.J. Hitch and Roland McKean. This work codified much that was known already, made original contributions itself and pointed to research opportunities ahead. Two directions into which other economists moved were towards an understanding of arms races, led by the pioneering work of Lewis Richardson (Arms and Insecurity, 1960), Walter Isard and others, and towards an appreciation of the impact of defence expenditures on economic growth, led by Emile Benoit's Defense and Economic Growth in Developing Countries (1973).

To many in the home discipline of economics the defence economists of the 1950s, 1960s and 1970s must have seemed a strange breed, dancing to a different drummer from those with whom they had studied in graduate school. In fact the circumstances of these defence economists have had few parallels in the history of the discipline, and they did not last for long. Perhaps the debacle in Vietnam and the wind-down of the Cold War explain their loss of influence. Or perhaps they were not well equipped for the challenges of the 1980s when the Reagan administration in the United States and the Thatcher government in Britain talked of defeating the enemy rather than avoiding conflict. Moreover, the warfare that loomed was embedded in ethnic, religious and historical grievances about which economists knew rather little.

Birth of a sub-discipline

As economists retreated from the pinnacle of power in the 1980s, down from cabinet and sub-cabinet positions to advisors, analysts and consultants, a new sub-discipline of ‘defence economics’ emerged. In the words of two of its founders it was concerned with such topics as ‘the analysis of alliance burden sharing, the effects of contract design on procurement, the impact of defence expenditures on economic growth, and the economic consequences of arms control treaties’ (Sandler and Hartley, 1995, p. 1). This new applied sub-discipline was comparable to the older agricultural and labour economics, and to such
newer ones as health and environmental economics. Defence economists adhered to the core theory accepted in the mother discipline, and they applied approved analytical tools to problems that were perceived to be susceptible to the economists’ methods. What distinguished these applied fields was knowledge of institutional facts in particular areas and some attention to policy issues prominent there. Sandler and Hartley, authors of a survey of the literature in the mid-1990s, described the field as follows: ‘Defence economics involves the application of economic reasoning and methods to the study of defence-related issues. Defence economics differs from other fields of economics in at least three ways: (1) the set of agents studied (e.g. defence contractors, branches of the military); (2) the institutional arrangements of the defence establishment (e.g. procurement procedures); and (3) the set of issues investigated’ (Sandler and Hartley, 1995, p. xi). They suggest that economists explore four ‘basic economic problems’: allocative efficiency, public choice considerations (why elected officials and bureaucrats behave the way they do), the distributive implications of defence decisions, and stability issues, including paths after shocks. A specialized journal, *Defense and Peace Economics*, was founded in 1990 to weld together two strands that during the cold war had gone in rather different directions. Sandler and Hartley recognize that recent events have shifted attention away from long-standing concentration on superpower confrontation to a variety of new issues such as the consequences of the break-up of the socialist world, the increased number of regional conflicts such as the Gulf War of 1991 and subsequent Iraq War that followed the relaxation of superpower hegemony, the proliferation of relatively inexpensive conventional weapons (some second-hand), the responsibilities of the arms exporters, the design of arms control treaties, and the macroeconomic implications of military downsizing. In the 1990s there was even talk of a peace dividend – an idea that seems merely poignant in the 21st century. Terrorism, guerilla warfare, the security implications of economic coalitions, and burden sharing within alliances remained topics on which economists found they had interesting things to say. Some issues, like procurement practices, are common to all parts of the public sector but receive disproportionate attention in defence economics because of the magnitude of defence expenditures. A textbook for an undergraduate course on ‘The Economics of War’ published in 2006 (Poast, 2006) lists aspects of international conflict that may be understood better using the economist’s tools: how to achieve mobilization or disarmament; the special problems presented by recruitment of a military labour force and weapons procurement; conflict in developing countries, the small-arms trade, peacekeeping; and the dilemmas of terrorism and the proliferation of the weapons of mass destruction in the 21st century.

John Maynard Keynes remarked in 1930 that he looked forward to the day when economists would be ‘thought of as humble, competent people, on a level with dentists’ (Keynes 1930, p. 332). It appears that in the 21st century economists concerned with the study of war have gained this status. It is now well accepted that war, like all human activity, requires the recognition of scarcity and the need to make choices based on forgone opportunities. This is the domain of economics. Defence economists stand ready to advise on these allocative decisions and to remind policymakers of the applicability of such concepts as externalities and public goods. The heroic years of defence economics are almost certainly gone for ever; the economists are today, as they say, on tap but not on top. Nevertheless, their usefulness remains, even if at a more modest level than before. The study of war is now an accepted part of economics, assigned to its own sub-field and dependent heavily on the tools and methods of public economics. In its current posture economics is less likely to find a cure for conflict than to make it more efficient and its prevention less costly. In a world full of shortages and sufferings this is no small task.
accomplishment.

Warburton, Clark (1896–1979)

L. Yeager

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

monetarism; monetary disequilibrium; quantity theory of money; real business cycles; Warburton, C.

Article

American economist; pioneer, before Milton Friedman, in research later labelled ‘monetarist’, and a critic of Keynesianism during the years when that doctrine was crowding out attention to money. Warburton was born on 27 January 1896 near Buffalo, New York, and died on 18 September 1979 in Fairfax, Virginia. After overseas military service during the First World War, he earned bachelor's and master's degrees from Cornell University. He published his 1932 Columbia Ph.D. dissertation as The Economic Results of Prohibition. He held teaching positions in India and the United States in the 1920s and early 1930s and worked at the Brookings Institution from 1932 to 1934, coauthoring America's Capacity to Consume. He then joined the newly organized Federal Deposit Insurance Corporation. Although routine FDIC work consumed much of his time (as his files reveal), he still managed to publish over 30 papers on monetary economics, most of them empirically oriented, from 1943 to 1953. Altered FDIC policy then impeded his research and publication until about 1962, when he took a brief leave to serve with the Banking and Currency Committee of the US House of Representatives. He was elected President of the Southern Economic Association for 1963–4. After retiring from the FDIC in 1965, he taught briefly at the University of California, Davis.

Warburton originally accepted a ‘real’ theory of the business cycle, but scrutiny of statistical and qualitative history changed his views. Using quarterly as well as annual data, he found that deviations from trend of the quantity of money generally preceded turning points in business conditions (and velocity deviations followed). While accepting a quantity-of-money theory of the price level in the long run, he recognized how elements of wage and price stickiness cause monetary disturbances to impinge on output first; he espoused a ‘monetary disequilibrium theory’ (which, despite its venerability, has ironically been mislabelled ‘Keynesian’ in recent years). He understood that disequilibrium does not necessarily imply irrational behaviour by individuals.

Warburton emphasized the role of money and inadequate monetary policy in the Great Depression of the

1930s. He continued to criticize the Federal Reserve for deficiencies in its economic theory and research and, in particular, for relying on interest rates in deciding and implementing policy. He believed that pure fiscal policy, unsupported by changes in the quantity of money, is ineffective as a tool of demand management. Sceptical of the authorities’ ability to fine-tune the economy, he recommended a policy of steady growth in the quantity of money at a moderate rate appropriate to trends in the labour force, productivity and velocity.

For Warburton, monetarism was an interpretation reached inductively, not a comprehensive ideology. (So far as any ideology came across in conversations, it was a rather conventional New Deal reformism or liberalism with humanitarian underpinnings.)

Nineteen of Warburton's papers dating from 1945 to 1953 are reprinted, along with a new introduction, in Depression, Inflation, and Monetary Policy (1966). Up to his death, Warburton pursued research not only in substantive economics but also in the history of monetary doctrines. These continuing interests are manifest in his last article (published posthumously in History of Political Economy, 1981) and in voluminous manuscripts now deposited in the library of George Mason University, Fairfax, Virginia. Plans exist for editing and publishing much of this material.

Warming, Jens (1873–1939)

P. Nørregaard Rasmussen
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
multiplier; Warming, J.

Article

Jens Warming was born on 9 December 1873 and died on 8 September 1939. After graduating in law, Warming took up economics. In 1919 he became Professor in Applied Statistics at the University of Copenhagen, following more informal attachments to the university. Along with his teaching he produced a number of books describing empirically a wide variety of aspects of the Danish economy. In a way he created the field ‘applied statistics’ as an academic discipline in Denmark. He not only presented figures, but he surrounded them with reasoning, sometimes naive and not very well articulated, often full of wisdom. One example is his warning of the danger of overfishing because no rent is collected (Warming, 1931b). Another most important example is his discovery of the multiplier process, which he presented as early as 1928 and again in 1929–30 and 1931. These important contributions in economic theory were quite often formulated in a somewhat odd way, and they certainly did not attract his fellow economists in Scandinavia.

Warming’s formulation of the multiplier runs as follows: assume a closed economy (an assumption he later modified) and consider an investment of, say, 100 units in a railway. This creates an income of equal size, part of it appearing as an increase in savings, but another part as consumption, that latter creating new incomes. This process, he argues, will go on until voluntary savings will increase, so that the newly-constructed railway ‘gets an owner’ (1929–30). This clearly means that the total voluntary savings in the end equal the impulse, that is, 100 units. An investment will ‘finance itself’, as he argued at length. However, it does not seem as if Warming was considering the multiplier as part of a more general theory of employment.

The original purpose of the term ‘Washington Consensus’ was to distinguish between a number of policies that remain the subject of partisan controversy and a group of policies that were thought to be consensual in the post-1989 world. After its creation in 1989 the term acquired at least two more meanings. Some used it to describe the policies of the IMF and World Bank, which came to embrace not only institutional reform and a concern with governance but also the two-corners solution for exchange rates and capital account convertibility. Others used the term as a synonym for laissez-faire.

The term ‘Washington Consensus’ was coined in 1989. The first written usage was in my background paper (Williamson, 1990) for a conference that the Institute for International Economics convened in order to examine the extent to which the old ideas of development economics that had governed Latin American economic policy since the 1950s were being swept aside by the set of ideas that had long been accepted as appropriate within the Organisation for Economic Co-operation and Development (OECD). In order to try to ensure that the country papers for that conference dealt with a common set of issues, I made a list of ten policies that I thought more or less everyone in Washington would agree were needed
more or less everywhere in Latin America, and labelled this the ‘Washington Consensus’. Little did it occur to me that 17 years later I would be asked to write about a term that had become the centre of fierce ideological controversy. On the contrary, I thought of the Washington Consensus as distinguishing between (a) what had become consensual and (b) what was likely to remain partisan, issues such as income distribution, capital account convertibility, the usefulness of incomes policy, the need to eliminate indexation, the size of the public sector, and the priority to be given to population control and environmental preservation.

The set of ‘consensual’ policies was:

1.  **Fiscal discipline.** This was in the context of a region where almost all the countries had run large deficits, which had led to balance of payments crises and high inflation that hit mainly the poor because the rich could park their money abroad.
2.  **Reordering public expenditure priorities.** This suggested switching expenditure in a pro-poor way, from things like indiscriminate subsidies to basic health and education.
3.  **Tax reform:** constructing a tax system that would combine a broad tax base with moderate marginal tax rates. This need not imply redistribution of income to the rich if the broadening of the tax base focuses on eliminating loopholes that are exploited by those who can afford to employ tax lawyers.
4.  **Liberalizing interest rates.** This was subsequently formulated in a broader way as financial liberalization, to cover also policies like bank privatization and allowing financial institutions to determine the allocation of credit.
5.  **A competitive exchange rate.** It was asserted (though this may not have been accurate reporting of the Washington scene) that there was a consensus in favour of ensuring that the exchange rate would be competitive.
6.  **Trade liberalization.** It was acknowledged that there was a difference of view about how fast trade should be liberalized, but it was asserted to be widely held that trade needed to be liberalized and countries stood to gain by outward-oriented policies.
7.  **Liberalization of inward foreign direct investment.** This specifically did not include comprehensive capital account liberalization, which did not command a consensus in Washington.
8.  **Privatization.** This was the one area in which what had originated as a neoliberal (Thatcherite) idea won broad acceptance. We have since been made very conscious that it matters a great deal how privatization is undertaken: it can be a highly corrupt process that transfers assets to a privileged elite for a fraction of their true value, but the evidence that it ultimately brings net benefits is quite strong.
9.  **Deregulation.** This focused specifically on easing barriers to entry and exit, not on abolishing regulations designed for safety or environmental reasons.
10.  **Property rights.** This was primarily about providing the informal sector with the ability to gain property rights at an acceptable cost.

The term ‘Washington Consensus’ proved controversial right from the start. Both reformers and critics took it to imply a belief that policy reforms had been imposed by Washington institutions like the International Monetary Fund (IMF) and the World Bank. The reformers resented the implication that
they had been following orders rather than implementing policies that they had concluded were needed in their countries. The critics took it as confirmation of their darkest fears. It might have been better if the revolution in economic policy for development had been called something else, but the fact that there was such a revolution is clear. In the 1960s mainstream development thinking held that inflation was at worst harmless and at best a method of extracting resources for investment. Orthodox thought advocated import-substituting industrialization rather than export expansion through globalization. Governments sought to expand the industrial sector by creating more state firms rather than by creating a market-friendly environment. All this changed in the late 1980s, perhaps aided by the collapse of the Communist alternative model, which was widely welcomed in Washington. That was what the Washington Consensus was about.

As time progressed the term came to mean at least three different things. Some people stuck to the original concept. Others used it to mean the evolving policies of the IMF and the World Bank, presumably on the ground that originally it had pretty much described the policies they advocated in 1989. Policy evolved importantly in at least four dimensions. First, in common with development thinking in general, Washington came to understand the importance of institutions in promoting development. Thus, first Naím (1994) and subsequently Burki and Perry (1998) and Kuczynski and Williamson (2003) argued that one needed to supplement the prescriptions of the Washington Consensus with institutional development. Second, the Washington institutions came to place a great emphasis on governance, especially on avoiding corruption. Third, in the IMF in particular opinion moved strongly away from the concern with a competitive exchange rate and the implication of the desirability of an intermediate regime toward the ‘two-corners solution’ (which argues that to avoid speculation one should have either a firmly fixed or a freely floating exchange rate, but nothing in between). Fourth, again especially in the IMF, there emerged a strong preference for rapid capital account liberalization. Some of those (like the author) who had been very attached to the original concept of the Washington Consensus found these last two doctrines alien.

The third concept of the term involved an even more radical change from the original, though this is the version that appears to have been widely used by critics. It refers to a programme often described as ‘neoliberal’ (a term that was at one time used to describe the agenda of the Mont Pèlerin Society, of which Milton Friedman and Friedrich von Hayek were prominent members). In addition to the items in the original list, the programme includes low taxes, a minimal state that denies having any responsibility for income distribution, either a currency board or freely floating exchange rates, and rapid liberalization of the capital account. It has even been suggested that the Washington Consensus implies a belief that all markets are perfectly competitive so that neoclassical economic analysis is literally true always and everywhere and government action is always a mistake (Stiglitz, 2006, p. 24). Despite the name, those who used the term in this way regarded it as unnecessary to establish that these attitudes characterized large parts of Washington. Personally I do not recall having met anyone in Washington who subscribes to these rather bizarre beliefs.

The most controversial elements of the Washington Consensus proved to concern microeconomic liberalization. Points 4 and 6–9 of my original list pointed in that direction, as did especially the last alternative interpretation of the phrase alluded to above. In the wake of the collapse of communism I overestimated the extent to which the desire for an active government role in managing the economy would be replaced by the acceptance of market mechanisms. The experience of East Asia was frequently invoked to question whether a commitment to laissez-faire had really been the key to the region's fast
growth. On the contrary, many critics of the Washington Consensus argued that the success of the East Asian countries was due to their governments having implemented industrial policies. This runs into the objection that at least one of the East Asian success stories (Hong Kong) had developed under the closest to a laissez-faire system that the world has ever seen. Why should one attribute the success of Korea and Taiwan to what distinguishes them from Hong Kong and to some extent Singapore rather than to what they have in common (for example, macro stability, high savings, export orientation, good education and an early demographic transition)? The old questions of market versus state, or even the merits of industrial policy, have not been settled by these arguments.

wavelets

James B. Ramsey
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Wavelets provide a flexible basis for representing a signal that can be regarded as a generalization of Fourier analysis to non-stationary processes, or as a filter bank that can represent complex functions that might include abrupt changes in functional form, or signals with time varying frequency and amplitude. Of greatest import for economic analysis is the orthogonal deconstruction of a signal into time scale components that allow economic relationships to be analysed time scale by time scale and then re-synthesized.

Article

Wavelets provide a powerful tool for analysis for economics and finance, as well as for scientists in a wide variety of fields, such as signal processing, medical imaging, data compression and geology. One interpretation of wavelets is that they are a collection of functions that provide a basis for the representation of test functions that may be complicated with localized shocks, have abrupt changes in functional form, or are signals with time varying frequency and amplitude. Another interpretation is that wavelets are a generalization of Fourier analysis in which stationarity of the time series is no longer critical and localization of a signal can be achieved. In this light, to borrow a great insight by Strang (see Strang and Nguyen, 1996), Fourier analysis is best at representing functions that are composed of linear combinations of stationary inputs, but wavelets are like musical notation in that each note is characterized by its frequency, its position in time, and its duration. A further interpretation of wavelets is that of a filter bank, so that different classes of wavelet functions are generated by prescribing different banks of filters. Filter banks can achieve results that are not possible with a single filter (Strang and Nguyen, 1996). Yet another interpretation is that of a decomposition of a signal in terms of different time scales, an interpretation that is at the heart of much economic analysis as represented by the long-standing notions of the 'short, medium and long runs' and is fundamental to the concept of the 'business cycle'.

At this time there is a vast literature on wavelets in mathematics, statistics, and various branches of engineering, but relatively little in economics, although that situation is changing fast. An introduction to the economic literature that is highly recommended is Gençay, Selçuk and Whitcher (2002). This is the most comprehensive and detailed coverage with numerous descriptions of economic applications and discussions of the statistical properties of the wavelet estimators. Bruce and Gao (1996) discuss the properties of wavelets and give instructions for calculating wavelets using S-Plus; Chui (1992), Percival and Walden (2000), and Strang and Nguyen (1996) develop the mathematics at a moderate level of difficulty and discuss the statistical properties of wavelets. Silverman and Vassilicos (1999) provide interesting examples of the applications of wavelets and further discussions of the statistical properties (see also Ramser, 1999a). Two lower-level introductions for economists are Crowley (2005) and Schleicher (2002).

Two informative examples

Let \( \mathbf{X} \) represent an \( N \) dimensional vector of observations on a time series or a function \( f(\cdot) \) evaluated at the discrete points \( t=1,2,\ldots,N \). One may consider an orthonormal transformation from \( \mathbf{X} \) to an \( N \) dimensional vector \( \mathbf{W} \), with elements, \( w_{ij} = x_i \), \( i=1,\ldots,N \), where \( \mathbf{W} \) is generated from an \( N \times N \) dimensional orthonormal matrix \( \mathbf{W} \): \( \mathbf{W} = \mathbf{W} \mathbf{X} \) and \( \mathbf{I}_N = \mathbf{W} \mathbf{W}^T \). Let \( N=2^J \) for some integer \( J \). This assumption, while inessential, is analytically convenient and is useful for defining an efficient algorithm for evaluating the wavelet coefficients. The \( N^2 \) elements of the transformation matrix \( \mathbf{W} \) are the filter elements to be defined below and the \( N \) elements of the vector \( \mathbf{W} \) are the wavelet coefficients that are given by the inner product \( \mathbf{W} \mathbf{X} \).

The wavelet defined here is known as the discrete wavelet transform (DWT). By choosing an orthonormal transform it is immediate that the modulus of \( \mathbf{W} \) is the same as that of \( \mathbf{X} \); that is, \( ||\mathbf{X}|| = ||\mathbf{W}|| \), where \( ||\mathbf{X}|| \) is given by \( \mathbf{X}^T \mathbf{X} = \sum x_i^2 \), and where \( x_i^2 \) is the energy contributed by the \( n \)th wavelet coefficient. The power of wavelet analysis lies in the choices made for the components of \( \mathbf{W} \). Two examples illustrate the choices that can be made and indicate the scope that a wavelet analysis offers. (I am indebted to Percival and Walden, 2000, for the examples to follow.) The first example is the oldest and simplest function used to generate a wavelet transformation. For the sake of simplicity of exposition, choose \( N=2^J=2^{16} = 65536 \). The notation, \( \mathbf{W}_{ksi} \), indicates the \( k \)th row of the matrix \( \mathbf{W} \), \( i=0,1,\ldots,N-1 \). The function used to generate the elements of \( \mathbf{W} \) for the DWT is the Haar function.

The unshifted filters are $\psi_0^T, \psi_1^{T}, \psi_2^T, \psi_3^T, \psi_4^T, \psi_5^T, \psi_6^T$. The remaining rows of $W$, are circularly shifted versions of the filter terms defined above. We have:

$$W_{1,0}^T = \{0, 0, 0, 0, 0, 0, 0, 0\} \quad W_{1,1}^T = \{0, 0, 0, 0, 0, 0, 0, 0\} \quad W_{1,2}^T = \{0, 0, 0, 0, 0, 0, 0, 0\} \quad W_{1,3}^T = \{0, 0, 0, 0, 0, 0, 0, 0\} \quad W_{1,4}^T = \{0, 0, 0, 0, 0, 0, 0, 0\} \quad W_{1,5}^T = \{0, 0, 0, 0, 0, 0, 0, 0\} \quad W_{1,6}^T = \{0, 0, 0, 0, 0, 0, 0, 0\}$$

The filter $\psi_{16}^T$ yields the 'scaling coefficient', and the remaining filters, $\psi_{11}^T, \psi_{12}^T, \psi_{13}^T, \psi_{14}^T, \psi_{15}^T$, yield the wavelet coefficients. From the above equations one sees that the Haar filters involve first differences between scale averages at non-overlapping intervals. At the lowest scale, $2^{-1}$ for $j=1$, the first differences are between adjacent observations, at the next scale level, $2^{-2}$ for $j=2$, the differences are between adjacent pairs of observations, at the scale $2^{-3}$ for $j=3$ the differences are between groups of four terms, and so on. At the highest scale, $J=4$, we have two filters of the data, a first difference between the first and last eight of the observations, and an average over the full set of observations. The latter is a 'father' wavelet transform and the remaining rows of $W$ are the 'mother' wavelet transforms.

In order to gain further insight, consider a Daubchies wavelet designated as D(4) (see Daubchies, 1992), which is a member of a sequence of discrete wavelet filters in which the Haar is D(2). Define $Y_t = aX_t + bX_{t-1}$ and form the backward second discrete difference, $\gamma_t^{(2)}$, by:

$$\gamma_t^{(2)} = \gamma_{t-1}^{(1)} - \gamma_{t-2}$$

For a particular choice of 'a' and 'b', the nth D(4) wavelet can be written as:

$$W_N = Y_{2n+1} - 2Y_{2n} + Y_{2n-1} = aX_{2n+1} + (2 - 2a)X_{2n} + (a - 2b)X_{2n-1} - h_0X_{2n+1} + h_1X_{2n} + h_2X_{2n-1} + h_3X_{2n-2}$$

Imposing orthonormality {and some other conditions to ensure uniqueness}, enables one to derive the values for $h_n$, $n=0, 1, 2, 3$, namely:

$$h_0 = \frac{1+\sqrt{3}}{4\sqrt{2}}, \quad h_1 = \frac{-3+\sqrt{3}}{4\sqrt{2}}, \quad h_2 = \frac{-3+\sqrt{3}}{4\sqrt{2}}, \quad h_3 = \frac{-1-\sqrt{3}}{4\sqrt{2}}$$

Repeating the exercise above with $N=2^4=16$ observations, we have:

$$w_{1,0}^T = \{h_1, h_0, 0, \ldots, 0, h_3, h_2\}, \quad w_{1,1}^T = \{h_3, h_2, h_1, h_0, 0, \ldots, 0, 1\}$$

where $w_{1,0}^T = T^2w_{0}^T$. orthonormality requires that $\|w_{0}^T\|^2 - h_0^2 + h_1^2 + h_2^2 + h_3^2 = 1$ and $\|w_{1,0}^T - w_{1,1}^T\| = h_0h_2 + h_1h_3 = 0$. $w_{1,0}^T$ applied to the time series yields the mean.

A wavelet filter of length $L$ must satisfy at a minimum for all nonzero integers $n$ the following conditions.
Wavelets and multiresolution analysis (MRA)

One can approach the definition of wavelets from a related perspective that indicates the similarities to and differences from Fourier transforms. In both cases, one is considering a projection of a signal onto a set of basis functions for the space containing the test function. In the case of the Fourier transform the basis functions are rescalings of the fundamental frequency, for example,

\[ e^{-i\omega_0 t} \]

where \( \omega_0 \) is the fundamental frequency and \( n \) provides the scaling. In this expression there is no resolution in the time domain, and the signal is assumed to be stationary. In contrast, the wavelet-generating functions are defined over very general spaces and each function is compact. One has the recursive relationship:

\[
\sum_{l=0}^{n-1} h_{l} y_{l+n+2} = \sum_{l=-\infty}^{\infty} h_{l} y_{l+n+2} = 0.
\]  (5)

For the Haar wavelet, \( D(2) \), and the Daubchies \( D(4) \) wavelet \( L \) is respectively 2 and 4.

where \( s \) indicates the scale of the function, \( k \) is the location index; the term \( \sqrt{s} \) ensures that the norm of \( g(\cdot) \) is 1. The projection of the signal onto the scalable function \( g(\cdot) \) depends on two parameters; \( s \), which defines the time scale and implicitly designates a relevant range of frequencies, and \( k \), which indicates the centre of location of the projection. The compactness of \( g(\cdot) \) together with the time index \( k \) implies that the analysis of a time series is essentially local at each scale, whereas the Fourier analysis is essentially global. There is considerable latitude in the choice of the function \( g(\cdot) \), or in the choice of the filters that generate the functions \( g(\cdot) \). Desirable criteria include symmetry, smoothness and orthogonality. Whether one begins by specifying the properties of a basis function \( g(\cdot) \) or one begins by specifying the properties of a filter \( \{ h_l \} \), the process generates two related classes of wavelet transforms, the ‘father’ wavelet that yields the ‘scaling’ coefficients and the ‘mother’ wavelets that yield the detail coefficients.

One can link the filter coefficients to the definition of the father and mother wavelets and link the father and mother transforms themselves by noting that, for a given sequence of low pass filter coefficients, \( l(k) \), and the corresponding high pass filter coefficients, \( h(k) \), one solves for \( \Phi(\cdot) \), father, and \( \psi(\cdot) \), mother, from:

\[
\Phi(t) = \sqrt{2} \sum_{k=0}^{N} l(k) \phi(2t - k)
\]  (7)

\[
\Psi(t) = \sqrt{2} \sum_{k=0}^{N} h(k) \phi(2t - k),
\]

For the Haar example above, the filter coefficients are:

\[
l(k) = \left\{ \frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2} \right\} \quad \text{and} \quad h(k) = \left\{ -\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2} \right\}
\]

From these equations, one derives the scaling, or ‘smooth’ coefficients and the wavelet or ‘detail’ coefficients of the function \( f(\cdot) \) by the integrals,
Wavelets: The New Palgrave Dictionary of Economics

where \( \Phi_{j,k} \) and \( \psi_{j,k} \) are the scaled and translated versions of \( \Phi \) and \( \psi \) defined in equation (7). The function \( f(t) \) can be synthesized by the equations:

\[
f(t) = \sum_{k} \hat{f}(k) \Phi_{j,k}(t) + \sum_{k} \hat{f}(k) \psi_{j,k}(t) \]

An easy way to visualize the above scale and locational decomposition of the signal is as a series of maps of ever greater detail as elements of \( D_{j} \) are added; \( S_{j} \) provides a smooth outline, \( D_{j} \) adds the highest scale detail; and the \( D_{j} \) add ever more detail as \( j \) decreases. One can approximate the function \( f(t) \) by truncating the expansion at some \( j \), \( 1 < j < J \). This is known as a multiresolution analysis (MRA), which can yield enormous data compression by representing the function \( f(t) \) with relatively few coefficients.

There are many choices for the basis function, or alternatively choices for the filter banks that provide a great deal of richness for the wavelet approach. Two generalizations of note are wavelet packets and an exploratory technique known as waveform dictionaries. The former analyses signals by basis functions that differ by location and scale as well as for wavelets, but also by an oscillation index; wavelet packets are most useful in representing time series that have short term, localized oscillations (Bruce and Gao, 1996). Waveform dictionaries (Mallat and Zhang, 1993) provide a modification to wavelet analysis. The basic function providing the basis is a function \( g(\cdot, \cdot) \) defined by:

\[
g_{j,k}(t) = \frac{1}{\sqrt{s}} g \left( \frac{t - u}{s} \right) \phi_{j,k}(t)
\]

where \( g_{j,k}(t) \) has its frequency energy centred at \( \omega \) and is proportional to \( 1/s \). The dictionary of functions \( g_{j,k}(t) \) illustrate a very important principle of these transforms. Improved resolution in the time domain reduces resolution in the frequency domain and vice versa; this is a version of the Heisenberg uncertainty principle.

Applications in economics and finance

All analytical procedures can be assessed on the basis of their contribution in four categories: provide estimators in novel situations; improve efficiency or reduce bias; enhance robustness to modelling errors; or provide new insights into the data-generating processes. Wavelets have provided benefits in all these categories.

One advantage of the waveform dictionary approach indicated in eq. (11) is that the researcher need not prejudge the presence of frequency components as well as the occurrence of short-term shocks. The process is exploratory and projection pursuit methods can be utilized to isolate local and global characteristics. Wavelet dictionaries have been used as an exploratory tool in the analysis of financial and foreign exchange data (Ramsey and Zhang, 1996; 1997). In the analysis of daily stock-price data and tic-by-tic exchange rate data, there was no strong structural evidence for any frequency, but there was weak evidence for frequencies that appeared and disappeared or that waxed and waned in strength. Most of the power was summarized in terms of time-localized bursts of activity. The results in both papers indicated that, while for any given time period surprisingly few wavelet coefficients were needed to fit the data, the relevant coefficients varied randomly from period to period. Each burst was characterized by a rapid increase in amplitude and fast oscillation in frequency; in short, market adjustment processes seem to be characterized by a rapid increase in oscillation amplitude and frequency followed by a decay in frequency and amplitude; adjustment is neither smooth nor fast.

For a deep analysis of the scaling properties of volatilities and the relationship between risk and time scales, see Gencay, Selcut, and Whitcher (2001; 2003). Another example in these references is the estimation of time varying Betas in the capital asset pricing model (CAPM). The analysis indicated that in the cases examined beta coefficients varied substantially over time, thereby modifying the structure of optimal investment strategies.

Wavelets have been instrumental in improving the robustness and efficiency of estimation in numerous examples (see Jensen, 1999; 2000) for efficiency gains and enhanced robustness of estimates for the fractional differencing parameter in long memory processes (see also Genay, Selcut, and Whitcher, 2002). This reference is also useful for examples of estimation of covariance matrices and providing confidence intervals.

Wavelets have been successfully employed in situations not amenable to standard approaches – for example, forming estimators in testing for serial correlation of unknown form in panel models. As Hong and Kao (2004) state in their abstract: ‘This paper proposes a new class of generally applicable wavelet-based tests for serial correlation of unknown form in the estimated residuals of a panel regression model, where error components can be one-way or two-way, individual and time effects can be fixed or random, and regressors may contain lagged dependent variables or deterministic/stochastic trending variables.’

Ramsey and Lampart (1998a; 1998b) discovered that the relationship between economic variables – for example, between money and income, or between consumption and income – can be decomposed into relationships at separate
scales with interesting implications for economic theory. The insights gained include reconciling a number of anomalies in the consumer and monetary theory literature as well as introducing the notion that observed time series are an aggregation of behavior at different time scales; for example, the time path of consumption totals represents the actions by consumers operating on a variety of time scales. In the same papers the authors also discovered that at certain time scales the relationship between economic variables may be subject to variations in the delay. These results have been confirmed by other researchers (for example, Gencay, Selcut, and Whitcher, 2002). For an alternative approach to testing for causality in the frequency domain using wavelets, see Dalkir (2004). Yet another insight provided by wavelet analysis is the distinction between ‘smoothing’ and denoising. The former, traditional in econometrics, is based on the assumption that the signal is smooth relative to the noise, whereas the latter allows for the signal to be as irregular as the noise, but with greater amplitude. For smooth signals subject to noise, the obvious approach in order to minimize the effect of the noise is to average in some manner. However, if the signal is not smooth, averaging is not a suitable approach in that the averaging process distorts the signal itself. One can claim that denoising is often more relevant to economic and financial analysis than is smoothing (see Ramsey, 2004). These remarks are particularly relevant in the context of estimating relationships involving regime shifts, threshold models, and other non-differential changes in variable values. In an important series of papers Donoho, Johnstone and coauthors explored the use of wavelets and the concept of shrinkage whereby the size of the wavelet coefficient estimates is reduced to allow for the presence of noise (see Donoho et al., 1995). Further, shrinkage can be applied differentially across scales thereby refining the technique (see Ramsey, 2004, for more recent references and Gencay, Selcut, and Whitcher, 2002, for a thorough development of wavelet denoising).

Forecasting is an important topic; see Fryzlewicz, van Bellegem and von Sachs (2002) and Li and Hinich (2002), who demonstrate how the wavelet approach disentangles the variation in forecastability over time scales; that is, the ability to forecast varies across time scales. At the simplest level a given time series can be decomposed into trend, business cycle and seasonal components by wavelets and individually structured forecasting methods applied to each component separately before synthesizing the entire signal in order to produce forecasts for the whole series (see Ramsey, 2004, for a brief review of the literature on forecasting using wavelets).

Wealth is a fundamental concept in economics – indeed, perhaps the conceptual starting point for the discipline. Despite its centrality, however, the concept of wealth has never been a matter of general consensus. Although wealth has not become a focus of heated controversy comparable to that of value (despite the fact that the two terms are inextricably conjoined, as we shall see), conceptions of wealth have clashed profoundly and even irreconcilably. The result has been a continuing discussion of deep importance for economics – not only for its intrinsic interest, but because it calls into question the very scope and content of the discipline itself.

At the root of the long history of disagreement about wealth lie two conflicting conceptions of what the word implies. One of these, far more ancient than the formal study of economics and still very much in general use, is the idea of wealth as tangible possessions. For over a century, however, this conception has been challenged by another, which has identified the nature of wealth in the pleasures or ‘utilities’ generated by tangible goods, rather than the goods themselves. In the differing implications arising from these ‘objective’ and ‘subjective’ conceptions of wealth lie consequences of great significance for a discipline that has traditionally considered itself to be concerned with the study of wealth.

The objective conception of wealth is as old as written history, but the economist has not been interested in records of slaves and land and gold, other than to remark (usually as an economic anthropologist) on the extraordinary variety of objects that have been utilized as embodiments of wealth. The analytic problem to which economists have been drawn has been the attempt to establish a common denominator in which to sum up the value represented by a heterogenous collection of objects. ‘The entire study of wealth is, indeed, meaningless unless there be a unit for measuring it;’ wrote J.B. Clark, ‘for the questions to be answered are quantitative. How great is the wealth of a nation?’ (Clark, 1899, p. 375).
In ordinary discourse, this common denominator has always been money, and we will later consider the cogency of this common sense rule. For the economist, however, the challenge has been to discover some metric less arbitrary and unstable than a monetary sum. Thus the idea of objective wealth becomes inextricably entwined with the need to discover a standard – an embodiment of ‘value’ – by which its extent can be calculated. In the late mercantilist period this measure of extent was conceived by Petty and Cantillon to be the ‘amounts’ of land and labour that entered into the production of things – a considerable advance over earlier ideas that gold and silver possessed intrinsic value. This dual standard was subsequently reduced by Adam Smith to labour alone. ‘It was not by gold or silver, but by labour that all the wealth of the world was originally purchased’, he wrote in *The Wealth of Nations*, ‘and its value, to those who possess it and who want to exchange it for some new productions, is precisely equal to the quantity of labour which it can enable them to purchase or command’ (Smith, 1776, p. 48).

The choice of an objective standard of wealth – in Smith's case the labour ‘commanded’ by goods – focused the discipline of economics on the processes by which these embodiments of wealth were amassed. By the 17th century, the rise of a market organization of trade and production had already brought to the fore the distinctively ‘economic’ problem of wealth – namely, the need to explain its accumulation as the outcome of impersonal processes rather than as the spoils of power. From Smith's Physiocratic predecessors through John Stuart Mill, the principal aim of political economy was accordingly to investigate the consequences of a competitive struggle for wealth, with respect both to its distribution among individuals and social classes, and to its effect on the development of the system as a whole.

Almost from the outset, however, the conception of wealth as an objective element in the economic process posed troublesome questions. One of these was the appropriate treatment of labour that produced services rather than tangible goods. Because services are flows, they cannot be included in wealth, if the latter is defined as a tangible stock. The difference, as Cassel explained, involves time: stocks are present in their entirety at a moment in time; flows require the passage of time (Cassel, 1918, p. 31). A second difficulty concerned the classification of different kinds of labour. Smith, for example, differentiated between productive and unproductive labour, calling ‘productive’ only the labour whose product could be sold to replenish the working capital of the manufacturer, and designating as ‘unproductive’ all services – ‘how honourable, how useful, or how necessary soever’ – because these activities consumed, but did not renew, the fund of circulating capital whence they derived their subsistence (Smith, 1776, p. 331).

In addition, Smith and Ricardo recognized that labour was itself a heterogenous rather that a simple ‘substance’, and that some means would have to be found to reduce its complexity to a uniform basis. Both consigned the solution of the problem to the workings of the market. This may have been adequate for a rough and ready explanation of wage differentials originally established by market considerations and subsequently perpetuated by social inertia, but it concealed the deeper problem of reducing a spectrum of labour skills to a common denominator of ‘simple’ labour without recourse to market forces – that is, to supply and demand.

Finally, as Marx was to point out, the classical economists did not perceive that labour was a concrete activity – the labour of Ricardo's deer hunter not being substitutable for that of his salmon fisherman – so that a level of ‘abstract’ labour had to be posited if labour was to serve as a universal equivalent, or measuring rod, for wealth. Although the full difficulty of reducing labour to its abstract essence escaped Marx himself, for all these reasons the concept of labour as a simple and self-evident metric became
wealth: The New Palgrave Dictionary of Economics

increasingly difficult to accept.

In accounting for the decline of the objective view of wealth, however, it is likely that the difficulties enumerated above did not play so important a role as another, quite separate, objection. This was the awareness that wealth as an objective entity did not express the attribute of goods that seemingly endowed them with desirability, namely their capacity to yield pleasure or utility to their possessors or beneficiaries. Oddly enough, we can also trace this view of wealth to Smith, who declared that ‘Every man is rich or poor according to the degree in which he can afford the necessaries, conveniencies, and amusements of human life’ (Smith 1776, p. 47).

It was Ricardo who first pointed out the inconsistency in Smith’s views, in that the subjective enjoyments yielded by wealth – its ‘riches’ – were not the same as the expenditure of labour power required for its creation – its ‘value’. Thus for Ricardo, two countries might be equally ‘rich’ in necessaries and conveniences, but the value of the riches of one would be larger than that of the second if they required more labour to produce (Ricardo, 1821, ch. 20).

Ricardo's distinction between riches and value marks a sharp distinction between subjective (enjoyment) and objective (embodiment) conceptions of wealth, but Ricardo himself did not pursue the analytic and conceptual horizons opened up by the subjective view. That was to be the work of the post-classical period, culminating in the marginalist ‘revolution’ of the 1870s. Although this episode is famous for its shift in the concept of value from labour to utility, it is apparent that this shift entailed an equally deep-seated and far-reaching change in the conception of wealth, and as a consequence, in the study of economics. The works of Gossen, Menger, Jevons and Walras – the pioneers in this redirection of economics – display considerable variations in their internal details but not in their underlying depiction of the task of economics. This was now seen as an examination of the conditions for the optimization of enjoyments (utilities), not for the maximization of tangible wealth (capital). Thus Jevons wrote in The Theory of Political Economy, ‘The problem of economics may, as it seems to me, be stated thus: Given, a certain population, with various needs and powers of production, in possession of certain lands and other sources of material: required, the mode of employing their labour which will maximize the utility of the produce’ (Jevons, 1871, p. 254, original in italics).

A striking consequence of this shift was the necessary divorce of economics from any quantitative estimation of the extent of wealth. Utility in the post-classical sense was not the same as the ‘use-values’ that had always been recognized by Smith or Ricardo or Marx as the prerequisites of exchangeability. Their use-values referred to objective attributes of goods – the hardness of diamonds, the softness of cloth – from which was derived the capacity of commodities to yield subjective satisfactions. The utilities of the marginalists, on the other hand, referred exclusively to the states of mind induced by the possession or use of objects. Unlike use-values, therefore, utilities were subject to continual, possibly radical shifts, induced by changes in tastes or income or the relative scarcities of objects – in all cases, changes in the relation between possessors and objects, and not changes in the physical character of the goods themselves.

From this perspective, utility therefore had no objective existence whatsoever. ‘We can never say absolutely that some objects have utility and others have not’, Jevons wrote; and following in that line, Robbins declared in The Nature and Significance of Economic Science (1932, p. 47) that ‘wealth is not wealth because of its substantial qualities. It is wealth because it is scarce’.

The emphasis on the psychological element of wealth and on the role of scarcity in conferring desirability to goods clarified many questions, for example the ancient water–diamonds paradox.
addition the utility approach appeared to resolve the problem of valuation at a level of greater generality than labour. It could be used, for example, to explain exchange value in the case of goods that required little or no labour, such as Ricardo's ‘rare statues and pictures’, within the same analytic framework as in the case of goods in which labour constituted a major element of cost. Thus the rise of a subjective orientation to wealth and value – we can by now surely appreciate their inextricable association – seemed an immense liberation to economists who had struggled within the constraints of an objective theory of wealth and value, whether exclusively denominated in labour or not.

The new orientation was not, however, without its problems. In so far as marginal utility is normally a direct function of scarcity, its adoption as the metric of wealth entailed the awkward conclusion that wealth as a sum of enjoyments and conveniences might well increase as a consequence of the diminution of material abundance. Some of the marginalists accepted this result; others, such as Menger, called it only an ‘apparent’ paradox, on the grounds that the continual augmentation of goods would gradually remove them from the category of ‘economic’ goods, thereby excluding them from consideration as wealth (Menger, 1871, 111). This seems a question-begging resolution. In addition, the replacement of an objective by a subjective standard of wealth led to the even more awkward conclusion that the aggregation of the wealth of individuals was impossible on the same grounds as the aggregation of their feelings or experiences. It was such considerations that led Robbins to declare in his influential essay mentioned above that ‘in any rigid determination of Economics, the term wealth should be avoided’ (Robbins, 1932, p. 47n).

All attempts to define wealth have therefore led to difficulties and even paradoxes. The conceptual and mensurational problems of an objective approach denominated in labour have been equalled, perhaps even surpassed, by those of a subjective approach denominated in utilities. Notwithstanding Robbins's reservations, however, economists have not abandoned the use of wealth as a fundamental constitutive element of economics, nor have they given up attempts to measure it. Here we can trace the general line of development once more to Adam Smith, this time to his famous abandonment of the category of labour as the measuring rod of value and his substitution of a cost of production measure which simply added up the income flows – wages, rents and profits – accruing to the three major classes. From Ricardo on, Smith has been accused of circularity or inconsistency in this choice of an ‘adding-up’ approach to value, in which no attempt was made to discover a common denominator of wealth. But as a practical solution to the problem of measuring a concept that was universally regarded as real and important, whatever its intrinsic difficulties, Smith's approach was not without merit. The cost of production, or adding-up, approach to national wealth provided a common sense basis for the representation of national power or collective well-being, regardless of the unexamined problems behind these representations.

At all events, in modern times the measurement of wealth has become a major preoccupation for virtually all advanced nations. In *The Statistical Abstract of the United States*, for example, we find time series of various stocks and flows that have been selected as being of particular significance for the measurement of national wealth. The stocks include such items as estimates of financial and real assets, business and residential capital, consumers’ stocks of durables, land and selected government assets; while the flows concentrate on gross national product and its components. These items have been selected partly on the basis of the availability of data and partly on the basis of their importance for national economic policy. They are neither a complete nor a consistent set of accounts, a number of important stocks and flows being absent, such as the stock of human capital, or the flow of unpaid
labour in household work. The method of valuing both stocks and flows also differs from the public to the private sector, since the standard valuation is that of ‘market values’, which cannot apply to public goods or services. This is not the place to discuss the problems of national accounting, but it is worth noting that the same standard of practicality is applied as we find in Adam Smith, as well as the same absence of any firm conceptual foundation.

There remains another aspect to the concept of wealth. It is expressed with his usual vigour by John Bates Clark in *The Distribution of Wealth*: ‘Amounts of wealth are usually stated in money … The thought in the minds of men who use money as a standard of value runs forward to the power that resides in the coins. The intuitions that are at the basis of this popular mode of speech are nearer to absolute truth than much of economic analysis. They discern a power of things over men …’ (1908, p. 376).

The aspect of wealth to which Clark directs attention is once more anticipated by Smith, who writes, ‘Wealth, as Mr. Hobbes says, is power … the power of purchasing; a certain command over all the labour, or over all the produce of labour which is then in the market’ (Smith, 1776, p. 48). This definition contains an insight of great significance. To the extent that wealth is a form of power, its inadequate denomination in terms of labour commanded or utilities generated becomes explicable by virtue of the inapplicability of either metric to the ‘substance’ in which power must be measured. What might that substance be? Smith and other early investigators of the nature of wealth-seeking society assumed it to be the expression of a universal desire to be admired. ‘The rich man glories in his riches, because he feels that they naturally draw upon him the attention of the world … and he is fonder of his wealth, upon this account, than for all the other advantages it procures him’, Smith wrote in *The Theory of Moral Sentiments* (1759, pp. 50–1).

What was unknown to Smith, or to others, like Senior, who followed his general lead in the psychology of wealth, is that prestige and wealth do not seem to be universally conjoined. Contemporary anthropologists emphasize that wealth differs in a crucial respect from prestige in that the defining characteristic of wealth is its ability to confer social power on its possessors, whereas the enjoyment of prestige carries no such intrinsic rights. As a consequence, we find that in primitive societies, where there is universal access to the resources needed for subsistence, wealth does not exist as a social category, in that no individual or group enjoys command over the labour or the product of others, save for the claims conferred by relations of kinship or communal obligation (Sahlins, 1972; Fried, 1967). From the anthropological viewpoint, then, primitive societies enjoy Ricardian riches, but no Smithian or Marxian value. From this vantage point, ‘wealth’ ceases to appear as an eternal attribute of human society, whether as tangible goods or the utilities enjoyed by their beneficiaries. Rather, the crucial element in the conception of wealth, and in the constitution of economics as its study, lies in the historical advent of the institution of property, construed as the right to exclude others from the material or other resources to which legal title has been gained. From this perspective, the fundamental problem posed by wealth is that of tracing the evolution of the social stratification characteristic of all post-primitive societies. Wealth is the economic face of that political stratification, lodged in the hands of a class whose ability to grant or deny access to resources becomes the ‘economic’ basis for both prestige and power.

Article

German economist and cultural sociologist, born 30 July 1868 in Erfurt; died 2 May 1958 in Heidelberg. He studied in Berlin and was Privatdozent there 1900–1904, Professor in Prague 1904–7 and in Heidelberg from 1907 until his death, interrupted by voluntary retirement between 1933 and 1945. Weber's *Reine Theorie des Standorts* (1909) established him as the leading location theorist since Von Thünen, although his theoretical model has been anticipated by Wilhelm Launhardt (1882). Weber's interest in the location of the emerging modern industries arose from his earlier study of home industries, their struggle for survival, and the resulting social conditions of those working under the putting out system. Only Part I was published, an intended empirical Part II never appeared. Under Alfred Weber's guidance several theses were written on particular industries. Alfred Weber's article in the *Grundriss der Sozialoekonomik*, Part VI (1922) is a restatement of his book.

After the First World War, Weber turned to ‘cultural sociology as cultural history’ (1935). This work, while overshadowed by that of his more famous brother, Max (1864–1920), and lacking its precision, provides a fresh perspective of the development of Western civilization.

Alfred Weber, although not an impressive speaker, was a highly influential teacher. Together with Karl Jaspers he re-established academic traditions of excellence at the University of Heidelberg in the post-Second World War years.

The location of industries according to Weber is governed by cost minimization. When production costs are independent of location, this means the minimization of transportation costs. In the case of two resource deposits and one market, the optimal location may fall inside the triangle spanned by the three given locations. Economies of joint location, based on the exchange of intermediate goods or the joint use of indivisible facilities induce ‘agglomeration’ of industrial activities in large centres.

Max Weber was one of the leading historical political economists in the Germany of the 1890s. Weber's early work in political economy reflected the distinctive concerns of a younger generation of the Historical School, which sought to demonstrate the theoretical character of the concepts used in historical economics and the historical presuppositions of theory. Over time, Weber's research became increasingly wide-ranging and theoretical, involving an elucidation of the character of Western rationalism as applied to the basic structures of economy and society, and reflecting a shift in his disciplinary focus of interest from political economy to sociology.

Article

Max Weber was born in 1864 at Erfurt and died in 1920 at Munich. After early studies in the history of commercial law, he established himself as one of the leading figures in a new generation of historical political economists in the Germany of the 1890s. He was appointed to chairs in political economy at Freiburg in 1894 and at Heidelberg in 1896. A nervous breakdown commencing in 1898 led to his withdrawal from academic teaching, but did little to impair the flow of his writing. In 1904 he took over the editorship of the *Archiv für Sozialwissenschaft und Sozialpolitik*, the leading academic journal in ‘social economics’, devoted to the exploration of the interrelationship between economy on the one hand, and law, politics and culture on the other. This interconnection formed the main site of Weber's own research, whose focus became increasingly wide-ranging and theoretical, involving an elucidation

of the character and presuppositions of modern Western rationalism, as applied to the basic structures of economy and society. Weber was also actively and often controversially involved in the political issues of Wilhelmine Germany, from a progressive national-liberal standpoint, and during the war was one of the leading polemists for a democratization of the constitution. Such involvement gave particular sharpness to his discussions of social science methodology, the role of value judgements and the relation between academic analysis and political practice. It was only comparatively late in his life that he came to think of his work as ‘sociology’, though it is as one of the ‘founding fathers’ of sociology that he is now known. He resumed full-time teaching activity as professor at Munich in 1919 only shortly before his death.

Weber's early work in political economy can best be understood as reflecting the distinctive concerns of a younger generation of the Historical School (including Schulze-Gävernitz, Sombart, Max and Alfred Weber). At the methodological level they sought to resolve the controversy between the theoretical and historical schools by demonstrating the theoretical character of the concepts used in historical economics on the one hand, and the historical presuppositions of theory on the other. An important element in this resolution was to secure the acceptability of the Marxian concept of ‘capitalism’ as a valid concept for economic analysis, despite the untenability (as they saw it) of the labour theory of value, and exaggerated claims made for the materialist conception of history.

The recognition of the conflict between labour and capital as a systemic property of capitalism was central to Weber's early work. In his study of the impact of capitalist organization on the agricultural estates east of the Elbe, it supported his conclusion that class conflict had permanently undermined the economic basis of Junker political dominance in the Reich (Weber, 1892). From it he also derived a position on social policy which was critical of the paternalism of the ‘Kathedersozialisten’, arguing instead that trades unions should be given a secure legal status so that they could bargain for themselves on a more equal footing with capital. The distinctive Weberian conception of class conflict under capitalism was theorized neither in the Marxist terms of ‘exploitation’ nor in the neoclassical terms of ‘factor demand’, but in terms of a systematic competition for the social product on the basis of a power relation between the classes that was adjusted and underwritten at the political level.

If the incorporation of Marxian insights into the mainstream of social economics required that the analysis of class conflict be freed from the doctrine of surplus value, it also required a critique of the one-sided assumptions of historical materialism. This Weber offered in his most famous study The Protestant Ethic and the Spirit of Capitalism (1904). The argument of this work was that the profit-maximizing behaviour so characteristic of the bourgeoisie, which could be explained under fully developed capitalist conditions by its sheer necessity to survival in the face of competition, could not be so explained under the earlier phases of capitalist development. It was the product of an autonomous impulse to accumulate far beyond the needs of personal consumption, an impulse which was historically unique. Weber traced its source to the ‘worldly asceticism’ of reformed Christianity, with its twin imperatives to methodical work as the chief duty of life, and to the limited enjoyment of its product. The unintended consequence of this ethic, which was enforced by the social and psychological pressures on the believer to prove (but not earn) his salvation, was the accumulation of capital for investment. Early critics of Weber’s thesis misunderstood it as a purely cultural explanation for capitalism, as if ‘a Siberian Baptist or a Calvinist inhabitant of the Sahara’ must inevitably become a successful entrepreneur. Weber was in fact well aware both of the material preconditions for capitalist development, and of the social interests that are needed to support the dissemination of new ideas. The
crucial question about his thesis is whether the employment of wage labour that made unlimited accumulation possible in principle, also made it inevitable in practice; whether, that is, the Protestant ethic should be seen as providing a necessary motivation for capitalist accumulation, or rather a legitimation for it in the face of prevalent values favouring conspicuous consumption on the part of a leisured class. Weber himself saw it as both. His work is the most sophisticated in a long tradition of exploration of the cultural preconditions for capitalist accumulation, from Adam Smith's celebration of ‘parsimony’, to recent explanations of Britain's economic decline in terms of the gentrification of its entrepreneurial spirit.

At one level the ‘Protestant ethic thesis’ can thus be read as a critique of historical materialism, with its explanation of capitalist development as the necessary outcome of the feudal order, rather than as the result of a unique conjunction of favourable historical conditions, cultural and political as well as economic. At another level it can be read as an extended critique of the ahistorical theorizing of Carl Menger and the Austrian school. In Weber's view the methodical, calculating, welfare-maximizing behaviour of the neoclassical models was not a universal characteristic of human rationality as such, but a product of modern Western rationalism. His subsequent studies of the economic ethic of the major world religions (Confucianism, Hinduism, Buddhism, ancient Judaism; collected in Weber, 1921) were designed to elucidate this distinctive cultural complex. They showed that, while instrumental rationality was a universal category of social action, only in the modern West had the goal-maximizing calculation of the most efficient means to given ends become generalized. And while other cultures had attempted to make the world intelligible through the development of elaborate theodicies, or to create internally consistent systems of ethics or law, the distinctive features of Western rationalism were the scientific assumption that all things could be comprehended by reason, together with the attitude of practical mastery which sought to subject the world to human control rather than merely adjust oneself to it. In Weber's major unfinished theoretical work, *Economy and Society* (1922), capitalism was shown to be simply one expression, rather than the unique locus, of this ‘rationalization’ process. The work is structured around the antithesis between ‘traditional’ and ‘rationalized’ forms of action and organization in all spheres of social life, and the transition between the two provides the key to the Weberian theory of modernization.

The conclusion of Weber's mature work, that capitalism was to be understood as part of a wider ‘rationalization’ process, coincided with his analysis of its most advanced forms in contemporary Germany. According to this analysis, the distinctive feature of capitalist concentration was the change in its internal mode of organization: the adoption of a complex technical division of labour and a hierarchical structure of administration that increasingly resembled the bureaucratic type already established in the political sphere. For Weber, the bureaucratic model of administration was becoming generalized throughout all sectors of contemporary society, because of its efficiency in performing complex organizational tasks. Along with it went the emergence of a new middle class, whose distinctive position in the class structure depended neither on property ownership (capital) nor its absence (labour), but on the possession of technical and organizational skills, and on its authority position within a bureaucratic hierarchy.

Some commentators have seen Weber as an early forerunner of the ‘managerial revolution’ thesis. Certainly he was among the earliest to identify technical knowledge and organization as crucial sources of social power in modern societies. But to Weber no manager could be a substitute for the risk-taking entrepreneur who stood at the head of large capitalist organizations. The bureaucratic system, with its
secure career and promotion prospects, represented a conservative principle in social life, in contrast to the dynamic principle of the market. Like his junior colleague, Joseph Schumpeter, Weber saw the major source of economic innovation to be provided by the captains of industry, ready to chance their judgement in the competition of the market place. This was directly paralleled in the political sphere by his theory of competitive leadership democracy, according to which the leaders of mass parties with their bureaucratic machines competed for support in the electoral market place. If the creative force of individualism, deriving from the Protestant ethic, had itself unintentionally produced the age of organization, in which competition at the individual level was eliminated, nevertheless the role of individualism was reasserted in Weberian social theory at the head of organizations, in the form of ‘charismatic’ leadership.

Weber's theory of bureaucracy also provided the basis for a thoroughgoing critique of socialist planning, as prefigured in the wartime German economy. Weber was quick to echo von Mises's contention that a coherent system of allocation was impossible without market indicators, since it confirmed his own historical analysis of the preconditions for rational economic calculation. However, his distinctive criticisms of socialist planning derived from the massive extension of bureaucratic coordination he believed it would entail. Without market competition, he argued, the economy would simply stagnate. Yet the workers would remain subordinate to the same hierarchy of authority at the work place, since this was determined by the technical requirements of production, not by the particular system of ownership. Indeed, their subordination would become a new form of slavery, since the separate hierarchies of the economic, legal and political spheres would be fused into a single, all-embracing structure of power. It was the dictatorship of the official, he concluded, not of the worker, that was on the march (Weber, 1918).

Overall, the progressive widening in the focus of Weber's theoretical concerns, from the conditions for economic rationality to the general theme of ‘rationalization’, and the subsumption of capitalism itself into the wider category of bureaucratic organization, reflected a shift in his disciplinary focus of interest from political economy to sociology. This was not just a personal development of Weber's, but one typical of the period in which he lived. With the narrowing of theoretical focus represented by neoclassical economics, it was left to the nascent discipline of sociology to take over some of the wider concerns of political economy. The rich tradition of the German Historical School, and the methodological debates which it had aroused, made German sociology particularly well placed for this enterprise. It was also particularly urgent in a country where the claims of Marxism to provide a convincing overall theory of society were widely accepted within the labour movement. It was no accident, therefore, that the most sustained rebuttal of these claims should come from the same context. As suggested above, however, Weber's approach to Marxism was not one of outright rejection, but of incorporating its insights into a different theoretical framework which left the validity of private property ownership intact. If the general presuppositions of liberalism had been thematized in the form of political philosophy in the 18th century, and of political economy in the 19th, they can be said to have received their distinctive 20th-century expression in the form of Weberian sociology.

Weintraub was born in Brooklyn, New York, on 28 April 1914 and died in Philadelphia, Pennsylvania, on 19 June 1983. Professor at the University of Pennsylvania from 1950 until his death, Weintraub was widely known as the originator (with Henry Wallich) of tax-based incomes policy (TIP); his professional reputation is based on his early criticism (1959b) of the ‘neoclassical synthesis’ of Keynes's macroeconomics and Walrasian general equilibrium and his own highly original attempts to produce a microeconomics compatible with Keynes's macroeconomic theory.

A postgraduate year (1938–9) at the London School of Economics convinced him of the implications of Keynes's *General Theory* for price theory. His Ph.D. dissertation (‘Monopoly and the Economic System’, St Johns, 1941) and a series of articles on the formulation of demand in conditions of imperfect competition and imperfect information produced his innovative *Price Theory* (1949).

After the war, Weintraub concentrated on producing a micro-theory compatible with Keynes's theory of the endogenous determination of the equilibrium level of output at less than full employment. His earlier work was extended to the demand for labour and the microfoundations of the aggregate demand and supply curves. Although this work, summarized in *An Approach to the Theory of Income Distribution* (1958), reached similar conclusions to the aggregate distribution theories then being worked out by Kaldor and Robinson, its inspiration was the formulation of a ‘Keynesian’ microeconomics rather than growth theory.

Evidence of the stability of the markup of prices over wage costs presented in *A General Theory of the Price Level* (1959a) led to a ‘watchtower approach’ to wage policy which preceded the widely discussed, but never applied, TIP proposal (1971a; 1971b).

Weintraub's prolific writing and lecturing activities were complemented in 1978 by the founding and editing (with Paul Davidson) of *The Journal of Post Keynesian Economics*.

welfare costs of business cycles

Ayse Imrohoroglu
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The welfare cost of business cycles measures the benefits that would be obtained by individuals from eliminating all the macroeconomic instability in a given economy. In a seminal paper, Lucas (1985) argued that these benefits are almost certain to be trivially small, especially when they are compared with the benefits that can be achieved with more growth for the post-war US economy.

Keywords

business cycles; Great Depression; National Bureau of Economic Research; risk aversion; stabilization policy; unemployment insurance; welfare cost of business cycles

Article

The welfare cost of business cycles measures the benefits in terms of additional consumption that would be obtained by individuals from eliminating all the macroeconomic instability in a given economy. Hodrick and Prescott (1997) and Lucas (1977) define business cycles as recurrent fluctuations of output about trend and the co-movements among other aggregate time series. These fluctuations are typically represented as expansions and recessions in economic activity. The National Bureau of Economic Research, a private non-profit organization that is responsible for updating the business cycle chronology, defines a recession as ‘a significant decline in economic activity spread across the economy, lasting more than a few months, normally visible in real gross domestic product (GDP), real income, employment, industrial production, and wholesale-retail sales’ (NBER, 2003, p. 1). One of the prevailing views in macroeconomics is that business cycles are welfare reducing and governments should try to stabilize the economy by using fiscal or monetary policies.

In his seminal work, Lucas (1985) proposes a simple framework to think about how to compute the cost of economic instability, and challenges the paradigm that business cycles have large welfare costs. His measure of the welfare cost for the United States turns out to be trivially small, which disputes the need
Lucas proposes that in order to understand the welfare cost of instability we need to start with the preferences of a hypothetical consumer who is faced with a sequence of consumption goods over time labelled \( \{c_t\} \). The expected utility of such a sequence can be calculated by,

\[
E\left\{ \sum_{t=0}^{\infty} \beta^t \frac{1}{1-\sigma} (c_t^{1-\sigma} - 1) \right\}
\]

where \( U(c_t) = (c_t^{1-\sigma} - 1) / (1 - \sigma) \) is the period utility function, \( E \) is the expectations operator, \( \beta \) is the subjective discount factor and \( \sigma > 0 \) is the coefficient of relative risk aversion. An important property of this utility function is that consumers would prefer smooth consumption streams to fluctuating ones or that they would prefer a deterministic consumption path to a risky path with the same mean.

In this construct, in order to understand how consumers may feel about economic instability, we can simply ask them to evaluate their lifetime utility under two different scenarios. In particular, suppose the consumers are asked to compare the lifetime utility of a perfectly smooth consumption path with a consumption stream that increases in good times and decreases in bad times while maintaining the same average level over time. The latter consumption stream is the one that results in the case of business cycles. Surely, consumers who care about smoothing consumption over time will rank the utility generated by such a stream lower than the one from the smooth consumption stream. In fact, the higher the value of \( \sigma \), the lower the utility of a fluctuating consumption stream will be. With this in mind we can ask a second question. What would it cost to compensate all individuals in terms of extra consumption, uniform across time and different shocks, so that they will be indifferent between the smooth and the fluctuating consumption paths? This turns out to be a fairly easy calculation where the following equation provides a quantitative answer:

\[
\lambda = \frac{1}{2} \sigma \mu^2
\]

where \( \lambda \) is the compensation parameter, \( \sigma \) is the coefficient of relative risk aversion and \( \mu \) measures the standard deviation in consumption.

Our hypothetical example can be made concrete by examining the properties of personal expenditures on consumption in a particular economy. Lucas (2003) uses US data for the period 1947–2001 and calculates the standard deviation of the log of real per capita consumption about the linear trend to be 0.032. Using this estimate, we can arrive at several measures of the cost of instability based on different assumptions on the coefficient of relative risk aversion. The amazing part of the findings is that the...
The magnitude of these estimates range between one 20th of one per cent to one or two tenths of a per cent of consumption for risk aversion parameters between one and four. (Risk aversion coefficients in this range are considered to be consistent with many observations in an economy. However, much higher values are needed for some other observations such as the equity premium, which is discussed shortly.) For example, if $\sigma = 2$ and $\nu = 0.032$, then the consumption compensation that is required to make an individual indifferent between a fluctuating versus a constant consumption stream is about 0.001. For the US economy that would suggest that an annual consumption compensation as low as $28.96 per person would be sufficient to make individuals indifferent between a fluctuating and a smooth consumption stream. (Personal consumption expenditures in the United States in 2004 were $8.6 trillion. One-tenth of a per cent results in a total consumption compensation of $8.6 billion. Using the 2004 population of 297 million people results in consumption compensation per person of $28.96.) Such a welfare cost is negligible not only in an absolute sense but also when compared with other welfare cost measures. For example, Lucas (2000) calculates the welfare loss of a one per cent reduction in the growth rate of the economy to be as high as 20 per cent of consumption and the welfare cost of ten per cent inflation to be one per cent of income annually. Both of these estimates are more than an order of magnitude higher than the welfare cost of economic instability.

Lucas proposes to take the low cost findings seriously as giving a range of estimates for the size of the potential gains from developing policies that would eliminate fluctuations in the United States. Taking these results seriously is exactly what the profession did. Twenty years after Lucas's (1985) study, many economists continue to work on this subject, investigating whether the conclusions reached in his framework are valid under more complicated and sometimes more realistic frameworks. Many of the assumptions in the original framework have been challenged. One of the main assumptions is that all agents are identical and have access to fully developed capital markets. One can easily imagine that, while the costs of instability may be low for some consumers, such as those with large savings, they may be devastating for some others, who may not have the means to insure themselves against these shocks. Several papers have investigated the welfare costs of instability for heterogeneous agents with limited access to capital markets. (Starting with Imrohoroglu, 1989, papers that have introduced incomplete markets and examined the role of idiosyncratic risk include Atkeson and Phelan, 1994; Gomes, Greenwood and Rebelo, 2001; Krusell and Smith, 1999; 2002; and Krebs, 2003.) Krusell and Smith (1999) examine an economy with substantial heterogeneity where individuals face idiosyncratic and aggregate risk and can smooth their consumption only through private savings. Their economy generates a wealth distribution that resembles US wealth distribution reasonably well. They investigate whether the welfare costs of cycles may be very high for some members of the society such as the unemployed even if in aggregate the costs are relatively low. Their findings indicate that while the welfare effects of eliminating cycles do differ across consumers they are extremely small for almost all consumers. Only for a very few individuals with almost zero consumption are welfare losses found to be as high as two per cent of average consumption.

Some of the papers in this area have highlighted the importance of understanding the interaction between aggregate and individual shocks in an economy. For example, how long-lasting are the effects of a bad shock? Do aggregate shocks compound the effects of individual shocks? Storesletten, Telmer and Yaron (2001) show that, in an environment where small aggregate shocks can have a long-lasting impact on individuals’ earnings, the welfare cost of business cycles can be much higher than the original.
estimates. (Beaudry and Pages, 2001, also study idiosyncratic wage risk that worsens in recessions, and obtain high estimates. However, they do not allow for savings to help smooth consumption in the economy with fluctuations.) Atkeson and Phelan (1994), on the other hand, discuss the connection between aggregate and idiosyncratic risk, and suggest as a serious possibility that the elimination of aggregate risk does not affect individual risk at all. In their framework welfare cost estimates are close to zero. However, if the effects of a bad shock are assumed to be permanent, as in Krebs (2003), then the welfare costs of business cycles can be as high as 7.5 per cent of consumption. In such a framework, even if credit markets are perfect, individuals will not borrow to smooth the negative shocks they face since the effect of those shocks will persist for ever.

Another set of papers have introduced different preferences or have implicitly or explicitly used higher risk-aversion coefficients in examining the welfare cost of business cycles. While higher costs are obtained in some of these environments, there are questions about the soundness of using very high risk-aversion coefficients. For example, Tallarini (2000) finds much larger costs in a model with Epstein–Zin type preferences where preference parameters are chosen to be consistent with observed asset market data. However, the main factor behind this finding is the use of a high risk-aversion parameter to be consistent with asset price determination. (Similarly, Alvarez and Jermann, 2004, find large welfare costs of economic instability in a framework that uses high risk aversion to match the six per cent equity premium in asset markets. See also Dolmas, 1998; Obstfeld, 1994.) Otrok (2001), on the other hand, suggests that in a model that allows for potential time-non-separabilities in preferences, which is calibrated to be consistent with observed fluctuations in a general equilibrium model of business cycles, the welfare cost of business cycles turns out to be quite low.

It might also be possible to obtain a higher cost of fluctuations if there are links between economic growth and fluctuations. For example, Ramey and Ramey (1995) demonstrate a strong negative relationship between volatility and growth in a panel of 92 countries. However, in examining the welfare cost of instability, Epaulard and Pommeret (2003) find the volatility in the US economy to be too small to generate large benefits from stabilization policies even if reductions in volatility induce growth. Jones, Manuelli and Stacchetti (1999) demonstrate that the relationship between volatility in fundamentals and mean growth can be positive or negative. Their quantitative results indicate that the size of this effect is not large enough to generate large welfare costs of instability. Barlevy (2004a), on the other hand, proposes a set-up where eliminating fluctuations reallocates investment from periods of high investment to periods of low investment. This mechanism results in achieving higher growth rates without necessarily requiring higher investment levels. In such a framework, he finds the welfare cost of instability to be substantially higher than in the original Lucas estimates. The key to obtaining such large costs in his model is the presence of diminishing returns to investment, for which there is some, but not overwhelming, evidence.

It may be important to point out that the way Lucas, and Hodrick and Prescott have defined business cycles, namely, as fluctuations around a trend, has an important implication for the welfare cost calculations. If instead recessions were viewed as inefficient declines in output, as in the Keynesian view, and stabilization policies were seen as policies that would prevent economic activity from falling below its maximum potential, then the welfare cost measure could be higher. This is the case in DeLong, and Summers (1988) and Cohen (2000), who obtain welfare costs of stabilization of around 1.6 per cent and one per cent respectively. In their frameworks stabilization increases the average level of
It is important to stress that the estimates that have been discussed so far have been for the post-war US economy. The low cost estimate that is obtained in many of these papers is partly due to the relative stability of the US economy since the 1950s. Welfare costs of business cycles are higher in economies that are faced with larger fluctuations in consumption. Using the volatility of consumption in the United States prior to the Second World War, or the fluctuations in consumption that are observed in many developing countries, results in significantly higher welfare cost measures (see, for example, Pallage and Robe, 2003). In addition, in the post-war period the US economy had a well-developed unemployment insurance system that may have helped reduce the volatility in consumption. Economies with less-developed welfare systems also yield higher welfare costs of instability. (Chatterjee and Corbae, 2007, find that the potential benefit of reducing the likelihood of economic crises such as a Great Depression-style collapse of economic activity can range between 1.05 and 6.59 per cent of annual consumption. They also find that uninsured unemployment risk contributes significantly to the size of these gains.) Although there is still some debate over the size of the welfare costs of business cycles, the weight of the evidence seem to suggest that they may not be too high for the US economy. (See also Barlevy, 2004b, for a survey of the literature on the welfare cost of business cycles.)

Abstract

Welfare economics attempts to define and measure the ‘welfare’ of society as a whole. It tries to identify which economic policies lead to optimal outcomes, and, where necessary, to choose among multiple optima. This article answers three fundamental qsts with three fundamental theorems. In a competitive economy, will an equilibrium outcome be optimal? Can any optimal outcome be achieved by a modified market mechanism? Is there a reliable way to measure social welfare, or to derive the preferences of society from the preferences of individuals? The negative answer to the third question is partly overcome by the theory of implementation.

Article

In 1776, the same year as the American Declaration of Independence, Adam Smith published *The Wealth of Nations*. Smith laid out an argument that is now familiar to all economics students: *(a)* the principal human motive is self-interest; *(b)* the invisible hand of competition automatically transforms the self-interest of many into the common good; *(c)* therefore, the best government policy for the growth
of a nation's wealth is that policy which governs least.
Smith's arguments were at the time directed against the mercantilists, who promoted active government intervention in the economy, particularly in regard to (ill-conceived) trade policies. Since his time, his arguments have been used and reused by proponents of laissez-faire throughout the 19th and 20th centuries. Arguments of Smith and his opponents are still very much alive today: the pro-Smithians are those who place their faith in the market, who maintain that the provision of goods and services in society ought to be done, by and large, by private buyers and sellers acting in competition with each other. One can see the spirit of Adam Smith in economic policies involving deregulation, tax reduction, denationalizing industries, and reduction in government growth in Western countries; and in the deliberate restoration of private markets in China, the former Soviet Union and other eastern European countries. The anti-Smithians are also still alive and well; mercantilists are now called industrial policy advocates, and there are intellectuals and policymakers who believe that: (a) economic planning is superior to laissez-faire; (b) markets are often monopolized in the absence of government intervention, crippling the invisible hand of competition; (c) even if markets are competitive, the existence of external effects, public goods, information asymmetries and other market failures ensure that laissez-faire will not bring about the common good; (d) and in any case, laissez-faire may produce an intolerable degree of inequality.
The branch of economics called welfare economics is an outgrowth of the fundamental debate that can be traced back to Adam Smith, if not before. It is the economic theory of measuring and promoting social welfare.
This entry is largely organized around three propositions. The first answers this qst: in an economy with competitive buyers and sellers, will the outcome be for the common good? The second addresses the issue of distributional equity, and answers this qst: in an economy where distributional decisions are made by an enlightened sovereign, can the common good be achieved by a slightly modified market mechanism, or must the market be abandoned? The third focuses on the general issue of defining social welfare, or the common good, whether via the market, via a centralized political process, or via a voting process. It answers this qst: does there exist a reliable way to derive the true interests of society, regarding, for example, alternative distributions of income or wealth, from the preferences of individuals?
This entry focuses on theoretical welfare economics. There are related topics in practical welfare economics which are only mentioned here. A reader interested in the practical problems of evaluating policy alternatives can refer to entries on consumer surplus, cost–benefit analysis and compensation principle, to name a few.

The first fundamental theorem, or, laissez-faire leads to the common good

‘The greatest meliorator of the world is selfish, huckstering trade.’ (R.W. Emerson, Work and Days)

In The Wealth of Nations, Book IV, Smith wrote: ‘Every individual necessarily labours to render the annual revenue of the society as great as he can. He generally indeed neither intends to promote the public interest, nor knows how much he is promoting it…. He intends only his own gain, and he is in
this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention." The first fundamental theorem of welfare economics can be traced back to these words of Smith. Like much of modern economic theory, the first theorem is set in the context of a Walrasian general equilibrium model, developed almost a hundred years after *The Wealth of Nations*. Since Smith wrote long before the modern mathematical language of economics was invented, he never rigorously stated, let alone proved, any version of the first theorem. That was first done by Lerner (1934), Lange (1942) and Arrow (1951).

To establish the first theorem, we need to sketch a general equilibrium model of an economy. Assume all individuals and firms in the economy are price takers: none is big enough, or motivated enough, to act like a monopolist. Assume each individual chooses his consumption bundle to maximize his utility subject to his budget constraint. Assume each firm chooses its production vector, or input–output vector, to maximize its profits subject to some production constraint. Note that we assume self-interest, or the absence of externalities: an individual cares only about his own utility, which depends only on his own consumption. A firm cares only about its own profits, which depend only on its own production vector. The invisible hand of competition acts through prices; they contain the information about desire and scarcity that coordinate actions of self-interested agents. In the general equilibrium model, prices adjust to bring about equilibrium in the market for each and every good. That is, prices adjust until supply equals demand. When that has occurred, and all individuals and firms are maximizing utilities and profits, respectively, we have a competitive equilibrium.

The first theorem establishes that a competitive equilibrium is for the common good. But how is the common good defined? The traditional definition looks to a measure of total value of goods and services produced in the economy. In Smith, the ‘annual revenue of the society’ is maximized. In Pigou (1920), following Smith, the ‘free play of self-interest’ leads to the greatest ‘national dividend’.

However, the modern interpretation of ‘common good’ typically involves Pareto optimality, rather than maximized gross national product. When ultimate consumers appear in the model, a situation is said to be Pareto optimal if there is no feasible alternative that makes everyone better off. Pareto optimality is thus a dominance concept based on comparisons of vectors of utilities. It rejects the notion that utilities of different individuals can be compared, or that utilities of different individuals can be summed up and two alternative situations compared by looking at summed utilities. When ultimate consumers do not appear in the model, as in the pure production framework to be described below, a situation is said to be Pareto optimal if there is no alternative that results in the production of more of some output, or the use of less of some input, all else equal. Obviously saying that a situation is Pareto optimal is not the same as saying it maximizes GNP, or that it is best in some unique sense. There are generally many Pareto optima. However, optimality is a common good concept that can get common assent: No one would argue that society should settle for a situation that is not optimal, because if A is not optimal, there exists a B that all prefer.

In spite of the multiplicity of optima in a general equilibrium model, most states are non-optimal. If the economy were a dart board and consumption and production decisions were made by throwing darts, the chance of hitting an optimum would be zero. Therefore, to say that the market mechanism leads an economy to an optimal outcome is to say a lot. And now we can turn to a modern formulation of the first theorem:

*First fundamental theorem of welfare economics:* Assume that all individuals and firms are self-interested price takers. Then a competitive equilibrium is Pareto optimal.
To illustrate the theorem, we focus on one simple version of it, set in a pure production economy. For a general version of the theorem, with both production and exchange, the reader can refer to Mas-Colell, Whinston and Green (1995).

In a general equilibrium production economy model, there are $K$ firms and $m$ goods, but, for simplicity, no consumers. We write $k = 1, 2, ..., K$ for the firms, and $j = 1, 2, ..., m$ for the goods. Given a list of market prices, each firm chooses a feasible input–output vector $y_k$ so as to maximize its profits. We adopt the usual sign convention for a firm's input–output vector $y_k$: $y_{kj} < 0$ means firm $k$ is a net user of good $j$, and $y_{kj} > 0$ means firm $k$ is a net producer of good $j$. When we add the amounts of good $j$ over all the firms, $\sum y_{kj}$, we get the aggregate net amount of good $j$ produced in the economy, if positive, and an aggregate net amount of good $j$ used, if negative. What is feasible for firm $k$ is defined by some fixed production possibility set $Y_k$. Under the sign convention on the input–output vector, if $p$ is a vector of prices, firm $k$'s profits are given by

$$\pi_k = p \cdot y_k$$

A list of feasible input–output vectors $\mathcal{V} = (V_1, V_2, ..., V_K)$ is called a production plan for the economy. A competitive equilibrium is a production plan $\hat{\mathcal{V}}$ and a price vector $p$ such that, for every $k$, $\hat{V}_k$ maximizes $\pi_k$ subject to $y_k$'s being feasible. (Since the production model abstracts from the ultimate consumers of outputs and providers of inputs, the supply equals demand requirement for an equilibrium is moot.)

If $\mathcal{V} = (V_1, V_2, ..., V_K)$ and $\mathcal{Z} = (Z_1, Z_2, ..., Z_K)$ are alternative production plans for the economy, $\mathcal{Z}$ is said to dominate $\mathcal{V}$ if the following vector inequality holds:

$$\sum_k Z_k \succeq \sum_k V_k$$

The production plan $\mathcal{V}$ is said to be Pareto optimal if there is other production plan that dominates it. (Note that for two vectors $a$ and $b$, $a \succeq b$ means $a_j \geq b_j$ for every good $j$, with the strict inequality holding for at least one good.)

We now have the apparatus to state and prove the first theorem in the context of the pure production model:

**First fundamental theorem of welfare economics, production version:** Assume that all prices are positive, and that $\hat{\mathcal{V}}$, $p$ is a competitive equilibrium. Then $\hat{\mathcal{V}}$ is Pareto optimal.

To see why, suppose to the contrary that a competitive equilibrium production plan $\hat{\mathcal{V}} = (\hat{V}_1, \hat{V}_2, ..., \hat{V}_K)$ is not optimal. Then there exists a production plan $\mathcal{Z} = (Z_1, Z_2, ..., Z_K)$ that dominates it. Therefore
Taking the dot product of both sides with the positive price vector $p$ gives

$$p \cdot \sum_k z_k > p \cdot \sum_k \hat{y}_k.$$

But this implies that, for at least one firm $k$,

$$p \cdot z_k > p \cdot \hat{y}_k,$$

which contradicts the assumption that $\hat{y}_k$ maximizes firm $k$'s profits. Q.E.D.

First fundamental theorem drawbacks, and the second fundamental th

The first theorem of welfare economics is mathematically true but nevertheless open to objections. Here are the commonest.

First, the theorem is an abstraction that ignores the facts. Preferences of consumers are not given, they are created by advertising. The real economy is never in equilibrium, most markets are characterized by excess supply or excess demand, and are in a constant state of flux. The economy is dynamic, tastes and technology are constantly changing, whereas the model assumes they are fixed. The cast of characters in the real economy is constantly changing, the model assumes it fixed.

Second, the theorem assumes competitive behaviour, whereas the real world is full of monopoly and market power.

Third, the theorem assumes there are no externalities. In fact, if in an exchange economy person 1's utility depends on person 2's consumption as well as his own, the theorem does not hold. Similarly, if in a production economy firm $k$'s production possibility set depends on the production vector of some other firm, the theorem breaks down. In a similar vein, the theorem assumes there are no public goods, that is, goods like national defence, judicial systems or lighthouses, that are necessarily non-exclusive in use. If such goods are privately provided (as they would be in a completely laissez-faire economy), then their level of production will be suboptimal.

Fourth, the theorem ignores distribution. Laissez-faire may produce a Pareto optimal outcome, but there are many different Pareto optima, and some are fairer than others. Some people are endowed with
resources that make them extremely rich, while others, through no fault of their own, are extremely poor. The first and second objections to the first theorem are beyond the scope of this article. The third, regarding externalities and public goods, is one that economists have always acknowledged. The standard remedies for these market failures involve various modifications of the market mechanism, including Pigouvian taxes (Pigou, 1920) on harmful externalities, or appropriate Coasian legal entitlements to, for example, clean air (Coase, 1960).

The important contribution of Pigou is set in a partial equilibrium framework, in which the costs and benefits of a negative externality can be measured in money terms. Suppose that a factory produces gadgets to sell at some market-determined price, and suppose that, as part of its production process, the factory emits smoke which damages another factory located downwind. In order to maximize its profits, the upwind factory will expand its output until its marginal cost equals price. But each additional gadget it produces causes harm to the downwind factory – the marginal external cost of its activity. If the factory manager ignores that marginal external cost, he will create a situation that is non-optimal in the sense that the aggregate net value of both firms’ production decisions will not be as great as it could be. That is, what Pigou calls ‘social net product’ will not be maximized, although ‘trade net product’ for the polluting firm will be. Pigou's remedy was for the state to eliminate the divergence between trade and social net product by imposing appropriate taxes (or, in the case of beneficial externalities, bounties). The Pigouvian tax would be set equal to marginal external cost, and with it in place the gap between the polluting firm's view of cost and society's view would be closed. Optimality would be re-established.

Coase's contribution was to emphasize the reciprocal nature of externalities and to suggest remedies based on common law doctrines. In his view the polluter damages the pollutee only because of their proximity; for example, the smoking factory harms the other only if it happens to locate close downwind. Coase rejects the notion that the state must step in and tax the polluter. The common law of nuisance can be used instead. If the law provides a clear right for the upwind factory to emit smoke, the downwind factory can contract with the upwind factory to reduce its output, and if there are no impediments to bargaining, the two firms acting together will negotiate an optimal outcome. Alternatively, if the law establishes a clear right for the downwind factory to recover for smoke damages, it will collect external costs from the polluter, and thereby motivate the polluter to reduce its output to the optimal level. In short, a legal system that grants clear rights to the air to either the polluter or pollutee will set the stage for an optimal outcome, provided that bargaining is costless. If bargaining is costly, then the law should be designed with an eye towards minimizing social costs created by the externality.

With respect to public goods, since Samuelson (1954) derived formal optimality conditions for their provision, the issue has received much attention from economists; one especially notable theoretical question has to do with discovering the strengths of people's preferences for a public good. If the government supplies a public judicial system, for instance, how much should it spend on it (and tax for it)? At least since Samuelson, it has been known that financing schemes like those proposed by Lindahl (1919), where an individual's tax is set equal to his marginal benefit, provide perverse incentives for people to misrepresent their preferences. Schemes that are immune to such misrepresentations (in certain circumstances) have been developed (Clarke, 1971; Groves and Loeb, 1975).

But it is the fourth objection to the first theorem that may be most fundamental. What about distribution? There are two polar approaches to rectifying the distributional inequities of laissez-faire. The first is the
command economy approach: a central bureaucracy makes detailed decisions about the consumption decisions of all individuals and production decisions of all producers. The main theoretical problem with the command approach is that it fails to create appropriate incentives for individuals and firms. On the empirical side, the experience of the late Soviet and Maoist command economies establish that highly centralized economic decision making leaves much to be desired, to put it mildly.

The second polar approach to solving distribution problems is to transfer income or purchasing power among individuals, and then to let the market work. The only kind of purchasing power transfer that does not cause incentive-related losses is the lump-sum money transfer. Enter at this point the standard remedy for distribution problems, as put forward by market-oriented economists, and our second major theorem.

The second fundamental theorem of welfare economics establishes that the market mechanism, modified by the addition of lump-sum transfers, can achieve virtually any desired optimal distribution. Under more stringent conditions than are necessary for the first theorem, including assumptions regarding quasi-concavity of utility functions and convexity of production possibility sets, the second theorem gives the following:

*Second fundamental theorem of welfare economics:* Assume that all individuals and producers are self-interested price takers. Then almost any Pareto optimal equilibrium can be achieved via the competitive mechanism, provided appropriate lump-sum taxes and transfers are imposed on individuals and firms. One version of the second theorem, restricted to a pure production economy, is particularly relevant to an old debate about the feasibility of socialism; see particularly Lange and Taylor (1939) and Lerner (1944). Anti-socialists including von Mises (1922) argued that informational problems would make it impossible to coordinate production in a socialist economy; while pro-socialists, particularly Lange, argued that those problems could be overcome by a central planning board, which limited its role to merely announcing a price vector. This was called 'decentralized socialism'. Given the prices, managers of production units would act like their capitalist counterparts; in essence, they would maximize profits. By choosing the price vectors appropriately, the central planning board could achieve any optimal production plan it wished.

In terms of the production model given above, the production version of the second theorem is as follows:

*Second fundamental theorem of welfare economics, production version:* Let \( \hat{y} \) be any optimal production plan for the economy. Then there exists a price vector \( p \) such that \( \hat{y}, p \) is a competitive equilibrium. That is, for every \( k \), \( \hat{y}_k \) maximizes \( \pi_k = p \cdot y_k \) subject to \( y_k \) being feasible.

The proof of the second theorem will not be presented here.

**Adjusting the economy and voting**

We rarely choose between a laissez-faire economy and a command economy. Our choices are almost always more modest. When choosing among alternative tax policies, or trade and tariff policies, or development policies, or anti-monopoly policies, or labour policies, or transfer policies, what shall guide the choice? The applied welfare economist's advice is usually based on some notion of increasing total output in the economy. The practical political decision, in a democracy, is normally based on voting.
Applied welfare economics

The applied welfare economist usually focuses on ways to increase total output, ‘the size of the pie’, or at least to measure changes in the size of the pie. Unfortunately, theory suggests that the pie cannot be easily measured. This is so for a number of reasons. To start, any measure of total output is a scalar, that is, a single number. If the number is found by adding up utility levels for different individuals, illegitimate interpersonal utility comparisons are being made. If the number is found by adding up the values of aggregate net outputs of all goods, there is an index number problem. The value of a production plan will depend on the price vector at which it is evaluated. But, in a general equilibrium context, the price vector will depend on the aggregate net output vector, which will in turn depend on the distribution of ownership or wealth among individuals.

An early and crucial contribution to the analysis of whether or not the economic pie has increased in size was made by Kaldor (1939, p. 550), who argued that the repeal of the Corn Laws in England could be justified on the grounds that the winners might in theory compensate the losers: ‘it is quite sufficient [for the economist] to show that even if all those who suffer as a result are fully compensated for their loss, the rest of the community will still be better off than before’. Unfortunately, Scitovsky (1941) quickly pointed out that Kaldor's compensation criterion (as well as one proposed around the same time by Hicks) was inconsistent. Consider a move from situation A to situation B. It is possible to judge B Kaldor superior to A (the move is an improvement) and simultaneously judge A Kaldor superior to B (the move back would also be an improvement). This Scitovsky paradox can be avoided via a two-edged compensation test, according to which B is judged better than A if (a) the potential gainers in the move from A to B could compensate the potential losers, and still remain better off, and (b) the potential losers could not bribe the gainers to forgo the move.

However, while Scitovsky's two-edged criterion has some logical appeal, it still has a major drawback: it ignores distribution. Therefore, it can make no judgement about alternative distributions of the same size pie. Even worse, both the Kaldor and the Scitovsky criteria would approve of a change that makes the wealthiest man in society richer by $1 billion, while making each of the million poorest people worse off by $999. This is a judgement that many people would reject as wrong or immoral.

Another important tool for measuring changes in economic welfare is the concept of consumer's surplus, which Marshall (1920, book 3, ch. 6) defined as the difference between what an individual would be willing to pay for an object, at most, and what he actually does pay. With a little faith, the economic analyst can measure aggregate consumers’ surplus (note the new position of the apostrophe) by calculating an area under a demand curve, and this is in fact commonly done in order to evaluate changes in economic policy. The applied welfare economist attempts to judge whether the pie would grow in a move from A to B by examining the change in consumers’ surplus (plus profits, if they enter the analysis). Some faith is required because consumers’ surplus, like the Kaldor criterion, is theoretically inconsistent; see for example Boadway (1974).

Under certain circumstances, however, consumers’ surplus inconsistencies can be ruled out. In particular, if individual utility functions are all quasilinear, of the form \( u_j(x_i) = v_j(x_{i_1, j \neq m}) + x_{im} \), then consumers’ surplus paradoxes disappear. (Here \( u_j(x_i) \) is person i's utility, as a function of his consumption bundle \( x_i = (x_{i1}, x_{i2}, \ldots, x_{im}) \), and the utility function can be separated into two parts, the first one of which is a function \( v_j(\cdot) \) which depends on quantities of all the goods except the mth, and the
Voting

In many cases, interesting decisions about economic policies are made either by government bureaucracies that are controlled by legislative bodies, or by legislative bodies themselves, or by elected executives: in short, either directly or indirectly, by voting. The second theorem itself raises qsts about distribution that many would view as essentially political. How should society choose the Pareto-optimal allocation of goods that is to be reached via the modified competitive mechanism? How should the distribution of income be chosen? How can the best distribution of income be chosen from among many Pareto optimal ones? Majority rule is a commonly used method of choice in a democracy, both for political choices and economic ones, and we now turn our attention to it.

The practical objections to voting, the fraud, the deception, the accidents of weather, are well known. To quote Boss Tweed, the infamous 19th century chief of New York's Tammany Hall: ‘As long as I count the votes, what are you going to do about it?’ We will examine the theoretical problems.

The central theoretical problem with majority voting has been known since the time of Condorcet's *Essai sur l'application de l'analyse à la probabilité des décisions rendues à la pluralité des voix*, published in 1785: Voting may be logically inconsistent. The now standard Condorcet voting paradox assumes three individuals 1, 2 and 3, and three alternatives \(x\), \(y\) and \(z\), where the three voters have the following preferences:

<table>
<thead>
<tr>
<th>Voter</th>
<th>Preference</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>(x) (y) (z)</td>
</tr>
<tr>
<td>2</td>
<td>(y) (z) (x)</td>
</tr>
<tr>
<td>3</td>
<td>(z) (x) (y)</td>
</tr>
</tbody>
</table>

(Following an individual's number the alternatives are listed in his order of preference, from left to right.) Majority voting between pairs of alternatives will reveal that \(x\) beats \(y\), \(y\) beats \(z\), and, paradoxically, \(z\) beats \(x\).

It is now clear that such voting cycles are not peculiar; they are generic, particularly when the alternatives have a spatial aspect with two or more dimensions (Plott, 1967; Kramer, 1973). This can be illustrated by taking the alternatives to be different distributions of one economic pie. Suppose, in other words, that the distributional issues raised by the first and second theorems are to be ‘solved’ by majority voting, and assume for simplicity that what is to be divided is a fixed total of wealth, say 100 units.
Now let $x$ be 50 units for person 1, 30 units for person 2 and 20 units for person 3. That is, let $x = (50, 20, 30)$. Similarly, let $y = (30, 50, 20)$ and $z = (20, 30, 50)$. The result is that our three individuals have precisely the voting paradox preferences. Nor is this result contrived, it turns out that all the distributions of 100 units of wealth are connected by endless voting cycles (see McKelvey, 1976).

The reader can easily confirm that for any distributions $u$ and $v$, that he may choose, there exists a voting sequence from $u$ to $v$, and another back from $v$ to $u$!

The reality of voting cycles should give pause to the economist who recommends legislation about economic choices, especially choices among alternative distributions of income or wealth.

**Social welfare and the third fundamental theorem**

How then can economic choices be made; how, for example, might the distribution problem be solved? One potential answer is to assert the existence of a Bergson (1938) economic welfare function $E(\cdot)$, that depends on the amounts of non-labour factors of production employed by each producing unit, the amounts of labour supplied by each individual, and the amounts of produced goods consumed by each individual. Then solve the problem by maximizing $E(\cdot)$. If necessary conditions for Pareto optimality are derived that must hold for any $E(\cdot)$, this exercise is harmless enough; but if a particular $E(\cdot)$ is assumed and distributional implications are derived from it, then an objection can be raised: why that Bergson function $E(\cdot)$, and not a different one?

At first, in his modestly titled ‘A Difficulty in the Concept of Social Welfare’ (1950), and later, in his classic monograph *Social Choice and Individual Values* (1963), Kenneth Arrow brought together both the economic and political streams of thought sketched above. Arrow’s theorem can be viewed in several ways: it is a statement about the distributional qsts raised by the first and second theorems; it is an extension of the Condorcet voting paradox; it is a statement about the logic of voting; and it is a statement about the logic of Bergson welfare functions, compensation tests, consumers’ surplus tests, and indeed all the tools of the applied welfare economist. Because of its central importance, Arrow’s theorem can be justifiably called the third fundamental theorem of welfare economics.

Arrow’s analysis is at a high level of abstraction, and requires some additional model building. From this point onward we assume a given set of at least three distinct alternatives, which might be allocations in an exchange economy, distributions of wealth, tax bills in a legislature, or candidates in an election. The alternatives are written $x$, $y$, $z$ and so on. We assume a fixed society of individuals, numbered 1, 2, …, $n$.

Let $R_i$ represent the preference relation of individual $i$, so $xR_i y$ means person $i$ likes $x$ as well as or better than $y$. (Strict preference is shown with a $P_i$, and indifference with a $I_i$.) A preference profile for society is a specification of preferences for each and every individual, or symbolically, $R = (R_1, R_2, \ldots, R_n)$. We write $R_S$ for society’s preference relation, arrived at in a way yet to be specified.

Arrow was concerned with the logic of how individual preferences are transformed into social preferences. That is, how is $R_S$ found? Symbolically we can represent the transformation this way:

$$R_1, R_2, \ldots, R_n \rightarrow R_S.$$
Now if society is to make decisions regarding things like distributions of wealth, it must ‘know’ when one alternative is as good as or better than another, even if both are Pareto optimal. To ensure it can make such decisions, Arrow requires that $R_S$ be complete. That is, for any alternatives $x$ and $y$, either $xR_SY$ or $yR_SX$ (or both, if society is indifferent between the two). If society is to avoid the illogic of voting cycles, its preferences ought to be transitive. That is, for any alternatives $x$, $y$ and $z$, if $xR_SY$ and $yR_SZ$, then $xR_SZ$. Following Sen (1970), we call a transformation of preference profiles into complete and transitive social preference relations an Arrow social welfare function, or more briefly, an Arrow SWF.

Anyone can make up an Arrow SWF, just as anyone can make up a Bergson function, or for that matter a simple moral judgement about when one distribution of wealth is better than another. But arbitrary judgments are unsatisfactory and so are arbitrary Arrow functions. Therefore, Arrow imposed some reasonable conditions on his function. Following Sen's (1970) version of Arrow's theorem, there are four conditions:

1. Universality. The function should always work, no matter what individual preferences might be. It would not be satisfactory, for example, to require unanimous agreement among all the individuals before determining social preferences.
2. Pareto consistency. Social preferences should be consistent with the Pareto criterion. That is, if everyone prefers $x$ to $y$, then the social preference is $x$ over $y$.
3. Independence. Suppose there are two alternative preference profiles for individuals in society, but suppose individual preferences regarding $x$ and $y$ are exactly the same under the two alternatives. Then the social preference regarding $x$ and $y$ must be exactly the same under the two alternatives. In particular, if individuals change their minds about a third ‘irrelevant’ alternative, this should not affect the social preference regarding $x$ and $y$.
4. Non-dictatorship. There should not be a dictator. In Arrow's abstract model, person $i$ is a dictator if society always prefers what he prefers; that is, if $i$ prefers $x$ to $y$, then the social preference is $x$ over $y$.

An economist or policymaker who wants an ultimate answer to qsts involving distributions, or qsts involving choices among alternatives that are not comparable under the Pareto criterion, could use an Arrow SWF for guidance. Unfortunately, Arrow showed that imposing conditions 1 to 4 guarantees that Arrow functions do not exist:

**Third fundamental theorem of welfare economics**: There is no Arrow social welfare function that satisfies the conditions of universality, Pareto consistency, independence, non-dictatorship.

In order to illustrate the logic of the theorem, we will use a stronger assumption than independence. This assumption is called neutrality–independence–monotonicity (NIM), defined as follows. Suppose for some group of individuals $V$, some preference profile, and some pair of alternatives $x$ and $y$, all members of $V$ prefer $x$ to $y$, all individuals not in $V$ prefer $y$ to $x$, and the social preference is $x$ over $y$. Then for any preference profile and any pair of alternatives $w$ and $z$, if all people in $V$ prefer $w$ to $z$, the social preference must be $w$ over $z$. In short, if $V$ gets its way in one instance, when everyone opposes it, then it must have the power to do it again, when the opposition may be weaker.

A group of individuals $V$ is said to be decisive if for all alternatives $x$ and $y$, whenever all the people in $V$
prefer $x$ to $y$, society prefers $x$ to $y$. Note that if person $i$ is a dictator, $\{i\}$ is decisive, and conversely. Assumption NIM asserts that, if $V$ prevails when it is opposed by everyone else, it must be *decisive*. If the social choice procedure is majority rule, for example, any group of $(n + 1)/2$ members, for $n$ odd, or $(n/2) + 1$ members, for $n$ even, is decisive. Moreover, it is clear that majority rule satisfies the NIM assumption, since if $V$ prevails for a particular $x$ and $y$ when everyone outside of $V$ prefers $y$ to $x$, then $V$ must be a majority, and must always prevail. (Majority rule is just one example of a procedure that satisfies NIM; there are many other procedures that also do so.)

Now we are ready to turn to a short and simple version of the third theorem.

*Third fundamental theorem of welfare economics, short version:* There is no Arrow SWF that satisfies the conditions of universality, Pareto consistency, neutrality–independence–monotonicity, and non-dictatorship.

The proof goes as follows. First, there must exist decisive groups of individuals, since by the Pareto consistency requirement the set of all individuals is one. Now let $V$ be a decisive group of minimal size. If there is just one person in $V$, he is a dictator. Suppose then that $V$ includes more than one person. We show this leads to a contradiction. If there are two or more people in $V$, we can divide it into non-empty subsets $V_1$ and $V_2$. Let $V_3$ represent all the people who are in neither $V_1$ nor $V_2$. ($V_3$ may be empty). By universality, the Arrow function must be applicable to any profile of individual preferences. Take three alternatives $x$, $y$ and $z$ and consider the following preferences regarding them:

- For individuals in $V_1$: $x \ y \ z$
- For individuals in $V_2$: $y \ z \ x$
- For individuals in $V_3$: $z \ x \ y$

(At this point the close tie between Arrow and Condorcet is clear, for these are exactly the voting paradox preferences!)

Since $V$ is by assumption decisive, $y$ must be socially preferred to $z$, which we write $yP_z$. By the assumption of completeness for the social preference relation, either $xR_y$ or $yP_x$ must hold. If $xR_y$ holds, since $xR_y$ and $yP_z$, then $xP_z$ must hold by transitivity. But now $V_1$ is decisive by the NIM assumption, contradicting $V$'s minimality. Alternatively, if $yP_x$ holds, $V_2$ is decisive by the NIM assumption, again contradicting $V$'s minimality. In either case, the assumption that $V$ has two or more people leads to a contradiction. Therefore $V$ must contain just one person, who is, of course, a dictator! Q.E.D.

Since the third theorem was discovered, a whole literature of modifications and variations has been spawned. But the depressing conclusion has remained more or less the same: there is no logically infallible way to aggregate the preferences of diverse individuals into a social preference relation. Therefore, there are no logically infallible ways to vote, or to solve the problems of distribution of income and wealth in society.
Social welfare after Arrow

Social choice functions and strategy

The third fundamental theorem of welfare economics tells us that we cannot find an Arrow social welfare function satisfying certain reasonable requirements. An Arrow function maps preference profiles (that is, preference relations for each and every member of society) into social preference relations. But in order to make judgements about what alternative is best for society, it is not really necessary to have a social preference relation. Suppose we just had a rule that tells us, if the set of alternatives is $x, y, z$ and so on, and the preference profile is $R = (R_1, R_2, ..., R_n)$, then the best alternative is such-and-such? Such a rule would be a mapping from preference profiles into alternatives, written symbolically as follows:

$$R_1, R_2, ..., R_n \rightarrow x.$$

Such a rule is called a social choice function, or SCF for short. An Arrow function produces a social ranking of all the alternatives; an SCF, in contrast, just produces a winner. As an example, think of plurality voting, with some kind of rule to break ties. The essential difficulty with SCFs is that they may create obvious incentives for people to misrepresent their preferences, so as to obtain better (for them) social choices. As an example, consider again the Condorcet voting paradox preferences:

$$1: \ x \ y \ z$$
$$2: \ y \ z \ x$$
$$3: \ z \ x \ y$$

Suppose the three people use plurality voting (each person casts one vote for his favorite), and, in case of a tie, the social choice is the outcome closest to the beginning of the alphabet. Under this rule, if 1 votes for his favourite, $x$, and persons 2 and 3 do likewise, there is a three-way tie, which is resolved with the (alphabetical) choice of $x$. Now put yourself in the shoes of person 2. You will immediately see that, if persons 1 and 3 continue to vote for their favourites, and if you switch from your favourite $y$ to your second favourite $z$, then social choice changes, from $x$ to $z$, making you better off! You are in effect being asked ‘what is your preference relation?’ Instead of answering honestly ($y \ z \ x$), you offer, in effect, a false preference relation ($z \ y \ x$).

Reporting a false preference relation in order to bring about an SCF outcome that you prefer to the one you get if you are honest, is called strategic behaviour, or strategizing. It is obviously a bad thing if an SCF produces lots of opportunities for strategic behaviour: if individuals are commonly strategizing,
there is no reason to believe that the outcome, based as it is on false reports, is truly best for society. If an SCF has the property that it is never advantageous for anyone to report a false preference relation it is called *strategy-proof*. For instance, suppose an SCF always chooses the alternative that is first in the alphabetical list of alternatives. This SCF would be frustrating and idiotic, but it would be strategy-proof.

**The Gibbard–Satterthwaite theorem**

This leads to a natural qst: are there SCFs that are immune to strategic behaviour, and that satisfy a few other reasonable conditions? Note that the question is very similar in style to the question that Arrow asked about Arrow SWFs. What would the reasonable conditions be? First (similar to Arrow), the SCF ought to be *universal*; that is, it should work no matter what the profile of individual preferences might be. Second (also similar to Arrow), there should be no dictator. In the SCF context person *i* is a *dictator* if the social choice is always a top-ranked alternative for person *i*. Third (and different from Arrow), the SCF should be *non-degenerate*. This means that, for any alternative *x*, there must be some preference profile which would give rise to *x*'s being the social choice. (This requirement excludes the SCF that always chooses the first alternative in the alphabetical list.) Now we can ask the qst: do there exist SCFs which are universal, non-degenerate, strategy-proof and non-dictatorial?

This question was asked and answered, independently, by Gibbard (1973) and Satterthwaite (1975). The Gibbard–Satterthwaite result turns out to be logically very close to third fundamental theorem of welfare economics; in fact, Gibbard uses Arrow's theorem to prove his theorem, and Satterthwaite shows that his theorem can be used to prove Arrow's. Following is the Gibbard–Satterthwaite theorem. The proof is omitted; a simplified and restricted version of the theorem, and a simple proof, can be found in Feldman and Serrano (2006):

**Gibbard–Satterthwaite th:** There is no social choice function that satisfies the conditions of universality, non-degeneracy, strategy-proofness and non-dictatorship.

Like the third fundamental theorem, the Gibbard–Satterthwaite theorem is starkly negative; it says that, if you want a decision-making process, an SCF to be precise, that has desirable characteristics, including being immune to strategic manipulation, you are bound to be disappointed. To put it differently, for any reasonable SCF, there will be circumstances under which some person will want to falsely report his preferences, resulting in a perversion of the process, and an outcome that may not be desirable for society.

If a decision-making process works in a way that offers each individual *no* incentive to misrepresent his preferences, no matter what preferences the other *n* – 1 individuals might be reporting, we say that honestly reporting one's preferences (or telling the truth) is a *dominant strategy*. The Gibbard–Satterthwaite result then says that, if a social choice function satisfies the conditions of universality, non-degeneracy and non-dictatorship, truth-telling will not be a dominant strategy. That is, there will be some reported preference relations of all individuals except *i*, which will provide an incentive for individual *i* to lie. If everyone else is saying such-and-such (which might be true or false), person *i* will give a false report. This is what strategy-proofness excludes.

But what if we narrowed this broad notion of strategy-proofness; what if we required that *i* not have an incentive to lie when the others are reporting the truth, rather than requiring that *i* never have an incentive to lie, no matter what the others are reporting?
Implementation and the Maskin Theorem

If telling the truth is a best strategy when others are telling the truth, rather than always, then truth telling is a Nash strategy, rather than a dominant strategy. The theory of implementation, or mechanism design, provides a way out the negativity of the Gibbard–Satterthwaite theorem; it provides a way to implement an SCF, or support its choices, by incorporating truth telling about preferences into Nash equilibrium strategies in games.

The major theorem on implementation is due to Maskin (1999), whose paper first circulated in 1977. In Maskin's model, there is a social planner (or central authority) who wants to bring about choices according to a given SCF, which we now call $F$. The planner knows $F$, as do all the members of society. Given any preference profile $R$, the SCF produces an outcome $F(R) = x$. But the planner does not know the true preferences of the individuals. He must rely on the individuals to report their preferences, and they may lie. We assume for simplicity that every individual knows the true preference relation for himself and every other individual; that is, each $i$ knows the true preference profile, but the social planner doesn't. (This is obviously a strong assumption.) From this point on, when one preference profile may be true and another may be false, we will use the unadorned $R$ to represent the true profile. The social planner receives reports on preferences, or preference profiles, from the individuals, but they may be lies. We let $\hat{R}_i$ represent a reported preference relation for person $i$, which may be false; similarly $\hat{R} = (\hat{R}_1, \hat{R}_2, ..., \hat{R}_n)$ represents a reported preference profile, which may be false; and $\hat{R}_i = (\hat{R}_1, \hat{R}_2, ..., \hat{R}_n)$ represents a preference profile, reported by person $i$, which may be false. The social planner wants to devise a method, a mechanism, to induce individuals to honestly report preferences. That way he will get hold of the true preference profile $R$, and produce the desired outcome $F(R) = x$.

How might this be done? The intuition is to ask each and every individual to report a preference profile. (Note that, since we assume all the individuals know each other's true preferences, it is no more challenging for an individual to report a preference profile, comprising preference relations for everyone in society, than it is to report his own preference relation.) If all the reported preferences profiles agree, there's a good chance they are all true, and the planner might accept the generally agreed-upon profile. If they all agree except for one, the one that's out of line probably comes from a liar, and he should be given a motive to avoid lying. (If the social planner were a despot, the out-of-line person would be shot. Note also that there must be three or more individuals in society to discover whose report is out of line.) Finally, when the reported preference profiles generally disagree, the social planner needs a way to avoid having the process stop at an inappropriate Nash equilibrium.

Let us be more precise. Maskin's algorithm for implementing an SCF works as follows. Each person $i$ reports a message $m_i$, which is composed of an alternative $x$, a preference profile $\hat{R}_i$, and a non-negative integer. (i) If every message is the same, of the form $(x = F(\hat{R}), \hat{R}, 0)$, then the social planner chooses $x$. (ii) If every message but one is the same, of the form $(x = F(\hat{R}), \hat{R}, 0)$ for every person but $j$, while $j$ reports a message of the form $(\forall y \neq x, \hat{R}_j = (\hat{R}_1, \hat{R}_2, ..., \hat{R}_n)$, anything), then the social planner chooses $y$, unless person $j$ would like $x$ less than $y$ according to $\hat{R}_j$, the person-$j$ preference relation that all the other people are reporting. If this is the case the planner chooses $x$. (Person $j$ is not shot. He simply does not gain, and
may lose, from his deviation.) (iii) In all other cases, the social planner finds the person who proposes
the highest integer (with some method for resolving ties), and chooses the alternative named by that
person.

Now the qsts can be framed. First, given this mechanism, would \( m_1 = m_2 = \ldots = m_n = (F(R), R, 0) \),
with \( R \) the true preference profile, constitute a Nash equilibrium? Second, if \( (m_1, \ldots, m_n) \) is any Nash
equilibrium list of messages in this mechanism, can we be sure the resulting chosen alternative will be \( F(R) \)?

The answers are ‘yes’ and ‘yes’, under certain general assumptions. The assumptions of Maskin's
theorem are as follows. First, there must be three or more individuals (so that a deviant message can be
spotted). Second, a mild diversity condition must be satisfied. Maskin uses a condition called no veto.
Loosely speaking, this means that, if \( n - 1 \) people prefer \( x \) to all the other alternatives, then the SCF
must choose \( x \). Alternatively, one can assume the existence of a private economic good, that everyone
values. This guarantees that individuals will disagree about what alternatives are best. In this article we
will simply assume diversity, meaning the following: for any given alternative \( x \), there exist at least two
people, each of whom prefers something else to \( x \).

Third, the social choice function \( F \) must satisfy an intuitive condition called Maskin monotonicity. (The
condition is actually a distant relative of the NIM assumption used in the simple version of Arrow's
theorem presented above.) Maskin monotonicity means the following. Let \( \hat{R} \) and \( R \) be any two
preference profiles. (These may be true or false; it does not matter in this context.) Suppose \( F(\hat{R}) = x \),
and suppose that, for all individuals \( i \) and all alternatives \( y \), \( x_{\hat{R}_iy} \) implies \( x_{R_iy} \). Then \( F(R) = x \). (In other
words, in a hypothetical transition from \( \hat{R}_i \) to \( R_i \), for every person \( i \) the set of alternatives that \( i \) likes less
than \( x \) or the same as \( x \) has expanded, or at least hasn't shrunk. Since \( x \) was the social choice under \( \hat{R} \), \( x \)
must continue to be the social choice under \( R \).) With these three conditions, Maskin proved:

Maskin th: Assume \( n \geq 3 \). Assume diversity and Maskin monotonicity. Then the mechanism described
above implements the SCF \( F \), in the sense that truthful messages leading to \( F(R) \) comprise a Nash
equilibrium, and in the sense that any Nash equilibrium list of messages results in the social planner
choosing \( F(R) \).

We will not provide all of the proof, but the logic is as follows. First, establish that
\( m_1 = m_2 = \ldots = m_n = (F(R), R, 0) \) is a Nash equilibrium, where \( R \) is the true preference profile. This is
rather obvious, given rules (i) and (ii) of the Maskin algorithm. Second, establish that under rules (ii)
and (iii), there are no Nash equilibria. This follows rather easily from the diversity assumption. Third,
establish that, if \( m_1 = m_2 = \ldots = m_n = (F(\hat{R}), \hat{R}, 0) \) is any Nash equilibrium, then \( F(\hat{R}) = F(R) \). That is,
given a Nash equilibrium based on a universally reported, but possibly false, preference profile, the
outcome implemented is the same as if the true preference profile had been reported. This follows from
the assumption of Maskin monotonicity.

Maskin also provided a near converse this theorem, which says that Maskin monotonicity is a necessary
condition for any SCF \( F \) to be implementable. Relatively simple proofs of both Maskin theorems are
available in Feldman and Serrano (2006).

Last words
Where does welfare economics now stand? The first and second theorems are encouraging results that suggest the market mechanism has great virtue: competitive equilibrium and Pareto optimality are firmly bound. The third theorem exposes impossibilities and paradoxes in economic choices, voting choices, and, in general, almost any choices made collectively by society. The Gibbard–Satterthwaite theorem, like the third theorem, is a starkly negative result: any plausible social choice function will, under some circumstances, produce incentives for someone to lie. But the Maskin theorem is a ray of hope; it suggests a way for a social planner to design a game, whose Nash equilibria will implement a desired social choice function.

welfare state

Assar Lindbeck

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article starts out with a brief discussion of the historical background, the justifications and the political forces behind the creation of the modern welfare state. It also summarizes its major achievements in terms of economic efficiency and redistribution. The article also tries to identify some major problems of contemporary welfare-state arrangements, distinguishing problems caused by exogenous shocks from those related to endogenous behaviour adjustments by individuals to the welfare state itself. The latter include tax distortions, moral hazard, and endogenous changes in social norms concerning work and benefit dependency.

Keywords

According to a narrow definition, the welfare state comprises two types of government spending arrangements: (a) cash benefits to households (transfers, including mandatory income insurance) and (b) subsidies or direct government provision of human services (such as child care, preschooling, education, health care and old-age care). By broader definitions, the welfare state may also include price regulation (such as rent control and agricultural price support), housing policies, regulation of the work environment, job-security legislation, and environmental policies. This article is confined to the narrow definition.

Across developed Organisation for Economic Co-operation and Development (OECD) countries, total welfare-state spending (‘public social spending’), including spending on education, varies today (2006) from about a fifth of GDP to about a third. As we would expect, the share is tightly related to the degree of ‘universality’ of public social spending, that is, the extent to which benefits are extended to individuals in all income classes rather than largely targeted to particular groups of individuals, such as low-income groups. Broadly speaking, the lowest figures are currently found in Anglo-Saxon countries, while the highest appear in the Nordic countries – with other countries in Western Europe somewhere in-between. Indeed, nowadays welfare states are usually classified in the context of such geographical clusters rather than according to distinctions between Bismarck- and Beveridge-type welfare states, or distinctions in terms of ideological categories along the lines suggested by Esping-Andersen (1990).

Justifications and explanations

Urbanization has diminished the reliability of the family as a basis for reallocating income (or consumption) over the individual’s life cycle, reducing income risk, and providing human services. Moreover, in connection with industrialization, new types of labour contracts emerged according to which unemployment and retirement became more discrete (abrupt) events than earlier (Atkinson, 1991). Industrialization and the subsequent increase in office work also required an expansion of education at all levels. Meanwhile, progress in health and medicine enhanced the usefulness of professional medical services.

Needless to say, such developments by themselves do not justify government intervention in the fields of income insurance and human services, rather than simply leaving people to rely on voluntary solutions via markets and private networks (‘civil society’). There are, however, well-known efficiency and distributional justifications for government intervention in these fields (see, for instance, Barr, 1998). It is useful to divide the efficiency justifications into three categories.

First, the microeconomic literature identifies a number of limitations (‘failures’) in markets for voluntary income insurance: advantageous selection (‘cream skimming’) of insurance applicants, when insurance providers can differentiate between low-risk and high-risk individuals; adverse selection, when insurance providers cannot do so; myopia, when individuals underestimate their future income needs; and free riding on the altruism of others, when individuals expect others to assist them in case of economic distress. Mandatory income insurance (‘social insurance’) helps solve all these problems. Moreover, poor individuals may simply believe that they cannot afford to save or to buy income insurance: their marginal evaluation of immediate consumption is higher than their marginal evaluation of...
welfare state: The New Palgrave Dictionary of Economics

of future income security. Paternalistic governments may prefer to deal with this issue by mandatory insurance rather than by cash transfers to such individuals. In addition, a monopoly provider may largely avoid marketing costs – although at the expense of individuals’ freedom of choice. Even if some of these problems may also be mitigated by group insurance, such arrangements are associated with well-known weaknesses. For instance, occupational income insurance often results in limited portability across jobs, and sometimes deficient financial viability, in particular when individual production firms or industries are in charge of the programmes. In some countries, however, such problems are avoided by institutional integration of occupational and government-operated arrangements (‘corporatist’ systems), such as in Germany and France.

Second, mandatory income insurance may also bring about risk sharing across generations. This is difficult to achieve by voluntary contracts alone since the potential parties of such contracts may not live simultaneously – both when the contract is signed and when it is supposed to be fulfilled.

Third, economists generally agree that investment in human capital (such as education and health care) tends to be suboptimal without government intervention (in the form of subsidies or direct government provision), either because of the difficulties in borrowing with expected future human capital as collateral or because of unexploited (positive) externalities in connection with such investment.

While the efficiency gains from government intervention in the context of the first two justifications show up in improved income smoothing and risk sharing, the efficiency gain according to the third justification takes the form of higher labour productivity and/or faster economic growth – provided disincentives due to higher government spending do not dominate these potential efficiency gains.

The distributional justifications for welfare-state arrangements also appear in different forms. First, in the case of policies designed to fight poverty, it is natural to refer to genuine altruism or enlightened self-interest (a desire to mitigate negative externalities, such as ugly neighbourhoods and street crime). Intergenerational transfers in favour of old cohorts – for instance, via a pay-as-you-go (paygo) pension system – may also be justified by altruism, since lifetime income tends to be lower for older cohorts than for subsequent cohorts in growing economies.

Second, income insurance automatically reduces the overall dispersion of the ex post distribution of income. This holds for both yearly and lifetime income. Moreover, social insurance, as usually designed, may often reduce the ex ante dispersion of the distribution since such arrangements are seldom actuarially fair. A fairly common belief is that increased income security, and perhaps also a reduction in the overall dispersion of the distribution of income, up to a point tends to promote social peace, and that this in turn is favourable for economic growth; indeed, there is some empirical evidence in support of this view (Alesina and Rodrik, 1994). In other words, a distributional argument may, up to a point, be turned into an efficiency justification for income insurance and redistribution of lifetime income.

Of course, neither historical background factors nor theoretical justifications (rationales) by themselves can explain the actual emergence and expansion of welfare-state arrangements. References to the political processes are required. In countries where policies are based on electoral processes, the distribution of voting power across socio-economic groups is a natural starting point. It is also tempting to explain politically generated redistribution across generations by the distribution of voting power across cohorts. For instance, current generations may transfer resources to themselves at the expense of future generations, which (by definition) do not have voting rights, although they may later renege on political favours acquired by earlier generations. At the same time, young adults with children would be expected to push politically for education (and infrastructure investment), while older cohorts are
particularly likely to push for paygo pension systems and old-age care. The political outcome of such
diverse interests, then, would be expected to depend on the relative power of different cohorts.
Indeed, some authors have tried to explain the emergence of modern social spending in western
countries from the mid-19th century to the early 20th century by the gradual widening of franchise
(Flora and Alber, 1981; Lindert, 2004). This is no doubt a realistic hypothesis. There are, however,
obvious limitations to policy explanations in terms of relative voting powers of different interest groups.
In the late 19th century (and even earlier), some welfare-state arrangements actually emerged in favour
of individuals without voting rights; important examples include poor relief, mandatory and subsidized
(even free) primary education, work-injury insurance and modest pensions. It is, therefore, tempting to
assume that altruism and enlightened self-interest also help explain early welfare-state reforms – another
example of how a justification may be turned into an explanation of actual development.
Moreover, the main expansion of welfare-state spending did not take place until half a century after the
emergence of general franchise – indeed, mainly during the first three decades after the Second World
War. One explanation for this apparent time lag may be that urbanization and industrialization were
gradual processes, so that the political demand for new social arrangements likewise emerged gradually.
It may also have taken considerable time to mobilize new groups of eligible voters. The time lags, and
related gradualism in the expansion of welfare-state spending, could perhaps also be regarded as the
result of an ‘experimental approach’ on the part of politicians or voters, due to uncertainty about the
effects in various dimensions of higher welfare-state spending and related tax increases.

Achievements

Not only the level but also the composition of welfare-state spending, such as between transfers and
human services, differs across countries. For instance, while about half of total public social spending
consists of transfers in Western Europe as a whole (varying from 33 per cent in Iceland to 60 per cent in
Austria), the corresponding figure is about 42 per cent in Anglo-Saxon countries outside Europe.

Transfers

What, then, is the relation between the size of aggregate government transfers on the one hand, and the
degree of income security and government-induced redistribution of income across households on the
other? To answer the first aspect of the question, it is important to consider the extent to which
government-provided arrangements are a substitute for private income insurance. To answer the second
aspect of the question, we would ideally also need to determine the extent to which government transfers
have resulted in induced (endogenous) changes in the distribution of factor income (general equilibrium
effects). Unfortunately, our knowledge on both issues is quite limited.
Scattered evidence suggests, however, that voluntary private income insurance and social insurance are
rather close substitutes at the margin. In particular, government-provided benefits tend to be topped up
by occupational pensions in countries with only modest public benefits (Pearson and Martin, 2005, pp.
8–10). As a result, total yearly per capita disposable income of retirees does not differ much across the
eight west European countries studied by Forssell, Medelberg and Ståhlberg (2000), in spite of
considerable differences in the replacement rates in government-operated pension systems. It is also
noticeable that total (public plus private) pensions are at least as large as a share of GDP in the United States as in western Europe (indeed, they are somewhat larger in the United States) in spite of the fact that the GDP share of public pensions is higher in western Europe, and that the population is younger in the United States (Table 1). Another example is that total per capita sick-pay benefits do not vary much among six west European countries studied by Kangas and Palme (1993), in spite of quite different replacement rates in government-operated systems – although the substitution is not complete.

Composition of total public social expenditures in 2001 (% GDP)

Figures for private health spending only cover private insurance programmes and exclude individual private health costs.

Sources: Adema and Ladaigue (2005); OECD (2004).

There seems to be less substitution between public and private provision in countries where there is no government-operated system at all. The relatively low coverage of sick-pay insurance, sick-care insurance, and paid parental leave (‘parent insurance’) in the United States is a suggestive illustration. Thus, in areas where there is no government-operated system at all, it seems that the earlier discussed obstacles to the emergence of voluntary insurance arrangements ‘kick in’.

Since the distribution of disposable income is considerably more even than the distribution of factor income, it is natural to argue that welfare-state arrangements, and their financing, actually contribute to reducing the unevenness of the distribution of income. Moreover, based on data from the Luxembourg Income Study (LIS), Korpi and Palme (1998) found that the relative difference between the market-income Gini coefficient and the disposable-income Gini coefficient tends to be larger in countries with universal transfer systems than in those with a strongly targeted system. (Market income is then defined as factor income plus occupational pensions.) In this sense, universal systems tend in fact to be more redistributive than targeted systems. However, this conclusion does not hold concerning the redistribution per unit of aggregate public social spending; rather, the reverse tends to be the case (although the difference is not statistically significant).

The observation that welfare-state arrangements, in fact, have reduced the dispersion of the distribution of yearly income relies, of course, on the implicit assumption that an induced widening of the distribution of factor income has not offset the direct impact on the distribution of disposable income.
One indicator that such adjustments have not taken place is that the distribution of yearly factor income did not become more uneven – at least not much – during the period when the generosity of public benefit systems increased the most, that is, from the late 1940s to the mid-1970s. Moreover, the subsequent widening of the distribution of yearly factor income in a number of countries (until about the mid-1990s) has been particularly pronounced in the United States and the United Kingdom, that is, in countries where welfare-state spending has increased less than in other countries. Thus, it seems reasonable to assume that government transfer systems (including social insurance) have, in fact, reduced the dispersion of the distribution of yearly disposable income.

Human services

In most developed countries, government intervention in the area of human services mainly takes the form of direct provision rather than general subsidies of such services. The effects of these policies would, however, be expected to differ systematically between low- and high-income citizens. One reason is that the per capita volume (or quality) provided by the government is often larger than what low-income individuals would have chosen themselves. Since human services cannot be resold in the market, the consumption of such services would be expected to increase among low-income groups. By contrast, it would be expected to fall among high-income groups, on the realistic assumption that human services, in contrast to income-insurance cash benefits, are difficult to supplement. (For instance, as a rule, parents do not divide up their children's attendance between a public and a private childcare centre or school.) Such a fall in consumption of human services among high-income groups would also be expected to take place among individuals who abstain from the public services offered and instead buy their services in the market. The reason, of course, is that their disposable income is reduced by the taxes they have to pay to finance the provision of human services to other citizens (basically reflecting an income effect).

There is a corollary to this reasoning: unless the volume provided is quite large, it is probably easier for the government to control the distribution than the aggregate volume of human services by direct provision. Total per capita consumption would therefore be expected to differ less across countries than the volume of government-provided services. Indeed, in spite of the fact that public-sector provision of human services is a larger share of GDP in western Europe than in the United States, 15.1 per cent as against 11.9 per cent, total (public plus privately provided) consumption of such services is larger in the United States than in Europe, 19.1 per cent as against 16.0 per cent (Table 1). In fact, this is the case for both education and health care – possibly partly reflecting a high income elasticity of demand for such services (with an ‘automatic’ supply response when such services are provided by markets).

It is probably easier to boost the aggregate consumption of human services by subsidies than by direct government provision – although the opposite is often asserted to be the case. (The government can be rather confident that general subsidies do increase the aggregate consumption of such services, in contrast to the case of direct government provision.) It is also cheaper for the government to boost such consumption by a certain volume by way of a subsidy than by way of direct provision. (While in the case of government provision the government has to finance the entire spending on such consumption, it has to finance only a fraction of total spending in the case of subsidies.)

There are other important differences between subsidies and direct government provision of human services. A subsidy allows the price to clear the market (zero excess demand), which implies that...
individuals will be able to choose volume and quality themselves, based on each individual's preferences and budget constraint. When judging the usefulness of allowing freedom of choice in the consumption of human services, it is, however, important to consider a number of other aspects as well, such as the efficiency of production and the quality of the services, the distribution of the services among households, and possible tendencies towards clustering ('segregation') of specific types of consumers (in terms of income, education, ethnicity, ideology and so on) on specific providers.

The age-specific nature of public social spending, of course, results in redistribution of resources (income as well as human services) over each individual's life cycle (intra-individual redistribution). Usually, resources are transferred to individuals below age 20–25 and above age 60–65, and extracted (via taxes) from individuals in the age groups in-between. Indeed, we may regard public financing of education as a (collectively decided) loan from the middle-aged to the young, and public financing of pensions as a subsequent payback of the loan via payroll taxes (Becker and Murphy, 1988). By these arrangements, two problems of intergenerational contracting are solved simultaneously: a liquidity constraint is removed for investment in human capital, and a universal pension system is created. Indeed, in countries with highly universal welfare-state arrangements, the bulk of social spending constitutes such intra-individual redistribution rather than inter-individual redistribution of lifetime income ('wealth'), in contrast to countries with strongly targeted systems. For instance, the universal character of public social spending in Sweden and Italy helps explain the high shares of aggregate social spending that constitute intra-individual redistribution over the individual's life cycle in these countries (83 per cent and 76 per cent, respectively, according to Finance Department, Sweden, 2003, and O'Donoghue, 2001). The figure is, however, also boosted in countries, such as Sweden, where benefits usually are taxed. By contrast, the strongly targeted character of the social system in Australia helps explain its rather modest fraction of public social spending that consists of such intra-individual redistribution (38–52 per cent according to Falkingham and Harding, 1996). As pointed out above, in countries with large intra-individual redistribution over each individual's life cycle, the remaining part of public social spending (and its financing) is often sufficient, however, to generate considerable inter-individual redistribution of yearly income.

So far we know very little about the consequences of welfare-state arrangements for the distribution of lifetime disposable income. However, some simulations based on Swedish data indicate that lifetime income ('wealth') is to a considerable extent redistributed from the upper part of the distribution of lifetime income (the highest two quintiles) to the lower part (the lowest three quintiles) – if we abstract from conceivable general equilibrium effects (Finance Department, Sweden, 2003).

Problems

It is useful to classify major problems of contemporary welfare-state arrangements into (a) basically exogenous disturbances and (b) basically endogenous developments caused by the welfare state itself.

Exogenous factors

It is a commonplace that recent and predicted future changes in demography in developed countries, in particular the ‘graying’ of the population, simultaneously boost social spending and have a negative...
influence on the tax base – since there are seldom automatic adjustments of social security contributions and benefit rules in response to changes in demography. Indeed, in the EU-19 the number of individuals above the statutory retirement age is already close to 25 per cent of the number of individuals of working age – and is projected to rise to about twice that figure or even more within three or four decades. It is difficult to alleviate this problem in the medium term except via immigration and tougher social-insurance legislation in the form of higher contribution rates, reduced benefits, stricter controls, and a higher effective retirement age.

The slowdown in the rate of productivity growth in the market sector in developed countries after the mid-1970s has created more or less the same financing problems, since neither the contribution rates nor the benefit rules in the social insurance systems are automatically (fully) adjusted to changes in productivity growth. So far, politicians have usually tried to deal with this problem in the same way as they have tried to adapt to demographic changes, that is, by ad hoc reductions in benefits and increases in social-insurance contributions. In recent years, the internationalization (globalization) of national economies has become perhaps the most hotly debated exogenous factor behind actual and predicted future welfare-state problems in developed countries. International trade theory predicts that the entry into the world economy of a number of countries with abundant low-wage labour (including China, India, the former Soviet republics and countries in eastern Europe) will reduce both the wage-income share of national income and the relative wages of low-skilled workers. Clearly, these consequences are bound to create problems for policy ambitions concerning the distribution of income in many developed countries. It is often also argued that the rate of structural change is likely to accelerate, thereby resulting in tendencies toward higher structural unemployment, due primarily to limited flexibility of the allocative mechanisms in national economies. With given social legislation, this would certainly boost transfer payments (including unemployment benefits) and give rise to an erosion of the tax base, thus threatening the financial sustainability of the welfare state.

If such problems were actually to arise, the standard policy advice is, of course, measures to promote the flexibility of domestic product and factor markets, for instance, along the lines of the so-called Lisbon Agreement among EU countries in 2000. Important examples are retraining of workers, easier entry and expansion of firms, less strict job-security legislation, and more flexible relative wage rates – possibly combined with employment subsidies for low-skilled workers (the ‘working poor’).

Another common worry in connection with the internationalization process is that important tax bases tend to become more internationally mobile. While, so far, this has occurred mainly for capital income, there is a possibility that similar (although less pronounced) consequences will emerge for other tax bases as well, possibly resulting in increased tendencies towards tax competition among governments. To the extent that such developments actually occur, increased international tax coordination (‘harmonization’) is perhaps the most frequently recommended, and predicted, policy response. Moreover, increased migration to developed countries may place an additional strain on the financial position of various welfare-state arrangements, in spite of the fact that such immigration is likely to ‘improve’ the age structure of the population, since migrants may face difficulties in obtaining employment. Poorly functioning labour markets, partly as a result of regulated wages, would be an explanation. To the extent that governments are unable to alleviate these deficiencies, politicians will most likely remain under political pressure to stiffen the restrictions on immigration.

Internationalization is, however, not the main reason for the serious unemployment problems in Western Europe in recent decades, boosting welfare-state spending and damaging the tax base. Regardless of
whether the background is a higher equilibrium unemployment rate or increased unemployment
persistence (after unemployment-creating macroeconomic shocks or increased microeconomic turmoil),
approximately the same types of structural reform are potentially useful. If the problems are caused by
persistence mechanisms, there is, however, also a strong case for liberalizing job-security legislation,
and adopting other policy measures that reduce the market power of labour-market insiders – both
phenomena contributing to inertia of the employment level. Counter-cyclical demand management
policies (monetary and fiscal policy) are also more useful if it is unemployment persistence (after
unemployment-creating macroeconomic shocks), rather than higher equilibrium unemployment, that is
the problem.
Baumol's 'cost disease' (Baumol, 1967) regarding labour-intensive human services – such as childcare,
education and old-age care – is another largely exogenous threat to the financial viability of today's
welfare-state arrangements. More specifically, since the relative costs of such services tend to increase
over time (owing to slow productivity growth for such services), it will be necessary to raise tax rates
gradually (without apparent limits) in countries where these services are tax-financed, even if the
provision of such services is allowed to increase only rather slowly. The problem is somewhat different
in the case of health care. After all, productivity in the health-care sector tends to rise rather rapidly
along with advances in medicine and surgical techniques. However, since these improvements partly
take the form of increased possibilities to treat health problems that could not be treated before, it is
unavoidable that the demand for health care will also be boosted (at given incomes and prices). As a
result, health care will, in fact, be exposed to similar financing problems as other human services,
although partly for different reasons.
As a result of Baumol's cost disease, countries that today rely mainly on tax financing of human services
will sooner or later have to limit the rate of expansion of such services (to the same rates as the increase
in labour productivity of such services) or they will have to introduce complementary methods to
finance human services, such as user fees and (voluntary or mandatory) insurance. Indeed, countries that
are unwilling to accept such complementary financing methods may very well find themselves unable to
finance equally large volumes of human services as countries with other financing methods. Perhaps
these considerations help explain why both education and health spending, as mentioned above, are
higher in the United States than in western European countries (although relatively high wages in the
health sector in the United States is another explanation).

Endogenous factors

In contrast to the welfare-state problems discussed above, disincentive effects via tax distortions and
moral hazard are (by definition) the result of endogenous adjustments of individuals to the welfare-state
itself. In the case of income insurance, moral hazard (ex post) arises simply because the individual will
be able to choose more leisure at a very low cost to himself in terms of lost income. It is also well known
that health-care insurance induces some patients to ask for excessive medical tests and expensive
treatment, demands that many physicians may be willing to satisfy.
Formally, the individual will (tautologically) choose work rather than benefits only if
\[ u(w(1 - t)) > u(bw) + \alpha - f(n) \]
where \( u \) is consumption utility, \( w \) the wage rate, \( t \) the average tax rate, \( b \) the benefit (replacement) rate, and \( \alpha \) the difference between the utility of leisure and the intrinsic utility that one may derive from work. \( f(n) \) denotes the disutility of stigmatization when breaking the
prevailing work norm, where \( n \) is the aggregate number of individuals (or peers) who actually obey the work norm (or a norm against living on government benefits). I assume that the disutility of being stigmatized increases with the number of individuals who work rather than live on benefits; hence, 
\[
\frac{d}{dn} f(n) > 0.
\]
If we abstract, for the time being, from the social norms expressed by the stigmatization term \( f(n) \), the individual may prefer to live on benefits rather than on work already when the after-tax rate \((1 - t)\) is only modestly higher than the benefit rate \((b)\), provided he evaluates leisure at least somewhat more than work (so that \(a\) is at least somewhat positive).

Of course, sufficiently strong social norms in favour of work (or against living on benefits), that is, a sufficiently high value of the \( f(\cdot) \) function may prevent widespread and frequent reliance on benefits even if the difference in income when one works and when one lives on benefits is quite small. After a while, however, some ‘entrepreneurial’ individuals may be tempted to exploit the benefit systems. As a result, social norms in favour of work (against exploiting the benefit systems) may erode among others as well (Lindbeck, Nyberg and Weibull, 1999; Lindbeck and Persson, 2006). The long-term negative effects of more generous welfare-state arrangements on aggregate labour supply may then be stronger than suggested by traditional microeconomic studies of the elasticity of labour supply with respect to after-tax wage rates. (Empirical research on the role of social norms in favour of work or against living on benefits is, however, still at an early stage.)

As an illustration of the potential importance of moral hazard for per capita hours of work, we may note that about a fifth of the population of working age (15–64) in western Europe today (2006) lives on various cash transfers from the government – the most important examples include unemployment benefits, labour-market programmes, social assistance, sick-pay insurance, and early retirement pensions (OECD, 2003, pp. 188–90). Such moral hazard effects of generous welfare-state arrangements in western Europe are, therefore, an important explanation for the limited per capita hours of work in that part of the world. As a comparison, per capita hours of work (per year) in the United States are between 30 per cent and 50 per cent higher than in western Europe. (Prescott, 2004, has instead tried to explain this phenomenon by the higher marginal tax rates in western Europe, assuming quite high labour-supply elasticities with respect to after-tax wage rates.)

The character and size of the incentive effects of welfare-state arrangements depend, of course, on the specific rules of both the benefit arrangements and the financing of these. For instance, to the extent that tax-financed benefits are paid to retired individuals rather than to individuals of working age, the negative substitution effects of the tax wedges on labour supply are counteracted by positive income effects of the tax payment (since, in this case, the taxpayers of working age do not get anything back in exchange for the tax payments). It is also well known that the negative substitution effects of marginal tax wedges on the labour supply are mitigated if there is a (positive) link between the individual’s contributions to various social-insurance systems and his expected future benefits – as in the case of actuarially fair or ‘quasi-actuarial’ social-insurance arrangements – provided the individual is aware of this link. It is also a commonplace that negative incentives to acquire education as a result of marginal (in particular, progressive) tax rates are often counteracted, or perhaps even overcompensated, by subsidies to investment in human capital. Moreover, in some countries tax revenues are used to finance services that are close substitutes for home production, and hence complements to work in the open labour market. Subsidies to childcare and old-age care outside the family are important examples. In this special case, the negative substitution effects of tax wedges on the labour supply would be counteracted
The modern welfare state is a success in the sense that it has contributed to solving a number of potentially serious social problems. It encounters, however, financial difficulties in several countries. Some welfare-state arrangements, and their financing, have also created new problems, including benefit dependency and other incentive effects. These developments are, of course, the background for ongoing and planned reforms of, and retreats from, existing welfare-state arrangements in a number of countries. At the same time, strong political demands have emerged for new or improved social arrangements in several areas. For instance, increased female labour-force participation has raised the demand for paid parental leave, subsidized childcare, and old-age care outside the family – basically to facilitate everyday life among families with two income earners. In some countries, such arrangements are also regarded as important methods for restoring rapidly falling birth rates. The reduced stability of the family has also generated a political demand for legislated property rights in spouses’ social-insurance benefits, in particular pensions.

There is also evidence of increasing individualization of values and lifestyle in developed countries, as compared with a number of decades ago, when today’s welfare-state arrangements were designed (for evidence of such value changes, see Inglehart et al., 2004). Obvious ways of adjusting various benefit systems to these new values are more individually differentiated and portable social entitlements (nationally as well as internationally), as well as increased freedom for the individual to choose type of (mandatory) income insurance and quality of various types of (subsidized) human services, for instance via voucher systems (in a wide sense of the term).

Moreover, the incidence of economic and social misery among specific minority groups has recently increased in several developed countries – partly as a result of rising long-term unemployment,
immigration of low-skilled groups from poor countries, alcoholism, drug abuse and de-institutionalization of the mentally ill – the ‘truly disadvantaged’ individuals. These problems require more than a generally improved situation in the labour market; new types of targeting social policies are necessary to help specific minority groups. A generally accepted view among social workers seems to be that it is also important to integrate more closely the administration of social insurance, social assistance, labour-market exchange systems, health care, rehabilitation, labour-market training and so on. Moreover, in some cases non-governmental organizations, including non-profit organizations, seem to be more successful than governmental organizations in such endeavours. These observations raise the issue of the potential usefulness of new divisions of tasks among governments, markets, the family, and civil society.

Wells, David Ames (1828–1898)

Warren J. Samuels

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
free trade; individualism; laissez-faire; Wells, D. A.

Article

Wells was born on 17 June 1828 in Springfield, Massachusetts, and died on 5 November 1898 in Norwich, Connecticut. Trained at Williams College and Lawrence Scientific School at Harvard, Wells first taught and published as a geologist and chemist. After newspaper work, Wells turned to economics in his mid-forties. After publishing on the national debt, he was appointed to a series of federal and state tax positions, where he issued influential reports, revised tax laws, and originated the stamp system for collecting taxes on tobacco and liquor. He lectured in economics at Yale, Harvard and elsewhere, succeeded John Stuart Mill in 1874 as foreign associate of the French Academy, was president of the American Social Science Association, and received honorary degrees from Oxford, Harvard and Williams. His economic interests were practical and empirical, rather than theoretical; his place was transitional between the popular writer and the technically trained professional investigator.

Politically active, he was a leading exponent of laissez-faire doctrine, which he equated with individualism (in the manner of William Graham Sumner, with whom he was associated), free trade and the gold standard. Although an early protectionist disciple of Henry C. Carey, he later actively wrote and campaigned in favour of free trade. He opposed fiat money, the greenbacks and free silver. At one point he proposed the conversion of the greenbacks to interest-bearing government bonds; at another, he advocated a ‘cremation theory of specie resumption’, with the Secretary of the Treasury to burn a volume of greenbacks each day until they attained parity with gold.

Considered by some to be so doctrinaire as to be impervious to the stresses brought by industrialization in the late 19th century, he was none the less concerned with economic instability. Here he departed from orthodox doctrine, emphasizing the existence of unemployment due to both technology and overproduction relative to present demand, aggravated by the decline of available public lands as an alternative open to labour. His remedy was freer trade.

Through his will, he established the David Ames Wells Prizes in economics at Harvard University.
Recipients have included John H. Williams, Jacob Viner, James W. Angell, Seymour E. Harris, Edward Chamberlin, Robert Triffin, Paul Samuelson, Lloyd Metzler, Robert Solow, Peter Kenen, Lester Thurow and Donald McCloskey.

West, Edward (1782–1828)

Mark Blaug
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
differential rent; diminishing returns; free trade; Malthus, T. R.; market price; natural price; Ricardo, D.; wages fund; West, E.

Article

Edward West is remembered – if he is remembered at all – for having stated the theory of differential rent based on the principle of diminishing returns in a long pamphlet just before Ricardo did so, and in virtually the same form and language. This has earned West the title of ‘the first, though not the name-father and greatest of the “Ricardian” school’ (Cannan, 1893, p. 219). However, it appears that Ricardo developed the principle of diminishing returns independently of West and even of Malthus (who also published the idea more or less simultaneously) and at any rate Ricardo’s exposition in his Essay on Profits (1815) was clearer then anyone else’s, was more carefully set out and went beyond West in spelling out its implications for the distribution of income between wages, profits and rent. In addition to his Essay on the Application of Capital to Land, with Observations Shewing the Impolicy of any Great Restriction of the Importation of Corn (1815), West only wrote one other work on economics, a short book entitled Price of Corn and Wages of Labour, with Observations upon Dr. Smith’s, Mr. Ricardo’s, and Mr. Malthus’s Doctrines Upon those Subjects (1826). At the time of his death, he was working on a treatise in political economy, the manuscript of which has been lost.

West was born in 1782 near London, educated at Harrow and University College, Oxford (where he studied classics and mathematics), and then went on to study law. In 1817, two years after the Essay on the Application of Capital to Land, he published a major treatise on the law of ‘extents’ (indemnities against direct or indirect debts to royalty), which was instrumental in reforming the use of extents in the Court of Chancery. In 1822 he was knighted and appointed Recorder of Bombay, followed two years later by the post of Chief Justice of the Crown in the Bombay province of India. The publication of his book on the Price of Corn in 1826 showed that he maintained his interests in economics until his death in India in 1828.

The similarity between the ways in which both West and Ricardo expressed the principle of diminishing...
returns in agriculture – in terms of diminishing average rather than marginal products of composite doses of capital-and-labour applied to a fixed quantity of heterogeneous land and inclusive, not exclusive, of technical progress in agriculture – is startling, and so is the fact that both of them employed it to deduce a falling rate of profit on capital that could be postponed, but not permanently reversed, by the abolition of the Corn Laws. The only striking difference between the two 1815 pamphlets lay in the implications the two authors deduced from diminishing returns: Ricardo inferred that rents per acre would rise as more capital and labour were applied to ever inferior land, while West inferred that rents would fall, so that free trade would benefit landlords as well as capitalists and workers. This was a point on which West later changed his mind: in the Price of Corn, he agreed with Ricardo's inference about both rents per acre and the rental share. Unlike Ricardo, West realized that free trade would not imply complete specialization as between manufacturing in Britain and agriculture in Britain's trading partners: diminishing returns would operate abroad to raise the price of exported corn even as free trade would diminish the pressure on the costs of raising corn at home, so that eventually ‘the actual price of both in the market must meet’. In this way, he met what was at the time a critical objection to the notion of free trade, namely that it would make Britain for ever dependent on foreign food supplies. 

West's Price of Corn is a notable book if only because it was virtually the first work to attack the wages fund doctrine embedded in the writings of Adam Smith and Ricardo. ‘The opinion that the demand for labour is regulated solely by the amount of capital’, West asserted, ‘has led perhaps to more false conclusions in the science than any other cause’. The demand for labour, he insisted, is not governed by the stock of wage goods inherited from the past but by the total level of private and public investment and consumption spending in the economy. It followed, he concluded, that ‘the demand for the money wages of labour may be increased without any increase of the capital of the country’. The book contained a number of other insights, although opinions must differ as to how original these really were. There was the idea that price is determined by demand and supply, each of them considered as schedules of quantities at various hypothetical prices (an idea also found in Malthus); that the long-run ‘natural’ price of commodities is equal to average costs, including normal profits; that all manufacturing firms have identical cost functions; that the short-run market price of industrial goods cannot fall below average variable costs; and that the effect of a change in agricultural output on the price of corn depends on both the price and income elasticity of demand for corn. For some commentators these insights make him a ‘Marshallian before Alfred Marshall’ rather than a Ricardian before Ricardo (Grampp, 1970).

Wheatley, John (1772–1830)

Frank Whitson Fetter

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Bank Charter Act (1844); note issue; Wheatley, J.

Article

Lawyer and economist, Wheatley was born in Erith, Kent, of a prominent landed and military family, and died at sea on a voyage from South Africa to England. A memorial plaque to him is in the Wheatley chapel of the Erith parish church. At Oxford he was a member of Christ Church, and after receiving his BA in 1793 was admitted to Lincoln's Inn, but his activity in the law was limited, and his life was devoted largely to writing on economics and playing a small part in Whig politics. With him at Christ Church was Charles Watkin Williams Wynn, nephew of Lord Grenville, and Wheatley was active in support of Grenville's successful campaign in 1809 for Chancellor of Oxford University; he had correspondence with Wynn in 1812 about running for Parliament on the Whig ticket, but nothing came of this; a book of 1816 took the form of a letter to Lord Grenville, and his pamphlet of 1823 was a letter to Wynn.

Wheatley published ten books and brochures, two of these in India and one in South Africa. He lived in these two countries for the last nine years of his life, evidently to escape creditors. His works published in India and South Africa received little contemporary attention, and today are extremely rare. Of the others, Remarks on Currency and Commerce (1803), and the first volume of An Essay on the Theory of Money and Principles of Commerce (1807) received the most contemporary attention, and best stated his theoretical position on the monetary controversy that followed the suspension of cash payments by the Bank of England in 1797. Wheatley stated, in an even more extreme way than Ricardo did later, that exchange fluctuations were due exclusively to domestic price changes, and that the Bank of England, through its credit policy, could control prices, and thus exchange rates. These books of 1803 and 1807 criticized the Bank for its monetary expansion, but following the resumption of specie payments in 1821 Wheatley in his book of 1822 had become a severe critic of both the Bank and of the Tory government for the price deflation. His efforts, both in his book and in correspondence with Whig leaders, to launch an attack on the government's monetary policy, made no headway. In several publications he stressed the
danger, for monetary stability, of permitting the issue of notes by banks other than the Bank of England. No economist of his period so well anticipated the note issue provisions of the Bank Act of 1844, which led to the elimination of all notes other than of the Bank of England. Wheatley's views on political issues were something of a paradox. As a Whig he was frequently a voice for reform; with the background of the landed gentry he sometimes disagreed with Whig positions that threatened the supremacy of the landed aristocracy. He supported free trade, a commercial union with France, removal of restrictions on West Indian trade, and the abolition of slavery. He favoured primogeniture, maintenance of great landed estates, the political supremacy of the landed gentry, and an unreformed Parliament. In foreign policy his imperialist views foreshadowed the idea of the ‘white man's burden’.

Selected works

1821. A Plan to Relieve the Country from Its Difficulties. Shrewsbury. This short pamphlet is an extract from the book of 1822 that appeared shortly afterwards.

1823. Letter to the Rt. Hon. Charles Watkin Williams Wynn, President of the Board of Control, on the Latent Resources of India. Calcutta.

1828. Tempora praeterita: Or, More Currency and More Corn. Cape Town. This was published anonymously, but in correspondence Wheatley admitted authorship.

The Wheatley letters to Lord Grey are in the Grey of Howick papers at the University of Durham; the Wheatley letters to Charles Watkin Williams Wynn are at the National Library of Wales at Aberystwyth.

Whewell, William (1799–1866)

G. Campanelli
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
fixed capital; mathematical economics; mathematical method in political economy; production price; Whewell, W.

Article
Whewell was born in Lancaster and died in Cambridge. He received his early education at Lancaster Grammar School and Heversham School, Westmoreland, and in 1812 he went up to Trinity College, Cambridge. In 1817 he became a Fellow of the college, in 1823 a tutor. In 1841 he was made Master, an appointment which he held until his death.

Whewell was at the centre of a ‘network’ of Cambridge scientists and exercised considerable influence upon scientific and philosophic circles in Victorian England. In 1820 he became a Lecturer in Mathematics, in 1828 he was appointed Professor of Mineralogy and in 1838 Professor of Moral Philosophy. He was active as an honorary member of 25 scientific, historical and philosophical societies in several countries. To mention a few of the most important in England: he was one of the founders of the Cambridge Philosophical Society in 1818; in 1820 he was elected a Fellow of the Royal Society; in 1831 he became a member of the British Association and in 1841 was appointed President. Whewell was primarily a philosopher and mathematician, and he published his major works in these fields (Whewell, 1837; 1840). Political economy was one of the many other subjects dealt with by him. However, his contributions in this field – written over the whole period from 1829 to 1862 – give clear proof that his interest in economics was lifelong. Whewell's major works in political economy were four papers on mathematical economics which were read before the Cambridge Philosophical Society (Whewell, 1829; 1831; 1850a; 1850b) and a book – Six Lectures on Political Economy (1862) – which was composed for the edification of the Prince of Wales, the future Edward VII. In the Six Lectures Whewell presented, in a very elementary way, the principal ideas of Smith, Ricardo and Jones. Whewell's four papers represent the earliest systematic application of mathematical symbols of political economy in England. Whewell believed that the arithmetic used by classical economists was inadequate, and that the more general language of algebra should take its place. He pointed out that the adoption of a
Whewell's method had two main advantages. Firstly, that many aspects of political economy could be presented in a more simple, clear and systematic form. Secondly – and more importantly – the use of mathematics could help to avoid the danger of drawing false conclusions for assumptions made. To illustrate this point, in his 1829 paper Whewell used mathematics to discuss Ricardo's theory of the incidence of a tax on wages. Ricardo had argued – against Smith – that a rise in the prices of goods due to a rise in wages would in turn affect wages and ‘the action and reaction first of wages on goods and then of goods on wages, will be extended without any assignable limits’ (Ricardo, 1821, p. 225).

Whewell, on the contrary, showed that if Ricardo had considered the mathematical implications of his theory, he would have found that an unlimited rise in prices and wages was impossible. Indeed, if it is assumed that only a part of the value of goods is wages, and only a part of the labourer's consumption consists of manufactured goods, then the paths that both prices and wages follow take the form of geometric series which converge.

But Whewell's most notable contribution to political economy was his mathematical formulation of Ricardo's theory, and in particular his analysis of fixed capital (Whewell, 1831). This analysis is important not only because it represents the first mathematical treatment of machinery in Ricardo's model, but also and mainly because it constitutes an original contribution to the subject. In 1831 Whewell had already provided an exact formulation for the reduction of fixed capital to dated quantities of labour. He also worked out a simple model to quantify the substitution effect between labour and machinery. Finally, through the annuity formula, he arrived at the equation which defines the production price in the presence of fixed capital.

These results also suggest that the dating of the genesis of fixed capital models may need to be reappraised, for it is usually thought that Bortkiewicz (1907) – on the basis of Dmitriev's contribution (1904) – was the first economist to treat fixed capital mathematically within the theory of production price.

Whewell has been consistently neglected in the history of economic analysis. The few authors who were acquainted with Whewell's work – of whom the most authoritative were Jevons (1871) and Schumpeter (1954) – considered his analysis as purely derivative: supposedly he merely translated into algebraic form results which others had previously expressed in non-mathematical language. The only exception was Walras, who regarded Whewell's contribution as ‘really remarkable’ (Walras, 1875, p. 32). Whewell was in fact more than a translator: he was a major contributor to the early development of mathematical economics in England, and above all a pioneer in the general debate on fixed capital.

Wicksell effects

Edwin Burmeister

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
capital deepening; capital goods; capital theory; capital theory paradoxes; numéraire; production possibility frontier; Wicksell effects; Wicksell, J. G. K.

Article

In realistic economic models with \( n \) different types of capital goods, the value of the capital stock is

\[
V = \sum_{i=1}^{n} P_i K_i
\]

where \( P_i \) is the price of the \( i \)th capital good in terms of some numéraire. The value of capital, however, is not an appropriate measure of the ‘aggregate capital stock’ as a factor of production except under extremely restrictive conditions. Wicksell (1893; 1934) originally recognized this fact, which subsequently was emphasized by Robinson (1956).

If attention is restricted to alternative steady-state comparisons, in constant-returns-to-scale economies without joint production \( V \) is a function of the interest rate, \( r \); see, for example, Burmeister and Dobell (1970). The Wicksell effect is the change in the value of the capital stock from one steady state to another, namely

\[
\frac{dV}{dr}.
\]
The term ‘Wicksell effect’ was introduced by Uhr (1951), but its importance was not widely recognized until the writings of Robinson (1956) and Swan (1956).

The Wicksell effect is the sum of the price Wicksell effect (which is the revaluation of the inventory of capital goods due to new prices) and the real Wicksell effect (which is the price-weighted sum of the changes in the physical quantities of different capital goods):

\[
\frac{dV}{dr} = \sum_{i=1}^{n} \frac{dP_i}{dr} K_i + \sum_{i=1}^{n} P_i \frac{dK_i}{dr}.
\]

(3)

Numerical examples show that the price Wicksell effect can be negative, that is,

\[
\sum_{i=1}^{n} P_i \frac{dK_i}{dr} < 0
\]

(4)

is possible, even when (i) the total Wicksell effect is positive \([dV/dr > 0]\), or (ii) particular capital stocks are increasing with \(dK_i/dr > 0\) for some but not all \(i\); see Burmeister and Dobell (1970, pp. 289–93). In neoclassical models with only one capital good \((n=1)\), the real Wicksell effect is always negative. Moreover, the sign of the price Wicksell effect depends upon the choice of numéraire, and hence so does the total Wicksell effect given by (3). The sign of the real Wicksell effect, however, is independent of the choice of numéraire.

One central issue of the Cambridge controversies in capital theory involves Wicksell effects. Does a decrease (increase) in the steady-state interest rate always imply a rise (fall) in per capita steady-state consumption provided the rate of interest is greater (less) than the rate of growth of labour? In one-capital good models, the answer to this question is, ‘Yes’. In general, the answer is, ‘Yes’, if and only if the real Wicksell effect is negative; see Burmeister and Turnovsky (1972) and Burmeister (1976).

To establish this relationship between the behaviour of per capita consumption and the real Wicksell effect, consider a technology which can be represented by a production possibility frontier

\[
Y_1 = T(Y_2, \ldots, Y_n; L, K_1, \ldots, K_n)
\]

(5)
where \( Y_i \) is the output of commodity \( i \), \( L \) is the labour which grows at the exogenous rate \( g \), and \( K_i \) is the stock of commodity \( i \) used as a capital input. It is assumed further that \( T(\cdot) \) is twice continuously differentiable, exhibits constant returns to scale, and has a Hessian matrix \([T_{ij}]\) that is negative semi-definite and whose rank varies with the degree of joint production in the economy; see Samuelson (1966), Burmeister and Turnovsky (1971), and Kuga (1973). The analysis which follows can be generalized to non-differentiable technologies as in Burmeister (1976), but for simplicity only differentiable technologies are considered here. In steady-state equilibria all quantities grow at the rate \( g \), implying that the output of every commodity must satisfy

\[
Y_i = C_i + K_i = C_i + gK_i, \quad i = 1, \ldots, n, 
\]

(6)

where \( C_i \) denotes the consumption of commodity \( i \). Substituting these steady-state restrictions into (5) and using lower-case letters to denote per capita quantities, we have

\[
c_1 + gk_1 = T(c_2 + gk_2, \ldots, c_n + gk_n; 1, k_1, \ldots, k_n).
\]

(7)

Let the prices of commodities and the rental rates for capital goods, both in terms of the wage rate as *numéraire*, be denoted by \( p_i \) and \( w_i \) respectively, \( i=1,\ldots,n \); also let \( r \) denote the interest or profit rate. It is well-known that intertemporal profit maximization and/or efficiency necessitates that

\[
\frac{\bar{p}_i}{p_i} + \frac{w_i}{p_i} = r, \quad i = 1, \ldots, n.
\]

(8)

Imposing the steady-state requirement that relative prices remain constant, (8), implies that

\[
w_i = r p_i, \quad i = 1, \ldots, n.
\]
Using the well-known marginal conditions

\[
\frac{\partial T}{\partial (c_i + gk_i)} = -\frac{p_i}{p_1} \quad \text{and} \quad \frac{\partial T}{\partial k_i} = \frac{w_i}{p_1}, \quad i = 1, \ldots, n,
\]

we see that a vector

\[
(c^*, k^*, r^*, p^*) = (c_1^*, \ldots, c_n^*, r^*, p_1^*, \ldots, p_n^*) \geq 0
\]

satisfying (7) and (10) represents a steady-state solution at the growth rate \( g \). It thus follows immediately from differentiation of (7) that almost everywhere

\[
\sum_{i=1}^{n} p_i \left( \frac{dc_i}{dr} \right)_{(r^*, p^*)} = (r - g) \sum_{i=1}^{n} p_i \left( \frac{dk_i}{dr} \right)_{(r^*, p^*)};
\]

see Burmeister (1976) for details.

Now let \( \nu \) denote the per capita value of capital in terms of the wage rate as numéraire:

\[
\nu = \sum_{i=1}^{n} p_i k_i.
\]

The change in the per capita value of capital across alternative steady-state equilibria is obtained by differentiating (13); thus almost everywhere the per capita Wicksell effect is...
Comparing (14) and (12), it is seen that it is the real Wicksell effect which determines whether or not ‘consumption’ is well-behaved across steady-state equilibria. That is, if the real Wicksell effect is negative and

\[
\sum_{i=1}^{n} p_i \cdot \frac{d k_i}{dr}(r^*, p^*) < 0,
\]

(15)

then almost everywhere

\[
\sum_{i=1}^{n} p_i \cdot \frac{d c_i}{dr}(r^*, p^*) \triangleq 0 < r < g.
\]

(16)

In particular, when \(\xi_2 = \xi_3 = \ldots = \xi_n\) and only commodity 1 is consumed, consumption as measured by \(c_1\) rises (falls) as \(r\) is increased from \(r^*\) to \(r^* + \Delta r^*\) when \(r^*\) is greater (less) than \(g\). (The familiar golden rule condition giving maximum per capita steady-state consumption holds at \(r^* = g\).)

It follows, then, that a negative real Wicksell effect is the appropriate concept of ‘capital deepening’ in a model with many heterogeneous capital goods. That is, when (15) and hence (16) hold, an economy with a low interest rate (but exceeding \(g\)) has ‘more capital’ than one with a higher interest rate in the sense that it is capable of providing more steady-state per capita consumption. Although (15) and (16) always hold in a neighbourhood of \(r^* = g\), examples show that they do not generally hold everywhere. This possibility – that (16) does not hold everywhere – is perhaps the most interesting conclusion to emerge from the Cambridge controversies and has been termed a ‘paradox’. However, the ‘paradox’ involves comparisons of alternative steady-states rather than comparisons of alternative feasible paths; Bliss (1975) provides a lucid explanation of why such ‘paradoxes’ are in fact not surprising or damaging to
Wicksell effects: The New Palgrave Dictionary of Economics

the neoclassical paradigm.
Imposing some set of conditions on the technology $T(\cdot)$ should be sufficient to assure that the real Wicksell effect is always negative. Such conditions would be of interest – especially if they could be empirically tested – since they would validate the qualitative conclusions derived from the one-good models often used in macroeconomics without any theoretical justification for ignoring capital aggregation problems. Moreover, Burmeister (1977; 1979) has proved that a negative real Wicksell effect is a necessary and sufficient condition for the existence of an index of capital, $\kappa$, and a neoclassical aggregate production function $F(\kappa)$ defined across steady-state equilibria such that (i) $c=F(\kappa)$, (ii) $r=F'(\kappa)$, and (iii) $F''(\kappa)<0$. Unfortunately, no set of such sufficient conditions is known, but the literature on capital aggregation suggests that they would impose severe restrictions on the technology.

Article

Life and career

Johan Gustav Knut Wicksell was born in Stockholm on 20 December 1851, the youngest of six children of Johan and Christina Wicksell. One child died in infancy, so Knut grew up with three sisters a few years older than he, and a brother, Axel, one year older. Knut's mother died when he was not quite seven, an event that greatly affected the sensitive boy. His father, a produce dealer, remarried in 1861 but died five years later when Knut was 15. After that the children moved to live for a time with an aunt and their maternal grandmother. In the last decades of his life Knut's father had become moderately well-to-do by investing profits from his grocery business in rental properties. The estate that was left at his death yielded an income sufficient to provide for the children and their education through gymnasium (high school), and for the two boys a start at the University of Uppsala.

At the gymnasium Knut had already shown considerable aptitude for languages and an unusual ability at mathematics. Thus, when he enrolled at Uppsala University 1869, it was with the intention of becoming a mathematician with physics as a second field of study.

From about age 15 Knut came increasingly under the influence of a pietistic pastor of the Swedish Lutheran Church. This religious phase lasted about seven years, in the course of which he became a devout Christian; he withdrew from most social activities to study the Bible and meditate. At the same time he made rapid progress in his studies of mathematics, physics and astronomy, earning his first degree, BS cum laude, in 1871, after only two rather than the usual four years at the university, and then...
proceeding to graduate studies. However, doubts had begun to assail his faith, and in spring 1874 he had an emotional crisis from which he emerged, and for the rest of his life remained, a free thinker. He became a strictly a-religious philosophical rationalist who, later on, became known as an outspoken and witty critic of the Christian religion in all its forms.

Until 1873 Wicksell maintained himself at the university on the modest annual income he received as his share of his father's estate, on a small inheritance from his grandmother, and on a succession of grants from private foundations. Now the last were drying up and the money from his grandmother was nearly gone. To add to his scant resources, he filled a vacancy as a teacher at a secondary school at Uppsala, 1873–4. The year after that he worked as a private tutor to the son of an ironmaster. Also from time to time he borrowed various amounts from one of his sisters who had established herself in Stockholm as a physiotherapist.

In fact, Wicksell's financial condition remained precarious and often severely strained, except for the years 1885 and 1888–9 when he was studying abroad largely supported by grants, for most of his adult life until 1901. Then, at age 50 and supporting his wife and two school-age sons, he was finally appointed professor extraordinarius (about equivalent to associate professor) at Lund University, and then, from 1904, he served there as ordinarius or full professor for 12 years, until his retirement in 1916. In 1875 he passed two of three required examinations for the degree *philosophiae licentiatus* in mathematics (the *phil. lic.* is a graduate degree taken prior to the student's beginning work on the doctoral dissertation). Soon after that he began to doubt that he would be able to make any significant contributions to mathematics. While contemplating a change of career either to humanities or to the emerging social sciences, he immersed himself, over a long transition period, in the activities of the students' organization, the Student Corps. He was elected as its curator, 1877–9. In that post he became well known for his critical social views and for his surprising effectiveness as a speaker. At this time he also wrote some ‘social indignation’ poetry as well as some plays, one of which proved popular and was performed at Uppsala and also in some other towns.

In 1879 two events, in themselves inconspicuous, occurred which strongly influenced Wicksell's subsequent career. He moved to share an apartment with two advanced graduate students, H. Ohrvall in medicine, and T. Frölander in law, and he acquired a book just recently released in Swedish translation, G. Drysdale's tome, *The Elements of Social Science*, with its challenging subtitle, ‘Physical, Sexual, and Natural Religion; An Explanation of the True Causes and Cure of the Three Primary Evils of Society – Poverty, Prostitution, and Celibacy’. This work, published in England 1854, became very popular in the Swedish translation of 1878, and went through over 30 reprintings over the years.

The three men, whose outlook on society was in several respects similar, became lifelong friends. What cemented their friendship was that they set about on their own and jointly to study Drysdale's thoroughly neo-Malthusian treatise. It discussed frankly several subjects then regarded as unmentionable in 'polite society', such as sex, methods of birth control, the allegedly harmful psychological effects of celibacy if continued for a decade or more past puberty, prostitution as the only alternative for the young among the poor, the need for family planning, and the need to limit population growth in order to raise the standard of living for the working class above bare subsistence.

Wicksell treated this book as a revelation. It focused his mind on 'the social question', that is, on the social sciences towards which his inclination guided him more and more. As an early result of studying Drysdale, supplemented by some writings of J.S. Mill, in February 1880 he gave a lecture to a
temperance lodge at Uppsala on 'The Most Common Causes of Habitual Drunkenness and How to Remove Them'. His address got a mixed reception but was reported in the local newspaper, which led to an insistent demand for him to repeat his lecture two weeks later in a much larger hall which was filled to overflowing.

There he attributed alcoholism, widespread among factory workers, to the poverty and monotony of their lives, with wife and children crammed into crowded and often insanitary housing. For this the local inn offered almost the only relief and relaxation available. And with the young workers this led to the use of the services of prostitutes since these workers for years earned too little to marry and start a family. The remedies he urged were for the medical profession to be assigned the duty of disseminating information about birth control techniques, and for the public health authorities to set and enforce standards of sanitation and room space per occupant in housing in the factory districts of cities and towns. The reaction to his lecture was strong. Papers by the Young Socialists and by some student organizations praised him. Medical and temperance organizations either reviled or ridiculed him, and several newspapers questioned his competence to pronounce on some of the sensitive issues he had covered.

From now on the die was cast. There would always be one or more reporters present at his future appearances, because these were certain to be newsworthy. Reporters would summarize his talks and write longer accounts about how his audience reacted, especially the critics and opponents among them, and how he, in turn, responded to critics. Most of the reportage depicted him as a non-revolutionary radical social reformer, and that was how public opinion came to view him. We may add that he himself did nothing to modify and much to strengthen that impression.

Later in 1880 he issued his lecture as a tract of some 90 pages and along with it a pamphlet, 'Answers To My Critics', both of which sold in several thousand copies. In fact, this became something of a pattern. Between 1880 and 1885, and again in 1886–7, after his return from his first stay abroad, Wicksell had in substance turned into a radical public lecturer and journalist. This was how he earned his spartan maintenance, by paid public lectures sometimes followed by publishing tracts based on them, and by paid articles written in neo-Malthusian spirit on various 'social questions' for several, sometimes in a given week for as many as ten, different city and town newspapers.

In 1885 he set aside his journalistic work for a time and completed the last requirement for the phil. lic. degree in mathematics by a research paper, the other requirements he had met in 1875. Now, however, he wanted to shift into the social sciences rather than go on for a doctorate in mathematics. To do that at any level higher than the elementary meant study abroad, for at that time the social science disciplines were not separate fields but were elements of the curricula in law, philosophy, the humanities or theology in Sweden's universities. But he had no funds for going abroad. Then help came unexpectedly. His sisters had an opportunity to sell the rental properties of the Johan Wicksell estate to a buyer at a favourable price if Knut and his brother, Axel, who had emigrated to the United States, would agree, as they did. Knut's share of the proceeds was sufficient to pay off his old debts and also to maintain him for about a year abroad, and so in autumn 1885 he went to London.

In London Wicksell spent his days studying some of the classical economists and treatises by Cairnes, Jevons, Walras and Sidgwick, his first exposure in depth to economics, and his weekends in meetings with persons to whom he was introduced by Charles Drysdale, an engineer who continued the neo-Malthusian activities his father, George Drysdale, had initiated. Thus he met prominent British neo-Malthusians, Annie Besant among them, Karl Kautsky and some labour leaders, and the leading Fabians.
By summer 1886 he returned to Uppsala and Stockholm to resume his public lecturing, writing for several newspapers, and composing tracts. This was now a matter of necessity, for he had used up his patrimony during his stay in Britain. In 1886–7 he delivered 42 public lectures in towns in central Sweden, in Copenhagen and Christiania, for fees which paid very little above his travel and maintenance expense. The subjects he spoke on were as follows:

- Marriage 14 lectures
- Population Control 10 lectures
- Socialism 6 lectures
- Prostitution 5 lectures
- Spiritualism 2 lectures
- Why Not A Free-Thinker? 2 lectures
- Religion 1 lecture
- Euthanasia 1 lecture
- Impression of Britain 1 lecture

At the end of 1885 Victor Lorén, a wealthy young man, greatly interested in promoting the social sciences after studying them in Germany with Roscher, bequeathed his estate to a foundation bearing his name, with instructions that it should be used for the promotion of studies and research and publications by scholars devoted to economics and related social sciences. Wicksell was still in London when early in 1886 he was informed that the Lorén Foundation was awarding him a grant for up to three years to study economics at universities in Germany and Austria. Lorén's relatives unsuccessfully contested his will in court, but this held up the grant until the summer of 1887, when the suit was settled.

If the Lorén Foundation had not given him that large grant (and later smaller ones for each of the five treatises he published between 1893 and 1906) Wicksell could hardly have become an economist, much less a major figure in this discipline. As it was, he went first to London to renew acquaintances. In October 1887 he went to the University of Strassburg to follow lectures by Brentano on labour economics, on money and credit by both Brentano and Knapp, and on economic distribution by Singer. In spring 1888 he was in Vienna to listen to Carl Menger's lectures. In July he returned for a short stay in Sweden. On his way there he met Anna Bugge, a Norwegian gymnasium teacher, who later became his wife. By autumn 1888 he was at the University of Berlin to follow the lectures of Adolph Wagner on public finance. In spring 1889 he returned to Sweden to seek a lectureship in economics at the University of Stockholm. He was turned down as being ‘too notorious’ a person. Summer 1889 he decided to spend the rest of his grant studying economics in Paris. Before going there he took a trip to Christiania to see Anna Bugge, with whom he had corresponded while in Germany. There he proposed a common-law marriage to her, but out of consideration for her parents she turned him down, whereupon he left in a huff for Paris.

A word may be needed here about the romantic side of Wicksell's life. It is known that he was infatuated in his early twenties with two young ladies. But he was always shy and very hesitant in socializing with young women. So the first young woman moved to Switzerland and married there. The second one was a case of love at a distance, for he failed even to make contact with her. The third and last incident occurred years later. For a part of the summer 1886 he was invited to stay in his friend Frölander's household in Stockholm, where he gave most of his lectures. But there he soon found himself becoming
infatuated with his friend's wife. So before he might say or do something to jeopardize their friendship, he made the proper excuses and returned to his lonely lodgings in Uppsala.

Anna, however, did not want to give up Knut. She decided she would be happier with than without him even at the cost of estrangement from her parents. She joined him in Paris that summer; he was then 37 and she 26.

In Paris he attended lectures on public finance by Leroy-Beaulieau and on population theory by Desmoulin, and he began to publish in economics. His first article, the translated title of which is ‘Empty Stomachs – Full Stores’ came out in a Norwegian journal Samtiden in 1890. His second article, ‘Überproduktion oder Überbevölkerung’ (Excess production or excess population) appeared in Zeitschrift für die gesamten Staatswissenschaften, also in 1890. In both he argued that it was fluctuations in capital formation that made the difference between prosperity and depression. In recovery a rate of capital formation is generated which fails to be sustained because consumption demand, though rising, lags behind the rate at which productive capacity expands on a growing capital base.

In summer he and Anna returned to Stockholm. Though soon to be a father (their first son, Sven, was born in October 1890, and a second son, Finn, in 1893), Wicksell had no settled way of earning a living. Economics was then taught only in the faculties of law. Those teaching it in addition to a doctorate in economics also had to have at least an undergraduate degree in law in order to give courses on law and economics as related mainly to taxation and public finance. So he had no alternative but to return to being a freelance journalist and public lecturer.

During the years 1890–9 Wicksell had more trials and tribulations, only a few of which can be related here. He gave rather few public lectures, but some had a very negative effect on his public image. In 1892 the government wanted to increase the duration of the compulsory military service to strengthen the country's defences. In November Wicksell lectured in Stockholm on the question, ‘Can Sweden Protect her Independence?’ He argued, and most of his listeners might have agreed with him, that no matter how long the draft were extended, it would not be adequate for defending Sweden against attack by a major military power. But they disagreed vehemently when he went on to say that since the country could not defend itself on its own resources, it would make better sense to disarm and use the resources set free from defence for other domestic purposes. Then Sweden ought to negotiate for incorporation into the Russian empire with its much greater military resources. In return for the protection thus provided, the Swedes with their long traditions of democracy ought then to play a civilizing role within and for the Russian empire.

This performance earned him the sobriquet of ‘defence nihilist’, which did not deter him 12 years later when another draft extension was proposed from repeating this same lecture, May Day 1904. At that time it occasioned even greater offence and ridicule than in 1892.

His article ‘Kapitalzins und Arbeitslohn’ (Interest and wages), published in the Jahrbücher für Nationalökonomie und Socialwissenschaft und Statistik 1892, formed the basis for the marginal productivity theory of distribution – one of Wicksell’s main contributions to economic theory – which he developed in his first treatise, Uber Wert Kapital und Rente 1893 (Value, Capital and Rent, translated 1934). This remarkable work received initially almost no attention in Sweden, but was favourably reviewed by both Böhm-Bawerk and Walras.

Next he turned to an examination of Sweden's taxes in his popular tract, Our Taxes – Who Pays and Who Ought to Pay Them? (99 pp., 1894), issued under the pseudonym of Sven Trygg. He was outraged at the regressiveness of the country's taxes. That, he concluded, had to be a consequence of the fact that
only the well-to-do could vote, as income and property qualifications for the franchise excluded almost all the workers and most of the small farmers.

The analysis of that tract was extended and refined in his second treatise, *Finanztheoretische Untersuchungen* (Studies in the theory of public finance), 1896. There he urged that the major part of the revenue burden be shifted from indirect to direct progressive taxes on income and wealth. That treatise also embodied his design on an ‘equitable’ tax system based on an application of marginal utility theory to the public sector, and a methodology (essentially marginal cost pricing) for pricing pure and less than pure public goods, the services of public utilities, and the products of market-sharing oligopolies and cartels.

In fall 1894, Wicksell applied at Uppsala University to have *Value, Capital and Rent* evaluated as a doctoral dissertation. The answer was ‘no’, with the added advice to use it for a viva voce examination of a *phil. lic.* degree in economics. David Davidson was appointed examiner and Wicksell passed with high marks in May 1895. Next he needed the doctorate. In 1896 he submitted the first part of his *Finanztheoretische Untersuchungen*, ‘Theory of incidence of taxation’, as a dissertation. Again Davidson was chief examiner, and the degree was awarded Wicksell *magna cum laude*.

That done, he began research on monetary theory and policy, which he completed as his third treatise, *Geldzins und Güterpreise*, 1898 (*Interest and Prices*, translated 1936), the home of the Wicksellian ‘cumulative price level fluctuations or processes’, allegedly generated by a divergence between the rate of return on newly created real capital and the bank-dominated market rate of interest.

Now he applied both at Stockholm and Uppsala universities for a docentship but was rebuffed because he lacked a degree in law. From 1890 into 1897 he had maintained his family slightly above subsistence level by earnings from his newspaper articles and tracts and from a succession of Lorén grants. However, in autumn 1897 he decided at real hardship, with no more Lorén money, to move from Stockholm to Uppsala to devote his entire energy to cramming through law courses as fast as possible to a *juris candidatus* of L.L.B. degree. To do this he had to maintain his family by borrowing from his friends Ohrvall, a physician, and Frölander, a banker-lawyer, both of whom were doing well. In 1899, in less than two years, he had earned his law degree, which usually takes undergraduates four years. He was appointed a docent at Uppsala University but without fixed salary. Consequently his income depended on how many law students came at a given fee per head to attend his tutorials.

At the Lund University faculty of law a professorial vacancy was created when an older professor's post, viewed as overloaded, was split to shift its courses in tax law and economics from the old position to the new one. But Parliament, in approving this, had voted less money for it than a full professor's salary. Wicksell and three others, including Gustav Cassel, competed for this post of professor extraordinarius. As the other candidates (Cassel for lack of a law degree) were eliminated as not sufficiently qualified, the appointment was offered to Wicksell in January 1900. For complex reasons the upgrading of this to ordinary or full professorship was delayed until January 1904, when Wicksell, at the age of 53, was finally securely established as a full professor.

At Lund, where his teaching of tax law courses required much more preparation than economics, he still found time to write *Föreläningar i Nationalekonomi* (*Lectures on Political Economy I*, 1901, translated 1934). *Lectures I* were an expansion and improvement, especially in capital theory, over what he had presented in *Value, Capital and Rent*.

His courses in law as related to taxation were well attended but those in economics attracted very few students, it being an elective subject. He soon found out that the students lacked the background to get
much out of a semester on *Value, Capital and Rent* and another on *Interest and Prices*. So he shifted his presentation from pure to applied economics to subjects such as agriculture and industry, commerce and consumption, social movements, social insurance, economic crises and inflation.

He had good relations with students. His approach to them was friendly. They, in turn, liked or were amused by his idiosyncrasies, and they admired his courage to fight for his convictions.

Unlike most professors, who at that time lectured in formal dress, swallowtail coats and all, Wicksell appeared in ordinary, rarely well-pressed, street clothing. Instead of a top hat or a Derby he wore a visored cap, much like a fisherman’s. Since he lived some distance from the university, he did the family's marketing at the nearby open-air market before his morning lectures. Consequently, as he strolled in to the lecture room, he would adorn one side of the lectern or the other with his market basket filled with produce, meats and fruits.

In 1905 he issued one of his best and last tracts, *Socialiststaten och nutidssamhället* (The socialist state and contemporary society, 40 pp.). He restated more systematically his perspective on socialism which he had lectured on in the 1880s. First he made it clear he considered a limited but not a complete achievement of a socialist economy (with all means of production other than labour collectively owned and administered) to be inevitable in the future. Under universal adult suffrage the workers would be the political majority. As such, they would not for long tolerate the great inequalities of income and wealth and the economic instability (of employment and economic insecurity and dependence in old age) of laissez-faire capitalism without seeking and taking remedial measures.

He warned against drastic measures of income redistribution taken by a workers’ government suddenly come to power. That would only yield a temporary gain followed by loss as private capital accumulation would all but cease before the workers’ regime would have developed the means to replace it by public accumulation. A socialist economy is best built gradually by peaceful means and under democratic governance. Nationalization initially of natural monopolies and cartels might suffice if followed by substantial expansion of tax supported social security and social insurance schemes. For the sake of efficiency, he held it was best to leave farming and most varieties of genuinely competitive enterprises in private and/or cooperative ownership.

Consequently he argued for a form of market socialism with a well developed welfare state. It is surprising to recognize the great extent to which his social vision has become a reality in Sweden (and in Scandinavia as a whole) after more than half a century of Social Democratic rule.

In 1906 Wicksell published *Lectures on Political Economy II*, the volume on money and credit. In part an expansion and revision of what he had put forth in *Interest and Prices*, yet *Lectures II* were much more than that. They were epoch-making less for their particular findings than for the broad framework and methodology they provided for analysis of money and credit. *Lectures II* were translated first into German in 1922 when, in the midst of the German hyperinflation they were read with greater than usual interest, and into English in 1935.

Wicksell’s years at Lund were very productive. He wrote about 50 articles and took an active part in the tax reform of 1910, in the national pension legislation of 1913, and, after the outbreak of the First World War, along with Davidson, he played an important role in the legislation and policies relating to banking, currency and exchange controls.

His work had continued in a tranquil manner until 1908. Then a young ‘anarchist agitator’ was sentenced to prison for ‘disturbing the religious peace’ by public blasphemy. He had published a parody of the Wedding at Cana in a socialist newspaper. His case, and two or three similar ones that had
occurred earlier, impressed Wicksell as infringements by the courts of freedom of speech and press, guaranteed by the Swedish constitution. Against better advice he decided to make a test case of himself. Accordingly in November 1908 at Stockholm he lectured to a large audience on ‘The Throne, the Altar, the Sword, and the Bag of Money’ in which, inter alia, he satirized the story of the Immaculate Conception. He raised and answered the question:

Why was not Joseph, the betrothed of the Virgin Mary, rather than the Holy Ghost allowed to father Jesus? Because then the world could not have been saved! Joseph's rights as an individual had to be set aside for the salvation of the many millions of souls in past centuries who would otherwise have gone to perdition and the further millions now and for all time to come until the Last Judgement.

Wicksell was tried and sentenced, against the protests of Social Democrats, organized workers and liberals, to two months in prison. He was allowed to select the jail where he would serve his time. Early in 1910, after a higher court had sustained the lower court's decision, he chose the jail, known to be better than most, at the small fisherman's town of Ystad in southern Sweden. There he suffered no hardship. His university salary was withheld as long as he was a guest of the government. He used his time to advantage by writing his last tract, *Laran om befolkningen, dess sammansättning, och förändringar* (The Theory of Population, its Composition, and Models of Change, 1910, 52 pp.). There, apart from the clear demographic analysis it presented, he reiterated the conclusion from his public lectures of the 1880s, that, because of partial depletion and increasing scarcity of natural resources (in Sweden's case primarily timber and iron ore), the country's optimum population should be three million instead of its five million inhabitants, and for Europe a reduction to three quarters of its population as of 1910. Like Malthus and many other writers on population, while he acknowledged the productivity increasing effect of technological progress, he failed to see, and greatly underestimated the fact, that some of the new technology virtually adds to existing resources, in part by turning former waste products to productive uses, in part by increasing the number of uses to which existing resources can be turned.

Wicksell's remaining years at Lund passed quietly. But as his retirement was approaching it threatened renewed hardships for him and Anna. Before coming to Lund they had no savings, and when leaving, they had very little more than their household effects in rented housing. Since Wicksell had served only 16 years at the university, compared with colleagues who at age 65 had usually served 25 or more years, he was barely entitled to two-thirds of the usual professional pension. As the First World War inflated prices, especially in Stockholm to which city he and Anna insisted on moving, two-thirds pension would not pay for much more than house rent.

Two of his friends who were members of parliament succeeded on a motion to obtain a supplementary allowance for him which raised his pension to 90 per cent of the usual amount. There still remained the problem of housing, which had become very expensive in the capital. So his two parliamentarian and several other close friends, including David Davidson and Eli Heckscher, gathered together and by their personal contributions they raised enough money to buy a lot for a house and garden in Mörby, a suburb of Stockholm, and to initiate construction to Anna's specifications. To complete the building of the house, Wicksell negotiated a small mortgage. By Christmas 1916 he and Anna moved into the first house they could call their own.
Now, in his last decade, a new phase of life began for both of them. Anna, who had taken a law degree in 1911 at Lund and had become a leader in the suffrage movement and later the peace movements, now had greater opportunity to be effective than at Lund. Wicksell, freed both from financial worries and the teaching of law courses, could devote himself full time to research and professional activities as an economist with the much greater resources at his disposal for research and opportunities for consultation of Stockholm as compared with Lund. The years 1917–26 were probably the most satisfactory and happiest in their lives.

Wicksell soon became very active. He wrote 29 articles from Mörby on wartime inflation and how to roll it back, on Scandinavia's post-war monetary problems, and on capital theory. From 1915 he had been a consultant to the governor of the Bank of Sweden. In 1916 he and Davidson were appointed to a parliamentary committee on banking and credit. Wicksell's involvement with its work and that of its successor committees lasted until his death. He and Davidson were both appointed as experts to another parliamentary committee on taxation of income and property which remained active from 1918 to 1922. These assignments improved Wicksell's finances, for he was paid somewhat more than his pension for his work with these committees.

Among achievements attributable to Wicksell's and Davidson's collaboration in these councils was the adoption in 1916 of the 'gold exclusion policy' for the Bank of Sweden (to limit inflation the Bank was relieved of the obligation to issue currency at the pre-war mint ratio to gold that had been turned in to it from Sweden's export surplus, and was given power to lower the price of gold in terms of currency). A second achievement was a thorough revision and improvement of the country's taxation of income and wealth.

In this decade, Wicksell also became a much sought-after adviser to young economists about their dissertations. At Lund he had only had three students in economics who took the intermediate graduate degree of phil. lic. under his guidance. In Stockholm, as a very active member of the Swedish Economics Association, and an indefatigable participant in the Economy Club, its inner circle of economists (as distinct from such members as bankers and industrialists), he had easy access to the club members’ graduate students. He was made president of that club, 1917–22. It was a source of satisfaction for him to be sought out to share in the problems of the young men.

Thus his teaching did not stop with his retirement, for Emil Sommarin, Erik Lindahl, the brothers Gustav and Johan Åkerman, Bertil Ohlin, and probably others such as Palander, Lundberg and Hammarskjöld consulted him about their dissertations in addition to benefiting from studying his treatises.

In the 1930s these persons, self-confessed ‘Wicksellians’, formed the core of the ‘Stockholm School of economists’. However, he remained estranged from Gustav Cassel, the third of Sweden's leading economists in the 1920s. This had nothing to do with Cassel's competition with him for the position at Lund in 1900; it was due to Cassel's character. Wicksell found him to be intellectually arrogant, rarely acknowledging the contributions or predecessors whose works he was using, and acting as if economics had been in its infancy prior to Cassel. Wicksell found some of his work to be superficial and his interpretations of several points in economic theory to be misleading. This he expressed clearly in his rather severe review in 1919, of Cassel's magnum opus, The Theory of Social Economy (Wicksell, 1919b).

After that the breach between them was complete. Cassel never replied to Wicksell's review. As a result, Cassel remained an outsider to ‘the Stockholm School’, although he was the mentor of one of its leading members, Gunnar Myrdal.
In spring 1926, Wicksell was working on an article ‘Zur Zinstheorie’ (On the theory of interest) for a Festschrift for Friedrich von Wieser, when he fell ill with a stomach disorder which was further complicated by pneumonia. He died on 2 May 1926, at age 74.

His widow Anna, then a delegate from Sweden to the League of Nations, survived him until 1928. Their eldest son, Sven, became a professor of statistics at Lund University and died in 1939. Their young son, Finn, died in an accident in 1913 at the age of 19, when a medical student at Lund University.

Knut Wicksell would doubtless have objected to the elaborate funeral that was arranged for him, evidently with his widow's consent. Throughout life he had steadfastly rejected as meaningless and offensive to his sense of rationality all pomp and circumstance, academic formalities along with marriage ceremonies, baptism and confirmation for his children.

**Contributions to economics**

In his own lifetime Wicksell did not receive much recognition for his creative work, not even in Scandinavia. It was not until the 1930s, when at the initiative of R.F. Kahn and J.M. Keynes, Geldzins as Interest and Prices and Vorlesungen as Lectures on Political Economy I and II were translated, that economists generally heard of Wicksell. Yet is it clear that his stature in the annals of economics grew steadily after his death. In summary form, his main contributions were these.

**Value, Capital, and Rent** he performed a remarkable labour of synthesis. He adopted the marginal utility and marginal productivity theory of value of Jevons, Menger and Marshall, added to it the Böhm-Bawerk analysis of capital, and fused the result in a Walrasian comparative static general equilibrium framework. In this process he became a founder of the marginal productivity (product exhausting) theory of distribution shortly ahead of Wicksteed. In his Studies in the Theory of Public Finance he pioneered a marginal utility approach to the public sector, synthesizing the benefit and ability principles of taxation, and urging that services of public sector enterprises and natural monopolies be provided on a marginal cost pricing basis.

**Lectures I** he completed the restructuring, begun in Value, Capital and Rent, of Böhm-Bawerk's theory of capital and interest. He reduced Böhm's trinitarian 'grounds' for interest to the simpler, more realistic explanation as the marginal productivity of waiting. He relaxed Böhm’s quantification of capital as an average period of production by a concept of capital as the time structure of inputs invested for various terms in production. He showed that this structure was capable of change in at least two dimensions, width and height. He endeavoured with partial success (on problems still unresolved about ‘Wicksell effects’ and ‘switching of techniques’) to develop a theory of the modes of change of this time structure of production, how it changes and interacts with variations in wages, rent, and interest, in conditions both of capital accumulation and technological change. He extended his treatment of these relationships from comparative static to dynamic analysis, using clear mathematical models for this purpose.

The greatest contribution to monetary analysis, both in terms of novelty back in 1898 and 1906, and in terms of eventual influence by fortifying the related analysis, independently worked up by J.M. Keynes three decades later in his Treatise on Money (1930), was Wicksell's work on monetary theory in Interest and Prices and especially in Lectures on Political Economy II.

Wicksell was a pioneer of applying an aggregate demand–supply approach with emphasis on the relations between investment and saving, to explain variations in value of money or fluctuations in
prices: ‘Any theory of money worthy of the name must be able to show why pecuniary demand for goods exceeds or falls short of the supply of goods in given conditions’ (Lectures II, p. 160).

Most versions of the quantity theory had the price level varying directly and proportionately to changes in the quantity of money. In that theory there was no link from the elasticity, as affected by bank credit, and quantity of money with individual income dispositions and entrepreneurial production decisions. Wicksell provided such a link in his hypothesis that in the absence of certain disturbances over which central banks have no control (such as large influx or efflux of gold, internal cash drains, large government deficits financed by loans from the central bank, fiat issues of inconvertible currencies, sudden and large changes in productivity or supply of goods), price level fluctuations were due to a persistent divergence between the bank rate or market rate of interest and the real rate, defined as the expected rate of return on newly produced capital goods.

The fluctuations of commodity prices, which are not due to a change in gold production [a gold standard currency is assumed here] … have another cause … changes in the real rate of interest … [to which] … the loan-rate does not adapt itself quickly enough. (Lectures II, p. 205)

Thus Wicksell's analysis showed, contrary to that of the simple quantity theory, that it was the quantity of money that adapted itself to the movement of the price level, and in doing so affected the distribution of income and the dispositions to invest and save in the process.

In his analysis monetary equilibrium and stability of prices required the simultaneous fulfilment of the conditions that: (i) the money rate of interest correspond to the real rate; (ii) at that money rate demand for loans for investment and for cash for real balances equal the supply of savings by individuals and business enterprises; and (iii) that interest rate must be neutral in its effect on prices. Then: ‘… equilibrium must ipso facto obtain – if not disturbed by other causes – in the market for goods and services, so that wages and prices will remain unchanged’ (Lectures II, p. 193).

The consistency and compatibility of Wicksell's three criteria for monetary equilibrium and a critique of them in conditions of changing productivity by Davidson were given a thorough exegesis and analysis in the later 1920s and early 1930s by Lindahl, Myrdal and Ohlin. Their work combined with the efforts of younger colleagues such as Lundberg, Hammarskjold and Svennilson greatly expanded the heritage of Wicksellian economic theory and gave rise to the doctrines associated with the Stockholm School of economics.

Selected works

1890b. Überproduction oder Überbevölkerung [Excess production or excess population]. *Zeitschrift für die gesamten Staatswissenschaften* 46.

1894. Våra skatter: hvilka betalar dem, och hvilka border betala? [Our taxes: who pays them, and who ought to pay them?] Stockholm. This was one of Wicksell's early and very popular tracts, written under the pseudonym of Sven Trygg. It provides non-technical background and may be viewed as an introduction to Wicksell (1896).

1907. *Krisernas gåta.* *Statsekonomisk Tidskrift.* Oslo. Trans. by C.G. Uhr as ‘The enigma of business cycles’ in *International Economic Papers* No. 3 (1953), 58–74. This article expands on and lifts to a higher level of analysis the rather primitive treatment of business cycles presented in Wicksell (1890a and 1890b) and in Wicksell's brief ‘Note on trade cycles and crises’ in *Lectures on Political Economy,* vol. 2.

1919b. Professor Cassels ekonomiska system. *Ekonomisk Tidskrift* 21, 195–226. This article, highly critical of several of Cassel's interpretations and formulations of economic theory, has been translated and added as Appendix 1 in *Lectures on Political Economy,* vol. 1, 1934.

1923. *Realkapital och kapitalränta.* *Ekonomisk Tidskrift* 25, 145–80. A review and a mathematical elucidation of the analysis in G. Åkerman's doctoral dissertation *Realkapital und Kapitalzins,* Lund, 1923. It has been translated and added to *Lectures on Political Economy,* vol. 1, as Appendix 2, ‘Real Capital and Interest’. Among other things, this article features demonstrations of both the ‘Wicksell effect’ and the reversal of that ‘effect’ in an effort to determine the relationship between the optimum durability of fixed capital and the rate of interest. As such, this article, long after Wicksell's death, has played an important role in the controversy over capital theory between the Cambridge (England) and Cambridge (Massachusetts) economists.

1925. *Valutaspörsmålet i de skandinaviska länderna.* *Ekonomisk Tidskrift* 27, 103–25. This article has been translated and added to *Interest and Prices* as an Appendix as ‘The Monetary Problem of the Scandinavian Countries’. It represents the several qualifications Wicksell was moved to add to his norm of price level stabilization for monetary policy, qualifications both to meet Davidson's criticism of this norm and to incorporate lessons from the monetary experiences and upheavals of the First World War and its aftermath in the early 1920s. The qualifications were introduced to make allowance for significant increases in productivity, and for something like its opposite, severe commodity shortages due to wartime blockades, crop failure and also for significant issues of fiat money by governments running large deficit budgets, and so on.

A full-scale bibliography of all of Wicksell's published writings is now available. Its author is Dr. E.D.
Knudtson, who has written *Knut Wicksells Tryckta Skrifter 1868–1950* [The published writings of Knut Wicksell, 1868–1950] edited by T. Hedlund-Nyström, and issued in the series Acta Universitatis Lundensis, Section I, Theologia-Juridica-et-Humaniora, No. 25, and published by the C.W.K. Gleerup Publishing House, Lund, Sweden, 1976. This bibliography runs to slightly more than 100 pages and accounts for 889 titles or items dating from Wicksell's student days in the later 1860s through his entire career, inclusive of his many popular articles for Sweden's leading newspapers, and beyond, to include also listings of the translations of his major works and reviews of these translations, which appeared between the decade or two after Wicksell's death.

Article

Wicksteed was born in October 1844 in Leeds, where his father, Charles Wicksteed, was a Unitarian minister. He died, at the age of 83, in March 1927, at Childrey in Berkshire. He attended Ruthin Grammar School in North Wales and then University College School, London, before studying at University College London (1861–4) and at Manchester New College (1864–7) in Gordon Square nearby. He received his Master's degree, with a gold medal for classics, in 1867. Wicksteed then became a Unitarian minister, first at Taunton in Somerset (1867–9), then at Dukinfield, east of Manchester (1870–4), and finally at Little Portland Street Chapel, London (1874–97). He left the ministry in 1897 and thereafter earned his living by writing and lecturing. From 1887 to 1918 Wicksteed was a most active University Extension Lecturer, lecturing on Wordsworth, Dante, Greek tragedy, Aristotle and Aquinas – and economics. He never held a university post.

The great breadth of Wicksteed's intellectual activity was far from being confined to his Extension lecturing. He had a considerable linguistic talent; whilst a minister in Dukinfield, for example, he learned Dutch for the express purpose of translation into English of Oort and Hooykaas's Bible for Young People (six volumes, 1873–9). And he completed a translation, with F.M. Cornford, of Aristotle's Physics only days before his death. Yet it was as a translator, expounder and interpreter of Dante that he became most widely known; his work as a Dante scholar, which extended over more than 40 years,
included translations of and commentaries on the *Vita Nuova*, the *Convivio, De Monarchia* and the *Divina Commedia*. Combined with his theological and philosophical interests, this study of Dante led Wicksteed to Aquinas and thus to the writing of his *Dante and Aquinas* (1913) and his *Reactions between Dogma and Philosophy, illustrated from the Works of S. Thomas Aquinas* (1920). That a study of Aquinas’ thought by a former Unitarian minister could be reviewed favourably in the *Blackfriars Review* is perhaps an indication of the catholicity of Wicksteed's interests and capacities. Nor did those interests extend only to the past; for example, Wicksteed publicly defended the poetry and drama of Ibsen at a time when Ibsen's work was the object of considerable hostility in England. And Wicksteed's numerous contributions to the *Inquirer*, the Unitarian newspaper, over a span of some 50 years, relate not only to theological and literary matters but also to many economic and political issues.

While he had earlier been influenced by the thought of Comte and of Ruskin, Wicksteed's first direct contact with political economy took the form of reading Henry George's *Progress and Poverty*, of corresponding with George in 1882 and 1883 and of being a co-founder, in 1883, of the Land Reform Union, which supported George's lecture tour of England and Scotland in 1883–5. (He continued to support some form of land nationalization long after this time.) It was probably late in 1882 that Wicksteed began to study the work of Jevons and thus to become ‘Jevons's only disciple’. By early 1884, however, he was playing an active role in promulgating Jevonian theory in the Economic Circle, which met until 1888 or 1889 (to be followed by the Economic Club and the British Economic Association, later to become the Royal Economic Society). Wicksteed became a close friend of George Bernard Shaw and of Graham Wallas, and was well-informed about Fabian and other aspects of the ‘social movements’ of the 1880s and 1890s, but was generally an acute and sympathetic observer, rather than a direct participant in those movements. He was, however, a founder member, in 1891, of the Labour Church movement and continued to give that movement strong support even after other early supporters had withdrawn their active sympathy.

Of Wicksteed's other writings in economics, the most important are probably his critique of *Das Kapital*, published in the socialist journal *To-Day* in 1884; his article on Jevons's *Theory of Political Economy* (1889); his various contributions to the first (1894) and second (1925) editions of *Palgrave's Dictionary of Political Economy*; and his ‘Scope and Method of Political Economy’ paper (1914), which originated as Wicksteed's Presidential Address to Section F of the British Association for the Advancement of Science in 1913. (All of these papers appear in the Robbins edition of the *Common Sense*.)

There are a few extant letters (Sturges, 1975, p. 128) and some handwritten sermons and letters at Manchester College, Oxford, but Wicksteed wrote to a correspondent (J.M. Connell) that ‘I have never kept careful records of my life and have next to no documents’. As to secondary material, the following may be consulted: Herford's full biography (1931); Robbins's editorial introduction (1933); the relevant chapters in Hutchison (1953) and Stigler (1941); Steedman's editorial introduction (1987); and the relevant entries in the *Encyclopaedia of the Social Sciences* (by H.E. Batson, vol. 15, 1935) and in the
Wicksteed's first contribution to economic theory was his October 1884 critique of *Das Kapital*, Volume 1. Resulting perhaps from a Fabian challenge within the Economic Circle, it was published in *To-Day*, which, in 1884, carried articles by many of the leading socialists of the time. Wicksteed's critique certainly converted George Bernard Shaw from the Marxian to the Jevonian theory of value and, since no effective reply was published, may have had a wider influence on the theory adopted by British socialists: some writers have regarded Böhm-Bawerk's later attack on the labour theory of value, of 1896, as inferior to that of Wicksteed. Displaying a firm grasp of many of the specific features of Marx's argument, Wicksteed was able to focus clearly on two central issues. Is the exchange value of ordinary commodities determined by labour time? And does Marx's argument apply to 'labour force' (as Wicksteed called it)?

With respect to the first question, Wicksteed follows Marx in saying that if two commodities are exchanged they must simultaneously differ from one another, to motivate the exchange, and have something in common, to make them commensurable. But he then seizes on Marx's point that labour time only 'counts' when producing something useful and argues that it was merely arbitrary for Marx to assert that commodities have only 'abstract labour' in common. On the contrary, Wicksteed insists, all commodities have 'abstract utility, *i.e.*, power of satisfying human desires' in common; moreover, this is just as true of exchangeable objects which are not freely reproducible. Thus, in a neat twist of the argument, he proposes 'abstract utility as the measure of value'. Wicksteed argues, nevertheless, that for freely reproducible commodities equilibrium relative prices will coincide with relative labour costs – but this is not because labour quantities determine prices but because labour will be so allocated as to produce those quantities of the commodities which imply marginal utilities proportional to the given labour costs. For old masters, the products of monopolized industries, and so on, even this coincidence will not hold.

Turning to 'the value of labour-force', Wicksteed then observes that, in a non-slave society, labour is not allocated to the production of 'labour-force' under competitive pressures. He deduces that there is no reason to expect that the ratio of the money wage rate to the labour value of the necessary wage goods will be equal to the money price-embodied labour ratio for ordinary commodities. Consequently, he concludes, Marx has failed to show that 'surplus labour' is the source of profit. Neither George Bernard Shaw nor any other contributor to *To-Day*, or to the other British socialist periodicals of the period, provided a remotely effective reply to Wicksteed's argument.

**The Alphabet**

Wicksteed's *Alphabet of Economic Science*, of 1888, was dedicated to members of the Economic Circle who had 'met to discuss the principles set forth in these pages'. Both the subtitle of the volume and certain remarks in Wicksteed's Introduction suggested that there might be successor volumes but this proved not to be the case. Although the work received the approbation of both Edgeworth and Pareto, it did not find a wide audience, which is perhaps not surprising given that it was simultaneously introductory and somewhat mathematical. As in his other books, Wicksteed disclaimed originality but showed himself to be, at the very least, a most careful and detailed thinker and expositor; in the case of the *Alphabet* a great many vivid examples are used to reinforce the reader's firm grasp of marginal principles. (The book's only index is indeed an index of examples.) As in his earlier reply to G.B. Shaw,
For Wicksteed, the theory of value – or ‘worth’ – means essentially the theory of demand (the theory of supply he refers to as that of production – or ‘making’). In both the discussion of ‘individual worth’ (pp. 1–67) and that of ‘social worth’ (pp. 68–138), stress is firmly laid on the distinction between total and marginal utility. (Wicksteed uses the latter term and avoids Jevons's ‘final utility’ and ‘final degree of utility’.) While the analysis is based on utility rather than on choice or preference – and ‘hedonistic value’ is referred to (p. 54) – Wicksteed's later stress on choice between satisfactions which are rendered comparable at the margin is already foreshadowed in the Alphabet. It is suggested that all marginal utilities and disutilities, for an individual, may be measured in terms of the hedonistic value, to that individual, of foot-pounds of lifting work or perhaps of one hour of correcting examination papers. Although the exposition is elementary throughout the book, the careful reader will notice Wicksteed's remarks on indivisible commodities and marginal analysis, on the acquiring of preferences, on minimum perceived differences, on traditions and habits, on the desire to impress or to give to others, and on negative marginal (and even total) utilities.

Turning to ‘social worth’, Wicksteed asserts at once that interpersonal comparisons of utility are impossible; all that can be said is that the ratio of the marginal utilities of any two commodities is the same for any two individuals who possess some of each commodity. (Wicksteed gives a particularly clear account of why this proportionality rule does not hold for an individual whose possession of one or both of the commodities is zero.) Yet he is still ready to argue, on grounds of ‘averages’ and probabilities, that a more equal distribution of income will probably make the objective social scale of relative prices a more reliable guide to the relative social importance, at the margin, of the various commodities. Wicksteed then discusses the market demand curve, the law of indifference (that is, of one price) and various kinds of price discrimination.

As indicated above, Wicksteed considers that ‘Strictly speaking [the allocation of productive resources] does not come within the scope of our present inquiry’ (p. 109) but he nevertheless devotes pages 109–24 to the allocation of ‘the labour (and other efforts or sacrifices, if there are any others) needful to production’ (p. 109). As in the To-Day essay of 1884, he argues that the relative prices of freely reproducible commodities will, in equilibrium, be equal to their relative effort-and-sacrifice costs but that this is not because production costs give commodities their exchange value. Rather it is because resources are reallocated until the commodities are produced in those quantities for which the marginal utilities – which are the sources of exchange value – will be proportional to the constant costs. Given that Wicksteed argues here in terms of ‘a unit of effort-and- sacrifice’ or ‘a unit of productive force’ (p. 112 and n.), it is not surprising that no theory of distribution is offered or, indeed, even hinted at.

Co-ordination of the Laws of Distribution

Wicksteed's QJE article of the following year, 1889, nevertheless contained an important passage criticizing and extending Jevons's marginal productivity theory of the interest rate, and distribution theory became more prominent in Wicksteed's lectures in the following years. This development culminated with the publication, in 1894, of his famous Essay on the Co-ordination of the Laws of Distribution. A number of writers in the early 1890s began to extend the marginal theory of intensive rent into a more general theory of distribution but it was Wicksteed's Essay which most clarified the
issues involved. He noted that the traditional exposition of intensive rent theory, in which varying amounts of ‘capital-and-labour’ were applied to a fixed amount of land, had two crucial properties. First, that the argument essentially concerned only the proportions between inputs, and not their absolute levels, and second that the whole argument was reversible – the logic is quite unchanged if varying amounts of land are applied to a fixed quantity of ‘capital-and-labour’. It was thus a mere matter of historical accident, Wicksteed argued, that the conventional diagram made one factor return appear as a ‘marginal product’ and the other as a ‘surplus’.

Having argued that it was in any case self-evident that a profit-maximizing entrepreneur would hire each input up to the point at which its marginal value product equalled its (given) price, Wicksteed set himself the task of demonstrating that marginal product pricing of all inputs would entail product exhaustion. (He did not show that there would be any objection in principle to a theory in which one return was determined residually – nor could he have done so.) This he did by a long and inelegant mathematical argument, which amounts to no more (and no less) than a proof of Euler's Theorem for homogeneous functions, in the two-variable case. (As was quickly pointed out by Flux in a review in the Economic Journal for June 1894; there is some evidence to suggest that Wicksteed was completely unaware of Euler's Theorem before reading Flux's review.) More interesting than the inelegance of Wicksteed's proof, however, is that he was not satisfied with the argument, for while he considered it to be a ‘truisim’ that there are constant returns to scale in physical production, he insisted that there might well not be constant returns in terms of revenue. Even if such ‘commercial’ factors as ‘goodwill’, ‘travelling’ and ‘notoriety’ could be increased in the same proportion as all the inputs to physical production, he argued, total revenue might increase in a smaller proportion. Wicksteed was thus led first to consider a monopolist (and to present quite explicitly the marginal revenue formula – already known to Cournot – of the imperfect competition theory of some 40 years later) and then to show how, as the number of firms in an industry becomes ever larger, the product exhaustion theorem will become ‘virtually’ correct. In his later review of Pareto's Manuale (1906) and in The Common Sense (1910, p. 373, n. 1) Wicksteed appeared to withdraw the sixth section of the Essay dealing with product exhaustion in the presence of monopoly, and so on (although not the Essay as a whole) but there has been considerable discussion of just how that apparent withdrawal ought to be interpreted.

Wicksteed's Essay constituted a major contribution to marginal productivity theory, by raising and discussing the product exhaustion question and by setting the theory very firmly in a multi-product, multi-input setting. (The practice of treating capital, or ‘capital-and-labour’, as a single sum of value is sharply criticized.) It is to be clearly noted, however, that the Essay presented partial equilibrium analysis throughout; Wicksteed always takes input prices as given and, contrary to some commentators, he never asserts that input supplies are exogenously determined. The Essay is a major text in partial analysis; it does not present a general equilibrium argument.

The Common Sense

From 1894 to 1910 Wicksteed published very little in the field of economics but in 1906 he was ready to begin work on his magnum opus The Common Sense of Political Economy, published in 1910. In this 700-page book, he sought to expound in minute detail the consequences of ‘the revolution that has taken place’ (p. 2) in economic theory. Disclaiming originality yet again, as he had done in 1888 and in 1894, and making very few explicit references to the work of others, Wicksteed presented a consistently...
subjective approach to all aspects of economic life. (Just five years earlier, in the *Economic Journal*, 1905, p. 435, he had written that ‘The school of economists of which Professor Marshall is the illustrious head may be regarded from the point of view of the thorough-going Jevonian as a school of apologists.’) Ranging from behaviour at the dining table to the significance of the division of labour in an advanced society, Wicksteed argued that attention to *selection between alternatives* was the key to understanding *all* aspects of allocation—whether of bread, of bricks, of friendship, of charity, of labour time or of prayers. Indeed, he even saw an intimate connection between careful marginal allocations and ‘the law formulated by Aristotle with reference to virtue’, that of the mean. The following discussion of Wicksteed’s long, immensely detailed and occasionally prolix work will have to centre on his positive contributions and no reference will be made to weaker parts of his analysis (for example, that on increasing and diminishing returns in Book II, Chapter 5) or to his discussion of distribution theory, already referred to above in relation to the *Essay* of 1894. (Wicksteed’s famous ‘Scope and Method’ paper, of 1914, presents an incisive epitome of the central themes of the *Common Sense* and may serve as an introduction to it.)

Wicksteed’s analysis of choice, in the *Common Sense*, is firmly based on the concept of a scale of preferences, diminishing marginal significance and equivalence at the margin; it has been freed from the notions of utility and marginal utility as quantities, which are still evident in the earlier *Alphabet*. Moreover, while there is some room for doubt, in the *Alphabet*, whether the ‘marginal utility’ of a commodity depends only on the quantity of that commodity or on the quantities of all the commodities possessed, it is completely clear, in the *Common Sense*, that the ‘marginal significance’ of a quantity of a particular commodity depends on all the quantities in question. Indeed it depends not only on all those quantities but on all the circumstances of the choosing individual, for Wicksteed is insistent throughout that *all* objects of choice, and not just marketable commodities, have a bearing on each choice. The principles at work in the allocation of money between potatoes and milk are the same as those involved in the allocation of time between friendship and prayer: ‘whatever our definition of Economics and the economic life may be, the laws which they exhibit and obey are not peculiar to themselves, but are laws of life in its widest extent’ (p. 160). Wicksteed’s firm refusal to draw boundaries is more readily understood when account is taken of his conviction that ‘these things, of which money gives us command, are, strictly speaking, never the ultimate objects of deliberate desire at all … as soon as we deliberately desire possession of any external object, it is because of the experiences or the mental states and habits which it is expected to produce or to avert’ (p. 152). In modern terms, the underlying preference ordering is over mental experiences, not over commodities, and there is no reason to expect that ‘economic’ choices will fall under different principles than do ‘other’ choices.

The individual’s preference ordering, Wicksteed argues, will be complete but will not always be consistent (transitive), although reflection will increase its consistency. The ordering often will not be, and will not need to be, fully present to the agent’s consciousness. Apparently ‘irrational’ behaviour based on impulse, habit or tradition certainly occurs but does not undermine the fundamental principles of rational behaviour; ‘Habit or impulse perpetually determines our selection between alternatives … But if [the terms on which alternatives are offered us] are altered beyond a certain point the habit will be broken or the unconscious impulse checked’ (pp. 28–9). Expectations, uncertainty and consumption loans are all discussed by Wicksteed, as is the fact that rational administration of one’s resources is itself costly, in terms of time and effort, and thus should not be pursued beyond a certain point. Throughout his analysis of choice between alternatives Wicksteed returns repeatedly to the idea that the most
heterogeneous of satisfactions not only can be but actually are compared at the margin. He is thus led to consider how this analysis can represent ‘the martyr who has borne the rack [and] is ready to be burnt to death sooner than depart a hair’s breadth from the formula of his confession’ (p. 404) or the man for whom there are ‘certain things which he would not do for any amount of money, however large’ (p. 405). Wicksteed's answer, in terms of all other considerations falling below a minimum sensible in such cases, appears to do little more than provide a polite reconciliation between his equality of marginal satisfactions and the presence of a lexicographic priority of honour over money, or of keeping the faith over escaping torture. Indeed, it is not clear how Wicksteed could maintain his own insistence that ethical considerations have priority over others (pp. 123–4), without allowing for at least some element of lexical ordering of alternatives. That said, Wicksteed's many subtle illustrations of how often disparate satisfactions are compared and equated at the margin remain highly instructive.

That Wicksteed pursued to the limit the concept of the rational maximizing individual is far from meaning that he had an asocial or ‘atomistic’ view of individual agents, or that he subscribed to the methodological fiction of the ‘economic man’. On the contrary, his most important contribution to marginal theory perhaps lies in his forceful rejection of the ‘economic man’ concept and his closely related demonstration that the marginal analysis of individual action is entirely compatible with the recognition of the intrinsically social nature of many, even most, of the individual agent's purposes and concerns. Whilst the whole of the Common Sense contributes powerfully to this ‘double’ argument, it is in Book I, Chapter 5, ‘Business and the Economic Nexus’, that these issues are confronted most directly. ‘But when we pass … to the phrase “the economic motive” … we are in the presence of one of the most dangerous and indeed disastrous confusions that obstruct the progress of Economics’ (p. 163), Wicksteed argues, for there can be no non-arbitrary way of distinguishing motives and considerations which do influence economic actions from those which do not. There are thus two coherent alternatives; ‘We may either ignore motives altogether, or may recognise all motives that are at work, according to the aspect of the matter with which we are concerned at the moment; but in no case may we pick and choose between the motives we will and the motives we will not recognise as affecting economic conditions’ (p. 165). (In fact Wicksteed very seldom adopts the former, external or behaviouristic analysis, even if there is one passage, p. 34, which strongly evokes the later ‘revealed preference’ approach.) If all motives are to be considered by the economic theorist, it follows, of course, that ‘The proposal to exclude “benevolent” or “altruistic” motives from consideration in the study of Economics is … wholly irrelevant and beside the mark’ (p. 179); the interests which an agent seeks to pursue may or may not be directly his own. (And motivations can very well be mixed.) But if all motives are to be taken into account, and if the principles guiding economic activity are simply the principles guiding all human activity, what defines the particular object of study of the economist? For Wicksteed, the answer lies in the concept of ‘economic relations’; ‘economic investigation is concerned [with] the things a man can give to or do for another independently of any personal and individualised sympathy with him or with his motives or reasons’ (pp. 4–5). When persons A and B stand in an economic relation to one another, they may well be furthering each other’s purposes in fact but A enters the relation with no thought or intention of promoting B's ends and B, likewise, is motivated by no desire to further the purposes of A; however rich and complex may be the motivations of A and of B, the economic relation between them is an impersonal one. ‘The economic relation does not exclude from my mind every one but me, it potentially includes every one but you’ (p. 174). To stress this point Wicksteed introduced the term ‘non-tuism’, which serves to focus attention upon the
fact that, in an economic relation, A's lack of concern for the purposes of B (and vice versa), by no means entails that A acts from selfish motives. ‘The specific characteristic of an economic relation is not its “egoism” but its “non-tuism”‘ (p. 180).

With respect to the ‘supply side’ – a term which he might well have rejected – Wicksteed's central contributions lay in his stress on the conception of costs as opportunity costs and in his related views on reservation price and the supply curve as a ‘reverse’ demand curve. Wicksteed laid considerable emphasis on the idea that, no matter how indispensable productive inputs might be, ‘within limits, the most apparently unlike of these factors of production can be substituted for each other at the margins’ (p. 361). (Although it is noteworthy that, in the Essay of 1894, he had explicitly drawn attention to the possibility of completely dispensable inputs, p. 37, n. 1.) This emphasis no doubt facilitated – but did not, of course, entail – his insistence on the opportunity costs view of cost of production. ‘Cost of production’, he wrote, ‘is simply and solely “the marginal significance of something else”’ (p. 382) or, less abstractly, ‘By cost of production, or cost price, when the phrase is used without qualification, I mean the estimated value, measured in gold, of all the alternatives that have been sacrificed in order to place a unit of the commodity in question upon the market’ (p. 385). As he had done in 1884 and 1888, Wicksteed argued that ‘there is a constant tendency to equality between price and cost of production, but not because the latter determines the former’ (p. 358). The central thrust of the opportunity cost doctrine was thus directed against the ‘real cost’ doctrines. In his 1905 attack on the ‘apologetic’ school headed by Professor Marshall (referred to above), Wicksteed had written that ‘To scholars of this school the admission into the science of the renovated study of consumption leaves the study of production comparatively unaffected. As a determining factor of normal prices, cost of production is co-ordinate with the schedule of demands registered on the “demand curve”‘. His conclusion in 1910 was more explicit: ‘The only sense, then, in which cost of production can affect the value of one thing is the sense in which it is itself the value of another thing. Thus what has been variously termed utility, ophelemity, or desiredness, is the sole and ultimate determinant of all exchange values’ (p. 391). This was naturally a striking and challenging conclusion but Wicksteed did not give adequate consideration to the implications for the opportunity cost doctrine of limitations to factor mobility or of the presence of non-pecuniary benefits. (See the entry reservation price and reservation demand for further discussion of Wicksteed's ‘rejection’ of the supply curve.)

If Wicksteed's Common Sense is not flawless, it remains a brilliant demonstration that a writer who had a strongly ‘social’ conception of the individual agent, who was friendly to the socialist and labour movements of his time, and who was sometimes a sharp critic of the market system, could yet be a purist of marginal theory.

Wiener process

A.G. Malliaris
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Brownian motion is the most renowned, and historically the first stochastic process that was thoroughly investigated. It is named after the English botanist, Robert Brown, who in 1827 observed that small particles immersed in a liquid exhibited ceaseless irregular motion. Brown himself mentions several precursors starting at the beginning with Leeuwenhoek (1632–1723). In 1905 Einstein, unaware of the existence of earlier investigations about Brownian motion, obtained a mathematical derivation of this process from the laws of physics. The theory of Brownian motion was further developed by several distinguished mathematical physicists until Norbert Wiener gave it a rigorous mathematical formulation in his 1918 dissertation and in later papers. This is why the Brownian motion is also called the Wiener process. For a brief history of the scientific developments of the process see Nelson (1967).

Bachelier, L.; Brownian motion: see Wiener process; geometric Wiener process; stochastic calculus; uncertainty; Wiener process

Article

Having made these remarks we now define the process. A **Wiener process** or a **Brownian motion process**

\[ \{ Z(t, \omega) : [0, \infty] \times \Omega \to \mathbb{R} \} \]

is a stochastic process with index \( t \in [0, \infty] \) on a probability space \( \Omega \) and mapping to the real line \( \mathbb{R} \), with the following properties:
1. (1) \(Z(0, \omega) = 0\) with probability 1, that is by convention we assume that the process starts at zero.
2. (2) \(0 \leq t_0 \leq t_1 \leq \ldots \leq t_n\) are time points then for any real set \(H_i\)

\[
P[Z(t_i) - Z(t_{i-1}) \in H_i \text{ for } i \leq n] = \prod_{i \leq n} P[Z(t_i) - Z(t_{i-1}) \in H_i].
\]

This means that the increments of the process \(Z(t_i) - Z(t_{i-1}), i \leq n\), are independent variables.
3. (3) For \(0 \leq s < t\) the increment \(Z(t) - Z(s)\) has distribution

\[
P[Z(t) - Z(s) \in H] = \left(\frac{1}{\sqrt{2\pi(t-s)}}\right) \int_H \exp \left[-\frac{x^2}{2(t-s)}\right] \, dx.
\]

This means that every increment \(Z(t) - Z(s)\) is normally distributed with mean zero and variance \((t - s)\).
4. (4) For each \(\omega \in \Omega\), \(Z(t, \omega)\) is continuous in \(t\), for \(t \geq 0\).

Note that condition (4) can be proved mathematically using the first three conditions. Here it is added because in many applications such continuity is essential. Although the sample paths of the Wiener process are continuous, we immediately state an important theorem about their differentiability properties.

**Theorem:** (non-differentiability of the Wiener process) Let \(\{Z(t), t \geq 0\}\) be a Wiener process in a given probability space. Then for \(\omega\) outside some set of probability 0, the sample path \(Z(t, \omega), t \geq 0\) is nowhere differentiable.

Intuitively, a nowhere differentiable sample path represents the motion of a particle which at no time has a velocity. Thus, although the sample paths are continuous, this theorem suggests that they are very kinky, and their derivatives exist nowhere. The mathematical theory of the Wiener process is presented rigorously in Billingsley (1999, ch. 37) and more extensively in Knight (1981).

The first application of Brownian motion or the Wiener process in economics was made by Louis Bachelier in his dissertation ‘Théorie de la spéculation’ in 1900. Cootner (1964) collects several papers and cites additional references on the application of the Wiener process in describing the random character of the stock market. In the early 1970s Merton, in a series of papers, established the use of stochastic calculus as a tool in financial economics. The Wiener process is a basic concept in stochastic calculus and its applicability in economics arises from the fact that the Wiener process can be regarded as the limit of a continuous time random walk as step sizes become infinitesimally small. In other words, the Wiener process can be used as the cornerstone in modelling economic uncertainty in continuous time. For purposes of illustration consider the stochastic differential equation

\[
\frac{dZ(t)}{dt} = \mu(t, Z(t)) dt + \sigma(t, Z(t)) dW_t.
\]
\[ dX(t) = \mu(t, x)dt + \sigma(t, x)dZ(t) \]  

which appears in the economic literature describing asset prices, rate of inflation, quantity of money or other variables. In (1), changes in the variable \( X(t) \), denoted as \( dX(t) \), are described as a sum of two terms: \( \mu(t, x) \) which is the expected instantaneous change and \( \sigma(t, x) dZ(t) \) which is the unexpected change. Furthermore, this unexpected change is the product of the instantaneous standard deviation \( \sigma(t, x) \) and uncertainty modelled by increments in the Wiener process. See Merton (1990, ch. 3) for a methodological essay on continuous-time modelling, and Malliaris and Brock (1982) or Chang (2004, ch. 2) for numerous applications of the Wiener process in economics and finance.

Economists have constructed various processes based on the Wiener process. Let \( \{Z(t), t \geq 0\} \) be a Wiener process and use it to construct a process \( \{W(t), t \geq 0\} \) defined by \( W(t) = Z(t) + \mu t, t \geq 0 \) where \( \mu \) is a constant. Then we say that \( \{W(t), t \geq 0\} \) is a Wiener process or Brownian motion process with drift and \( \mu \) is called the drift parameter. In this case the only modification that occurs in the definition of a Wiener process is in property (3) where \( W(t) - W(s) \) is normally distributed with mean \( \mu(t-s) \) and variance \( (t-s) \). Finally, let \( W(t) \) be a Wiener process with drift as just defined. Consider the new process given by \( Y(t) = \exp [W(t)], t \geq 0 \). Then \( \{Y(t), t \geq 0\} \) is called a geometric Brownian motion or geometric Wiener process.

The availability of an extensive mathematical literature on the Wiener process and the economists’ fundamental goal to model economic uncertainty in continuous time suggest that this process will continue to be an important tool for economic theorists.

Wieser, Friedrich Freiherr, (Baron) von (1851–1926)

E. Streissler

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Austrian economics; Austrian School; Böhm-Bawerk, E. von; countervailing power; efficient production; equimarginal principle in production; imputation; innovation; marginal utility; Menger, C.; Mises, L. E. von; natural value; opportunity cost; Schumpeter, J. A.; Wieser, F. F. von

Article

Wieser is commonly cited together with his senior, Carl Menger, and his exact contemporary, Eugen Böhm von Bawerk, as one of the founding trio of the Austrian School of Economics in the last quarter of the 19th century. The exact nature of his achievement, however, seems now practically forgotten: possibly because he produced an intractable mixture of deep and influential insights, very distinctly his own, intermingled with oratorical prose and often unpalatable value judgements; he was extremely successful in his own generation but appeared outdated in his attitudes half a century later.

Wieser was born on 10 July 1851, in Vienna. His father was Commissary-General of the Austrian army in the war of 1859, for which service he was ennobled, later becoming Vice President of the Austrian Court of Audit, a baron and a privy councillor (Geheimrat). But this high social status was only acquired after Friedrich Wieser's birth and very little money went with it so that the family lived in modest circumstances. Wieser went to the Benedictine Schottengymnasium in Vienna, one of the city's three elite schools. His classmate was Eugen Böhm von Bawerk, who became his close friend and brother-in-law. Together the two studied at Vienna University law faculty (which included courses in economics), together they entered the civil service in the fiscal division, and together they went on a two-year leave of absence to perfect themselves in economics at Heidelberg, Leipzig and Jena, with Knies, Roscher and Hildebrand. A little after Böhm, Wieser passed his ‘Habilitation’ in economics with Menger in 1883, was appointed associate professor in 1884 and full professor in 1889 at the University of Prague and was that university's Vice Chancellor in 1901–2. In 1903, he succeeded Menger in the chair of economic theory at Vienna University law faculty on the latter's early retirement, Böhm again joining him only a year later as extraordinarily appointed additional full professor. Böhm, Menger, and finally also Wieser served as members of the Austrian House of Lords (Herrenhaus). Wieser became Minister of Commerce...
in 1917, holding this office up to the end of the monarchy in 1918. He died on 23 July 1926.

Apart from the short ministerial interlude Wieser thus taught from 1884 to 1926 at the largest universities of Austria. Basically, he must be considered the most successful teacher (especially of undergraduates) and the orator of the trio. His influence was pervasive through his lecturing to tens of thousands of law students, many of whom he examined in person, and at second and third remove on even vaster numbers in the intellectual melting pot of Vienna. In a true oral tradition Wieser influenced present-day economics through what these frequently very young students – an appreciable percentage of whom later became themselves important in Western intellectual life – picked up in a kind of intellectual osmosis, mostly without realizing it and therefore usually without attributing the ideas to their teacher.

Wieser's main works are: his thesis of ‘Habilitation’ (Wieser, 1884), which encompasses a large part of his original thought, particularly the marginal productivity valuation of factors of production and his cost theory; Wieser (1889), mainly an elaboration of the former together with an attempt to give the marginal utility concept normative distributional content; Wieser (1914), the definitive textbook of the Austrian School and (with its rival, G. Cassel's more up-to-date *Theoretische Sozialökonome*, 1918) one of the two main theoretical textbooks in German of the early interwar period, a book still worth reading, especially the less well-known institutional chapters on large corporations and money and banking; finally Wieser (1926), a socio-philosophical tract in abject adulation of power (power being justified by mere ‘success’), whose lack of judgement can only be justified by the effect of the total breakdown of all established social and political order after the First World War on Wieser's own moral fibre.

Wieser prided himself on the invention of telling phrases, particularly the term ‘Grenznutzen’ in Wieser (1884), wherefore Marshall credits him, perhaps unjustly, with originating the term ‘marginal utility’. During his leadership the Austrian School had to sail under the flag ‘Grenznutzenschule’. In contrast to the purely analytic usage by the other members of the trio, ‘Grenznutzen’ had for Wieser a near mystic connotation and certainly normative content: more precisely, it is the average marginal utility in a competitive society with equality of incomes which is the ‘natural value’ of Wieser (1889).

‘Grenznutzen’ thus served Wieser, who was (unusual for an Austrian economist) a paternalistic interventionist, as a yardstick of policy evaluation.

In contrast to Menger and Böhm, Wieser was not a clear logical analyst but had influential visions. He was clearest in his cost and production theory, frequently being credited with introducing the opportunity cost principle that all costs are only utilities forgone, though Wieser's actual advance over Menger appears slight. Wieser certainly, however, gave what appears to be the first account of the principles of efficient production, which Menger had ignored (Wieser, 1884). Production is undertaken in expectation of the price the marginal valuation of consumers will allow, Wieser (1884) first formulating the equimarginal principle in production: the marginal product of each factor (or its cost) must be the same in all its different uses and as high as the least important marginal utility achievable from its given supply (Wieser's Law of Cost). In Wieser (1914) this is extended (contemporaneously with Wicksteed, *Common Sense of Political Economy*, 1910) to an analysis of differential quality rents on the lines of Ricardo: any more efficient factor earns as rent the additional value added over the least efficient equivalent factor. Some of his insights into capital and efficient production Wieser probably owes, as the terminology suggests, to Marx (Wieser never gives his authorities, apart from sparse references in Wieser, 1914): for example that the value of factors of production must reflect the socially necessary cost of production (the use of the best generally known technique); or that innovation brings
extra profits to the innovator, without changing the value of the (other) factors. (Marx, Engels, Ricardo, Jevons and Menger are the five authors Wieser acknowledges as inspiration in the Introduction to Wieser, 1884.) As to distribution, Wieser first posed the problem whether the marginal product reward of all factors of production would exactly exhaust the product (‘Zurechnungsproblem’, the problem of imputation), without being, despite many attempts, able to solve it.

These ideas were, however, all on the point of being discovered by others. Uniquely his own is the repeated stress, already in Wieser (1884), of the paramount importance of economic calculation and the need to have an economic measuring rod for all rational ‘planning’ for the future. (One is tempted to suspect this to be an obsession of the son of the Vice President of the Court of Audit.) The measuring rod for Wieser is marginal utility in its wide sense; but it was a small step, taken by Mises and Hayek, to make out of this need for a measuring rod in all economic planning the concept of the informative nature of prices. Economics may even owe the (then uncommon) term ‘planning’ for the rational activity in economics on the individual as well as the societal level to Wieser via Mises. Wieser already stated repeatedly that even a socialist economy would have to use the same economic measuring rod and basically the same principles of ‘planning’ as a capitalist one: out of which Mises developed the idea that, lacking prices, a socialist society could not plan rationally.

Besides his production and distribution-oriented ideas Wieser had a second influential vision: the importance of the creative individual in all economic processes. He felt deeply the basically contradictory nature of his two visions, the impersonal mass effects of efficient production on the one hand, an idea which he curiously traced to the influence of Herbert Spencer, and the elitist idea of the effects of the outstanding individual, which he attributed to the hero-worshipping teaching of history in the Schottengymnasium. In this vein, which he cultivated in his later years, he was again, above all, influential through the forceful and suggestive use of words, the terms ‘Führer’, ‘Pionier’, ‘Neuerung’ (German for innovation) being of his creation. Schumpeter adopted virtually all the terminology for his *Theory of Economic Development* (1912) from his acknowledged teacher Wieser and also the idea that economic ‘dynamics’ (in contrast to statics) is due to individual leadership activity. Wieser himself had developed relatively few concrete conclusions out of his leadership rhetoric, apart from remarks about the countervailing power of trade unions and the administrative and even innovative efficiency of large corporations in Wieser (1914), an idea taken up by Schumpeter only later. Wieser’s second vision degenerated into the lurid prose of Wieser (1926), where, for example, the ‘Führer’ (a pet word of Wieser’s), Adolf Hitler, is chided (in 1926!) for not quite making the grade. For Wieser, again in sharp contrast to the staunch liberal principles of Menger and Böhm, tended, in spite of his basic Catholic-conservative outlook, to flirt with any social movement that was new and appeared ‘great’, making commendatory references to socialism in his youth and to German nationalism and fascism in his old age.

Wilson, Edwin Bidwell (1879–1964)

Murray Milgate

Edited by John Eatwell, Murray Milgate and Peter Newman

Article

While primarily a mathematician, Wilson's relatively few contributions to economics in the interwar years, particularly two short papers on demand theory (1935 and 1939) and one on business cycles (1934), were not without their influence in Harvard economic circles of the day. Schumpeter drew on the arguments of Wilson's paper on the periodicity of US business cycles in his *Business Cycles*, and Samuelson's *Foundations* contains an acknowledgement to Wilson (with Schumpeter and Leontief) in its preface, and credits him with the suggestion of utilizing the Le Chatelier principle in economic analysis. The essay on cyclical fluctuations in business activity was an attempt to make deeper analytical use of the monthly index of US business activity prepared by Leonard Ayers and published in 1931. Using the device of the ‘periodogram’, invented by Arthur Schuster, Wilson is able to extract from Ayers' data ‘hidden’ cycles of different periodicities. The idea that behind any given aggregative series there might lurk different patterns of cyclical movement was, no doubt, a spur to Schumpeter's consideration of the simultaneous operation of Juglar, Kitchin and Kondratieff cycles in *Business Cycles*.

The two short essays on demand theory (1935 and 1939) are concerned with the derivation of the law of demand – that is, the inverse relationship between price and quantity demanded. The first generalizes Pareto's proof of the proposition, which had assumed additively separable utility functions. Wilson assumes instead only that $U_i(x_1 \ldots x_n)$, may take the form $U_i(x_1) + U_i(x_2 \ldots x_n)$ and derives from this the law of demand. The second paper is designed to show that Marshall's assumption of a constant marginal utility of money gave only a special case of the law of demand, and that the same result could be obtained without it. As Wilson observed, this ‘forces us over from the “index of ophelimity” to a utility definite except for a linear transformation, i.e., except for scale and origin’ (1939, p. 649). The importance of this result, especially given its relation to the Hicks–Allen theory of demand, for the subsequent debates over cardinal versus ordinal utility is readily apparent.

Wilson was born at Hartford, Connecticut, on 25 April 1879. After graduating from Harvard in 1899, he took his Ph.D. from Yale in 1901. From 1907 until 1922 he was on the faculty at MIT, first as professor of mathematics and later as professor of mathematical physics. From that date until his retirement, he was professor of vital statistics at the Harvard School of Public Health. He served as president of the American Statistical Association (1929), was vice-president of the National Academy of Sciences (1949–
Wilson, Edwin Bidwell (1879–1964), and was an honorary fellow of the Royal Statistical Society. He died on 28 December 1964.

Witte, Edwin Emil (1887–1960)
W. Cohen

Edited by Steven N. Durlauf and Lawrence E. Blume

**Keywords**
Witte, E. E.; Social Security in the United States

**Article**

Witte was Professor of Economics at the University of Wisconsin (1933–57), President of the American Economic Association (1955), first President of the Industrial Relations Research Association (1948), and Chief of the Wisconsin Legislative Reference Service (1922–33). His primary field was labour and social legislation. A student of John R. Commons, he was an institutional economist and a pragmatic social reformer.

His outstanding contribution was his significant role as Executive Director of President Franklin D. Roosevelt's Cabinet Committee on Economic Security (1934–5) which drafted the legislation that became the Social Security Act of 1935. Witte prepared the Committee's report and recommendations to the President. His *The Development of the Social Security Act* (1936) recounting the legislative history of the Act is an outstanding model of its type.

Witte published *The Government in Labor Disputes* (1932), assisted in the formulation of the Norris–LaGuardia Act (1932) restricting injunctions in labour disputes and he was Regional Director of the War Labour Board in Detroit (1942–5).

Witte received his Ph.D. in economics from the University of Wisconsin (1927) and was Chairman of the Department of Economics (1936–41 and 1946–57). Except for temporary assignments, he lived in Wisconsin all his life. He had a practical outlook on economic and political issues, coloured by LaFollette progressive populism.

Wold was born at Skien in Norway on 25 December 1908 but the family migrated to Sweden in 1912. His university education was at Stockholm, where he took his doctoral degree in 1938, under H.A. Cramér. He became Professor of Statistics at Uppsala in 1942, moved to Gothenburg in 1970, and retired in 1975.

His doctoral thesis (Wold, 1934) dealt with the theory of stationary time series. Two theorems first proved in it are of lasting value. The first is the Wiener–Khintchine relation for a discrete–time series, but probably more important was the Wold Decomposition Theorem, which represents a stationary time series as the sum of an (infinite) moving average of past innovations (linear prediction errors) and a perfectly predictable component. Wold was also influential in time series analysis through his student, P. Whittle.

However, most of Wold's later work has been in econometrics. Membership of a 1938 committee to study consumer demand, rationing in case of war being the motivating force, led him to the study of general economic modelling. His work on consumer demand culminated in Wold and Juréen (1952). Economic modelling, in turn, led him to the work of Tinbergen (1939) on the statistical measurement of business cycles. Tinbergen's model was linear and connected a vector, $y(t)$, of endogenous variables to a vector, $z(t)$, of exogenous variables and lagged endogenous variables by an equation

$$y(t) = By(t) + Gz(t) + \varepsilon(t), \quad E\{\varepsilon(s)\varepsilon(t)\}' = \delta_{s,t} \Omega$$

(1)

where the $\varepsilon(t)$ are errors. Wold observed that Tinbergen's equations were recursive in that after a rearrangement of the rows of (1) the matrix $B$ was lower triangular with zeros along the diagonal. If $\Omega$ is diagonal then (1) may be validly estimated by least squares and this will be the maximum likelihood method if the $\varepsilon(t)$ are also Gaussian. Wold sought to promote recursive modelling in contrast to the non-
causal modelling that became influential in econometrics following Haavelmo (1944). The recursive models are causal since, after the rearrangement of rows, elements of $y(t)$ can be regarded as arranged in a causal hierarchy. Wold's view does not seem to have prevailed. The complexity of economic phenomena, including the nonlinearity of economic behaviour, the poor quality of much data, and the large amount of aggregation, together with autocorrelation of $\varepsilon(t)$, make the issue seem somewhat removed from reality.

Wold (1959) also emphasized the distinction between prediction and structural estimation and has proposed an iterative estimation of (1), oriented towards prediction, where $y(t)$ on the right is replaced by $(I - \hat{B})^{-1}(\hat{C}z(t))$, with $\hat{B}$, $\hat{C}$ obtained from a previous iterations.

women's work and wages

Francine D. Blau and Lawrence M. Kahn
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Since the early 1980s the gender wage gap has fallen in most economically advanced countries, although a gender wage differential remains in all countries. We first document for several industrialized countries recent trends in the gender gap in labour force participation and earnings. We then outline several explanations for the gender wage gap at a given point in time, changes in the gender gap over time, and differences in its extent across countries. Next, we consider the empirical evidence in support of various explanations. We conclude with some thoughts about future prospects for the gender wage gap.

Article

Since the early 1980s the gender wage gap has fallen in most economically advanced countries, although a gender wage differential remains in all countries. While labour market outcomes for men and women may vary across a number of dimensions, economists have particularly focused on analysing gender differences in wages. This emphasis reflects a number of factors. The wage is a major determinant of economic welfare for employed individuals, as well as of the potential gain from market work for those not currently employed. Further, it affects decisions ranging from labour supply to marriage and fertility, as well as bargaining power and relative status within the family.
This article begins with an overview across a number of economically advanced countries of labour force participation and earnings differences between men and women in the labour market, and delineates the recent trends. We then consider the explanations that have been offered for the gender wage gap at a given point in time as well as for changes in the gender gap over time and differences in its extent across countries. Next, we consider the empirical evidence in support of various explanations. We conclude with some thoughts about future prospects for the gender wage gap.

Overview of gender differences in labour force participation and wages

Although the focus of this article is the gender wage gap, it is useful to consider the evolution of labour force participation rates by gender. Women's rising labour force participation implies that women's wage gains, discussed below, apply to an increasing share of the female population. In addition, changing female participation can mean that the qualifications and experience of the typical employed woman may be changing as well. To the extent that women's rising participation is associated with rising labour force attachment of women over the life cycle, the average level of labour market experience of women will eventually increase. Changing participation rates may also be associated with changes in labour force selectivity of women, depending on the relative qualifications of entrants and incumbents. And these factors in turn may help us explain the evolution of the gender wage gap. Table 1 shows that, across ten economically advanced countries, women's labour force participation rates rose steadily between 1979 and 2000, both absolutely and relative to men, with a faster increase in the 1980s than the 1990s. For example, taking an unweighted average of the countries listed in the table, we see that women were 64 per cent as likely as men to be in the labour force in 1979; by 1990, this ratio had risen to 77 per cent and, by 2000, it was 83 per cent. Throughout this period, Scandinavian women had especially high participation rates.

Women’s work and wages: The New Palgrave Dictionary of Economics

Notes: For 1990 and 2000, ages are 16–64 for Sweden, the United Kingdom and the United States. Germany is defined as West Germany in 1979 and 1990 and unified Germany in 2000.

Table 2 shows female to male pay ratios from the OECD across the same ten countries shown in Table 1. The entries in Table 2 are intended to show the price of labour; in some cases the data are available as weekly or monthly earnings of full-time workers (Panel A), and in others as annual earnings of full-time, year-round workers (Panel B). As may be seen in the table, women uniformly have lower wage rates than men. However, in all but one case, the gap fell between 1980 and 2000. (The exception is Sweden where the pay gap rose by one percentage point from an already low level in 1980.) For example, between 1980 and 2000, the ratio of women's to men's wages rose from an average of 69 to 77 per cent among the countries in Panel A, and from an average of 78 to 83 per cent among countries in Panel B. (US Current Population Survey data indicate that the gender gap in annual pay for full-time, year-round workers is slightly higher than the gender gap in weekly earnings for full-time workers, suggesting that the gap in weekly wages for the countries in Panel B may be even smaller than the figures shown in Table 2.) The gender wage gap is especially small in France, Australia, Sweden and New Zealand. The United States had one of the larger gaps in 1980, with only Japan having a lower female to male wage ratio. Over the 1980–2000 period, the gender wage gap fell by more, both absolutely and relatively, in the United States than in any of the other countries shown. Nonetheless, even in 2000 the gender wage gap remained relatively high in the United States, as other wage differentials such as those for education, cognitive ability or union membership have historically been (Blau and Kahn, 2002; 2005). As we shall see, the pattern of international differences in the gender wage gap is useful in shedding light on the impact of labour market institutions on the gender gap. This is because there are very large differences in the types of such institutions across the economically advanced countries that have consequences for the size of the gender wage gap.

Explanations for the gender wage gap

Traditionally, economic analyses of the gender wage gap have focused on what might be termed gender-specific factors, that is, (a) gender differences in qualifications and (b) differences in the labour market treatment of men and women (or labour market discrimination). More recently, following the work of Juhn, Murphy and Pierce (1991) on trends in race differentials, some advances have been made by considering the gender wage gap and other demographic wage differentials in the context of the overall structure of wages. Wage structure is the array of prices determined for labour market skills and the rewards to employment in particular sectors. In addition, gender-specific factors and wage structure can interact to affect the gender wage gap.

Gender-specific factors

Gender differences in qualifications have primarily been analysed within the human capital model (Mincer and Polachek, 1974). Given the traditional division of labour by gender in the family, women tend to accumulate less labour market experience than men. Further, anticipating shorter and more discontinuous work lives, women have lower incentives to invest in market-oriented formal education and on-the-job training. Their resulting smaller human capital investments will lower their earnings relative to those of men. Working in a similar direction is Becker's (1985) model in which the longer hours women spend on housework lower the effort they put into their market jobs compared with men and hence reduce their wages.

Gender differences in occupations are also expected to result if women choose occupations for which on-the-job training is less important. Women may especially avoid jobs requiring large investments in firm-specific skills (that is, skills which are unique to a particular enterprise), because the returns to such investments are reaped only as long as one remains with a particular employer. At the same time, employers may also be reluctant to hire women for such jobs because they bear some of the costs of firm-specific training (see the discussion of statistical discrimination below).

To the extent that gender differences in outcomes are not fully accounted for by productivity differences derived from these and other sources or by compensating differences in non-wage job characteristics such as risk of injury, models of labour market discrimination offer an explanation. In Becker's (1957)
model, discrimination is due to the discriminatory tastes of employers, co-workers or customers. Alternatively, in models of statistical discrimination (for example, Aigner and Cain, 1977), which assume a world of uncertainty, differences in the treatment of men and women arise from differences between the two groups in employer perceptions of the expected value of productivity or in the reliability with which productivity may be predicted. In either case, gender differences in wages or occupations may result. Another aspect of interest is the relationship between occupational segregation and a discriminatory wage gap formulated in Bergmann's (1974) overcrowding model. She argues that discriminatory exclusion of women from ‘male’ jobs results in an excess supply of labour in ‘female’ occupations, depressing wages there for otherwise equally productive workers. The same wage outcomes could also be observed if women voluntarily exclude themselves from male jobs due to gender differences in preferences for the jobs themselves or for various attributes of the jobs (for example, long hours or necessity for travel).

Two recently proposed models of discrimination suggest alternative motivations for male employees to discriminate against female coworkers than the personal prejudices assumed in the Becker model, particularly for resisting the introduction of women into traditionally male occupations. In Akerlof and Kranton (2000), occupations are associated with societal notions of ‘male’ and ‘female’, leading men to resist the entry of women due to the loss in male identity (or sense of self) that this would entail. In Goldin (2002), the entry of women is viewed as reducing the prestige of the occupation, based on perceptions that women are, on average, less productive.

An additional gender-specific factor potentially contributing to the observed gender wage gap is labour force selectivity. While one would ideally like to have evidence on the potential wage offers available to each individual in the population, we typically observe wages only for those who are actually employed. If there are unobserved differences in skills or labour market prospects between the non-employed and the employed, focusing on measured wages may give a misleading picture of the wage offers received by women relative to men (Heckman, 1979), both at a point in time and for trends over time and differences across countries.

**Wage structure**

The human capital model suggests that men and women tend to have different levels of labour market qualifications (especially work experience) and to be employed in different occupations and perhaps in different industries. Discrimination models too suggest that women may be segregated into different sectors of the labour market. This implies that the overall returns to skills and the size of premia for employment in particular sectors potentially play an important role in determining the gender wage gap. All else equal, the larger the returns to skills and the larger the rents received by individuals in predominantly-male sectors, the larger will be the gender wage gap. The framework provided by wage structure is particularly useful in analysing changes over time in gender differentials or differences across countries in gender gaps.

**Interactions between gender-specific factors and wage structure**

While gender specific factors and wage structure each potentially play a distinct role in affecting the
gender wage gap, they are likely to interact, making it sometimes difficult to disentangle their separate
effects. For example, as discussed in more detail below, since the 1970s, the labour market returns to
skills such as education, specialized training and experience have risen in many countries, likely due in
part to technological change, including computerization. To the extent that the prices of skills for which
women have a relative deficit have risen, such changes in wage structure will raise the gender wage gap.
However, technological change itself is not likely to have gender neutral effects on labour demand,
given occupational and industrial segregation patterns by gender. So, for example, it is likely that
computerization has reduced the demand for blue-collar production labour and therefore lowered the
relative demand for sectors where men are disproportionately represented (Weinberg, 2000; Autor, Levy
and Murnane, 2003).

These types of analyses raise the question of what the appropriate measure of wage structure or labour
market prices is. For a number of reasons it is often viewed as appropriate to use male prices/returns as
the measure of overall wage structure, with the maintained hypothesis that they therefore affect women's
relative wages as well. For one thing, it is believed that men do not encounter discrimination and thus
their returns are not contaminated by discrimination, although it is acknowledged that, were gender
discrimination to be eliminated, male as well as female prices would likely change (for example, the
supply of labour to some traditionally male occupations might increase). For another, the estimate of
male prices is less likely than female prices to be influenced by selection bias or workforce interruptions.
However, some research suggests that the connection between the male wage structure and women's
labour market outcomes may be complicated. For example, Fortin and Lemieux (1998) present a model
in which there is a fixed hierarchy of jobs. As women move up the hierarchy, they replace some men
who previously would have had middle-level positions, bumping them down the hierarchy. Thus,
increases in women's human capital or reductions in employment discrimination against women may
cause increases in male wage inequality, and the male wage distribution may change even with no
changes in the overall wage distribution. Topel (1994) makes a related argument to the effect that high-
skill women compete with low-skill men in the labour market and, thus, that increases in the supply of
high-skill women directly lower the real wages of low-skill men (through this increase in supply) and
thereby raise male wage inequality.

Evidence on human capital, discrimination and the gender wage gap

The typical approach to analysing the sources of the gender wage gap is to estimate wage regressions
specifying the relationship between wages and productivity-related characteristics for men and women.
While it would be preferable to analyse total compensation (including non-wage benefits and
compensating differentials for job amenities), virtually all studies focus on money wages since data on
total compensation are generally not available. The gender wage gap may then be statistically
decomposed into two components: one due to gender differences in measured characteristics, and
another which is ‘unexplained’ and potentially due to discrimination. Such empirical studies provide
evidence consistent with both human capital differences and labour market discrimination in explaining
the gender wage gap.

One problem with this approach is that evidence for discrimination relies on the existence of a residual
gender wage gap, which cannot be explained by gender differences in measured qualifications. This
accords well with the definition of labour market discrimination, that is, pay differences between groups that are not explained by productivity differences, but these may also reflect group differences in unmeasured qualifications. If men are more highly endowed with respect to these omitted variables then we would overestimate discrimination. And, conversely, to the extent that women are more highly endowed with respect to the omitted variables, discrimination would be underestimated. Another case in which discrimination would be underestimated would be if some of the factors controlled for (for example, occupation or tenure with the employer) themselves reflect the impact of discrimination.

Another challenge to empirically decomposing the gender wage gap into its constituent parts is the existence of feedback effects. The traditional division of labour in the family may influence women's market outcomes through its effects on their acquisition of human capital and on rationales for employer discrimination against them. But it is also the case that, by lowering the market rewards to women's human capital investments and labour force attachment, discrimination may reinforce the traditional division of labour in the family (for example, Weiss and Gronau, 1981). Even small initial discriminatory differences in wages may cumulate to large ones as men and women make human capital investment and time allocation decisions on the basis of them.

Representative findings from statistical analyses

Representative findings from analyses of this type may be illustrated by results from three recent studies of the gender wage gap in the United States (Blau and Kahn, 2006), Denmark (Datta Gupta, Oaxaca and Smith, 2006), and Sweden (Edin and Richardson, 2002). Each of these studies uses databases that have information on actual labour market experience, a variable that is crucial for the analysis and is often not available in nationally representative data sets.

For the United States, Blau and Kahn (2006) found a female–male ratio for average hourly earnings of 79.7 per cent in 1998. In light of the issues discussed above, they considered results when only human capital variables (that is, education and labour market experience) and race were taken into account, and results additionally controlling for occupation, industry and unionism. While gender differences in educational attainment were fairly small, and actually favoured women, men had more full-time work experience than women. Controlling for human capital, women earned 81 per cent of what men earned; the relatively small increase in the human-capital adjusted ratio compared with the raw ratio reflects the offsetting effects of adjusting for gender differences in education and experience. The gender ratio rose to 91 per cent when industry, occupation and union status were additionally controlled for. For Denmark, Datta Gupta, Oaxaca and Smith (2006) found an unadjusted gender ratio of 81.1 per cent in 1995. This rose to 83.2 per cent controlling for schooling and experience, and to 86.2 per cent additionally controlling for industry, occupation and region. Edin and Richardson (2002) found qualitatively similar results for Sweden in 1991. Thus, in all three countries measured characteristics explained some but not all of the gender wage gap.

Studies such as those discussed above suggest that gender differences in human capital (especially experience) can be an important factor helping to account for the gender wage gap at any given point in time. In the United States, improvements in women's relative experience were an important factor in explaining the rise in women's relative wages during the 1980s (Blau and Kahn, 1997; 2006; O’Neill and Polachek, 1993), while increases in women's relative experience and education both contributed to
female wage gains in the 1990s (Blau and Kahn, 2006). And since 1980 the unexplained wage gap in the United States has fallen, a finding consistent with a decline in discrimination or improvements in women's unmeasured characteristics, and also, as we shall see below, with shifts in relative demand favouring women. Sample selectivity can also affect measured gender wage gaps. For example, using different methodologies, Blau and Kahn (2006) and Mulligan and Rubinstein (2005) both find a role for selectivity in explaining these wage trends.

**Additional evidence on discrimination**

A problem with the types of statistical analyses just discussed is that evidence of discrimination is based on a residual or unexplained gender wage gap that is susceptible to a variety of interpretations, of which labour market discrimination is only one. Two lines of empirical research on discrimination pursue alternative approaches which lend additional support to the finding of discrimination.

First are two studies that use an experimental approach. Neumark (1996) analysed the results of a hiring ‘audit’ in which male and female pseudo-job seekers were given similar résumés and sent to apply for waiter or waitress jobs at the same set of Philadelphia restaurants. In high-priced restaurants where earnings of workers are generally higher than in the other establishments, a female applicant's probability of getting an interview was 40 percentage points lower than a male's, and her probability of getting an offer was 50 percentage points lower. A second study, by Goldin and Rouse (2000), examined the impact of the ‘natural experiment’ in which major symphony orchestras in the United States adopted ‘blind’ auditions. In a blind audition, a screen is used to conceal the identity of the candidate. Using data from actual auditions, the authors found that the screen substantially increased the probability that a woman would advance out of preliminary rounds and be the winner in the final round. Goldin and Rouse (2000) used their parameter estimates to conclude that the switch to blind auditions can explain one quarter of the increase in the female percentage in the top five symphony orchestras in the United States from less than five per cent of all players in 1970 to 25 per cent in 1996.

A second source of additional evidence on discrimination is provided by studies that examine predictions of Becker's (1957) discrimination model and obtain results which are consistent with the model and hence with discrimination against women. Becker and others have pointed out that competitive forces should reduce or eliminate employer discrimination in the long run because the least discriminatory firms, which hire more lower-priced female labour, would have lower costs of production and should drive the more discriminatory firms out of business. For this reason, Becker suggested that discrimination would be more severe in firms or sectors that are shielded to some extent from competitive pressures. Consistent with this reasoning, Hellerstein, Neumark and Troske (2002) found that, among plants with high levels of product market power, those employing relatively more women were more profitable. Similarly, Black and Strahan (2001) report that, with the deregulation of the banking industry beginning in the mid-1970s, the gender wage gap in banking declined. And Black and Brainerd (2004) found that increasing vulnerability to international trade reduced apparent gender wage discrimination in concentrated industries, again as predicted by the Becker model.

**Possible sources of the unexplained gender wage gap**
While there appears to be evidence from a variety of approaches that is consistent with discrimination against women in the labour market, this does not mean that the full unexplained gap estimated in traditional approaches may be attributed to discrimination. Some of the residual gap may be due to the impact of childbearing on women's wages. This is not a factor that can be examined simply by including a control for number of children in a wage regression, since the coefficient on children variables may be influenced by self-selection into motherhood and the endogeneity of number of children. Research that addresses some of these issues suggests a negative effect of children on wages, even when labour market experience is controlled for (for example, Waldfogel, 1998). This may reflect the fact that, in the past, the birth of a child often meant that a woman withdrew from the labour force entirely, breaking her tie to her employer and forgoing the returns to any firm-specific training she might have acquired, as well as any rewards for having made an especially good job match.

Another possible source of the unexplained wage gap is noncognitive skills/traits or what Fortin (2005) terms ‘soft factors’. For example, experimental evidence suggests there are gender differences in competitiveness (for example, Gneezy, Niederle and Rustichini, 2003), and negotiating skills (Babcock and Laschever, 2003). Fortin (2005) examines the impact of a number of noncognitive traits and attitudes in a wage regression context. While such findings are informative in elucidating the omitted factors that lie behind the unexplained gap in traditional wage equations, as Fortin acknowledges, the coefficients on soft factors in a wage equation cannot necessarily be given a causal interpretation. Both wages and attitudes, for example, may be determined by the same exogenous factor. And, as in the case of the traditional productivity proxies discussed above, there may be important feedback effects from differential treatment in the labour market to noncognitive traits. So, for example, income expectations may influence wages through negotiating behaviour or effort, but the source of women's lower income expectations could be, at least in part, anticipation of labour market discrimination. Nor is it clear that all such omitted factors favour men. Borghans, ter Weel and Weinberg (2005) argue for a female advantage in interpersonal interactions, which they proxy by altruism.

Just as the importance of gender differences in the traditional human capital variables may change over time, thus helping to account for the decline in the gender wage gap, so may the impact of noncognitive traits. In this regard, it is interesting that Fortin (2005) finds evidence that gender differences in work attitudes were much smaller in 2000 than in 1986. Further, Borghans, ter Weel and Weinberg (2005) find evidence of a growing importance of interpersonal interactions (in part due to increased computer use) in affecting wages that can help explain rapidly rising female relative wages in the 1980s as well as a slower rate of increase in the 1990s.

The impact of policy

Women's relative skills and the degree of employer discrimination can be affected by government policies directed at issues of combining work and family as well as equal employment opportunity laws. For example, many countries have enacted paid parental leave mandates which give parents who take time off to care for children or other relatives an entitlement to their jobs upon returning from the leave. While such policies may encourage firm-specific investments, thus raising women's relative wages (since parental leave is much more likely to be taken by women than men), they may also encourage labour force withdrawal for longer periods of time than otherwise, reducing women's accumulation of
experience. Mandated paid leaves, particularly of long duration, may also diminish women's opportunities by increasing employer costs of hiring women and hence providing incentives to discriminate against them. Thus, the effect of parental leaves on the gender wage gap is theoretically ambiguous. Ruhm (1998) in fact finds in a study of 16 Western industrialized countries that, other things equal, short mandated paid parental leaves lead to higher relative wages for women, while longer leaves lead to a higher gender wage gap. These results suggest that a number of offsetting factors may be at work, with the positive impact dominating for short leaves and the negative effect dominating for long periods of mandated parental leave.

While virtually all industrialized countries have enacted legislation outlawing employment discrimination against women, in some countries government intervention is more dramatic than in others. The major approach in the United States involves enforcement of antidiscrimination legislation, including equal employment opportunity as well as equal pay for equal work. Further, under some circumstances, affirmative action, or ‘pro-active steps … to erase differences between women and men, minorities and nonminorities, etc.’ (Holzer and Neumark, 2000, p. 484), is also required or voluntarily adopted by employers. There is some evidence for the United States of a positive effect of government anti-discrimination policies on women's earnings and occupations. Studies focusing specifically on the impact of affirmative action also suggest modest employment and wage gains for women attributable to this programme. (For a summary, see Blau, Ferber and Winkler, 2006, pp. 240–5.)

‘Comparable worth’ or equal pay for work of equal value (that is, even if men and women are doing different jobs) constitutes a stronger form of government intervention. In evaluating the impact of such a policy it is interesting to look at studies focusing on Australia, which has adopted government mandates in this area nationwide, and the United States, where such policies are limited to selected state or local government employees (Gregory and Duncan, 1981; Killingsworth, 1990; O’Neill, Brien and Cunningham, 1989). One would expect that if such policies lower the gender wage gap, they might also lead to a decrease in women's relative employment due to employer demand effects. Gregory and Duncan (1981) in fact find such a pattern: the gender wage gap fell dramatically immediately after the Australian tribunal began implementing comparable worth policies in the early 1970s, but female employment grew less rapidly than one would have predicted in the absence of the wage intervention. Similarly, in studies of the impact of the comparable worth policies in state governments in the United States, small positive wage and negative employment effects for women have been found (Killingsworth, 1990; O’Neill, Brien and Cunningham, 1989).

While these results for the impact of comparable worth in Australia and the United States on women's employment are consistent with the existence of competitive labour markets, to the extent that the labour market is characterized by monopsony, government-mandated wage increases for women need not result in a reduction in women's employment levels. Manning (1996) interprets the impact of the UK Equal Pay Act of 1970 and the Sex Discrimination Act of 1975 in this light. Specifically, he shows that these laws led to a major reduction in the gender wage gap in the United Kingdom with no apparent employment losses for women: after the legislation, wage changes and employment changes within industries were strongly positively related for women but much less so for men.

Differential monopsony power facing men and women could help to explain the existence of the gender wage gap (Madden, 1973) in general, as well as Manning's (1996) results for the policy intervention. For this explanation of the wage gap to make sense, women's supply of labour to the firm must be less wage
women's work and wages: The New Palgrave Dictionary of Economics

elastic than men's, giving employers greater monopsony power over women than men. This might seem counter-intuitive at first, in that there is clear evidence that women have a larger own-wage elasticity of labour supply to the labour market than men, although in the United States the gender difference has been decreasing as women's elasticity has declined since 1980 (Blau and Kahn, 2007; Heim, 2007). However, a variety of factors could still potentially result in women having a smaller responsiveness to wage changes at the firm level. Perhaps the most intriguing possibility is discrimination itself. Black (1995) develops a model in which search costs give employers a degree of monopsony power. If there is discrimination against women, women will face higher search costs than men, increasing employers’ monopsony power over them.

Evidence on gender differences in labour supply at the firm level is mixed. On the one hand, Viscusi (1980), Blau and Kahn (1981) and Light and Ureta (1992) all find that, for the United States, women's quit rates are at least as wage responsive as men's, suggesting that the monopsony model may have limited application in the United States. On the other hand, Barth and Dale-Olsen (1999) found that men's turnover in Norway is more wage-elastic than women's. Thus, Norwegian employers could potentially exercise differential monopsony power over women. Of course, the degree to which Norway's centralized wage-setting system would allow this to take place is an empirical question (Kahn, 1998).

Evidence on the impact of wage structure on the gender wage gap

The impact of wage structure on the gender wage gap is best studied in a comparative context. Since wage structure may differ across countries and change over time, investigations of the impact of wage structure have focused on (a) international differences in the gender wage gap at a specific point in time, and (b) changes in the gender wage gap in one country over time. A useful framework for analysing the impact of wage structure on demographic wage differentials was devised by Juhn, Murphy and Pierce (JMP) (1991) in their analysis of changes in black workers’ relative wages in the United States. Blau and Kahn (for example, 1992, 1996b) have adapted their framework to studying international differences in the gender wage gap as follows.

Suppose we have for male worker $i$ in country $j$ the following wage equation:

$$\gamma_{ij} = B_j'X_{ij} + e_{ij} = B_j'X_{ij} + F_j^{-1}(\theta_{ij}),$$

(1)

where $Y$ is log of wages, $B$ is a coefficient vector, $X$ is a vector of productivity-related characteristics, $e$ is a disturbance term, $F^{-1}(\cdot)$ is the inverse cumulative distribution function of male log wage residuals, and $\theta$ is individual $i$'s percentile in the male residual distribution. Estimating eq. (1) separately for each of two countries, differences in the gender wage gap may be decomposed into components due to inter-country differences in: (a) gender differences in the $X$ variables; (b) the male wage coefficients $B$; (c)
women's work and wages: The New Palgrave Dictionary of Economics

women's position in the male residual distribution (θ); and (d) the residual distribution F(·).

Components (a) and (c) represent gender-specific factors: inter-country differences in women's relative measured productivity (component a) and in women's placement in the distribution of male wage residuals (component c). The latter can represent discrimination or unmeasured productivity differences.

Components (b) and (d) represent the potential effects of wage structure: measured prices (component b) and the prices of unmeasured skills or rents due to unmeasured representation in favourable sectors (component d). Note that the sum of components (c) and (d) corresponds to the unexplained gap in a traditional decomposition of the gender wage gap, and component (c) may be viewed as the unexplained gap adjusted for differences in unmeasured prices.

Some examples may help to illustrate these components. It is straightforward that, if one country has a larger gender gap in experience, it will have a larger gender wage gap. But it is less obvious in the absence of this decomposition that, if the return to experience, which is part of the B vector, is higher in one country than another, then this difference will contribute to a higher gender wage gap in the first country, since women on average have less experience than men. Or suppose that X does not include data on the specific firm in which a worker is employed. If a country has especially high inter-firm wage differentials (part of the residual wage distribution F(·)) and if women are employed in low-wage firms on average, then this unmeasured price effect will raise that country's gender wage gap. The same decomposition can also be used to explain changes in the gender wage gap over time within a country.

It may be noted that the interpretation of the residual proposed by JMP has been questioned by Suen (1997). For further discussion of this issue, see our discussion below on the assumption in the JMP decomposition that male prices and male residuals are relevant indicators of the prices facing women in the labour market. A fuller discussion is provided in Blau and Kahn (2003).

The JMP decomposition has been used by Blau and Kahn (1992; 1996b) and Kidd and Shannon (1996) to study international differences in the gender wage gap at a point in time. For example, Blau and Kahn (1996b) compared the US gender wage gap in the late 1980s with that in nine other countries (Australia, Austria, West Germany, Hungary, Italy, Norway, Sweden, Switzerland and the United Kingdom). They found that, on average, the ratio of women's to men's pay was 4.3 percentage points lower in the United States than in the other countries: 65.4 per cent as against 69.7 per cent. US women had better measured characteristics and were placed higher in the distribution of male residuals than women in the other countries, suggesting that gender-specific factors could not explain the higher US gender wage gap. However, measured and unmeasured prices together had large effects raising women's relative wages in the other countries compared with the United States. Wage structure was thus sufficient to explain more than the full amount of the difference between the US gender wage gap and that in other countries. Blau and Kahn (1992; 1996b) interpreted this pattern as reflecting the impact of international differences in labour market institutions. In the other countries, unions cover a much larger portion of the labour market than in the United States, and wage-setting is much more centralized. Centralized collective bargaining tends to reduce wage differentials through the negotiation of relatively high wage floors, which would raise the relative wages of anyone near the bottom of the distribution, including women (Blau and Kahn, 1996a).

Kidd and Shannon (1996) also found an important role for wage structure in their study of the gender wage gaps in Australia and Canada for 1989–90. Specifically, the gender gap in hourly wages was about 0.14 log points lower in Australia than in Canada. They found that 0.05–0.09 log points of this
difference was due to the combined effects of observed and unobserved prices. This result is similar to that in Blau and Kahn (1992; 1996b) in that Australia has much higher coverage by collective bargaining than Canada.

The JMP decomposition has also been used to study the impact of wage structure on changes in the gender wage gap over time within a country. For example, in Sweden between 1968 and 1974, the trade union movement engineered a major compression of wages. Edin and Richardson (2002) used the JMP decomposition to find that wage structure, especially unobserved prices, contributed to a reduction of the gender wage gap during this period. Moreover, Datta Gupta, Oaxaca and Smith (2006) used a version of the JMP decomposition to study changes in the Danish gender wage gap between 1983 and 1995. This was a period of increased decentralization of the wage determination process, a development that is expected to lead to rising labour market prices and therefore a rising gender wage gap. The authors indeed found that the gender wage gap in Denmark increased during this period and that most of the increase can be accounted for by rising unmeasured prices.

Finally, this approach has been applied to understanding the trends in the gender wage gap in the United States. Blau and Kahn (1997) used the JMP decomposition to study the apparent paradox of a substantial decrease in the gender wage gap in the United States during the 1979–88 period, a time of rising skill prices. They found that women were able to overcome the negative effects of these price changes by improving their measured human capital and by moving up the distribution of male residuals. The authors further noted that the process leading to higher skill prices in the United States might not have been gender-neutral. Specifically, it is likely that part of the explanation for this development involves skill-biased technical change in which the demand for white-collar labour rose relative to blue-collar labour, a change that, given gender differences in occupational distributions, in effect raises the demand for women workers. Thus, while skill prices were rising, contributing to a reduction in women's relative wages, developments such as computerization and perhaps outsourcing of production labour disproportionately lowered the demand for male labour (Welch, 2000; Weinberg, 2000; Autor, Levy and Murnane, 2003). In the context of the JMP decomposition, such changes in labour demand would be reflected in higher placement of women in the distribution of male residuals (leading to a decrease in the conventional unexplained gender wage gap). As noted previously, convergence in the gender wage gap in the United States slowed during the 1990s. Using the JMP decomposition, Blau and Kahn (2006) found that the major reason for the slowdown was the considerably smaller narrowing of the unexplained gender wage gap in the 1990s than in the 1980s. This raises the possibility that the types of demand shifts favouring women that we have outlined here were smaller in the 1990s than in the 1980s, and Blau and Kahn present some evidence that is consistent with this as at least a partial explanation for the smaller decrease in the unexplained gender gap in the latter period.

The JMP decomposition assumes that male prices and male residuals are relevant indicators of the prices facing women in the labour market. Some support for this assumption is provided by the fact that wage coefficients and residual distributions have changed similarly for men and women over time in the United States and are similar to each other within countries at a point in time (Blau and Kahn, 2002). But it is possible to directly test whether male wage compression leads to a smaller gender wage gap, and Blau and Kahn (2003) have done so by compiling a microdata-set for 22 countries over the 1985–94 period. They find, looking across countries, that the gender wage gap is positively affected by a country’s male skill prices (that is, the level of male wage inequality adjusted for measured
characteristics), as well as by the relative net supply of women (that is, supply net of demand). A likely interpretation is that more compressed male wages are an indicator of smaller wage differentials in general, as suggested above in our discussion of centralized wage-setting institutions. Bolstering this interpretation is the authors’ further finding that, other things equal, greater coverage by collective bargaining reduces the gender wage gap. It thus appears that high wage floors negotiated by unions serve to lower the gender wage gap.

If labour markets are competitive, then union-negotiated wage floors should lower female relative employment. And this is precisely what Bertola, Blau and Kahn (2007) find in a study of relative employment in 17 countries over the 1960–96 period. Specifically, they find that greater coverage by highly centralized unions lowers female employment and raises female unemployment compared with men's. This suggests that unionization can raise women's relative wages at the expense of lowering their employment. This in turn suggests that Manning's (1996) evidence in favour of monopsony in the United Kingdom may describe an exceptional case in the OECD.

Future prospects

While it is difficult to speculate about the future, Tables 1 and 2 do suggest some convergence across countries in both female labour force participation (absolutely and relative to men) and in the gender wage gap. For example, calculations based on the data in Tables 1 and 2 indicate that the standard deviation across countries in the ratio of women's to men's labour force participation rates fell from 0.128 in 1980 to 0.072 in 2000, and that the standard deviation of the gender wage ratio fell steadily from 0.086 in 1980 to 0.066 by 2000. While the gender wage ratio appears to be converging at around 80 per cent for several of the countries in Table 1, further changes are not precluded. Throughout the OECD, women's education has been rising relative to men's, a trend that shows no sign of ending (Goldin, Katz and Kuziemko, 2006). Technological change, which has likely raised women's relative wages through demand effects, will probably continue and could even accelerate. Going against these trends is the likely continued decentralization of wage-setting institutions in many Western countries, spurred in part by globalization (Katz, 1993).

Wood, Stuart (1853–1914)

George J. Stigler

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

factor substitution; marginal productivity theory; technological substitution; wages fund; Wood, S

Article

A member of a prominent Philadelphia Quaker family, Wood was briefly active in economics twice in his life. The first period was 1873–5, when he received at Harvard the first Ph.D. in economics in the United States. The second period was 1888–90, when he wrote three first-class articles on wage theory. His primary interests during his adult life were in business and finance.

In the two years Wood was at Harvard he took courses in economics and its history, chiefly from Professor Charles Dunbar, and wrote an essay on ‘A Review of the “Principles of Social Science” by Henry C. Carey’. It was not an impressive piece, even allowing for the time, the age (21) of the writer and the extreme vulnerability of the target.

It is all the more impressive that 13 years later he wrote two fine articles on the marginal productivity theory and one on the history of the wages-fund theory. Wood must be acknowledged to be an independent discoverer of the marginal productivity theory, an honour he shares with Marshall, Edgeworth, Barone, Wicksell, Clark and other major economists. Wood's version was not mathematical, but it synthesized two important dimensions of substitution between capital and labour: the substitution between industries with different capital–labour ratios, and the substitution within enterprises. The formulation was a skilful synthesis incorporating consumer demands and factor supplies as well as technological substitution.

Wood's final contribution was a history of the wages-fund doctrine (which was to be treated no more penetratingly by Harvard's second Ph.D. in economics, F.W. Taussig). Perhaps one should mention one other, involuntary role Wood played in the study of the history of economics: he was the victim of a thinly disguised, utterly unfounded charge of plagiarism (of Lord Lauderdale) in the Journal of Political Economy in 1894.

worker participation and profit sharing

John Pencavel

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

democracy; incentives; productivity; profit-sharing; worker participation

Article

Market economies are called ‘capitalist’ because in such economies most production is carried out in organizations owned by those who supply the firms' financial capital. A firm is ‘owned’ by its capital investors because, first, the capital investors claim the firm's net receipts or profits and, second, they have the authority to direct and manage (often indirectly) the firm's activities.

Yet in all market economies some production takes place in firms where these two dimensions of ownership are embodied in those who supply labour rather than capital. In this instance, workers enjoy as incomes the firm's net receipts and the workers hire individuals to supervise and organize production. Capital may be obtained from the workers' savings or from loans from financial intermediaries. Examples of worker cooperatives include the plywood companies in the Pacific Northwest of the United States, the kibbutzim in Israel, and the Mondragon group in the Basque country of Spain.

Many enterprises fall between these two limiting cases. These other firms are characterized by the owners either sharing net revenues with others – ‘profit-sharing’ – or sharing in the activities of management – ‘worker participation’. (For recent research on the general issues, see the essays in Blair and Roe, 1999, and Ichniowski et al., 2000.)

Profit-sharing occurs when those who have the right to consume all the firm's profits distribute a portion of them to others within the organization. Because most firms are owned by those who supply capital, profit-sharing usually occurs when some portion of profits is distributed among the rank-and-file workers.

With explicit profit-sharing, a clear formula is established linking profits and the pay of individuals. Profit-sharing is implicit when workers in firms that habitually enjoy higher profits are paid higher wages. Profit-sharing may take the form of deferred income, as when a portion of net receipts is placed in retirement accounts so that the firm's employees hold part of the assets of the firm in which they work. A principal goal of these various profit-sharing arrangements is to affect incentives: by linking workers'
compensation to the firm's success in making profits, the workers' interests are aligned more closely with the capital owners'. However, some economists reason that, when the firm's net earnings are divided among a large number of people and one individual's effort contributes little to total output, the incentive for a single individual to apply effort is meagre. What empirical evidence there is suggests that, with profit-sharing, workers monitor one another so that any tendency to shirk is checked. When workers' pay is linked to profits, some automatic flexibility is imparted to a firm's payrolls so the effects of adverse shocks are communicated immediately and mechanically to the firm's costs. Some have suggested that, if profit-sharing payment schemes were widespread, recessions would be characterized by less unemployment. Kruse (1993) reviews profit-sharing.

‘Worker participation’ is a term embracing various arrangements by which workers are actively involved in the management of the enterprise where they work. These arrangements may include safety and health committees or panels to deal with worker grievances, or they may be more profound arrangements when workers are actively engaged in key management activities such as the organization of work and production. In Europe, works councils or workers' committees are empowered to be consulted and, sometimes, to share in determining any changes in the organization of production (also known as co-determination). One argument in favour of worker participation is that participation begets productivity. Modern ‘flexible’ or ‘lean’ production techniques entail greater employee involvement in shop-floor decisions, greater teamwork, information-sharing between management and rank-and-file employees, and reduced task specialization. An extensive research literature quantifies the effect of greater worker participation on productivity. A general finding is that there are positive, though small, productivity benefits accompanying worker participation.

A second argument for worker participation is that it is the extension to the workplace of democratic governance in the political arena. In much the same way as citizens in political democracies have an important voice in choosing those who determine the provision of public goods in society so an enterprise's workers should have a voice in shaping their work environment when public goods are also prevalent. Worker participation is the application of the democratic principle to the workplace.

The World Bank, established in 1944, remained an important source of funding for developing countries generally through the early 1990s. Then an impressive increase in private flows reduced its overall significance. What remained was technical assistance on the one hand, and continued increasing credits of the International Development Association to the lowest income countries on the other. Despite criticism from both by the Right and the Left, the World Bank has survived, and has given voice to rising concerns about highly unequal distributions of income in the developing world, moving away from its earlier emphasis upon economic growth alone.

Article

The World Bank was founded in July 1944 as part of a new financial architecture for the post-Second World War period. At the inaugural meeting at Bretton Woods, the International Bank for Reconstruction and Development (IBRD) was proposed in order to satisfy demands in lesser-income countries for long-term capital, a market that had virtually disappeared with the Great Depression. The International Monetary Fund (IMF), much more a subject of debate at the time, was to satisfy anticipated short-term balance of trade needs, thereby avoiding competitive currency devaluations. A third component, the later proposed, but unfounded, International Trade Organization, was to resurrect freer trade. GATT, now the World Trade Organization (WTO), took on that function in 1947. The Bank began in 1946 by focusing on reconstruction, which soon was successfully taken on by the
The Marshall Plan, and then increasingly committed itself to the multiple and changing problems of economic development within the world's poorer countries. This conversion came about much more rapidly than John Maynard Keynes, and most other key economists in the immediate post-war period, had anticipated. Rapid European and Japanese economic recovery soon left space for loans entirely to developing countries.

The Bank utilized its multilateral resources in an ingenious way. The capital inputs originally established for member countries – among which the United States initially played a dominant role – required an actual contribution of only 20 per cent of the original capital of the Bank, with the remainder callable. Private financial markets were to be the real source of the money, and this they have remained despite modest increases in capital starting in 1959. By contrast, during its first decades, almost all the IMF's resources came directly from governments, and until the 1970s its focus remained the balance of payments problems of the developed countries.

Private direct investment within the developing countries also received early emphasis through the creation of the International Finance Corporation in 1956. Its performance did not live up to initial hopes. Only since 1995, through direct integration with the Bank, has much greater attention been given to the high cost of typical business procedures in many countries. The publication *Doing Business* has taken on a more significant role as private investment flows have multiplied.

The creation of the International Development Association (IDA) in 1960 fundamentally altered the initial conditions of Bank resources. Its funds, exclusively directed to the poorer countries on favourable terms, required regular triennial contributions. This circumstance allowed periodic legislative discussion of Bank policies, and pressures for policy changes, emanating principally from the United States. Its location in Washington, and the influence of an American president, reinforced that tendency. The initial volume of resources allocated was small. But already by 1980 IDA loans were amounting to equivalent net additions to total Bank lending as the conventional commitments. This part of the story, which was not an issue at the Bank's foundation, has now become the central feature of its decisions. (Other parts of the World Bank, such as the later International Center for the Settlement of Investment Disputes, ICSID, and Multilateral Investment Guarantee Agency, MIGA, should also be noted. These new components corresponded to new functions as the Bank expanded.)

The quality and size of Bank staff, which now totals more than 10,000, also merit mention. Begun at a time when ‘development economics’ was not yet a part of the economics curriculum within universities, the Bank soon began to employ a talented and professional group that much helped to elevate the status of the sub-discipline. Creation of the *World Development Report* and other publications, regular conference activities, increasingly held abroad, as well as training for many developing country economists through a period at the Bank, have made this intellectual role a positive highlight.

Finally, over a more than 60-year history, the Bank has altered its emphasis dramatically. Now it is best known for its commitment to the elimination of poverty, a subject of little import at its foundation, when its contribution to economic growth was the focus. Now, too, the Bank is exposed to increased opposition from both Left and Right as it searches to retain a role, not only intellectually but also practically. Its net financial contribution has continuously declined as a sophisticated international capital market has expanded, placing more of a burden upon Bank leadership.

In this article, I explore three subjects. First is an assessment of the changing pattern of Bank lending and its effects. Second is an exposition and evaluation of the critiques increasingly directed at the Bank since the early 1990s. Third, by way of conclusion, I raise an essential question: what role should the
World Bank lending: 1946–2005

Table 1 provides the gross and net loan flows, as well as net transfers – with return interest payments subtracted – of the Bank and IDA at decadal intervals since the Bank’s foundation. It also presents net private capital flows and net official flows to the developing countries. All have been converted to constant dollars. Three central conclusions immediately follow.

World Bank lending, total official flows and total private flows, 1960–2005 ($ billion, 2000)\(^a\)

\(^a\)The US chain-type GDP price index (averaging calendar years) has been used. Categories may not sum due to rounding.

First, the gross real flows of regular disbursements, after an initial acceleration in the 1970s and continuing through to 1985, tend to stabilize thereafter. They then fall off considerably in later years. During the mid-1980s, net flows likewise began to diminish sharply, becoming negative by the early 21st century. Net transfers turn negative shortly after 1985 and become progressively more so thereafter. The Bank has ceased to be a source of resources for middle-income countries some time ago. That is the direct consequence of restricted gross outlays accompanied by amortization and market interest rate charges.

Additionally, the Bank altered its principal mandate in the 1980s, as it had done during the Robert McNamara presidency. Then, in the 1970s, the Bank launched new initiatives to deal with the extensive level of poverty found in the developing world. Income distribution, basic needs, reform of the agricultural sector all figured. With a debt crisis occurring soon after the oil shock of 1979, the Bank
underwent a transformation. Structural macroeconomic loans were introduced, moving away from the earlier sectoral emphasis. Conditionality loomed larger, and the Bank began to replicate the simultaneous involvement of the IMF. The Bank became notable for its emphasis upon the primary importance of market signals, as well as privatization and freer trade, sometimes to the exclusion of a positive role for the state that had figured importantly in the previous decade.

Second, IDA resources, regularly replenished and less diminished by repayments because of their longer term and lesser interest charges, grew substantially. But even these disbursements have not sustained their expansion. Now on a gross basis, they amount to nearly 80 per cent of regular Bank commitments, and will soon exceed them. On a net basis, the IDA proportion is much greater, as can be seen. The disparity is very much stronger when net transfers are recorded. Indeed, it is almost fair to say that the Bank's substantially increased commitment to the alleviation of poverty again in the 1990s was an almost inevitable consequence of its altered resource base. There was no other direction to take.

James Wolfensohn's active presidency, beginning in 1995, was also a major causal factor. Just like McNamara before him, Wolfensohn unleashed new programmes as an advocate of the poor. Coinciding with the rise of India and continuing rapid gains in China, and the beginning of recovery in Africa, his decade of engagement encountered a much better base for this renewed emphasis. Even the initial crises, in Mexico in 1995, in Asia in 1997, and in Russia in 1998 followed by Brazil within months, saw very rapid recovery; this was not a duplication of the lost decade of the 1980s. Wolfensohn transformed the Bank in terms of its managerial style, its relationship with non-governmental organizations (NGOs), its focus on institutions and governance and its emphasis upon concrete results.

Third, the Bank progressively became a marginal contributor of resources over this period, except to the very poor countries. This is clear if one compares the net private flows recorded in Table 1 with Bank, or even total official, lending. To compensate, the Bank's intellectual role has continuously had to be sharpened, redefined and extended, which helps to explain the expansion of branch offices abroad, the relocation of country directors, and the increase in activities within recipient borrowers. This is also why there has been such an emphasis upon information technology as an essential component for spreading knowledge about the development process. What started as a straightforward financial institution has been converted into a far more vocal and innovative participant in the advancement of the position of the poor. The Bank has led in the onerous task of reducing the accumulated debt that burdens many countries. It has also been active in defining a new vision, involving not only governments, but also civil society. But that transformation has not met with universal acclaim.

**Should the Bank survive?**

As the Bank approached its 50th anniversary in 1994, increasing unhappiness with its performance became evident. Since the McNamara years, there had been three successive presidents and a changed direction emphasizing macroeconomic programme loans to finance stabilization in a world increasingly adrift. A much broader range of internal reforms, going beyond the balance of payments and domestic savings, was now targeted. Stricter conditions were imposed. Almost 30 per cent of loans were allocated to stabilization objectives, and were concentrated among the highly indebted countries that were suffering from lack of private lending. Unfortunately, the record of accomplishment was not so high. The classification of risk in World Bank documents conveys that reality: in 1970, more than 70 per cent of loans were low risk; in 1980, 30 per cent. Arrears appeared. Positive IDA transfers compensated for
negative Bank flows in a number of countries newly eligible for these loans because of their declining income.

Critics multiplied, both on the Left and the Right. For both groups, the status quo was unacceptable. For the more radical, the correct solution was to close the Bank, but for most, the preferred outcome was an altered, more effective institution. Each side envisioned a redesigned Bank more able to accomplish its redesigned objectives.

For the Left, the Bank required nothing less than reinvention – as one critic would later put it – in its operations, concepts and distribution of power. Or, to put the matter another way, the object was a smaller, much more transparent, decentralized and pluralistic development bank. The new institution would be one where developing countries could exercise greater choice and have greater voice. Independent research and significant policy engagement would no longer be features of the Bank. Those functions would devolve to the developing countries themselves.

For the Right, the objective was an equally lesser institution, one that would provide grants to the poorest countries with limited alternative access to financial markets. These funds would be allocated to the conventional objectives identified at the Bank's outset, namely, health care, primary education and infrastructure. No attention would be directed to such issues as the environment, gender equality or labour standards. NGOs, which had become increasingly part of the developing community, would no longer be central participants. Shares of domestic contributions would vary, as a function of per capita income, from ten per cent to 90 per cent. Private capital markets could, and would, substitute for the very modest financial contribution of the Bank to the middle-income countries, and at much lesser cost. The Bank would no longer be engaged in lending to them. Instead, the Bank would limit itself to knowledge transfer and technical assistance for this group of countries. Independent auditors would conduct performance evaluation, emphasizing measured targets and results.

Neither of these directions of reform is now at the centre of discussion. The 60th anniversary has come and gone. One of the important reasons is the impressive acceleration of economic performance within the developing countries since the beginning of the 21st century. Another has been the ability of the Wolfensohn Bank to make itself more acceptable by adopting some of the suggestions from its critics on both sides. Thus the grant element in IDA loans has now risen to 30 per cent (as of 2007); there has been greater attention to the role of the state, as well as the private sector, within developing countries; transparency has increased; and there has been insistence upon country ownership, including broad participation of domestic groups, of the development projects being financed.

This may seem to work in the present. But there remains the question of what lies ahead.

The future of the Bank

Implicitly, and continuously, the Bank has throughout its history confronted the central issue of whether to give greater weight to growth or equity. During the crisis of the 1980s, the focus temporarily turned to economic recovery. Now, after the triumph of globalization, expansion of international trade and greater recognition of private sector importance, conditions have seemingly changed. They have also altered in a policy sense, with the establishment of the Millennium goals – UN-mandated objectives in a number of areas that developing countries are supposed to meet by 2015 – and a period of energetic commitment to expansion of social programmes to confront poverty.

As accelerating and generalized expansion has occurred for the first time in three decades, as of the early
21st century more countries are on the verge of graduation, and some of the IDA recipients are approaching their maximum income limit. At the same time, Bank evaluation has raised doubts about some of the new directions pursued: there has seemingly been too much effort directed to the social sectors, governance has not continuously improved nor has corruption been alleviated – despite the importance attached to these issues – and the numbers of people in poverty, other than in Asia, have since the mid-1990s been resistant to improvement. These difficulties are not easy to resolve.

An increase in international private resources as a source for investment has accompanied this expansion. These resources hardly show signs of stopping. Indeed, the speed of global recovery from the tumult at the end of the 1990s is a record accomplishment. Those crises were only a modest pause. In this new world, the Bank will eventually have to adapt. As the data of Table 1 clearly reveal, neither Bank nor IDA lending is a central source of finance. Although much assistance is granted for political advantage, bilateral overseas development assistance regularly exceeds its net contribution. The Asian and Inter-American Development Banks dominate in their regions.

One direction of change, in a continuation with the recent past, may require an even greater degree of engagement with other agencies of the United Nations, whether the issue is the proliferation of new viruses or the extension of HIV. Another is likely to be a more active participation in global environmental efforts as increasing scientific research indicates the speed and importance of recent climate change. A third may involve efforts to finance infrastructure projects through shared participation of the private and public sectors, with the Bank engaged as a major contributor in poorer countries. A fourth may entail serious accommodation to the implications of changing global supplies of petroleum for the poorest countries.

These are just some possibilities. Many additional ones are sure to emerge. The Bank will have to take on a different role and function. As many developing countries begin to increase their income, the process of graduation implies a change in future leadership at the Bank. No longer will the United States influence choices and policy options as in the past. A new generation of executive directors and employees will debate such future Bank directions internally. External critics will again evaluate whether the Bank should finally cease and desist. Ultimately, however, international institutions have an instinct for survival. The World Bank is probably no exception.

World Trade Organization

Robert W. Staiger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The success of the General Agreement on Tariffs and Trade (GATT)/World Trade Organization (WTO) as an international institution is widely acknowledged. Among multilateral institutions, the GATT/WTO has adopted a distinctive approach as a forum for international negotiation, based on reciprocal negotiations (over market access) that occur on a voluntary basis between pairs of countries or among small numbers of countries; the results of these bilateral negotiations are then ‘multilateralized’ to the full GATT/WTO membership under the GATT/WTO principle of non-discrimination. This article describes how recent economic research has attempted to understand and interpret these key design features of the GATT/WTO.

Keywords

Article

The World Trade Organization (WTO), like its predecessor the General Agreement on Tariffs and Trade (GATT), has in effect served as the constitution of the post-war international trading system. (The GATT was created in 1947, and the WTO came into existence on 1 January 1995, as a result of the Marrakesh Agreement of April 1994, also known as the WTO Agreement. The WTO Agreement includes the text of GATT: GATT therefore continues to exist as a substantive agreement, but the WTO Agreement also includes a set of additional agreements that build on and extend GATT principles to new areas. Hoekman and Kostecki, 1995, provide an excellent institutional overview of GATT and the WTO.) Since 1947, membership in the GATT/WTO has grown from 23 countries to its present size of
The success of the GATT/WTO as an international institution is widely acknowledged. Among multilateral institutions, the GATT/WTO has adopted a distinctive approach to serving as a forum for international negotiation. This approach is based on reciprocal negotiations (over market access) that occur on a voluntary basis between pairs of countries or among small numbers of countries, and the results of these bilateral negotiations are then ‘multilateralized’ to the full GATT/WTO membership under the GATT/WTO principle of non-discrimination.

As an object of study, the GATT/WTO has attracted the attention of legal scholars since the late 1960s. But until relatively recently, the GATT/WTO has not been the subject of systematic and formal economic analysis. This might seem surprising, because the familiar economic arguments for free trade would seem to provide an obvious foundation for the economic analysis of the GATT/WTO. But this foundation immediately runs into a pair of impediments. First, the case for free trade is a unilateral case, and it therefore leaves no room for the existence of a trade agreement of any kind: from this starting point, the economic logic of the GATT/WTO is immediately suspect. And second, the liberalizing force that the GATT/WTO has harnessed does not appear to be the consumer gains that come from freer trade: rather, the GATT/WTO is driven by exporter interests. Traditionally, most economists have interpreted these observations as evidence that a mercantilist logic lies at the foundation of the GATT/WTO and that, as a result, economic analysis of the GATT/WTO is futile.

A growing body of theoretical and empirical literature has begun to challenge this view. There are two main branches of this literature (for recent attempts to articulate theories that would constitute a third branch, see Ethier, 2006 and Regan, 2006). A first branch (terms-of-trade theories) emphasizes the role of trade agreements in providing governments with an avenue of escape from a terms-of-trade driven Prisoner's Dilemma. A second branch (commitment theories) emphasizes the role of trade agreements in providing governments with a means of making commitments to their private sectors. Commitment theories of trade agreements have been developed by a number of authors, and there is also some empirical evidence that the GATT/WTO may play this role (see, for example, Conconi and Perroni, 2003; Maggi and Rodriguez-Clare, 1998; 2007; and Staiger and Tabellini, 1987; 1999). But most of the literature to date adopts the terms-of-trade perspective. So I will focus here on interpreting and evaluating some of the key design features of the GATT/WTO from the perspective of terms-of-trade theories. (Empirical evidence relating to the terms of trade theory of trade agreements is surveyed in Bagwell and Staiger, 2002, ch. 11. More recent evidence appears in Broda, Limao and Weinstein, 2006; and Bagwell and Staiger, 2006a.)

All theories of trade agreements must identify a means by which the negotiating governments can gain from the agreement. This entails identifying a ‘problem’ that would arise in the absence of an agreement, when governments make unilateral trade policy choices. The purpose of a trade agreement can then be viewed as providing a ‘solution’ to the problem, so that the negotiating governments may share in the associated benefits. The terms-of-trade theory posits that governments can gain from negotiations by correcting the international inefficiencies that occur under unilateral trade policy choices as a result of international cost shifting. This cost shifting arises whenever the government of an importing country increases its import barriers and the prices received by foreign exporters fall as a
result, thereby improving the importing country's terms of trade. In this way, a portion of the cost of each government's import protection is borne by foreigners, and as a consequence the unilateral best-response levels of import protection chosen by each government are overly restrictive relative to internationally efficient levels: starting from its best-response (reaction curve) tariffs, each government can therefore gain by negotiating reciprocal liberalization with its trading partners. From the perspective of the terms-of-trade theory, then, the problem associated with unilateral trade policy choices is the cost shifting that importing governments are able to achieve on to foreign exporters; and the purpose of negotiated trade agreements is to give foreign exporters (or their governments) a ‘voice’ in the trade policy choices of importing governments, so that the ‘market access’ that each country affords its trading partners can be expanded to internationally efficient levels. (The link between the terms-of-trade theory of trade agreements and the emphasis on market access found in GATT/WTO discussions is identified and formalized in Bagwell and Staiger, 2002, ch. 2.)

In this environment, internationally efficient policies can be achieved if each government agrees to adopt the policies it would have chosen had it ‘ignored’ its ability to shift costs on to foreigners. Accordingly, internationally efficient levels of market access may be delivered under multilateral free trade, but only if all governments seek to maximize national income with their trade policy choices: when governments have broader (for example, political/distributional) goals, international efficiency will generally not correspond to free trade. Nevertheless, according to the terms-of-trade theory, the purpose of a trade agreement remains the same independent of government objectives. This feature suggests that, despite the potential for wide diversity across the objectives of GATT/WTO member governments, the underlying structure of the cost-shifting problem central to the terms-of-trade theory may yield simple and robust insights concerning the logic of key design features of the GATT/WTO.

I now illustrate the basic structure of the international cost-shifting problem at the heart of the terms-of-trade driven Prisoner's Dilemma, and describe how it can account for two pillars of the GATT/WTO: reciprocity and non-discrimination. Broadly speaking, the principle of reciprocity in the GATT/WTO refers to the ideal of mutual changes in trade policy that trigger changes in the volume of each country's imports that are of equal value to changes in the volume of its exports. And according to the non-discrimination principle, a country must provide every other GATT/WTO member country with access to its markets on terms no less favourable than it provides the ‘most-favoured’ country: hence, under the non-discrimination principle, each GATT/WTO member country faces ‘most-favoured-nation’ (MFN) tariffs from all other GATT/WTO member countries.

I begin with reciprocity. The essential point can be understood from the perspective of a standard two-country/two-good competitive general equilibrium trade model, in which country $A$ exports good $y$ to country $B$ in exchange for imports of good $x$. Following Bagwell and Staiger (1999; 2002), government preferences for the two countries can be represented very generally by the functions $W^i(p^i(\tau^i, p^w), \bar{p}^w)$, where $\tau^i$ is 1 plus the ad valorem tariff in country $i \in \{A, B\}$, $p^i$ is the relative price of good $x$ to good $y$ prevailing locally in country $i$, and $\bar{p}^w$ is the market-clearing ‘world’ relative price or terms of trade, which is itself a function of the two tariffs $\bar{p}^w(\tau^A, \tau^B)$. Under standard conditions $\bar{p}^w$ is decreasing in $\tau^A$ and increasing in $\tau^B$, while $p^A$ is increasing in $\tau^A$ and $p^B$ is decreasing in $\tau^B$. Apart from general concavity, the only condition that is imposed on government
welfare functions is that and , meaning that each government would like more tariff revenue if it could have this without any change in its local prices (and therefore without any change in the distribution or levels of factor incomes within its economy). Because no restrictions are placed on the way in which governments feel about changes in local prices, this representation of government preferences is general enough to include, in addition to the traditional Johnson (1953–4) national-income maximizing government, the leading models of political economy of trade protection (each of which effectively defines government preferences over redistribution and hence local prices).

The non-cooperative (Nash) tariffs chosen in this environment are defined by the two first-order conditions

\[ W^i_{p_A} \lambda^i W^i_{p_W} = 0 \quad \text{for} \; i \in \{A, B\}, \]

where \( \lambda^i \equiv \left[ \frac{\partial p^W}{\partial \tau^i} \right] / \left[ \frac{\partial p^i}{\partial \tau^i} \right] < 0. \) Notice that international cost shifting is embodied in the term \( \lambda^i W^i_{p_W} \) which enters into the first-order conditions, and the presence of this cost-shifting term guarantees that \( W^A_{p_A} < 0 \) and \( W^B_{p_B} > 0 \) in the Nash equilibrium. The international efficiency frontier is defined by the \((\tau^A, \tau^B)\) pairs from which it is not possible to adjust tariffs so as to help one country without hurting the other according to the government preferences \( W^A \) and \( W^B \). Formally, this frontier takes the form \((1 - \Lambda^A W^A_{p}) = 1 / (1 - \Lambda^B W^B_{p})\), where

\[ \Lambda^A \equiv (1 - \tau^A \lambda^A) / (W^A_{p_A} + \lambda^A W^A_{p_W}) \quad \text{and} \quad \Lambda^B \equiv (1 - \lambda^B / \tau^B) / (W^B_{p_B} + \lambda^B W^B_{p_W}). \]

From these expressions, a pair of observations can now be confirmed. First, the Nash tariff choices do not achieve the international efficiency frontier, and so there is indeed a ‘problem’ for an international agreement to solve. And second, politically optimal tariffs, defined by \( p^i = 0 \) for \( i \in \{A, B\} \) and interpreted as the unilateral tariff choices governments would make if they were not motivated by terms-of-trade considerations, do achieve the international efficiency frontier, and so politically optimal tariffs represent a complete ‘solution’ to this problem. From these observations an important conclusion can be drawn: even in the presence of politically/distributionally motivated governments, the purpose of a trade agreement is simply to prevent terms-of-trade manipulation.

From this backdrop, we may now ask the question, ‘Why would the principle of reciprocity have appealing features?’ The answer, simply stated, is that reciprocity describes a fixed-terms-of-trade rule to which mutual tariff changes must conform. (Formally, this can be seen following Bagwell and Staiger, 1999; 2002. Define a set of tariff changes \( \Delta \tau^A \equiv (\tau^A_1 - \tau^A_0) \) and \( \Delta \tau^B \equiv (\tau^B_1 - \tau^B_0) \) as conforming to reciprocity whenever

\[ \Delta \tau^A \equiv \left[ E^A(p^A_1, \theta^W_1) - E^A(p^A_0, \theta^W_0) \right] = \left[ E^A(p^A_1, \theta^W_1) - E^A(p^A_0, \theta^W_0) \right], \]

where \( \theta^w \equiv (\theta^w_0, \theta^w_1) \) and \( \theta^w \equiv (\theta^w_0, \theta^w_1) \) denote A’s imports and exports, respectively. Using balanced trade \((\theta^w = E^A(p^A, \theta^w) = E^A(p^A, \theta^w) = 0, )\)

And in an environment where terms-of-trade manipulation is the problem to be fixed, a fixed-terms-of-trade rule is bound to have some attractive uses. (Bagwell and Staiger, 2002, ch. 4 describe and interpret a number of ways in which the principle of reciprocity appears in the GATT/WTO.) Intuitively, the nature of international cost shifting ensures that, beginning from their Nash tariff choices,
government would desire tariff liberalization and the local price movements/greater trade volume that
this would bring if this liberalization could be achieved at a fixed terms of trade \( \hat{p}^W \) (that is, recall from
above that \( \hat{p}, A < 0 \) and \( \hat{p}, B > 0 \) at Nash). The principle of reciprocity can be understood to harness
this desire, and so to activate efficiency-enhancing tariff-liberalizing forces in this environment.

I now turn to the non-discrimination principle, as embodied in MFN. This requires an extension of the
basic two-country model described above to a three-country setting. To this end, let country \( C \) have a
similar trading pattern to \( B \), in that \( C \) also exports good \( x \) to country \( A \) in exchange for imports of good \( y \).

An important feature of the MFN rule is that, in requiring country \( A \) to impose a common tariff on
imports of \( x \) regardless of whether these imports of \( x \) originate in exporting country \( B \) or \( C \), this rule
ensures that a single market-clearing terms of trade \( \hat{p}^W(\tau, A, \tau, B, \tau, C) \) will prevail, and government
preferences may continue to be expressed with the simple representation \( \hat{p}^i(\hat{p}, (\tau, i), \hat{p}^W, \hat{p}^W) \) for
\( i \in \{A, B, C\} \). Notice that, in the presence of MFN, countries \( A \) and \( B \) can still negotiate a reciprocal
reduction in their respective tariffs \( \tau, A \) and \( \tau, B \) that provides each with more trade volume at a fixed
terms of trade \( \hat{p}^W \), thereby ensuring that they each gain relative to Nash; and strikingly, as long as \( A \) and
\( B \) abide by reciprocity, there will be no third-party effects of their bilateral negotiation on country \( C \),
whose welfare level \( \hat{p}^i(\hat{p}, (\tau, C, \hat{p}^W, \hat{p}^W) \) remains unaltered owing to the unchanged \( \tau, C \) and the fixed
terms of trade \( \hat{p}^W \). (For \( C \)'s welfare to remain unchanged, it is in fact not necessary that \( \tau, C \) remain
unchanged, but only that \( C \) remain on its tariff reaction curve and that \( \hat{p}^W \) remain unchanged: see
Bagwell and Staiger, 2006b.) Of course, \( A \) and \( C \) can engage in bilateral reciprocal negotiations that
have the same property. This has an important implication: the MFN rule permits the liberalizing force
of reciprocity to be harnessed in an essentially bilateral manner even in a multilateral world. (These and
related points are developed in Schwartz and Sykes, 1997, and Bagwell and Staiger, 2005; 2006b.)

In this general manner, the GATT/WTO pillars of reciprocity and non-discrimination can be understood
to underpin the architecture of an international negotiating forum in which the liberalizing force of
reciprocity can be harnessed in bilateral negotiations with an assurance of minimal third-party spillovers,
thereby permitting each member government – through a sequence of bilateral or small-numbers
negotiations – to engineer its escape from a terms-of-trade driven Prisoner’s’ Dilemma.

The two world wars of the 20th century were events in a single process of reaction against globalization that was prolonged and, from time to time, violent. From 1815 to 1914 trade and capital flows increased alongside global productivity. Everywhere, economic development tended to reduce local risks. At the same time, falling trade and transport costs exposed farmers, firms, and labouring households to new instabilities and risks that originated far away, in countries and markets across the world. Where governments and politicians embraced these long-range risks, liberalization fostered engagement in the global economy. Where political entrepreneurs mobilized reaction against them, however, resistance gained ground.

By the end of the 19th century, leaders of several newly industrializing countries were seeking to insulate their economies from global risks through tariff protection. German leaders, for example, aimed at national security through trade within a closed region based on a colonial empire. To secure this empire they launched a naval arms race; the arms race precipitated the formation of two Eurasian alliances that confronted each other in the First World War. On one side stood the Central Powers, primarily the German, Austro-Hungarian and Ottoman empires, joined in 1915 by Bulgaria; on the other side stood the Allies: the British, French and Russian empires, joined in 1915 by Italy, and in 1917 by the United States. But the war brought ruin to the three empires of the Central Powers and to the Russian empire too.

After the First World War, the instabilities intrinsic to the global economic order increased. The weakness of the formerly dominant British economy and the isolation of Germany and Russia undermined global market integration. The slump of 1929 sent deflationary ripples around the world and accelerated the disintegration. As the world market shrank, the great powers struggled over national shares. In the 1930s the world economy broke up into several relatively closed trading blocs. The British, French and Dutch reorganized their trade on colonial lines. With Hitler in power, Germany resumed the perspective of regulated trade within a colonial region in central and eastern Europe, and this led to rivalry with other interested regional powers. Italy established bilateral trade with the smaller states of the former Austro-Hungarian empire, and also set about winning an African empire. The Japanese competed with the Americans, the Dutch, the British and the Soviet Union for influence in east Asia and the Pacific. The Soviet Union developed a closed economic space behind the frontiers of the former Russian empire, and defended it against the Japanese.

The worldwide trade disintegration contributed to the causes of the Second World War. The economies of the Axis powers, Germany, Italy and Japan, were too small to prosper without specialization and external sources of food, fuel and other materials. A common thread in their course of external aggression was the attempt to secure these supplies by...
imposing a colonial regime upon trading partners. In this sense the national policies that led to the Second World War were a continuation of those that had led to the First World War. The second war continued some of the themes of the first, but it was not just a repeat. The object of the first war was regional – to control Europe, the Atlantic and the Near East. The second war was a struggle for global domination in the full sense. The first war was certainly fuelled by racial identities, but no one aimed at genocide, as they did in the second. The first war ended inconclusively, with a ceasefire and a peace treaty that tried to punish the aggressors, but there was no unconditional surrender, and in Germany those who wanted to try again eventually took power. In 1945 the aggressors were crushed militarily and morally, their surviving leaders were put on trial, and what they stood for was excluded from public life.

In this article we pursue the similarities and differences of the two wars in terms of economic history. We have two main themes. First, what is the power of the economic factors compared with others in helping to explain the outcomes of the two wars? Second, of the possible economic factors that should be considered, which contribute most to the explanation of the results? These are not new questions, of course; here, we outline briefly some alternative views.

Historians of the two world wars tend to narrate their story as a complex interplay of forces that worked at many levels. They tell a story of warfare that was increasingly mechanized and waged for years on end by massed forces. Nonetheless, war was waged by people, not by numbers. Economists, in contrast, have tended to give the centre stage to the numbers, conceding less to aspects of warfare such as leadership, discipline, heroism and villainy. Raymond Goldsmith (1946, p. 69), an economist who helped to manage the United States war economy in his youth, once observed that:

The cold figures of the output of airplanes, tanks, guns, naval ships, and ammunition, particularly when they are reduced to the still colder form of indices of aggregate munitions production of the major belligerents, probably tell the story of [the Second World War] as well as extended discussion or elaborate pictures … They back to the full the thesis, dear to the economist's ear, that whatever may have saved the United Nations from defeat in the earlier phases of the conflict, what won the war for them in the end was their ability – and particularly that of the United States – to produce more, and vastly more, munitions than the Axis.

To many historians this view remains unappealing; Richard Overy (1998), for example, has objected that it leaves no room for ‘a whole series of contingent factors – moral, political, technical, and organizational – [that] worked to a greater or lesser degree on national war efforts’.

The opposition between cold figures and hot blood is false to some extent. Of course, leadership and psychology mattered. But they mattered less than in previous eras because they had become problems that both sides could solve. In both world wars, multi-million armies took the field and stayed there for months and years, giving and taking appalling losses, without disintegrating. Since the moral fabric of military life could withstand the pressure, numbers of men and the volume of supplies assumed the decisive role.

If economics did matter, exactly what was it about the economies of the Allies that gave them superiority? In Goldsmith’s tradition, size mattered and only size. Niall Ferguson is a historian who gives economics the attention it deserves. Noting the overwhelming size advantage of the Allies in population and production on the eve of the First World War, he remarks (1998, p. 248), ‘To the economic historian, the outcome of the First World War looks to have been inevitable from the moment [the British] opted for intervention’. Given this advantage, he argues, the war should have been over quickly; the only explanation for the Allied failure to conclude the war much sooner is Allied mismanagement, so Ferguson concludes that the Allied economic preponderance was ‘an advantage squandered’. As a result, economic advantage came into play only after much time had passed and the military advantage of the aggressors had almost won the day.

There is much truth in this, but we will take a more nuanced view of what it was about economic life that could be decisive in warfare. The belligerents’ economies differed not only in the volume of national resources but also in their quality. The main factor in quality was the level of peacetime economic development, which we measure by average real incomes per head of the population. Richer countries could mobilize production, public finance, soldiers and weapons out of proportion to their general economic capacities; in other words, the level of economic development acted as a multiplier of size. For Britain in both world wars, control of the vast but impoverished population and territory of India, for example, mattered little compared with access to the rich markets of the United States.

The First World War

From an economic viewpoint, the First World War can be divided into two phases. In the late summer of 1914, both sides hoped for a quick victory with a limited commitment of resources to the war effort. This first phase is summed up in the memorable phrase ‘business as usual’, which was common currency in Britain at the time (Lloyd, 1924). It was hoped that the war could be fought along similar lines to previous centuries, with a clear distinction between soldiers doing the fighting and civilians getting on with normal life. However, from late 1916 both Britain and Germany stepped up mobilization in the direction of ‘total war’. In total war, industry was mobilized to provide unprecedented amounts of munitions, and industrial workers became as vital to the war effort as soldiers. During this second phase, keeping up production and avoiding economic collapse became central to management of the war. The first economy to collapse was on the Allied side; the Bolshevik Revolution of 1917 took Russia out of the war and led to a Soviet republic (Gatrell, 2005). In 1918, falling output in Turkey, Austria and Germany led to the collapse of the Central Powers and the break-up of their empires (Pamuk, 2005; Schulze, 2005; Ritschl, 2005). France also suffered a late collapse of output, but was shored up by the other Allies (Hautcoeur, 2005).
Size and development

The Allies mobilized more soldiers and produced more of most weapons than the Central Powers, as can be seen in Table 1. Furthermore, the degree of Allied superiority increased with the complexity of the weapons. Only in guns did the Central Powers have numerical superiority, while the Allied superiority in tanks reached a factor of nearly 90:1.

Table 2 shows that the balance between the two sides varied over time, as the alliances’ compositions changed. In 1914, the Triple Entente of the United Kingdom, France and Russia could also draw on their colonies, and were joined by other countries including Serbia, the British Dominions, Liberia and Japan. By November 1916, the Allies had been joined by a second wave of countries, including Italy, Portugal and Rumania. By November 1918, although Russia had dropped out, the Allies had been strengthened by the United States and a further wave of countries. By this time, the Allied side included 70 per cent of the world’s pre-war population and 64 per cent of its pre-war output. The scale of resources that could be mobilized by the Central Powers varied less over time. Austria-Hungary started the war, joined immediately by Germany and shortly after by the Ottoman Empire. By November 1915, Bulgaria had also joined, but Italy, defaulting on its treaty obligations, joined the Allies.

It is important to consider the level of economic development of individual countries as well as the volume of output that the two alliances could draw upon. Britain, for example, with a prewar population of 46 million, had average incomes of nearly $5,000 (at 1990 prices), but its colonies, excluding the Dominions, had a pre-war population of 380 million, mostly in India, with average incomes of less than $700. Thus the colonies, with nearly eight times the population of Britain, produced only about the same volume of output. But the colonial output was less available for fighting the Germans because most of it was needed to meet the subsistence needs of the colonial population. Furthermore, this population was difficult to mobilize because of its distance from the theatre of war and the level of development of colonial administration. Even within the Triple Entente, the low level of development in Russia limited the Allied mobilization. The Central Powers were similarly hampered by the low level of development of the Ottoman Empire and Bulgaria, and even the Hungarian half of the Habsburg Empire.

By comparing the information for the two alliances in Table 2, it is possible to calculate size and development ratios for three benchmark dates in Table 3. The ratios are calculated for each alliance as a whole, and also for the great powers only. The rationale for the latter is that if, as we argue, poor colonies did not count for much, it is helpful to see how the ratios look if we do not count them at all. The table establishes a striking result: judging by economic size, the Central Powers were doomed to defeat. In November 1914, the Allies had access to five times the population, 11 times the territory and three times the output of the Central Powers. If we look only at great powers, the Allied advantages in population and output were smaller, but larger in territory, reflecting the fact that German and Turkish colonies tended to be in the sandy deserts of Africa and the Middle East. However, the Allied advantage was limited by relatively low average incomes in Russia and the British and French colonies. Allied incomes were less than two-thirds the average level of the Central Powers, or 80 per cent if attention is confined to the great powers, if Russia is counted as a great power.

By November 1916 the Allied advantage had grown moderately in terms of population, territory and output, but the Central Powers continued to have an advantage in average incomes. By November 1918, however, the situation had changed dramatically, largely as a result of the United States replacing Russia. The Allied advantages in population, territory and output all increased markedly, and for the first time the Allies enjoyed an average income advantage if attention is restricted to great powers. Although it took some time for the American presence to be felt on the battlefield, it sealed the Central Powers’ fate.

### Development and mobilization

The ratios in Table 3 are based on the assumption that during the war the real output of a given country did not change. The reason for this assumption is statistical: it is difficult to track GDP changes in wartime in the poorer countries. What information we have suggests that Table 3 must understimate the actual swing in favour of the Allies during the war, because output increased in the United States and Britain but fell in the less developed economies of the Central Powers. This can be seen in Figure 1, which plots the change in GDP during 1913–17 against the level of per capita income in 1913 for nine countries. The relationship is strongly positive, reflecting the fact that rich countries were better able to mobilize output than poor countries. The biggest decline was in Russia, which was also the poorest amongst these countries in 1913, and collapsed in the Bolshevik Revolution of 1917.
1917. There were also substantial falls in output in Austria-Hungary, France and Germany, which all started the war with lower average incomes than Canada, Britain, New Zealand and the United States.

Figure 1
Production mobilization: nine countries, 1913–1917. Notes: Observations are, from left to right, Russia, Austria-Hungary, France, Germany, Canada, UK, New Zealand, USA and Australia. Source: Broadberry and Harrison (2005).

Another measure of mobilization which varied with the level of development is the change in government outlays as a share of GDP. This reflects the extent to which governments were able to convert output from peacetime uses to the war effort through taxation and spending. Figure 2 plots this measure of fiscal mobilization during the first year of the war against pre-war average incomes for eight countries. The relationship is positive, but not as clear cut as for production mobilization. In particular, it is necessary to control for distance from the main theatre of war in Europe, with the New World countries of Canada, Australia and the United States mobilizing fewer resources through taxation and public spending than the European countries.

Figure 2
Fiscal mobilization in the First World War: eight countries. Notes: Observations not labelled within the figure are, from left to right, Austria-Hungary, Italy, France, Germany and UK. Source: Broadberry and Harrison (2005), supplemented by Austria-Hungary from Schulze (2005).
Perhaps the most direct measure of mobilization is the share of the prime-age male population recruited into the military. This measure, plotted in Figure 3 against average incomes in 1913, is available for a relatively large sample of countries. Again, we find a relationship that increases with pre-war prosperity and decreases with distance from the main theatre of war. The figure is plotted in three distance bands, comprising the frontline Eurasian states, peripheral European countries isolated from the frontline by land or sea (Britain and Portugal), and non-European states. Cumulative numbers mobilized are shown as a proportion of males aged 15–49. After we have controlled for distance (that is, within each distance band), there is a positive relationship between military mobilization and the level of development. But dropping a band also lowers the mobilization rate substantially.

**Figure 3**

Military mobilization in the First World War: 18 countries and the French colonies. *Note:* Observations are, from left to right: Front line Eurasia: Serbia, Turkey, Russia, Bulgaria, Roumania, Greece, Austria-Hungary, Italy, France, and Germany. European periphery: Portugal and UK. Non-European states: French colonies, India, South Africa, Canada, New Zealand, USA, Australia. *Sources:* GDPs per head in 1913 from Tables 1 and 2 or, if not listed there, from Maddison (2001, p. 185); cumulative mobilization rates, 1914–1918, from Uurlanis (1971, p. 209).
Figures 1 to 3 show us that the level of development acted as a multiplier of size. Rich countries were able to mobilize production, public finance and soldiers out of proportion to the size of their economies measured by GDP.
Mobilization and agriculture

Why did being poor matter for large countries like Russia, Austria-Hungary and Turkey? During the First World War, the answer can be found in the performance of the agricultural sector, since these countries all ran short of food long before they ran out of guns and shells (Offer, 1989). Broadberry and Harrison (2005) attribute this to the negative impact of peasant agriculture on mobilization.

One of the most striking attributes of relative poverty was the role of subsistence farming. Contemporary observers were aware of these differences and interpreted them as follows: when war broke out, a country such as Russia would have an immediate advantage in that most of the people could feed themselves; moreover, the diversion of food supplies from export to the home market would actually increase Russia's advantage. In contrast, Britain would quickly starve (Gatrell and Harrison, 1993). This diagnosis could not have been more wrong. In practice a large peasantry proved to be a great disadvantage in mobilizing resources for war. Meyendorff (cited by Gatrell, 2005) described what happened in Russia as 'the Russian peasant's secession from the economic fabric of the nation'. And not only from Russia, for Italy, Austria-Hungary, the Ottoman Empire and Germany all had large peasant populations that proved extremely difficult to mobilize for much the same reason. In wartime peasant agriculture behaved like a neutral trading partner. Why should the Netherlands trade with Germany at war, given the latter's reduced ability to pay, except under threat of invasion and confiscation? Peasant farmers, trading with their own governments, made the same calculation. Thus the Russian economy looked large, but if the observers of the time had first subtracted its peasant population and farming resources they would have seen how small and weak Russia really was.

The peasant's propensity to secede is clearly visible from a comparison of the richer and poorer countries' experience. When war broke out British and American farmers were offered higher prices, responded normally to incentives, and boosted production. The fact that British farming had already contracted to a small part of the economy made its expansion easier: there were plentiful reserves of land unused or little exploited, and the high productivity of farm labour meant that large increases in farm output could be achieved with few additional resources (Olson, 1963; Broadberry and Howlett, 2005).

In the poorer countries, in contrast, wartime mobilization took resources away from farming, particularly young men and horses for the army. Once in the army these young men and horses still needed to be fed, which required a diversion of food supplies from rural households to government purchasers. But the motivation for farmers in the countryside to sell food was reduced, not increased. These were subsistence farmers who grew food partly for their own consumption; what they sold, they took to the market primarily to buy manufactured commodities for their families. But war dried up the supply of manufactures to the countryside. The small industrial sectors of the poorer countries were soon wholly concentrated on supplying the army with weapons and kit. Little capacity was left to supply the countryside, which faced a steep decline in supplies. Consequently, peasant farmers retreated into subsistence activities and the economy began to disintegrate. There might still be plenty of food, but it was locked in the countryside.

The farmers preferred to eat it themselves than sell it for a low return. What food it could get, the government gave to the army for a simple reason: hungry soldiers will not fight. Between the army and the peasantry the urban workers were caught in a double squeeze. As the market supply of food dried up, urban food prices soared, and an urban famine set in. In terms of the economics of famines, the primary cause was not a failure of production but the urban society's loss of food entitlements (Sen, 1983; Offer, 1989).

Aware of this, public opinion might blame unpatriotic speculators or incompetent officials. But the truth was that a poor country had few genuine choices. The scope for policy to improve the situation was more apparent than real, and government action often made things worse: the Russian, Austrian and German governments all began to ration food to the urban population, for example, while attempting to buy food from the farmers at purchasing prices that were fixed low for budgetary reasons. To repeat: in richer countries the government paid more to the farmers, and this worked, but in poorer countries the government tried to pay less and this had entirely predictable results: the farmers’ willingness to participate in the market was further undermined.

In summary, in wartime poor countries suffered the consequences of peasant agriculture, which was essentially a deadweight on their mobilization efforts. Economic mobilization led to urban famine, revolutionary insurrection, and the downfall of emperors in Russia, Austria-Hungary, Germany and Turkey. The same process began in France, which still had a large peasant sector in 1914, but Allied support nipped it in the bud.

War losses

After the First World War, there were several attempts to calculate the costs of the war. However, these studies fell out of fashion, tainted by association with inflated demands for reparations, and because later writers became interested in any positive developments that could be identified as arising out of the carnage and destruction. Thus in his popular survey of the First World War, Hardach (1987, p. 286) argues that Bogart's (1920) estimates of the costs of the war have not been revised in the light of later evidence because ‘the whole basis of calculation has been recognized as inappropriate’.

There are good grounds to be sceptical, however, about the revisionist view that associates war with accelerated economic development. Milward (1984, pp. 17–18), a leading revisionist, cites Bowley (1930) as a pioneer of revisionism, but Bowley himself (1930, pp. 21–3) pointed out how difficult it is to show that any wider changes were actually the result of the war and would not have occurred anyway in its absence. Classifying developments as (a) mainly unconnected with the war, (b) accelerated or retarded by it or (c) apparently arising out of it, Bowley was himself reluctant to put anything other than the key elements of Bogart’s ‘cost of war’ calculations such as loss of life and destruction of
capital into category (c). He did mention the new economic relations between Europe and the United States in this category, but with hindsight we can see that the process of US overtaking was already under way well before 1914 (Abramovitz, 1986; Broadberry, 1998).

Table 4, accordingly, provides updated estimates of the destruction of human and physical capital as the costs of war within a national balance sheet framework provided by Broadberry and Howlett (1998). The first element, the destruction of human capital, is measured by war deaths relative to the population aged 15–49. This differs from the true proportion of human capital destroyed by the war to the extent that younger cohorts had more human capital investment, particularly through education. Although Germany suffered the most casualties in absolute numbers, the proportionate losses were higher in France, Serbia-Montenegro and Roumania among the Allies, and in Turkey and Bulgaria among the Central Powers.

*Source: Derived from Broadberry and Harrison (2005, p. 28).*

The domestic physical capital losses in Table 4 build upon the work of Bogart (1920), who estimated property losses on land and shipping and cargo losses. These are expressed as a proportion of physical capital from modern historical national accounting sources. The French figures draw on estimates of losses from the Reparations Commission and capital stock data from Carré, Dubois and Malinvaud (1976, p. 151). Although these probably overstate French losses, alternative estimates by Villa (1993) yield implausibly low ratios, given the concentration of fighting on French soil (Hautcoeur, 2005, p. 199). Russia's losses were proportionately high, more because of the small size of the pre-war capital stock than a large absolute amount of wartime destruction.

For some countries in Table 4, we can estimate the change in overseas assets and national wealth. Nearly a quarter of British overseas investments was liquidated during the war, so that the reduction of national wealth was proportionally much greater than the loss of physical capital. The loss of French overseas assets was proportionally very high due to heavy exposure to Russian loans, so that, as in Britain, the share of national wealth lost in the war was proportionally greater than the share of physical capital lost.

Finally in Table 4, we have added in Germany’s reparations bill as a proportion of pre-war capital, since it represented an increase in foreign liabilities and hence a reduction in national wealth just as much as the liquidation of Britain's overseas assets meant a reduction in national wealth. Of course the extent to which Germany actually had to pay these reparations is much debated, but that does not alter the effect on the national balance sheet as it stood in 1919, immediately after the Treaty of Versailles. These figures include the A + B + C Bonds, which added up to a total of 132 billion Gold Marks.

### The Second World War

Like its forebear, the Second World War may be divided into two periods. In the first period, economic considerations were less important than purely military factors. This was the phase of greater success for the powers of the Axis, and it lasted from 1937 when the war began in the Pacific, or from 1939 in Europe, until the end of 1941 or 1942; the exact turning point differed by a few months among the different regional theatres. In this first period, Germany and Japan had advantages of strategy and fighting power on their side. As a result, they were able to inflict overwhelming defeats upon an economically superior combination of powers. In early 1942, Richard Overy writes (1995, p. 15), ‘no rational man … would have guessed at the eventual outcome of the war’.

This phase ended, however, without the decisive victory that previously appeared within the Axis powers’ grasp. What ended it? On the surface it was the military failures, not
economic weaknesses of the Axis. Beneath the surface, however, economic fundamentals reasserted themselves. While the Allies had given ground everywhere, their morale had stiffened, their economies were not exhausted, their cooperation was taking effect, and their industries were supplying the front with a rising flood of munitions that would eventually overwhelm the adversary.

In the second period of the war, which began in 1942, the early advantages of the Axis evaporated. There was a brief stalemate. A war of attrition developed in which the opposing forces ground each other down, with rising force levels and losses. Superior military qualities came to count for less than superior size, wealth and economic mobilization. Economic superiority let the Allies take risks, absorb the cost of mistakes, replace losses, and accumulate overwhelming force. This turned the balance against the Axis and won the war.

This narrative does not support the claim that only economics mattered. Economic factors were decisive, however, in the context of a simple fact. The Axis leaders had the chance to use the other factors to decide the war, and they failed. Their failure gave the Allies the chance to bring economics decisively into the equation.

### Size and development

Table 5 shows the volumes of combat resources that each side delivered to the theatres of the Second World War. A comparison of the totals with those in Table 1 shows a staggering increase: a quarter of a million tanks and half a million aircraft, for example, compared with 170,000 aircraft and fewer than 10,000 tanks in the First World War. One thing remained the same, however, across the two wars: the Allies supplied a greater volume of combat resources than their combined adversaries in almost every respect.

*Source:* Harrison (1998, pp. 14–16) except that numbers in the French armed forces in 1940 are corrected as noted by Harrison (2005). The number of ballistic missiles is an approximate upper limit based on Ordway and Sharpe (1979, pp. 405–7). Of the four bombs produced by the Manhattan Project one was tested at Alamogordo, two were exploded over Japanese cities, and one remained unused.

The Allied advantage did not hold at all points of time and place. As Goldsmith remarked, the pre-war rearmament of the Axis powers gave them an early start and this, combined with their purely military advantages, accounts for their early success. A balance struck at the end of 1940, for example, when France had dropped out, the United States remained neutral, and the Soviet Union was still Germany’s partner of convenience, would show a picture of Allied disadvantage. By 1942, however, reinforced by America and Russia, the Allies outnumbered and outgunned the powers that they faced in every major theatre. This was true even on the eastern front where Germany and the USSR confronted each other. These two powers were of similar economic size measured by GDP and industrial production, but the Soviet Union was substantially poorer in terms of the average incomes of its much larger population. Although this disadvantage was enlarged by devastating military and territorial losses in 1941 and 1942, the Soviet Union fielded a bigger army and supplied it more generously. We return to this anomaly below.

The relative economic sizes of the powers and their colonial possessions are shown in Tables 6 and 7. If we consider the world as it was on the eve of the war, then the populations available to the Allies – principally Britain and France with their colonies and dominions, but also including Poland and Czechoslovakia – amounted to nearly 690 million people occupying nearly 48 million square kilometres. The total output of this territory is estimated at one trillion dollars in 1990 prices. Against them stood the nearly 260 million people...
and more than six million square-kilometres available to the Axis powers—Germany, Italy and Japan, with the Italian and Japanese empires and annexations at the time such as Austria, Korea and Manchuria. The people and their lands on the side of the Allies exceeded those available to the Axis power by several times.

**Source**: Calculated from Table 6.

The size of this advantage is more statistical than real, although a real advantage remains after the statistics are stripped out. Africa and South Asia, poor, undeveloped and relatively sparsely settled, made up the greater part of the Allied advantage in size. When we turn to total output, it turns out that the Allied GDP exceeded that of the Axis territories by only one-third; this is because average incomes across the Allied territories – less than $1,500 in modern prices – stood at only one half the $2,900 level of the Axis territories. Here is an ironic comment on the colonial aspirations of the Axis powers: what they wanted so much, and did not yet have, was access to millions of square kilometres of poorly integrated, low-yielding farmland and remote semi-desert.

As before, since poor colonies did not count for very much, we also count the resources on either side considering the great powers only. The Allied size advantage now disappears since Germany, Italy and Japan together had twice the population and one and a half times the territory of Britain and France – but it is replaced by a development advantage: the GDP per head of the Allied powers exceeded that of the Axis powers by one half.

Tables 6 and 7 also show how this balance evolved from 1938 to 1942, when the domains under control of the Axis powers had reached their maximal extent. As their forces swept across Europe and the Pacific region the population under Axis control tripled, while territory and peacetime output potential doubled; the addition of hundreds of millions of east European and east Asian farmers led the average development of the Axis empires to decline somewhat, from $2,900 to less than $2,500 in modern prices. Britain, in contrast, lost its
allies France – with its empire – and Poland, but was joined by the Soviet Union and the United States. Between 1938 and 1942, therefore, the Allied population and territorial sway increased somewhat, but its peacetime output rose by three quarters (from one trillion to 1.75 trillion dollars). This is before the wartime doubling of United States output is taken into account. Joining the richest and poorest of the great powers into a single coalition had a mixed effect, of course, but the net result was an increase in the measured average level of development across all the Allied territories from less than $1,500 in modern prices to more than $2,200.

Table 7 converts these figures into ratios of Allied advantage or disadvantage. We see that in 1942, when things were at their worst, the Allied powers alone had nearly twice the population, more than twice the output, and more than 20 times the territory of the Axis powers. All they had to do was not to lose; given enough time, this economic preponderance would surely bring victory. The weakest link in the Allied chain was poor Russia, with its hundred million low-productivity peasants and seven million square kilometres of permafrost. Germany had forced Russia out of the First World War; could the same not happen again?

Development and mobilization

As with the First World War we will consider three dimensions of mobilization: production (the increase in total output that was achieved during the war), the government's fiscal leverage (the extent that output was mobilized through government spending and taxation out of peacetime uses into the war effort), and military mobilization (the degree of mobilization of the population into uniform). Each of these was powerfully influenced by the pre-war level of development of the economy. Figure 4 shows production mobilization plotted against pre-war average income. Under the pressure of war, rich countries expanded their economies; poor countries tended to collapse, and the collapse proceeded further, the poorer they were. Figure 5 shows the speed of fiscal mobilization. The slope of the relationship with pre-war economic development has the same positive sign: only rich countries achieved significant fiscal mobilization, but there is an exception: the Soviet Union. Some underlying figures are provided in Table 8: these confirm that the Soviet Union achieved a level of mobilization of GDP into the war effort – three-fifths at its peak – that was typical of much richer countries. Germany and Japan achieved similar degrees of mobilization only in the last spasm of the struggle that preceded immediate collapse and defeat.

Fiscal mobilization in the Second World War: six countries. *Notes:* Observations are, from left to right, the Soviet Union, Japan, Italy, Germany, the UK and the USA. *Source:* Harrison (1998, p. 21).
The Soviet anomaly demands explanation. A relatively poor country, Russia collapsed in the First World War, and the Soviet Union could have been expected to do so again in the Second World War, but did not. The course of inward-looking industrialization that Stalin pursued between the wars does not appear to be a sufficient explanation. More important was Stalin's victory in the destructive struggle to collectivize farming, which ensured state control over wartime food supplies and prevented the peasants from seceding from the war effort (Gatrell and Harrison, 1993). As a result the Soviet economy carried a disproportionately heavy economic burden in the Second World War without collapsing.

Finally, Figure 6 shows military mobilization; again, the rich countries mobilised much higher proportions of their population into military uniform. The figure also shows the moderating effect of distance: when we control for pre-war incomes, the countries separated from the fighting by oceanic distances put fewer men into the fighting forces. But the effect of distance was less in the Second World War than in the First World War, suggesting that the interwar decline of transport costs had brought about a more truly global struggle.

Figure 6

Inter-allied cooperation

In terms of cooperation within the opposing coalitions, the Second World War saw a repeat of the First World War with some differences. In both wars the German-led coalition failed to achieve significant economic cooperation among the powers, each of which aimed primarily to exploit its own internal and colonial spaces. The Allies, in contrast, achieved fuller cooperation. During the first war, this involved pooling the industrial and commercial resources of Britain and America with the fighting strength of France, Italy, and Russia; the result was to permit the aggregate military power of the Allies to be produced more efficiently. The main instruments of pooling were war credits from America to Britain, France and Italy, and from France and Britain to Italy and Russia. The amount was not enough to keep Russia in the war to the end, but enough that post-war repayments significantly complicated post-war international finance and trade.

The second time round, inter-allied cooperation assumed a larger scale. The main form it took was the transfer of industrial goods – equipment (including vehicles), materials, fuels and processed foodstuffs – from the United States to Britain and from both countries to the Soviet Union. Although the US legislative framework called it ‘Lend-Lease’, the goods were actually supplied free of financial charges, the aim being to promote the Allied partnership. Pooling of the resources counted in Tables 6 and 7 augmented their value, increased the Allied advantage, saved lives and resources, helped to prevent Soviet defeat, and brought forward the Allied victory. Allied cooperation was not problem-free. The main issue was that, while it saved lives and brought forward victory, it did so asymmetrically. By keeping the Russians in the war, it saved primarily American and British lives, and the Russians felt this deeply. On the other hand, the victory that it brought forward was brought to Berlin by the Red Army, and was much more favourable to post-war Soviet power than would have been the case without western assistance – a source of wartime chagrin and post-war recriminations among the donors.

War losses

The Second World War was fought on a global scale but half a dozen countries saw most losses of wealth and population. Nearly all the 55 million premature deaths, for example, are accounted for between the USSR (25 million), China (10 million), Germany (6.5 million), Poland (5 million), Japan (2.4 million) and Yugoslavia (1.7 million). Table 9 summarizes the data for the great powers as percentages of prewar populations and assets.

War losses attributable to physical destruction (per cent of assets)

Economic growth

Evidently, wartime economic mobilization tended to make the rich richer and the poor poorer. Thus, both wars tended to polarize the global distribution of income. It is of some interest, therefore, to examine whether postwar recovery and long-term economic growth succeeded in reversing this pattern.

Figure 7 suggests that each war was followed by recovery and that those economies most damaged by the wartime experience recovered most rapidly. It takes 1929 as the benchmark date for measuring recovery from the First World War, and 1973 as the benchmark for recovery from the Second World War. It shows that, the more a country's average income fell during each war, the more it tended subsequently to rise. Thus, at least some of each war's negative effects were transitory.

Figure 7
Economic recovery following two world wars. Note: Observations are Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Italy, Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, Switzerland, UK and USA. Source: Maddison (2001).
War damage: GDP per head in 1918, % of 1913

Postwar recovery: GDP

GDP per head in 1973, % of 1945
A more complex picture emerges when we turn to long-term economic growth. To what extent did the post-war recovery return each country to a path of convergence on the global productivity frontier? Figure 8 suggests that after the First World War there was little or no convergence. Some countries that were already rich did much better after the war than some countries that were already poor. In contrast, the Second World War was followed by convergent economic growth. This suggests that the Allies designed a much better international environment for genuine convergence after 1945 than after 1918.

Figure 8
Economic convergence through two world wars. Notes and Sources: as for Figure 7.
Conclusions

In this article we have shown that economics mattered, and we have shown how. Given time, resources won the two world wars. In mobilizing resources, the richer market economies had a significant advantage. It was more important to be rich than self-sufficient; probably, most pre-war efforts to protect jobs or diminish national dependence on trade in the name of strategic self-sufficiency were counterproductive. Poor economies, especially those with a large peasant population, tended to collapse under the stress of total war, although they tended to be less reliant on external trade. The main exception is the Soviet economy in the Second World War; its exceptional resilience is best explained by its rulers’ exceptional degree of control over the peasant farmers.

The pattern should not be overgeneralized. Broadberry and Harrison (2005) have suggested that the power of the relationship between economic and military performance is confined to a relatively short historical period. The era of ‘total war’ from 1914 to 1945 seems to have been unique. In both world wars the main combatants were able to devote more than half of their national income to the war effort. This is likely to have been impossible before 1914 because until then most people were too poor to be taxed at such rates; most economies had the bulk of their resources locked up in forms of subsistence agriculture that were resistant to mobilization; before mass literacy and the telegraph, typewriter and duplicator, commercial and government services were too inefficient to do much about it. In short, in earlier stages of global development total war could not be staged because too many people were required to labour in the fields and workshops just to feed and clothe the population, and it cost too much for government officials to count, tax and direct them into mass combat.

Since 1945 the economic factors in warfare may have lost significance again. This is because nuclear weapons can give devastating military force to any rich country however small, or any large country however poor, for a few billion dollars. Hence the marshalling of economic resources played a much more vital role in the outcome of the two world wars than was likely in any period before or after.

X-efficiency

Harvey Leibenstein

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

free-rider problem; incomplete contracts; Prisoner's Dilemma; social norms; X-efficiency.

Article

One has to distinguish the X-efficiency concept from the theory intended to explain it. As a concept X-inefficiency is similar to technical inefficiency. Leibenstein originated the concept of X-inefficiency because of a belief that there is nothing technical about the most substantial sources of non-allocative inefficiencies in organizations. At the time of the original article (Leibenstein, 1966), it seemed that no available concept, such as organizational inefficiency or motivational inefficiency, implied all the elements that could be involved in non-allocative inefficiencies. Hence, the comprehensive term, ‘X-inefficiency’, was used.

X-efficiency theory represents a line of reasoning based on postulates that differs from standard micro theory. A brief statement of the postulates and other elements of the theory follows. (a) Relaxing maximizing behaviour: it is assumed that some forms of decision making, such as habits, conventions, moral imperatives, standard procedures or emulation, can be and frequently are of a non-maximizing nature. They do not depend on careful calculation. Other decisions attempt at maximizing utility. In order to deal with the max/non-max mixture we use a psychological law, the Yerkes–Dodson Law, which essentially says that at low pressure levels individuals will not put much effort into carefully calculating their decisions, but as pressure builds they move towards more maximizing behaviour. At some point too much pressure can result in disorientation and a lower level of decision performance. (b) Inertia: we assume that functional relations are surrounded by inert areas, within which changes in certain values of the independent variables do not result in changes of the dependent variable. (c) Incomplete contracts: we assume the employment contract is incomplete in that the payment side is fairly well specified but the effort side remains mostly unspecified. (d) Discretion: we assume both that employees have effort discretion within certain boundaries, and that the firm, through its top management, has discretion with respect to working conditions and some aspects of wages.

Under these postulates the firm does not control all of the variables. Rather, the variables are controlled by employees on the one side, and management on the other; both jointly determine the outcome. Thus, this is a standard game-theory type problem. Given the postulates it is easy to suggest that a latent Prisoner's Dilemma problem exists. Employees have an incentive to move towards the minimum-tolerated effort level (E) and the firm has the incentive to move towards the minimum-tolerated working-condition-wage level (W). This is illustrated in Figure 1, where the discretionary effort options run from \( E_1 \) to \( E_n \), \( E_1 < E_2 < \ldots < E_n \), and the discretionary working-condition-wage options run from \( W_1 \) to \( W_n \), \( W_1 < W_2 < \ldots < W_n \). Under individual maximizing behaviour employees would want to end up at \( E_1 \), and the firm would want to offer \( W_1 \). This is the Prisoner's Dilemma solution. The optimal solution is \( E_n W_n \). However, the theory argues that in general the Prisoner's Dilemma solution will be avoided. The reason is that a system of conventions, which depends on the history of human relations within the firm, is likely to lead to an outcome that is usually intermediate between the Prisoner's Dilemma outcome and the optimal solution. In Figure 1 the line with the arrow \( MG \) represents a locus (one of many) of ‘mutual gain’ situations. That is, for any point on the locus there is a point further up in the direction of the arrow that involves greater effort, greater firm revenues, and a division of the increase in quasi-rents such that both wages and profits are improved. In other words, both the employees and the firm can gain.

We should note that for every effort option that employees choose the firm will want to choose the minimum wages and working conditions, $W_1$. Similarly, for every $W$ the firm chooses the employees will want to choose $E_1$. This is the Prisoner's Dilemma outcome, which the arguments that follow will suggest is not likely to occur. However, this adversarial-relations problem between employees and managers is compounded by another free-rider problem. Every employee has a free-rider incentive to move to the tolerated minimum level $E_1$, even though he or she might want others to work effectively. Since all employees and managers face these incentives, overall effort would be reduced to the minimum if they all followed their individual self-interest. Clearly, in this organizational situation individual rationality cannot solve the Prisoner's Dilemma problem. Something akin to “group rationality” (see Rapoport, 1970) is required to achieve an improved solution.

A formal theory of conventions (social norms) has been developed in recent years based on the work of T. Schelling, D. Lewis, and E. Ullman-Margalit. The basic ideas are that conventions should be viewed as solutions to multi-equilibrium, coordination problems and that conventions can provide superior solutions to the Prisoner's Dilemma outcome. An example is whether automobiles should be driven on the left or the right. Everyone driving on the right is a desired outcome, and everyone driving on the left is a desired outcome, but a mixture of left-hand and right-hand driving has a negative payoff. Obviously, a convention is required to choose between all left-hand or all right-hand driving. A coordinated solution is superior to an uncoordinated outcome. However, the various coordinated solutions that are possible need not be equally good. Thus, different times of starting work may not be equally preferred, but a coordinated time may still be preferred to an uncoordinated time. Hence, the conventional hours of starting work need not be optimal.

The point of all this is that effort conventions and working-condition conventions can bring about a non-Prisoner's Dilemma solution. This is shown by the point $C$ in Figure 1. The circle surrounding the point represents the inert area surrounding the solution. The distance between $C$ and $E_n W_n$ represents the degree of X-inefficiency in the system. Thus, the
X-efficiency is a coordinated solution that is superior to uncoordinated individual behaviour. Similar remarks hold for managerial decisions. Of course, the value of $W$ has to be viable in the sense that it must represent a long-run profitable outcome, although not necessarily the maximum profit level. There is a difference between the creation of a convention and adherence to it. The creation may come about through various means, such as the leadership of some managers, or some employees, or by some initial effort levels being chosen arbitrarily. Once established, a convention reduces the flexibility of employees' behaviour. Thus, new employees will adhere to the convention, and possibly support it through sanctions on others. Although stable small changes of its independent variables, an effort convention need not stay at its initial level indefinitely. The concept of inert areas suggests that a large enough shock can destabilize a convention. Once destabilized it is no longer clear whether the dynamics of readjustment will lead to a superior or inferior situation for both sides, or a situation under which one side gains at the expense of the other. Such considerations (and fears) help to stabilize the convention. It is of interest to note that under low-pressure conditions the postulate of non-maximizing behaviour enables us to recognize and understand why firm members may stick with their conventions and impose supporting sanctions even in situations where they would be better off not doing so. Non-calculating, situation-response behaviour helps to shore up the convention-solution to the Prisoner's Dilemma problem, and to shore up the persistence of non-optimal conventions. This helps to explain the existence and persistence of X-inefficient behaviour.

An illustration of X-inefficient behaviour was described in an article in the *New York Times* (13 October 1981) that compared two identically designed Ford plants, one in the UK and one in Germany, both designed to produce the identical automobile utilizing the same manpower and equipment. Nevertheless, the German plant produced 50 per cent more automobiles than its UK counterpart with 22 per cent less labour. Despite the identical plant design, the different effort conventions help to explain the X-inefficient result in the UK plant. The theory permits a number of inferences to be drawn, some of which (stated without proof) are as follows. Firms generally operate within rather than on their production frontiers. Given the output, costs per unit are generally not minimized. Innovations are generally not introduced when it is optimal to do so. Less output is not necessarily associated with more desired leisure. The price of the product can have an influence on the cost of production.

There have been a number of measurements of X-inefficiency and empirical tests of its inferences. Professor Roger Frantz (1987) has estimated that over 50 empirical studies exist that either measure the degree of X-inefficiency or provide econometric results that help to confirm the theory.

Yntema, Theodore O. (1900–1985)

Jacob L. Mosak

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Committee for Economic Development; international trade theory; price theory; Yntema. T. O.

Article

Yntema was born on 8 April 1900 and died on 18 September 1985. He distinguished himself in the academic world as well as in the worlds of public policy and of business. His training was as varied as his career: he received an AM degree in chemistry in 1922, became a CPA in 1924, an AM in business in 1924, and a Ph.D. in economics in 1929. His Ph.D. thesis, *A Mathematical Reformulation of the General Theory of International Trade* – still in print in 1985 – is an elegant mathematical extension to the field of international trade, of Alfred Marshall's price theory for a domestic economy. The year after receiving his Master's degree in chemistry he began a 25-year academic career at the University of Chicago. After one decade in accounting, he served a second decade as Professor of Statistics, a post which for three years he combined with that of Director of Research of the Cowles Commission for Research in Economics. The last five years he served as Professor of Business and Economic Policy, an area in which he could draw upon his wide experience as economic consultant to United States Government agencies and to private companies. During 1942–9 he served as Director of Research, and, in 1961–7, as Chairman of the Research and Policy Committee, of the Committee for Economic Development (CED), shaping it into one of the most influential public organizations in the field of economic and social policy. In 1949 he embarked upon a new career, going to the Ford Motor Company as Vice-President and Director, and serving as Chairman of its Finance Committee during 1961–5. In that capacity, he was responsible for introducing highly innovative systems of financial management and for the recruitment and supervision of a group of so-called ‘whiz kids’ who helped to revitalize the company, two of whom subsequently became presidents of the company.

Young, Allyn Abbott (1876–1929)

Peter Newman

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Chamberlin, E. H.; division of labour; external economies; increasing returns; Keynes, J. M.; Knight, F. H.; Pigou, A. C.; roundabout methods of production; supply price; Young, A. A.

Article

Allyn Young's career presents a puzzle. He is best known to modern readers, if at all, as the author of one much-reprinted article on 'Increasing Returns and Economic Progress' (1928). With such a narrow base his present fame can of course hardly compare with that of some other leading American economists of his day, such as Irving Fisher, Frank Knight, Wesley Mitchell and Thorstein Veblen. Yet during his life he was very highly regarded indeed, and not just by a US economics profession more insular than now. To Schumpeter, ‘his published work … [does] … not convey any idea of the width and depth of his thought and still less of what he meant to American economics’ (1954, p. 875, n23). To Keynes, in a letter of consolation to Young's widow, ‘His was the outstanding personality in the economic world and the most lovable’ (Blitch, 1983, p. 22). To Ohlin, he was ‘a man, who knew and thoroughly understood his subject – economics – better than anyone else I have ever met’ (Blitch, 1983, p. 14). The London School of Economics, in the mid-1920s flush with Rockefeller money and looking to make an ‘appointment to the new chair [that] should be so eminent as to be the basis of a major expansion’, chose Young ‘after a prolonged search of the English-speaking world’ (Robbins, 1971, p. 119).

Unlike those other American economists, he never wrote a book. Although he was an incorrigible contributor to such general compendia as the *Encyclopaedia Britannica* and *The Book of Popular Science*, and to such lesser magazines as the *Annalist* and *The Cornell Civil Engineer*, he wrote few major articles. One reason might have been that, as Keynes remarked in the same letter, he ‘would always share with others all his best ideas … it was his own work … which always came last’ (Blitch, 1983, pp. 22–3). Indeed, much of his best work was done through others, two of the great books in economic theory in the first half of the 20th century, Knight (1921) and Chamberlin (1933), originating
as doctoral dissertations written under his supervision. Thus like R.F. Kahn, though in the other Cambridge, Young remained an ‘elusive figure who hides in the prefaces of Cambridge books’ (Samuelson, 1947, p. 329).

His peculiar choices of what and how to publish are therefore one explanation of why today he is a minor figure; but they are not the whole, nor perhaps even the major, explanation.

Life

Allyn Abbott Young was born in Kenton, Ohio, on 18 September 1876, the eldest child of two schoolteachers; his given names were the surnames of his two grandmothers. His father was also a lawyer, and active in the Midwestern debates on ‘free silver’ which were part of the political phenomenon that was William Jennings Bryan (see Blitch, 1983, to whose article most of these biographical details are due; Dorfman, 1959, pp. 222–33, is also useful, but sometimes inaccurate). A prodigy, Young entered Hiram College in Ohio at 14 and graduated at 17, having studied languages as well as mathematics and physical sciences. After graduation he worked as a printer for some years in Ohio and Minnesota and saved enough money to further his education, so it was perhaps no accident that the chief example in his famous article (1928) was the printing trades.

In the fall of 1898 he entered the graduate programme in economics at the University of Wisconsin, then and for many years later a major centre of institutional economics. Richard Ely, his chief teacher, was so impressed by Young’s ability that in 1899 he secured for him a 15 months’ internship with the staff of the Twelfth Census in Washington, where he met and formed fast friendships with, among others, Wesley Mitchell and Walter Willcox, a professor at Cornell. In the fall of 1900 he returned to Madison and two years later obtained the Ph.D. with a thesis on ‘age statistics’. Two years after that he married a girl from Madison.

Young was unusually restless for the whole of his academic career, which began in 1902. He first spent two years at Western Reserve University in Cleveland, then one at Dartmouth College, one back at Wisconsin, four at the new Stanford University (where he was the first chairman but failed twice to persuade President Jordan that Veblen should be promoted to full professor), one as a visitor at Harvard, and two as chairman at Washington University in St Louis. The pace slowed somewhat with his appointment in 1913 at Cornell, but even there he took leave of absence for two years in 1918–19 to work with the Wilson Administration on preparations for the peace conference (Blitch has a long account of this episode). He received the traditional ‘call from Harvard’ in 1920 but instead returned dutifully to Cornell. However, the next year he yielded to the renewed invitation of the Harvard department and soon became one of its most popular and respected members, among faculty and graduate students alike.

But Young was too complex a man to stay long even at Harvard, that absorbing barrier of so many academic random walks. Instead, he accepted the attractive offer from London, for a period of three years and at a salary well above the usual English professorial level (Blitch says that ‘It was the first time that a chair in a British university had been offered to an American’). Unfortunately, according to Robbins (1971, p. 121), Young ‘gave … the impression of a profoundly unhappy man’ in the job, and in fact decided to return to Harvard when his three years were up, in spite of a handsome offer from Chicago. Tragically, in the winter of 1928–9 he became a victim of a severe influenza epidemic and very
quickly succumbed to pneumonia, dying in London on 7 March 1929 at the early age of 52.

Character

In appearance Young was tall and thickset, looking according to E.S. Mason ‘more of a poet than an economist’ (Blitch, 1983, p. 13). He was well-read in his own subject and many others, a musician, ‘singularly unworldly’, and famously absent-minded, sometimes having to be summoned to his lectures by colleagues or students.

His reputation stood very high as a teacher, but perhaps more as a supervisor of dissertations and discussant of work in progress than as a formal lecturer, where apparently he was given to long silences while he puzzled out what he wanted to say. Lauchlin Currie said that he ‘gave the impression of thinking as he went along’ (Blitch, 1983, p. 14). Such teaching was more suited to graduates or brilliant undergraduates like Kaldor than to an average undergraduate audience, and Robbins's report of the same style as Young practised it in England was distinctly cool: ‘The more frivolous spirits … would compile betting books on the length in seconds of the longest interval.’ He was still harsher on Young's poor administrative ability: ‘after his untimely death … [there was] … a condition of almost unimaginable confusion, no order or system anywhere’ (1971, p. 120).

In spite of this alleged lack, Young seems to have been a successful chairman at Stanford and in St Louis. Moreover, he was a loyal member of his profession, serving as Secretary of the American Economic Association (AEA) from 1914 until 1920, as President of the American Statistical Association in 1917, and in 1925, after Veblen had refused the position (Dorfman, 1934, 491–2), as President of the AEA. His most famous paper (1928) was actually delivered as the Presidential Address of Section F of the British Association, ‘the first American to be so honored’ (Blitch, 1983, p. 18).

His feelings of loyalty may on occasion have affected his judgement. As a member of Wilson's delegation to the Peace Conference in 1919 he had independently arrived at much the same position towards the Treaty that Keynes developed with such force in The Economic Consequences of the Peace, but unlike Keynes could not bring himself to make a clean break with his government. On his return to the United States he reviewed Keynes’ book in the New Republic (1919–20), and privately protested to Keynes at the latter's account of Wilson's behaviour. Keynes wrote a placatory reply, saying that ‘I still believe that essentially the President played a nobler part at Paris than any of his colleagues’ (1977, p. 45). In what he later called ‘an indiscretion which I regret’ (1977, p. 48), at a public debate Young quoted without permission from Keynes's letter, inadvertently making it appear that in the Consequences Keynes had consciously distorted the truth about Wilson for his own propagandist purposes. Keynes was furious – ‘Young was very wrong … to make reference to a private letter’ – and threatened to publish the whole correspondence. However, Young finally wrote a letter of apology to the New York Evening Post, which to Keynes seemed ‘quite satisfactory … I am now quite content to let the matter drop’ (1977, p. 49).

Forgiven, then; but not forgotten. In A Revision of the Treaty (1922, p. 3n) Keynes first quoted the reference in Young's original review to the Treaty's ‘timorous failure to reckon with economic realities’, and then scathingly remarked: ‘Yet Professor Young has thought right, nevertheless, to make himself a partial apologist of the Treaty, and to describe it as a “forward-looking document”.’ Young reviewed the new book, wrote an irenic letter to Keynes (Harrod, 1951, p. 312) and the episode finally closed,
apparently (to judge from Keynes's letter to Young's widow) without seriously affecting their mutual regard.

Works

Young's range as an economist was unusually wide, even in an age when it was easier to be at the frontier of research in several fields than it is now. Beginning in what would now be called demography (1900–1), he worked and published in several areas of applied economics, such as public utility regulation, antitrust policy, banking, index numbers, public finance, income distribution, and problems of war finance and reparations (for example, 1922–3). In the nature of the case, however, little of this applied work was of lasting importance, and so rather unjustly it will be his work in theory and doctrine that receives attention here.

It is typical of him that Young should have made his first major theoretical impact with two review articles, rather than with independently original work. The first, appearing in 1912 when he was already 36 and an established member of the profession, was a review of the fourth edition of Jevons's *Theory of Political Economy*, appearing 40 years after the original edition of 1871. Thus Young's review (reprinted in 1927) was perforce an essay in the history of economic thought rather than current economics. As such it was a penetrating contribution, well worth reading today and by no means inferior to some modern assessments of Jevons.

Matters were quite different with the second review article (1913), on Pigou's recently published *Wealth and Welfare*. It was this that made Young's international reputation, for he was the first to point out a basic flaw in Pigou's reasoning. The excess of ‘marginal supply price’ over supply price that Pigou saw as a reason for taxing decreasing returns industries turned out to be in Young's argument almost entirely a matter of those increases in rents of the relatively scarcer factors by which necessary transfers of resources are accomplished, and certainly does not correspond to increased real usage of resources. The international impact of this fundamental criticism was probably all the greater because at that time one did not look for such subtle general equilibrium reasoning to come from the heavily empirically-minded US profession. However, for reasons which were hardly Young's fault, it failed to sweep away as it should all arguments of the Pigovian kind, so that later Young's student Knight (1924) felt impelled to repeat essentially the same point, in an article that is today much better known than Young's original criticism.

It is curious that Young did not see fit to reprint this article in his collection (1927), which included far inferior pieces. A kind and modest man, possibly he did not want to upstage his friend Knight's recently published article on the same subject. It is far more likely however, that he did not want to give renewed currency to a view which, in 1927, he almost certainly no longer held. To Pigou's claim (1912, p. 177) that ‘Provided that certain external economies are common to all the suppliers jointly, the presence of increasing returns in respect of all together is compatible with the presence of diminishing returns in respect of the special work of each severally’, Young had in 1913 made the terse dismissive comment that ‘I cannot imagine “external economies” adequate to bring about this result’ (p. 678n). But it was precisely Young's vivid and convincing vision of such external economies as the main vehicle of increasing returns and economic progress that was the centrepiece of his famous article a year later, in 1928.

Between 1913 and 1928 Young contributed no major articles in economic theory. One reason may have
been his work on Ely's *Outlines of Economics*, which with Thomas Adams and Max Lorenz he had helped to revise in 1908 and whose revisions he supervised in 1916 and 1923, writing the whole of ten chapters and parts of others (Dorfman, 1959, p. 222 n. 2). This work was by far the most popular college textbook in economics in America, selling a total of 350,000 copies and outstripping its chief rival (Taussig's *Principles*) by two to one (Dorfman, 1959, p. 211n). Of much greater importance must have been his work arising from the peace conference, which seems to have preoccupied him for several years from 1918 on.

His paper of 1928 is not quite the isolated phenomenon that it appears. Several of his contributions to the great 14th edition (1929) of the *Encyclopaedia Britannica* are consistent with the approach taken in (1928), particularly his entry on ‘Capital’. This is not surprising, for the chief analytical innovation in (1928), as distinct from its new ‘vision’ of economic progress, was to make the degree of roundaboutness depend primarily not on the rate of interest but on the scale of production, taken in a broad sense.

Although no brief summary can do justice to Young's vision and its details as set out in (1928), the following passage taken from the essay on ‘Capital’ (1929, vol. 4, p. 796) is a modest if inadequate substitute for reading the paper itself:

> There is nothing inherently economical in roundabout methods, but the most economical methods often happen to be roundabout. The degree of roundaboutness which is most economical generally depends upon the amount of a particular kind of work which is to be done. And also the making and use of instruments involves an extension of the principle of the division of labour, and the division of labour, as Adam Smith observed, depends upon the extent of the market. The use of capital on a large scale in industry came later than its use in commerce, for the reason that not until there were markets which were able to absorb large outputs of standard types of goods was it profitable to make any extensive use of roundabout methods of production. Once established, however, industrial capitalism showed that it had within itself the seeds of its own growth. Cheaper goods, improved means of transport, and the increased advantages of specialization led to larger markets, so that the economies of industrial capitalism grew in a cumulative way. The increasing division of labour, by breaking up complex industrial processes into simpler parts, not only invited a larger use of instruments, but also prompted the invention of new types of instrument.

Apart from an interesting discussion by Marx, Young's article was the first serious advance beyond Adam Smith on the relations between increasing returns and economic growth. However, the problems of formalizing that persuasive vision into a tractable model have proved formidable indeed, the chief technical problems being those of non-convex technologies and the introduction of new intermediate commodities. So, old as it is, his paper remains important for us precisely because there is not much else. Although there have recently been some encouraging signs that this long drought may be coming to an end, these are not yet sufficient either in number or in quality to predict definitely that it will.

Conclusion
As a critic, Young was knowledgeable and perceptive and possessed of that rare ability of entering into and appreciating minds that were quite unlike his own. This can be seen not only in his reviews of Jevons and Pigou and Edgeworth (1925) and his work with countless graduate students (not just stars like Knight and Chamberlin), but in a wider perspective. Thus although he had a populist upbringing in the Midwest and was trained in the very citadel of institutional economics, it is clear from his writings that by nature he had much greater affinities with the modes of thought of traditional economic theory. To that extent he was seriously handicapped in living in a time and place that was at best atheoretical. Nevertheless, his sympathies were so far extended that he could refer to Veblen as ‘the most gifted man I have know’ (Dorfman, 1961, p. 299) and could review much too kindly the institutionalist manifesto edited by Tugwell (1924), trying hard to see the mazy merits of its case.

Perhaps that is the key to the puzzle about Allyn Young. He was above all a great critic, and great critics, like great journalists and great wits, seldom survive into posterity.

Young, Arthur (1741–1820)

K. Tribe
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
political arithmetic; Young, A.

Article

Born into a Suffolk clerical family in 1741, Arthur Young began his literary career at 17, writing novels and pamphlets. He began farming in his early twenties, and in 1767 he took on the tenancy of an Essex farm which was however beyond his means. Exchanging this tenancy for a smaller farm in Hertfordshire which proved equally unrewarding, his income during the 1770s was drawn as much from writing as farming. The publication of his accounts of travels in England and Ireland met with great success, but the long absences and expense involved led to the neglect of his farm. His response was to extend his literary activities: in 1784 he launched the *Annals of Agriculture*, a journal which rapidly gained international recognition. During the later 1780s he toured the Continent, and his observations of France on the eve of the Revolution remain a valuable source. On the establishment of the Board of Agriculture in 1793 Young became its Secretary, and it was his descriptive methods which were followed by the writers of the County Surveys for which the Board is best known. In 1811 Young became blind, and he died in 1820, leaving behind an autobiography which provided a social and personal record of a life devoted to farming and literary activities.

Young worked until his death on a book entitled *Elements of Agriculture*, a general survey of agricultural method and practice; but the work was never published, and indeed it is evident that Young's strength lay in his observational method and his systematic appraisal of rational agriculture, rather than his ability to produce a general survey of agricultural conditions. This is evident from his *Political Arithmetic* of 1774 and 1779, which, while combining an account of the agricultural state of England with commentary on the writings of Steuart, Davenant and the Physiocrats, lacks the originality of his agricultural writings. Even in the first of these writings, *The Farmer's Letters* (1767), he supported arguments for progressive husbandry and agrarian reform with the construction of 'model farms' which postulate ideal combinations of land, labour and capital for differing conditions of fertility and husbandry. This pattern was repeated in his *Six Weeks' Tour* (1768) and also in many subsequent works.
which record and comment upon the condition of farms and estates encountered on his route. Experiments carried out on his farm were also written up, while in *The Farmer's Guide* he produced a handbook for the establishment and conduct of a tenant farm – together with his *Rural Oeconomy*, an outline of capitalist farm management. Visitors to Young's own farm were often struck by his failure to follow his own recommended ‘best practice’ – instead of order and efficient supervision, they found disarray and confusion. It may be that Young devoted too much time to writing to properly supervise the work of the farm (the true business of the farmer in his view), or he may simply have lacked the application necessary; but his practical shortcomings do not diminish his real achievement – the establishment of a system of agricultural observation which was a model for 19th-century studies of agricultural production.

The Polish economist W.M. Zawadzki, was born in Vilno, historic capital of Lithuania, and studied mathematics and social sciences in Moscow, Leipzig and Paris. His first major work, *Les Mathématiques appliquées à l’économie politique*, was published in 1914 in Paris. After the First World War this book was recognized as a significant contribution to the development of general equilibrium theory as conceived by Vilfredo Pareto. At the beginning of his academic career, Zawadzki was also involved in the study of the role of theories of value in the history of economic thought. He came to the conclusion that, contrary to the prevailing view of the time, the idea of exchange value as something different from market prices should be discarded. This point of view is further developed in the book on *Value and Price*, containing extracts from the works of various economists and published in Polish under the editorship of Zawadzki in 1919. When the Econometric Society was founded in 1931 Zawadzki became one of its original members and was elected to the first committee of the society.

In 1919 Zawadzki contributed to the re-establishment of the ancient University of Vilno, closed down 80 years before by the Russians, and became there the Professor of Political Economy. At that time Zawadzki following the example of Vilfredo Pareto turned his attention to the problems of economic sociology. This found expression in his second major work *The Theory of Production*, published in 1923 in Polish and in 1925, with certain abbreviations, in French – an extensive study of production in various social, cultural and technical environments. Zawadzki distinguishes five types of environments in which regular production can take place: primitive, partriarchal, individualistic, based on compulsion and collectivist. The main part of the book is devoted to the analysis of the conditions of production in an individualistic environment. While admitting the feasibility of regular production in a collectivist society, Zawadzki is sceptical about the Marxist view that the conditions for collectivist systems can gradually emerge in the course of development of individualistic society. But he admits the possibility of
a revolutionary transition to collectivism as preached by George Sorel and the French syndicalist revolutionaries.

Zawadzki was the Polish Minister of Finance in 1931–5 and was to a very great extent responsible for keeping his country on the gold standard in spite of the abandonment of that system by Britain and the USA.

From 1936 until his death in 1939 Zawadzki was Professor of Economics in the Central School of Commerce, Warsaw. During that period he worked mainly in the field of monetary theory and had considerable influence as a teacher – several young economists adopted his ideas and tried to develop them.

Zeuthen, Frederik Ludvig Bang (1888–1959)

Hans Brems

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Chamberlin, E. H.; collective bargaining; duopoly; product differentiation; Robinson, J. V.; Zeuthen, F. L. B.

Article

Zeuthen was born on 9 September 1888 in Copenhagen. He took a degree in economics at the University of Copenhagen in 1912 and spent the next 18 years in the service of the Danish social security system. That system, already then full-fledged by American standards, was the subject matter of a large number of books and articles published by Zeuthen in the period 1912–28. But then, at 40, Zeuthen published his Fordeling (1928) in which is found, among other things, his use of inequalities in a Walras system as well as his theory of collective bargaining. The following year he published his article (1929) on product differentiation under monopolistic competition. Zeuthen's treatment of collective bargaining and monopolistic competition appeared in English (1930) with a preface by Schumpeter, who called it a 'bold raid into new and difficult country'. The new country would soon become part of mainstream economic theory. Also in English (1957), Zeuthen gave us his mature views on all this. He taught theory, labour economics and social security at his alma mater from 1930 to 1958 and died on 24 February 1959 in Copenhagen.

Inequalities in a Walrasian system

In a Walrasian system with fixed input-output coefficients, Zeuthen (1928, p. 27; 1932–3, pp. 2–3) saw that feasibility would require the sum of all inputs of any good absorbed in all processes to be smaller than or equal to the sum of all outputs of it supplied in all processes. By introducing a new variable, that is, the unused portion, Zeuthen could then turn his inequality into an equality and say that either the unused portion of the input or the price of the input would be equal to zero.

In a short paper Schlesinger (1935) agreed, but neither Zeuthen nor Schlesinger attempted to prove the
existence of a general equilibrium. Wald (1935; 1936) made the attempt for a stationary economy, and von Neumann (1937) succeeded for a growing one. Von Neumann formulated a primal and a dual problem. His primal problem was to maximize the rate of growth subject to the constraint that excess demand for any good must be non-positive. That constraint was what Zeuthen and Schlesinger had seen and Wald had worked on. Von Neumann's dual problem was this. We must minimize the rate of interest subject to the constraint that in any time-consuming process profits must be non-positive. That constraint was seen by neither Zeuthen nor Schlesinger. Taking his primal and his dual together, von Neumann found his familiar existence proof in which the maximized rate of growth equalled the minimized rate of interest.

Collective bargaining

Inherent in labour–management bargaining is the threat of conflict. Zeuthen's (1928; 1930, pp. 104–50) point of departure was the net outcome of a possible conflict as expected by labour and management, respectively.

As seen by labour, let the net outcome be $w(L)$ defined as the money wage rate after conflict reduced by labour's cost of conflict, that is, lost wages. As seen by management, let the net outcome be $w(M)$ defined as the money wage rate after conflict raised by management's cost of conflict, that is, lost orders. The lower bound to a negotiated money wage rate will then be what labour expects to live with after a possible conflict, that is, $w(L)$. A negotiated money wage rate equal to its lower bound $w(L)$ would leave labour indifferent and management eager to secure an agreement. To shake labour out of its indifference, management may be willing to raise the suggested wage rate. Thus suggestions at or near the lower bound $w(L)$ will very likely be abandoned in favour of higher ones.

The upper bound to a negotiated money wage rate will be what management expects to live with after a possible conflict, that is, $w(M)$. A negotiated money wage rate equal to its upper bound $w(M)$ would leave management indifferent and labour eager to secure an agreement. To shake management out of its indifference, labour may be willing to pare down the suggested wage rate. Thus suggestions at or near the upper bound $w(M)$ will very likely be abandoned in favour of lower ones.

Having established the existence of such centripetal forces – powerful near the bounds of the bargaining range, weaker towards its centre – Zeuthen found his negotiated money wage rate moving towards a point in which no party was more eager to secure an agreement than the other. Zeuthen's theory of an economic conflict and its resolution may well have been the first ever.

Product differentiation

Like Bertrand, Zeuthen (1929; 1930, pp. 24–5) assumed his duopolists to have a price policy but cautiously removed Cournot's and Bertrand's assumption of 'qualité indentique'. Zeuthen's product differentiation consisted in differences in product quality, geographical location, or advertising-generated image. Such product differentiation was not strong enough to protect a duopolist failing to match a price cut but strong enough to allow a duopolist matching any price cut to keep his old customers. Like Cournot and Bertrand duopolists, Zeuthen's duopolists would always sell at a common price but could attract new customers by lowering it. A ‘coefficient of expansion’ measured a duopolist's
ability to attract them by differences in product quality, geographical location, or advertising-generated image.

Unlike Joan Robinson's one-firm model three years later, Zeuthen's model had two firms interacting in a group equilibrium. Unlike Edward Chamberlin's group equilibrium three years later, Zeuthen's group equilibrium did not assume equal market shares: the more successful firm had the larger coefficient of expansion, hence the larger market share.

Abstract

This article reviews research in Austrian economics over the last 25 years, relating it to (but not discussing in detail) earlier classic work in the Austrian tradition. Core issues are business cycle theory, entrepreneurship, market processes and economic institutions, the communication of knowledge in markets, spontaneous order, and issues related to law and economics.

Introduction

In the past 25 years, a large amount of new research in Austrian economics has developed and expanded the basic themes that are central to its unique identity (O'Driscoll and Rizzo, 1996). These highly interrelated themes are (1) the subjective, yet socially embedded, quality of human decision making; (2) the individual’s perception of the passage of time (‘real time’); (3) the radical uncertainty of expectations; (4) the decentralization of explicit and tacit knowledge in society; (5) the dynamic market processes generated by individual action, especially entrepreneurship; (6) the function of the price system in transmitting knowledge; (7) the supplementary role of cultural norms and other cultural products (‘institutions’) in conveying knowledge; and (8) the
spontaneous – that is, not centrally directed – evolution of social institutions. The specific ways in which these themes have recently manifested themselves is the subject of this article.

Since our task is to discuss the developments in Austrian economics primarily since the last *New Palgrave* entry (1987) we shall not review the work of the many ‘classic’ Austrian authors. In addition, since our concerns are the substantive developments in the field, we omit many valuable contributions in the history of economic thought and in methodology.

**Macroeconomics and monetary theory**

There have been many advances in Austrian macroeconomics. These include new work on business cycle theory and on alternative monetary institutions. Each of these areas can be looked at from the general perspective of treating time, money and their related institutions seriously (*Horwitz, 2000*). Time is the medium of all action. Decisions are taken in time to produce consequences in the future. Taking time seriously means also taking the uncertainty that characterizes these decisions seriously. This applies to savings-investment choices, production plans, and the time structure of capital goods. In an Austrian (and Keynesian) perspective the pervasive uncertainty of the future makes money necessary. Thus, as time is the medium of all action, money is the medium of all exchange. All goods markets are accordingly affected by the supply and demand for money and the nature of monetary institutions.

The Austrian Business Cycle Theory (ABCT) received a major systemization and refinement in the work of Roger Garrison, culminating in his book, *Time and Money: The Macroeconomics of Capital Structure* (2001). The previous work in the subject was scattered in many articles by Friedrich Hayek and in the work of Ludwig von Mises. It was also very imperfectly linked to the brilliant, but underrated, work by Ludwig Lachmann, *Capital and its Structure* (1956). Garrison corrects these deficiencies and adds coherence to ABCT which had previously been unknown. In a sense, Garrison has done for ABCT what John Hicks and Alvin Hansen did for Keynes’s macroeconomics, except that the Garrison’s work is an accurate rendition of Hayek, Mises and Lachmann.

The subtitle of Garrison’s book, ‘The Macroeconomics of Capital Structure’, expresses the important claim that Austrian macroeconomics cannot adequately be appreciated without understanding that ‘investment’ is not a homogeneous decision. This insight is developed at length by Peter Lewin in *Capital in Disequilibrium: The Role of Capital in a Changing World* (1999), the most important work in Austrian capital
theory in many decades (see also Endres and Harper, 2008). The ABCT focuses on the inappropriateness of the capital structure (malinvestment) generated by artificially low real interest rates (that is, interest rates that are lower than the real supply of savings would allow). Thus, the term over-investment is, by itself, a misleading characterization of the ABCT process. While excessively low interest rates do increase the level of investment relative to its previous position, they do so in a biased way – those stages of production further from consumption are affected to a greater extent.

However, as Garrison’s recent work (2004) has shown, there are even more widespread distortions in the production structure generated by artificially low interest rates. These include initial ‘overconsumption’ as the result of reduced savings and of increased incomes on the part of factors of production. Increased investment in close temporal proximity to the overconsumption is labeled the ‘derived demand effect’. This is in addition to the ‘discount effect’, described above, which increases the profitability of new investment distant from consumption. These two contrary effects come at the expense of intermediate stages of production as well as reduced maintenance of existing capital at all stages. They may even result from the utilization of unused resources during periods of less than full employment. These effects show that the ABCT is a type of ‘coordinationist macroeconomics’ insofar as it describes the discoordination of various sectors of the economy, and is not simply a micro choice-theoretic approach to macroeconomics (Wagner, 2005).

Accordingly, in this Austrian view recessions are characterized not simply by low levels of aggregate economic activity but also by the misdirection of resources caused by previous boom-induced malinvestments. These systematic sectoral imbalances – too much investment in interest-sensitive areas of economic activity – must be corrected as recovery proceeds.

The Austrian theory, however, is not a complete theory of the business cycle. It accounts mainly for the process leading to and including the cycle’s upper turning point. It is a theory of the crisis. How long the resulting recession lasts is not predicted by the theory or even, strictly speaking, by the degree to which resources were misallocated. The length of the recession will depend, for example, on those factors affecting the mobility of resources.

None of this implies that Hayek, Garrison or Horwitz are insensitive to the problems that would be induced by an aggregate increase in the demand to hold money (a fall in income velocity), which can accompany recessions. This ‘secondary deflation’ should be avoided by a concomitant increase in the supply of money by the relevant monetary institutions. Horwitz (2000) is the first to integrate Austrian macroeconomics with monetary
disequilibrium theory to analyse deflationary processes. Nevertheless, recessions are not primarily deflationary phenomena (or at least need not be), but occasions for correction of the misdirection of resources. Some Austrians, however, argue that increases in the demand for money have significant negative consequences only in the presence of legal restraints on price flexibility (Salerno, 2003).

One of the most important possible obstacles to recovery from recessions may be in the behaviour of ‘big players’. These are agents whose discretionary behaviour, insulated from the normal discipline of profit and loss, can significantly affect the course of economic effects (Koppl and Mramor, 2003; Koppl, 2002; Koppl and Yeager, 1996). Thus, discretionary behaviour on the part of monetary authorities (in the United States, the Fed), fiscal policy makers (Congress or the Executive), or even in some cases private monopolists, can increase uncertainty faced by most economic agents (‘small players’). They will have to pay more attention to trying to guess the perhaps idiosyncratic behaviour of the big players. Economic variables will become contaminated with big-player influence. It will become more difficult to extract knowledge of fundamentals from actual market prices. And thus entrepreneurs will find it harder to determine where resources should be withdrawn and where they should be added in a way that is sustainable in the medium to long term.

An important variant of the ABCT in Risk and Business Cycles: New and Old Austrian Perspectives (1998), developed by Tyler Cowen, focuses on the integration of business cycle theory with developments in modern finance. The main sense in which this can be called a variant of ABCT is that changes in the riskiness of investment decisions are linked to the ‘old Austrian’ concern with the degree of futurity or roundaboutness in investments. For example, in Cowen’s analysis, an increase in the acceptable level of risk will encourage undertaking more longer-term investments (as well as, of course, investments of any given length with more uncertain yields). These can be both investments in durable capital goods (that is, investments with a continuous flow of payoffs over a long period of time) and investments with a long period of gestation before the ultimate output is produced. Cowen associates less risky (‘safe’) investments with consumption and shorter-term investments.

Cowen’s analysis is more general than the traditional ABCT because it allows many factors besides a fall in real interest rates to generate a lengthening of the capital structure. These include exogenous risk-preference shifts, increases in savings, easing financial constraints, and reductions in uncertainty (so as to reduce ‘waiting’ for acceptable investment opportunities). Any of these changes can generate an increase in the riskiness of investment. None of these changes must necessarily cause a cyclical boom and bust, but they might do so.
Horwitz (2000) shows that the traditional business cycle concerns of Austrian macroeconomics quite naturally lead into comparative institutional analysis. Therefore, the obvious question is: What kind of institutional framework is necessary or conducive to avoiding the distortionary effects of inflation and deflation? Austrians have been critical of both discretionary central banking policies and rigid monetarist rules. Some have favoured free banking while others have favoured a 100 per cent (usually gold) reserve requirement and hence have opposed fractional reserve banking.

The free banking school, represented by Selgin and White (1994), Horwitz (2000), Dowd (1996) and Sechrest (1993), emphasizes the importance of adjusting to changes in the demand to hold money (income velocity). For prices in particular markets to do their work appropriately in transmitting knowledge and allocating resources they must be free of the distortions induced by inflation and monetarily induced deflation. Free-banking advocates argue that bank profit maximization, under sound institutional constraints, will lead banks to expand or contract deposits or currency pari passu with changes in the demand for money. Banks will receive signals about the demand for (their) money as their reserves expand or contract. When reserves expand, the demand to hold is increasing, and vice versa. Profit maximization leads banks to increase the supply of money when reserves expand beyond their desired levels. Thus, no explicit monetary policy is needed to avoid unwarranted expansion or contraction on the ‘money market’, just as on commodity markets no deliberate industrial policy is needed to avoided unwarranted expansion or contraction of resources in different areas.

The advocates of 100 per cent reserve money follow the work of Murray N. Rothbard (2008). These include Block (1988), Hoppe (1994), and Huerta de Soto (1995). They argue that free banking - to the extent that it is fractional reserve banking - is ethically suspect. Regardless of the merits of this argument, our concern here is solely with economics. They further argue that fractional reserve banks are inherently inflationary because any creation of fiduciary media beyond an increase in specie will generate a business cycle. (The word ‘inflationary’ is being used here either as a definition - an increase in money not covered by an increase in specie - or as an intellectual place-card to suggest the generation of a cycle.) Critiques are offered in Horwitz (2000) and in Selgin and White (1994).

Entrepreneurship

The theory of entrepreneurship has been a subject of great importance in Austrian economics since the publication of Israel Kirzner’s Competition...
and Entrepreneurship (1973). One could argue, of course, that this was implicit in the prior works of Ludwig von Mises and Friedrich Hayek. Nevertheless, there is an important difference between implicit and explicit ideas. Over a long period of time, Kirzner refined his theory of entrepreneurial discovery or alertness in many books. Kirzner’s approach is predominantly cognitive. There are roots of this cognitive approach in the early work of von Mises (Ebeling, 2007). However, quite curiously in this time of the resurgence of psychology and economics, it is a cognitive theory without explicit cognitive foundations. Kirzner is interested in the market implications of the fact that there is entrepreneurial alertness. He is not interested, beyond some very general observations, in the causal factors that give rise to or are conducive to alertness.

Alertness, or equivalently, entrepreneurial discovery, is hard to define. It is a creative, spontaneous, and to a certain extent idiosyncratic, mental act that goes beyond the mere apprehension of objective data. First, while it usually begins with objective data, it critically involves drawing connections with other data when those connections are not obvious or even the result of complex computations. Second, true discoveries are not the result of deliberate acts of search. They cannot reliably be attained by the simple deployment of resources. Something more is necessary. This is not to suggest, however, that they must be viewed as random shocks to the economic system. They can be cultivated and prepared for by deliberate decisions, but they cannot be mechanically produced by them. We might say that while deliberate search is not a sufficient condition for discovery, it is necessary. Even better, eschewing the excessively constraining categories of necessity and sufficiency, we might say that the serendipity of discovery favours the searching mind (Holcombe, 2007; Shane, 2000). Finally, it is likely that many individuals can be exposed to the same data and yet not make the discoveries that the alert individual does.

In a market context, entrepreneurial cognition is the discovery of profit opportunities. In Kirzner’s perspective, this is based on noticing price inconsistencies, whether at a point in time or across time. Hence this is an arbitrage theory of profit. How well this conception of entrepreneurship takes uncertainty into account is a matter of some dispute (Kirzner, 1982). In the theory advanced by Young Back Choi (1993, 1999), however, uncertainty is more explicitly considered. In this perspective, related to Schumpeter’s classic analysis (1934), entrepreneurs break through the conventional way of looking at the world. These conventions were originally adopted to reduce uncertainty. But as time goes on the world changes and they become less and less effective. Profit opportunities accumulate. Entrepreneurs adopt new paradigms that
enable them to see the new profit opportunities that conventionalists cannot.

To the extent that entrepreneurial discovery is unconnected to any cognitive or psychological basis, it functions as a *deus ex machina* of the market process. It drives the processes that occur in response to errors and disequilibria. Ultimately, it is defined by what it does. This approach has been criticized because it presupposes empirical psychological processes that are not necessarily present in all circumstances (Jakee and Spong, 2003). Can we say anything systematic about the factors that, on an individual or social level, are conducive to discovery? If we can, we might begin to understand more precisely what it is, when it is successful and when it is not.

In the first unified analysis of the factors affecting entrepreneurship, David Harper focuses on the presence of a sense of personal agency as the primary factor. ‘It comprises two cognitive elements – beliefs in the locus of control (or contingency expectations) and beliefs in self-efficacy (or competence expectations)’ (Harper, 2003, p. 14). This means that the entrepreneurial agent believes that in a particular context results are contingent upon actions as opposed to luck or nature, and that he himself possesses the personal capabilities to effect these actions and thus to produce the overall results. Individual characteristics also interact with situations to make the development of a discovery propensity more likely. Harper goes on to show the ways in which economic, political and cultural institutions mediate the individual factors.

In most Austrian treatments entrepreneurial discovery is important because it drives the market process. Nevertheless, in path-breaking work Frederic Sautet (2000) shows that there are multiple levels of entrepreneurship. In the simple case, the entrepreneur is herself alert to profit opportunities outside of the firm. In the more complex case, the entrepreneur must face the fact that she often doesn’t know what her employees know. They are often closer to the local facts and may have a superior insight in some respects about profit opportunities in the firm (from restructuring) as well as outside of the firm. Thus, the entrepreneur in a ‘complex firm’ will seek to structure the firm with abstract or loose rules – some relating to compensation schemes – that encourage employees to make discoveries and communicate those appropriately. The firm itself can be a locus of entrepreneurship. In related work, Harper (2008b) suggests that a team of individuals, either inside or outside firms, might also constitute an entrepreneurial unit. Randall Holcombe (2007) utilizes an idea of entrepreneurship beyond pure cognitive alertness, which includes, as well, acting upon the perception of novel opportunities. In this view, the entrepreneur can never be certain that she has correctly perceived a profit opportunity until she acts and assesses the consequences.
Some Austrians have not followed Kirzner in their analysis of entrepreneurship. For example, Joseph Salerno (1993) rejects the characterization of alertness as the essence of entrepreneurship. He sees resource ownership as a necessary feature of entrepreneurial activity (Salerno, 2008). Along similar lines, K. Foss, N. Foss and P. Klein (2007, see also P. Klein, 2008; K. Foss and N. Foss, 2007) have weaved together aspects of Knight’s uncertainty theory (1971) and Austrian heterogeneous capital theory (Lachmann, 1956) to create a theory of entrepreneurial judgment. This theory makes entrepreneurship inseparable from asset ownership. The entrepreneur’s judgement is about the control of heterogeneous capital assets under conditions of radical uncertainty. These authors have applied their theory to understanding the internal operation of the firm.

Market processes and economic institutions

The entrepreneurial function is closely related to market processes and economic institutions. These interrelations are both complex and important. It will help to somewhat artificially separate them for our consideration.

A. The Austrian approach to market processes is distinctive in a number of respects (Wagner, 2007, 2010). It is sometimes described as a genetic-causal theory (Cowan and Rizzo, 1996). First, markets are in process and not continually in equilibrium. Thus, most Austrians do not take interpersonal equilibria of any kind simply as given or as consequences of an axiom of rationality. (An exception is Salerno, 1994, who considers momentary market-clearing equilibrium as an implication of rationality.) Lack of alertness can be responsible for economic errors and inconsistencies (or lack of interpersonal coordination). The market process consists of those entrepreneurial responses to error. Kirzner and others take the view that market processes are generally coordinating: that is, that they generally correct market errors. Austrians accept this as an empirical generalization. The extent to which the empirical generalization can be traced to an a priori discovery tendency is a subject of debate. Kirzner appears to accept this view because he sees the tendency to discover as equivalent to, or tightly connected to, the tendency toward greater coordination (Kirzner, 1997). Rizzo, however, rejects this equivalence (Rizzo, 1996). Other authors have also expressed similar, though not identical, criticisms (D. Klein and Briggerman, 2009; D. Klein, 1997). The neoclassical view that equilibrium is an implication of rationality should not, in this author’s opinion, be replaced with the view that a tendency to equilibrium is the implication of purposefulness. The former has empirical implications while the latter is not clearly
defined, unless it is meant as the positive heuristic of an empirical research program (Rizzo, 1982).

Second, market processes are not instantaneous but take time. In the passage of time (‘real time’), knowledge changes and unpredictable events occur (O’Driscoll and Rizzo, 1996). What were data at the start of a process may change because the process of ‘equilibration’ occurs in real time. Real time cannot elapse without knowledge changing.

Third, market processes take place in the context of radical uncertainty. This is to be distinguished from risk, in which all of the possibilities are known with objective probabilities. However, radical uncertainty is not simply a condition where the assigned probabilities are not objective, but one in which not all of the possibilities are known beforehand. (Still further complications ensue because sometimes individuals know that they don’t know the possibilities and sometimes they do not.)

This leads to the fourth feature of market processes: they are relatively indeterminate. If market processes – in the form of entrepreneurial discovery – cannot be predicted, then the economist cannot know at the beginning where they will lead. In the process of adjusting to change, new ‘data’ will be discovered (Rizzo, 2000, 1990). How far to take this point about the indeterminacy of market processes is subject to debate and may, in part, depend on definitional issues (Holcombe, 2007). Some have argued that Kirzner, in particular, has incorrectly downplayed this indeterminacy (Jakee and Spong, 2003).

This is not to rule out the use of constructs in which equilibria are reached as heuristic devices when appropriate (Holcombe, 2007). However, since they are simply heuristic devices they can be thrown out when circumstances do not warrant such ‘static’ dynamics.

The fifth, and final, feature of market processes is the communication of decentralized or scattered knowledge. Markets enable individuals to act on more knowledge than they can ever hope to possess explicitly. They can do this through entrepreneurially produced market prices and through non-price manifestations of market behaviour. As Hayek showed, the man on the spot may be directly aware of certain economically relevant conditions. If he acts by taking advantage of this knowledge in profitably buying or selling he will ensure that market prices communicate what he knows (Hayek, 1948; Kirzner, 1992a).

Prices are not the only communicators of knowledge in markets. Capital goods also embody knowledge. First, the particular use and combination of capital goods can, under non-distortionary conditions, convey knowledge about efficient resource allocation and possible profit opportunities (Lachmann, 1956). Second, even the physical design of capital goods can convey accumulated knowledge about successful production techniques (Baetjer, 2000).
In general, the communication of knowledge in market settings depends not only on catallactic phenomena but also crucially on the appropriate ‘institutional’ context. This includes legal and cultural products (Harper, 2003). In the latter category David Harper (2008a, forthcoming) has drawn attention to the role of numerical cognition - a product of both unique human biology and cultural development - in facilitating economic calculation. The development of conventionalized systems of number sequences and techniques of counting reduces transaction costs, and helps agents to make plans, compute values, scarcities, notice arbitrage opportunities, and ascertain the economically relevant aspects of capital goods.

B. Entrepreneurship does not simply operate within a familiar institutional structure like the market. It can also operate within structures like those involving social ties, philanthropy, non-profit organizations and so forth (Boettke and Coyne, 2009). There is also ‘political entrepreneurship’ within a given constitutional or governance structure, which seeks to create coalitions to effect specific legislation or transfers of wealth (‘rent seeking’). These non-market structures determine the precise form that entrepreneurship takes. The common differentiating factor that separates the entrepreneurship of the market process from these other forms of entrepreneurship is the absence of the discipline of monetary profit and loss in the latter cases. Although money may change hands as a result of these forms of entrepreneurial activity, their outputs are not valued according to market prices. Whether effective feedback mechanisms exist in these contexts is an open question (Boettke and Coyne, 2009).

Some Austrians, however, have emphasized that non-market institutions can indeed provide feedback to entrepreneurs and can generate a social learning or knowledge-communication process similar to market prices and profit-loss signals (Chamlee-Wright, 2008; Chamlee-Wright and Myers, 2008; Lewis and Chamlee-Wright, 2008). In particular, reputation and status are forms of ‘social capital’ that convey information. Under conditions of competition and effective monitoring of standards, knowledge can be transmitted far beyond networks of individuals in direct communication with each other.

An important example of the communication of knowledge in a non-market context can be found in the scientific community (McQuade and Butos, 2003). We discuss this below in the section on spontaneous orders. Entrepreneurship can also shape or create institutions. Rules of behaviour that surround and define markets, constitutional systems, social and cultural systems arise out of the previous framework of rules, whether it was de facto or de jure. (In fact, the distinction between de facto and de jure may not be all that important for the economics of institutions, aside from the possible issue of transaction costs.)
is path dependency in the development of institutions (Boettke, Coyne and Leeson, 2008). Those that develop as ‘indigenously introduced endogenous institutions’ are closely related to the informal practices and expectations of people, which in turn are grounded in local knowledge and values. Other institutions may be indigenously introduced but are exogenous in the sense that they are imposed by some formal authority, and do not gradually evolve from the informal traditions of a people. There is a risk that these institutions will not ‘stick’ because of conflict between the institution and the underlying norms. Externally (or foreign) introduced exogenous institutions exhibit the greatest probability of not succeeding because of the greater likelihood of conflict with underlying norms and expectations. Boettke, Coyne and Leeson (2008) refer to this analysis as an example of the ‘regression theorem’ first propounded by Ludwig von Mises (1953) in his analysis of the evolution of money.

Some of the evolution of framework institutions may simply be the undesigned outcome of individual behaviour that is not necessarily entrepreneurial, as when people follow each other in making a path through the snow (Kirzner, 1992b). In other cases, there may be alertness to possibilities of gain for the relevant acting parties in altering the political or social frameworks. Plausibly, the creation of the US Constitution was one such case.

Institutions exist at many levels. Perhaps the most basic are those that involve informal institutions like customs, traditions, norms and religion (Williamson, 2000). These take the longest time to change. They may also determine the standards by which lower-level institutions and behaviour within them are evaluated. A new political system is good or bad depending on the (more basic) norm structure in place.

**Spontaneous orders**

Our discussion of entrepreneurship and of institutions leads naturally into a discussion of spontaneous order, an idea very closely associated with Austrian economics. Unfortunately, the term ‘spontaneous order’ is opaque. Somewhat more descriptive is the expression made famous by F.A. Hayek, ‘the results of human action but not of human design’ (Hayek, 1967), and even more descriptive is the idea of unintended social order produced by individually purposeful behaviour.

A spontaneous order is an organic or emergent form of coordination that manifests itself in social institutions, some organizations and clusters of individual plans. Orders of this kind arise without the design and maintenance (oversight) of a social planner. Nevertheless, spontaneous orders are generated by individual agents who do plan and carry out actions
within their sphere of activity. Social order emerges as individuals adjust their plans to each other and to the environment over time.

Spontaneous order theories come in different varieties. Some refer to order produced on markets, while others concern order produced in non-market settings. These theories can be purely positive (descriptive) or they can also be normative. When they are normative their normativity can be relative to the society as a whole or simply to particular subgroups.

At the most basic level, spontaneous order can refer simply to the welfare-enhancing outcomes of competitive market processes operating within the ‘fixed’ constraints of property, contract and tort law. This is best studied within the context of market entrepreneurship.

Bruce Benson (1989), in his path-breaking study of the spontaneous evolution of commercial law, shows how market interactions, based on basic property constraints, can give rise to commercial (contract) law without a law-giver. The self-interested interactions of merchants lead them to develop and adhere to rules that increase their trade and hence overall social cooperation. These rules develop through a process of trial and error in which entrepreneurial alertness at a higher level – the level of rules of the game – doubtless plays an important role. Similarly, Stringham (2002, 2003) and Stringham and Boettke (2004) show that the self-interested interaction of participants in financial markets has generated useful regulations that govern the operation of these markets.

Peter Leeson (2007, 2009), in a number of studies of the organization of 18th-century pirate activity, shows how an outlaw subgroup of society developed maximizing (or ‘rational’ in a limited sense) rules of governance without central direction. Outside of a market context, pirates converged on a set of rules whereby their ability to steal wealth from the rest of society was enhanced. This involved rules within the pirate society itself as well as rules governing its treatment of others. Within their society ‘democracy’ was used; outside of it the use of brutality was constrained. This case is a good example of a spontaneous ordering process with ‘good’ consequences within the subgroup and yet negative consequences for society as a whole. Pirates steal resources from the rest of society. The success of any such rogue subgroup weakens the possibilities of voluntary exchange and other forms of peaceful interaction.

Thomas McQuade and William Butos (2003; see also Butos and Koppl, 2003; Butos and McQuade, 2006) further develop the spontaneous-order approach in the case of the organization of scientific research communities. Even where markets in the traditional sense may be missing, spontaneous – that is, non centrally directed – ordering processes are still present. They focus on the evolved non-market mechanism of publication–citation–reputation. Scientific knowledge is viewed as a
‘by-product’ of the intentional activities of scientists to publish their results, get citations and enhance their reputations. Within this process competition among scientists tends to filter out inferior ideas. The resultant product (‘science’) is orderly in the sense that it tends to be reliable and codifiable. A set of procedures is put into place which acts as a filter to discriminate between rival claims. Furthermore, what comes out of the filter can be collected, integrated with other knowledge and transferred to other scientists.

These illustrations suggest the need for a more general theory of spontaneous order that would clarify the various conditions under which such ordering-processes will take place. Specifically, it should also explore the role of markets and market prices, since it is clear that spontaneous order can develop without markets. From the welfare point of view the research discussed above leaves us with a puzzle: When do spontaneous orders produce an enhancement of social welfare and when a reduction in it, as in the case of pirate societies?

Law and economics

One of the most important areas of research in Austrian economics is the vibrant area of law and economics. Some of the contributions mentioned above in connection with spontaneous order and institutions could be included in this section. The field’s uniquely Austrian features consist of attention to (1) the process of law and state intervention in markets; (2) the need for relatively stable law in a world of external change; (3) the influence of decentralized knowledge on the character and limits of law; and (4) the privatization of some of the basic functions of the state.

1. The most significant work on the processes generated by intervention since the classic analyses of Ludwig von Mises (1977), F. A. Hayek (1994) and Israel Kirzner (1985) can be found in Sanford Ikeda (1997, 2003, 2005) and in Mario Rizzo and Glen Whitman (2003). Ikeda’s framework focuses on the deviation of the actual outcomes of intervention from the intended outcomes. This gap, based on an assumption of radical ignorance, generates price distortions, whether because the intervention takes the form of price regulations or because redistribution of wealth degrades incentives and thus individual responses to underlying economic data. These economic changes interact with largely, though not entirely, endogeneous changes in ideology to produce a tendency toward further policy intervention. Rizzo and Whitman, on the other hand, begin from the largely philosophical and jurisprudential literature of ‘slippery slopes’. They construct a general approach that emphasizes the role of changes in ideas, or more precisely, in the arguments that rationalize or justify legislative policies or judicial decisions. The mechanism by which these arguments
change is a combination of the largely unanticipated consequences of decisions and the higher-level theories in which acceptable arguments are embedded.

Recently, Rizzo and Whitman (2009; see also Whitman and Rizzo, 2007) have applied their slippery slope analysis in conjunction with many of the assumptions and findings of behavioral economics to demonstrate the expansive tendencies inherent in the supposedly moderate policies of new or ‘libertarian’ paternalism.

The Rizzo–Whitman and Ikeda approaches seem largely compatible. Ikeda stresses more traditional economic processes, while Rizzo and Whitman stress the details of the intellectual changes that occur in the context of economic or other processes. In neither of these approaches is the ‘slippery slope’ consequence of policies inevitable. They each describe tendencies that could be counterbalanced in specific cases, but which often have not been.

2. The classic work of Hayek (1960, 1973) on the rule of law simultaneously stresses the importance of stability in the legal framework and its adaptability to changing external circumstances. The solution to this paradox can be found in the level of abstraction of the relevant rules. For example, the abstract form of contract law can remain stable while the prices, conditions and content of exchanges vary at a point in time or over time. The consequences of abstraction in legal rules are examined in Whitman (2009). Whitman shows that an intermediate level of abstraction is optimal from the perspective of generating rules with predictable consequences.

From a slightly different perspective, Rizzo (1980a, 1980b, 1985) and Roy Cordato (2007) both criticize the cost–benefit framework in many conceptions of negligence law because it produces legal decisions that lack predictability to those for whom the particular law is relevant. Peter Lewin (1982) extends the critique to pollution externalities and social cost. The economic data upon which efficient legal decisions are to be made are often unavailable, complex or transient. This is especially true in a world characterized by radical uncertainty. Thus the so-called economic approach to tort law is defective on its own terms. Lack of predictability generates costs. In terms of the abstraction language of Whitman’s analysis, the problem of the efficiency approach is that it enshrines a standard, rather than a set of specific rules, which is too abstract.

Similar criticisms of the so-called economic approach to property rights that derives from Ronald Coase and Harold Demsetz have been advanced by Walter Block. Block argues that the Coasian cost–benefit approach effectively abolishes property rights (1977, 1995, 2000). This view is extended to the analysis of the recent US Supreme Court eminent domain case, Kelo v. City of New London (Block, 2006).
3. The decentralization of factual knowledge is a critically important factor limiting the feasibility of many forms of intervention. As in the earlier analysis of Mises (1977), the critiques discussed here begin from the announced goals of the interveners and do not challenge their worthiness. The approach is thus non-normative. It simply seeks to answer the question: Can the policies achieve the goals that their advocates have set? Rizzo (2005) tackles this question in the case of moral paternalism: that is, the form of paternalism that coerces the individual in the interests of her moral betterment. Using the internal standards of three major ethical approaches – utilitarianism, natural law and Kantianism – Rizzo argues that the factual knowledge needed to determine just what the moral course of action is in concrete cases is not available to the paternalist. Rizzo and Whitman (forthcoming) also apply this kind of analysis to a form of economic paternalism based on behavioural economics. They argue that the factual knowledge that behavioural economics claims is relevant to the crafting of policies designed to improve the decisions of individuals exceeds what is known to the policy makers.

4. Most economic analysis proceeds on the assumption that the state exercises at least its minimum functions: that is, provision of protection, enforcement of property rights and contracts, and the adjudication of disputes. Nevertheless some economists in the broad Austrian and spontaneous order tradition have argued that privatization of at least some of these functions is feasible and desirable. Bryan Caplan and Edward Stringham (2008) have compared the private and public adjudication of disputes. They find that private adjudication is more efficient in areas of commercial disputes, and more generally in those areas where prior relationships exist among the parties. They also speculate on a broader use of private adjudication. In a related area of public choice economics, Powell and Stringham (2009) survey a surprisingly large extant literature on the economics of a stateless society.

Article

Alfred D. Chandler Jr. (15 September 1918 – 9 May 2007), a Pulitzer Prize-winning historian who pioneered the field of business history, was born in Guyencourt, Delaware, near Wilmington. He received a bachelor of arts degree from Harvard College in 1940 and served in the US Navy from 1941 to 1945. In the late 1940s, Chandler returned to school to study history, attending the University of North Carolina before going back to Harvard to complete his Ph.D. in 1952. He published a revision of his dissertation as his first book, Henry Varnum Poor: Business Editor, Analyst, and Reformer (1956). Poor (1812 – 1905), Chandler’s paternal great-grandfather, was the long-time editor of the American Railroad Journal and Poor’s Manual of Railroads of the United States. Chandler’s book explained how Poor, through his detailed reports on individual railroad companies and their operations, helped to invent the role of the modern business analyst and investment advisor.

From 1950 to 1963, Chandler taught at the Massachusetts Institute of Technology, and then left to join the history department at Johns Hopkins, where he remained until 1970. While at Hopkins, he edited the papers of President Dwight D. Eisenhower. From 1970 to 1989, Chandler was a professor at Harvard Business School, where he held the Isidor Straus Chair in Business History. While there, Chandler inaugurated the course entitled ‘The Coming of Managerial Capitalism: The United States’. He encouraged other historians to come to the school, including his successors in the Straus Chair, Thomas K. McCraw and Geoffrey Jones, and he sponsored research fellowships for graduate students and international scholars to travel to the business school’s Baker Library. From the 1970s onward, he lived in a building within walking distance of the campus, in
a large 17th-floor apartment overlooking the Charles River and filled with artwork, including paintings by his wife, the former Fay Martin.

Chandler was the sole author of six books and co-author or editor of more than 30 others. His most famous works focused on the rise of big business and the coming of a managerial class: *Strategy and Structure: Chapters in the History of Industrial Enterprise* (1962); *The Visible Hand: The Managerial Revolution in American Business* (1977); and *Scale and Scope: The Dynamics of Industrial Capitalism* (1990). As many commentators acknowledged, these books were so original in their approach and so impressive in their depth of research that they set the agenda for the entire field of business history for many years afterward.

The first of these, *Strategy and Structure*, analysed DuPont, General Motors, Sears and Standard Oil, and showed how each of these four companies came to adopt a multidivisional structure, or M-form, by the 1920s. No previous historian had provided such a rich account of how big businesses actually worked, or described how middle managers confronted the complexities of daily business life, filled as it was with committee meetings, budget decisions and forecasts. ‘Only by showing these executives as they handled what appeared to them to be unique problems and issues can the process of innovation and change be meaningfully presented,’ Chandler wrote in 1962. His detailed investigations were the basis for his influential argument that a company’s strategy must shape its structure, not the other way around, as was often the case.

In *The Visible Hand*, Chandler sought to explain the rise of big business in the United States in the decades from 1840 to 1920, and to answer the question why large firms arose in some industries and not in others. Chandler argued that in industries whose firms were able to benefit from economies of scale and scope, the ‘visible hand’ of management came to replace the ‘invisible hand’ of the market in coordinating the production and distribution of goods. This was to become his most famous book, winning not only the Pulitzer, but also the Bancroft Prize and the Thomas Newcomen Book Award.

In *Scale and Scope*, Chandler branched out into comparative international history, comparing his story of the ascendancy of capitalism in the United States, from the late 19th to the mid-20th century, with the histories of Britain and Germany. Success in steel, chemicals, automobiles and other industries that emerged during the second industrial revolution, Chandler argued, was achieved through making a three-pronged investment: in mass-production facilities, in international marketing and distribution networks, and in proper management of resource allocation. While Chandler praised German industry, which had developed strong capacities in research engineering, banking, and the production of producer goods, he believed that Britain’s tradition of ‘personal capitalism’ had
prevented that country from making progress in developing large-scale industries.

These three books attracted their share of admirers throughout the world, and ‘Chandlerian’ business history quickly became the focus of conferences and academic papers. In 1973, Derek F. Channon published *Strategy and Structure of British Enterprise*; this was followed three years later by Gareth P. Dyas and Heinz T. Thanheiser’s *The Emerging European Enterprise: Strategy and Structure in French and German Industry*. The First Fuji conference, held in Japan in January 1974, was devoted to the ‘Strategy and Structure of Big Business’. Chandler’s work was also central to curricula at business history units formed at the London School of Economics (in the late 1970s), and in the decades afterward at such places as the universities of Glasgow, Leeds and Reading in the United Kingdom, Bocconi University in Italy, and the Copenhagen Business School in Denmark.

Chandler also received his share of criticism, in part because of his narrow focus on the rise of big business and his relative neglect of the roles of politics, finance, and culture in explaining the growth of the American economy. Some, including Philip Scranton (1997) and Charles F. Sabel and Michael Piore (Pire and Sabel, 1984), argued that Chandler downplayed the contribution of small and medium-sized firms and overlooked the ways in which the supplanting of independent artisans and flexible manufacturers by middle managers created problems for the American economy. Chandler’s most controversial book was *Scale and Scope*. British writers, in particular, bristled at Chandler’s view that the preponderance of family-owned firms in the United Kingdom had contributed to that country’s relative decline. Barry Supple, writing in the *Economic History Review* (1991), argued that Chandler’s assumption that the American model should be the ‘standard against which to assess the structural characteristics and achievements of the business systems of other countries has some pitfalls’ (p. 512).

But Chandler was not an apologist for American industry, nor was he wholly enamoured with business success. He objected to many trends that were taking place in American management practice in the 1960s, including the conglomerate movement. Late in his career, he wrote admiringly of the triumph of Japanese industry over US competitors in the electronics industries in the final third of the 20th century. In the 1990s, Chandler became fascinated with the question of why some industries failed and others rose in their place. He completed his final two books, both touching on these themes, while in his 80s: *Inventing the Electronic Century: The Epic Story of the Consumer Electronics and Computer Industries* (2001); and *Shaping the Industrial Century: The Remarkable Story of the Modern Chemical and Pharmaceutical Industries* (2005).
While most historians have focused on these core books, Chandler’s other works should not be neglected. He co-wrote (with Stephen Salsbury) *Pierre S. du Pont and the Making of the Modern Corporation* (1971), a long and rich primary-source study that recounts Pierre’s role in making DuPont the largest US chemical and explosives company and General Motors the world’s biggest car manufacturer. Chandler also edited, or co-edited, many volumes, including, with Franco Amatori and Takashi Hikino, *Big Business and the Wealth of Nations* (1997); and with James W. Cortada, *A Nation Transformed by Information: How Information has Shaped the United States from Colonial Times to the Present* (2000). He published 60 articles, many of which are listed in the bibliography of Thomas K. McCraw’s edited collection, *The Essential Alfred Chandler* (1988). One extremely insightful article, published in 1994 and hence not mentioned in McCraw’s volume, is his 72-page international comparative study, published in *Business History Review*, ‘The competitive performance of U.S. industrial enterprises since the Second World War.’ Chandler was also the general editor of the scholarly monograph series Harvard Studies in Business History, published by Harvard University Press.

Throughout his career, Chandler’s work attracted attention because he continued to ask and answer broad and challenging questions. In the 1950s and 1960s, he analysed the workings of firms, while most economists and historians at the time found them uninteresting. In the 1970s and 1980s, he turned his attention to international business and to comparative analysis. The influence of Chandler’s work extended far beyond the discipline of history. He made vital contributions to organizational sociology, global business studies, and to the field of strategic management. Among his many honours he had the distinction of being listed as an eminent scholar by the Academy of International Business.

Chandler’s significance to business history has been summarized in McCraw (1988) and in Richard John’s 1997 essay “Elaborations, revisions, dissents: Alfred D. Chandler, Jr.’s, The Visible Hand after twenty years.” In 2008, a year after Chandler’s death, both *Business History Review* and *Enterprise & Society* published reflections by prominent scholars on his legacy.

international coordination of regulation

David Lazer
Edited by Steven N. Durlauf and Lawrence E. Blume
Back to top

Abstract

Trade among states with diverse regulatory systems creates the possibility of taking advantage of the cost differentials in production that result. However, it is increasingly clear that what happens in one jurisdiction affects policy in other jurisdictions. It is often argued that this creates a ‘race to the bottom’ effect, where the most lax regulation gains an advantage, but the evidence on this is mixed, at best, and there is a plausible argument too for a ‘race to the top’ effect, where states set high regulatory standards as a barrier to entry.

Keywords

comparative advantage; Delaware effect; California effect; policy information interdependence; race to the bottom; race to the top; regulation; regulatory competition

Article

Regulation is a pervasive element of modern government. The regulatory state has its hand in everything from the food we eat to the couches we sit on. The regulations we live with are necessarily a collective affair – as a general proposition two people who live in the same jurisdiction cannot choose different regulatory regimes. However, it is increasingly clear that regulation is a collective affair more broadly – what happens in one jurisdiction affects other jurisdictions. This interdependence creates potential governance challenges, in part due to strategic dilemmas that these interdependencies may create, as well as accountability issues that occur when important policies affecting a polity originate outside of that polity.

Samuelson (1949) offered an evocative thought experiment that sheds some light on the potential dilemmas. Imagine, Samuelson asked, the integrated
economy of a world with no boundaries, no transportation costs. Now assume angels come along and divide the world up into different nations, with different allocations of factors of production. The question Samuelson posed was how international trade might allow the world to recapture that lost paradise, where the trade of goods is a substitute of sorts for a homogeneous distribution of factors of production. Interestingly, international trade creates an opportunity where none existed in Samuelson’s integrated economy, if we assume that Samuelson’s integrated economy had a single regulatory regime. Specifically, trade among states with diverse regulatory systems creates the possibility of taking advantage of the cost differentials in production resulting from that regulatory heterogeneity. For example, if we imagine that state A has strict regulation of public good 1 and relaxed regulation of public good 2, and state B has relaxed regulation of public good 1 and strict regulation of public good 2, then both states can benefit from trade. Those sectors that can produce more cheaply in A (because of its more relaxed regulation of public good 1) will naturally arise there (even in the absence of capital mobility), and similarly with respect to sectors that would produce more cheaply in B. Generally, the basis for trade (national and international) rests in significant part on the pillar of heterogeneity (that is, comparative advantage). Samuelson’s angels create the possibility of exchange based on regulatory heterogeneity that did not exist in the integrated economy.

The preceding assumes that policy is exogenous and that all factors of production are immobile. What happens if we relax these assumptions? One possibility is that regulatory policies will diverge, because trade reduces the adverse economic effects of those policies. To take an extreme example, imagine a state with a preference for strong regulation of a particular sector that makes some good for which there is inelastic demand. In a closed economy the benefits of strict regulation need to be weighed against the fact that the costs of that regulation will be fully borne by consumers. In an open economy, it may be possible to regulate that sector out of existence, with fairly minimal welfare impacts on society — because that sector may locate in another jurisdiction where the demand for regulation in that sector is lower. That is, it is theoretically possible that trade will enable some jurisdictions to regulate more strictly, thus raising the average level of regulation in the international system.

Receiving far more attention, however, is the possibility of a ‘race to the bottom’ (RTB), where the combination of trade and factor mobility yields uniform downward pressure on regulation across all jurisdictions. RTB has been asserted in many settings, although proven in few. The essential intuition is fairly simple. Consider the following simple model of the world, where there are two factors of production, say labour and
capital. Labour is assumed to be immobile and capital mobile. If we assume that labour and capital are complements in production at the national level, this would yield a competition at the national level for division of the surplus produced through their combination. This intranational competition, in turn, has an international dimension because capital can flow to jurisdictions that offer the biggest share of that surplus. That is, effectively, labour from different jurisdictions will compete to attract capital. More capital will yield a larger surplus; however, the competition among jurisdictions means that most of that surplus will go to capital. We can see this type of dynamic, for example, in the competition among states in the United States to attract automobile factories, where, as Donahue (1997) documents, foreign manufacturers garnered enormous incentives from US state governments.

There is also clearly a RTB effect when there are physical externalities from one jurisdiction to another – for instance, when power plants are placed close to borders, and pollution spills over to the neighbouring jurisdiction. Except where noted, for this paper the case of physical externalities will be bracketed, because analytically it is uninteresting. In other words, it is clear that there is a potential for a collective failure when there are physical externalities (the most obvious contemporary example is carbon emissions).

When applied to the regulatory context, regulation may be seen, in part, as an effort by a jurisdiction to reallocate some of the surplus towards immobile actors. Environmental protection offers a nice illustration. Efforts to protect the local environment increase costs to capital. As a result, capital is less likely to locate in a highly regulated jurisdiction, lowering wages (relative to a more lax regulatory jurisdiction) to the point that capital is indifferent between locating in jurisdictions with different levels of regulatory stringency. The preceding discussion would suggest that given a large number of jurisdictions, and a lack of collusion among those jurisdictions, the net effect of dividing the world up will be to redistribute from immobile factors of production to mobile factors of production. In the example above, this redistribution would take place from the environment and from labour to capital.

The above discussion notwithstanding, RTB has had far more currency among politicians than economists. While analytic models, following from the studies of regulatory federalism by Tiebout (1956), sometimes find the possibility of an RTB, it is far from the typical finding (Oates, 2002). It should be noted, however, that the federal context is an imperfect analogue for the international context. For example, these models assume strong sorting effects of citizens with respect to, for example, preferences for environmental protection. It is less likely that such significant sorting effects exist at the international level.
Similarly, empirically, there is relatively little support for RTB dynamics. For example, there is little evidence that firms locate based on relaxed regulatory regimes (Bartik, 1988). There is also little evidence that increased capital mobility over the last few decades has created downward movement in regulation, and some evidence that supports the opposite proposition (such as Engel, 1997; Fredriksson and Millimet, 2002; Frankel and Rose, 2005).

The lack of RTB effects may in part reflect that costs imposed by a regulatory system are a fairly small factor in the decision on location (Jaffe et al., 1995). Further, one likely and important reason for the lack of observation of RTB dynamics is the inability of researchers to capture the full range of reasons why firms decide to locate in particular jurisdictions. The decision to locate an oil rig in a particular location may be affected by environmental regulations, but first and foremost is certainly driven mostly by whether there is oil present at that location. An oil company, all else being equal, may prefer to drill in locations with less stringent environmental rules. However, those locations with the most desirable locations for drilling oil are also therefore in a position to seek a larger share of the income produced from that oil. This share, in those jurisdictions with preferences for a cleaner environment, would likely in part be extracted through stronger environmental regulations. Empirically, this might yield the outcome that those locations with the most drilling will also have the strongest regulations.

Such a snapshot might be misleading, since it might still be the case that regulatory competition results in more lax regulation than in a counterfactual world where capital were not mobile, or where policymakers colluded.

More generally, there are a variety of reasons why particular locations might offer particular advantages for capital. Some of these may be exogenous (such as those related to the location of particular natural resources). Others may be endogenous. For example locating particular physical capital (such as factories) in a specific location might facilitate the creation of human capital in that location, which might be relatively immobile. Closely related, there might be returns to scale at the industry-jurisdiction level. That is, the productivity of a firm might be positively related to the number of other firms in a jurisdiction or region. In fact, clustering of sectors in particular regions is quite common (Krugman, 1996). If the emergence of such a cluster reflects external economies, this creates the possibility that a jurisdiction containing such a cluster can increase the stringency of its regulations without a worry that capital will flee (Baldwin and Krugman, 2004).

The debate in the legal literature regarding the clustering of industry incorporations in Delaware offers an illuminating case study that illustrates this point. The starting point for this literature is the
observation that Delaware towers over the rest of the United States in terms of number of incorporations. This was originally viewed as evidence of a lax regulatory regime in Delaware (Cary, 1974). The essential argument was that corporations located in Delaware because doing so minimized the burdens placed on corporate management, often at the expense of shareholders. The hypothesized RTB was branded, as a result, as the ‘Delaware effect’. This argument came under sharp criticism in the 1990s. The first critique was that there would be shareholder pressure (exerted in part through the stock price) against locating in a jurisdiction that did not preserve shareholder value (Revesz, 1992). The dominance of Delaware thus reflects the capacity of Delaware to effectively manage corporate governance while still preserving shareholder value. That is, the dominance of Delaware reflects the benefits of regulatory competition, where Delaware simply provides superior governance to everyone else. A second critique (of both the benefits and the costs of regulatory competition) was that there are economies of scale in providing good corporate governance (Kahan and Kamar, 2003). For example, good corporate governance requires predictability, and predictability is facilitated by ample case law. Delaware, by dint of historical accident, had garnered an insurmountable lead in effectively producing good corporate law. The implication of this, in turn, is that Delaware has a fair degree of slack in extracting some surpluses from the regulated parties, as long as it does so in a way that does not threaten its competitive advantage in corporate governance.

Note that there are RTB debates in other domains, such as welfare benefits (Dahlberg and Edmark, 2008; Bailey and Rom, 2004) and corporate tax rates (Basinger and Hallerberg, 2004).

While these RTB debates rage on, with strong intuitions and political appeal ranged against modest analytic and empirical support from the economics literature, there is a stronger consensus about the potential capture of the regulatory system by domestic interests (Bartel and Thomas, 1987) – which I will label ‘regulation as protection’ (RAP). To paraphrase Clausewitz, regulation may be viewed as market competition through other means. It is rare for regulation to be neutral in its impact on producers in a given sector. A more restrictive regulation has the potential to benefit some producers at the expense of others. For example, requirements for greater efficiency in cars benefit producers that already produce high-efficiency cars, at the expense of producers of low-efficiency cars. In the context of international trade, the alignment of interests will often be domestic producers opposed to international producers interested in entering the domestic markets and domestic consumers who might benefit from increased competition in the home market. The potential scenario is for domestic producers to hijack the domestic regulatory apparatus as a means to block international competition.
It is also clear that in many sectors there are strong drivers for convergence in regulation. A simple example is the mandate in a jurisdiction to drive on one side or the other of the road. Given significant traffic between two jurisdictions, it is clear that there would be a strong benefit to a consistent standard for driving. Thus, for example, Canada, which had a patchwork of standards in the first half of the 20th century at the provincial level, with some provinces mandating left-hand traffic, and others right-hand traffic, gradually converged to right-hand traffic, with uniformity emerging by the middle of the century. This presumably was driven in part by the need for internal consistency, and in part because of the degree of traffic between the United States and Canada. In the regulatory context, such convergence may be seen fairly routinely across policy areas, for example in food safety (Lazer, 2001), where small countries adopt the standards of their large export markets. Regulatory convergence more generally may take place to guard export markets. As Vogel (1995) argues, this type of push for convergence often occurs in international trade when there are increasing returns to scale in production, combined with potential divergence in product standards. Thus, for example, Vogel documents the flow of environmental standards for automobiles around the world, which he labels the race to the top (RTT) ‘California effect’ in contrast to the RTB ‘Delaware effect’. Vogel argues that there is potentially a systematic bias toward higher standards because of the efficiency imperatives of having consistent standards. Such an imperative should lead toward convergence on the strictest standard on the system (or at least a standard that would encompass the large majority of the system), so as to achieve efficiencies in scale of production. Such a diffusion pattern should follow the reverse direction of exports, for example, as Prakash and Potoski (2006) found with respect to the spread of ISO 14001 adoption.

Finally, even in the absence of trade or factor mobility, there is significant potential for regulatory interdependence due to policy information interdependence (PII). Policy is necessarily experimentation, and novel policies even more so. Regulation in jurisdiction A creates insights in jurisdiction B as to what would be good or bad policy, where this information spreads through various informational networks (Wolman and Page, 2002; Lazer, 2005). Emulation may reflect lesson drawing or serve the function of policy legitimation (Bennett, 1997; Busch, Jorgens and Tews, 2005). There is a substantial literature on policy emulation (e.g. Rose, 1993; Haas, 1992), and it is clear that there is no reason to expect domestic regulatory policy to be exempt from emulation (e.g. Simmons and Elkins, 2004).

This array of interdependencies offers an array of empirical challenges for the researcher and governance challenges for the policy maker. For the researcher, the potential presence of different processes (which, if
validated, have very different normative implications) creates a
difficult but not impossible nut to crack (for various recent efforts to
deal with exactly this issue, see Braun and Gilardi, 2006; Simmons, Dobbin
and Garrett, 2006; Levi-Faur, 2005).
For the policy maker each of these kinds of regulatory interdependencies
creates different types of collective strategic interaction problems
(Lazer, 2001, 2006), which in turn translate into a collective governance
challenge (Scharpf, 1997). RTB and RAP might be categorized as a
prisoner’s dilemma, where the potential dysfunctional equilibrium would
be either suboptimally lax standards in the case of RTB, or suboptimally
strict standards in the case of RAP. RTT may be viewed as a coordination
game, where one potentially problematic outcome is the emergence of
suboptimally strict standards (or perhaps worse would be the case where
the RTT did not occur, where a critical mass of support did not emerge
for any standard), with a handful of large jurisdictions driving the
standards for the world. All of these issues might call for some type of
negotiated standard. However, such centrally negotiated standards might
eliminate some of the very benefits of trade in the first place. And the
presence of PII would suggest a different kind of public goods issue than
is usually associated with regulation - the public good of information.
This construction of regulatory interdependence suggests a dual conundrum.
The first aspect of this is how to take advantage of the publicness of
the information, and the second is how to support continued production
of this public good (Lazer, 2005).

Abstract

A matching model takes a set of payoffs or outputs for all possible matches and produces a set of matches where no couple would prefer to deviate and become matched, instead of their assigned matches. Matching models are increasingly being estimated in empirical work in industrial organization, labour economics, public economics, and other fields. This article surveys methods for and applications of structural estimation for two-sided matching games.

Article

Economists often observe data on relationships. We see who is in a relationship with whom: which firms merged with each other, which men are married to which women, and which bidders won which items in an auction. A matching model or matching game is one theoretical framework for modelling the equilibrium formation of these relationships. A relationship is termed a match. A matching model takes a set of payoffs or outputs for all possible matches and produces a set of matches where no couple would prefer to deviate and become matched, instead of their assigned matches. The robustness of the equilibrium to deviation by any potential couple suggests ‘pairwise stability’ as the term for an equilibrium.

The key economic idea in matching models is the rivalry to match with the most attractive partners. In marriage, men compete with each other to marry the most attractive women while women compete with each other to
marry the most attractive men. There is scarcity on both sides of the market. This entry focuses on research that formally estimates the parameters of a matching model using data on who matches with whom. Economists adopting this structural approach typically observe data on who matches with whom as well as exogenous characteristics of each agent. For example, economists studying marriage will observe the race, schooling level, religion, physical attractiveness and wage of each man and each woman. The data also record which men married which women. Economists are willing to assume that the data represent a pairwise stable outcome to a particular matching game.

The structural approach means that researchers impose the structural model and estimate unknown parameters in the model. The advantages of the structural approach apply to more economic situations than just matching models, and have been explored elsewhere (Reiss and Wolak, 2007). A quick summary is that the structural approach allows the computation of counterfactuals and the measurement of economic parameters that cannot be directly observed. Using the example of marriage, one type of counterfactual would be to explore how the equilibrium set of matches is altered as demographics change. Measurement is also important: if men and women each have several characteristics, how important are each of the characteristics in the payoffs to a match?

This article focuses on the use of matching games in structural empirical work. Other literatures have focused on centralized market design (for example the medical resident matching programme in the United States) and the descriptive interpretation of matching patterns.

Back to top

Two-sided matching games

Most but not all empirical work has focused on two-sided matching games: agents can be divided into two sides, say men and women. Roth and Sotomayor (1990) is a useful text that explains simple matching games. For the purposes of this article, I divide two-sided matching games into models with and without transfers. Gale and Shapley (1962) introduced the model where agents do not exchange money: men have preferences over women and women have preferences over men. Generically there will be a lattice of multiple pairwise stable outcomes in this model. Koopmans and Beckmann (1957), Shapley and Shubik (1972), and Becker (1973) study models where matched agents can exchange money and where agents have transferable utility. For one-to-one matching games such as marriage, generically there will be one set of pairwise stable physical matches in these models; there may be a continuum of transfers that support these physical matches.
The choice of modelling framework depends on the researcher’s understanding of the market in question.
The above papers allow each man, say, to marry at most one woman. There are extensions to many-to-one and many-to-many two-sided matching games. Complementarities between multiple matches involving the same agent are key to some of the empirical applications below (Fox, 2009a; Fox and Bajari, 2009). There are also one-sided and many-sided matching games. There are more general matching games where other contract elements, such as the hours of work in a labour market, are determined as part of the pairwise stable outcome (Crawford and Knoer, 1981; Kelso and Crawford, 1982; Hatfield and Milgrom, 2005). Matching games are mathematically linked to hedonic equilibrium models, although I will not explore the link here (Rosen, 1974). There is also a clear link to models of frictions, such as search models, that also have observed agent heterogeneity (Shimer and Smith, 2000; Atakan, 2006).

Estimation methods

Matching games share many similarities with the literature on estimating static, discrete Nash games, such as the well-known entry models of Berry (1992) and Bresnahan and Reiss (1991). Matching games use pairwise stability and not Nash equilibrium, but many estimation challenges are similar. A key difficulty in matching games is that the number of agents in a market can be in the hundreds or thousands, compared to the three or four firms deciding to enter a market in some entry applications. The number of agents in matching empirical applications can make some estimators computationally infeasible.

Nested solution methods

The most straightforward way to estimate a matching game is to use simulated maximum likelihood or the simulated method of moments. These estimators require solving the model a fixed number of times for each iteration of an outer optimization routine. Simulation estimators are conceptually straightforward but computationally burdensome. Boyd and colleagues (2003) use the simulated method of moments to study the matching of public school teachers to schools in New York state. They use data on wages and assume the wages are exogenously determined. Their model without endogenous transfers has multiple stable matches, and they use the lattice structure of the equilibria to impose an equilibrium selection rule in estimation.
Full likelihood methods

In many cases, the full likelihood can be written down. In a study of the matching of venture capitalists to entrepreneurs, Sørensen (2007) uses an augmented likelihood approach where the unobserved payoffs of each match are treated as nuisance parameters and integrated out using a blocking structure in a Markov Chain Monte Carlo (MCMC) procedure. Sørensen does not use endogenous transfers and hence imposes an aligned preferences assumption that he proves generates a unique pairwise stable outcome.

The full likelihood approach can be computationally intractable in large matching markets. In a study of the matching between investment banks and firms undertaking an initial public offering, Akkus (2008) shows that the likelihood simplifies if the values of realized matches are recorded in the data. By using data on the payoffs of matches, estimation becomes easier.

Inequality methods

With an application to automotive suppliers and automotive assemblers, Fox (2009a) introduces a maximum score estimator to estimate a many-to-many matching game where transfers are endogenous, but not in the data. The maximum score estimator maximizes the number of inequalities implied by pairwise stability that hold true. This approach breaks the computational curse of dimensionality because not all inequalities need to be included for the estimator to be consistent.

Logit methods

Dagsvik (2000) and Choo and Siow (2006) study games with transfers, and assume that the payoffs to matches have error terms that satisfy the parametric logit property. To a large degree, the logit assumption allows researchers to derive closed-form equations that allow estimation, especially for very large markets that plausibly have a continuum of agents, such as the US national marriage market.

Identification

In matching games, agents on the same side of the market are rivals to match with agents on the other side of the market. The fact that a man did not match with the most attractive woman does not mean that the man did not prefer that woman to his actual wife. The equilibrium budget set...
of each agent is unobserved. Thus, it is not clear what can be learned (identified) from data on who matches with whom. 

**Fox (2009b)** studies identification in matching games with transfers and finds two sets of results. First, the relative importance of complementarities in payoffs for say schooling, compared with say wealth, is identified using data on matches but not the equilibrium transfers that are present in the model. Second, the ordering of production levels (which matches give higher payoffs) is identified using the same data. 

**Selection correcting outcome equations**

**Sørensen (2007)** explores the use of a matching model to parametrically selection correct an auxiliary outcome equation. The outcome, the success of an investment in his application, is not determined as part of the matching game, but the outcome is only observed in the data for realized matches. Sørensen’s approach is analogous to using a single agent decision model to selection correct an outcome equation (Heckman, 1979). **Sørensen (2009)** extends the framework of Heckman (1990) to study identification in selection models where selection is induced by a matching game. 

**Empirical applications**

I now catalogue some of the many empirical applications of matching games. 

**Marriage and family economics**

**Choo and Siow (2006)** explore whether changing matching patterns in the US marriage market are due to changes in preferences or changes in the exogenous characteristics of potential spouses. They also explore the effects of the legalization of abortion. There have been a large number of marriage and family economics papers following up on the Choo and Siow framework, many by the original authors. See **Siow (2008)** for a complete survey of this material. 

**Bruze (2009)** estimates a matching game where labour supply and the split of consumption between men and women are part of the pairwise stable contract terms. He explores the return to an agent for finding a higher-earning spouse in college. 

**Hitsch, Hortaçsu and Ariely (2009)** use revealed preference information from an online dating site to avoid the need to use an equilibrium model to estimate preferences. They use the preference estimates to simulate a pairwise stable outcome and find it matches well with actual sorting on the site.
Industrial organization, corporate finance and marketing

Hall (1988) is an early paper that emphasizes the need for matching models to study mergers. She did not estimate a full matching game because of computational concerns. It is common to have data on realized interfirm relationships. Sørensen (2007) studies the matching of venture capitalists to entrepreneurs with a focus on selection correcting an outcome equation where the success of an investment is regressed upon the experience of the venture capitalist. The basic approach of Sørensen allows for match-specific error terms, and he can allow for time-invariant characteristics of a venture capitalist by using fixed effects/panel data. Chen (2009) uses a similar selection-correction framework where the outcome equation of interest is the price of a bank loan. Akkus (2008) uses the selection-correction approach to regress the degree of first-day underpricing on the experience of an investment bank. Park (2008) uses a similar MCMC estimator to investigate the decision of a mutual fund manager to engage in a merger as a function of past returns.

Fox and Bajari (2009) was the first paper to estimate a many-to-one matching game where complementarities across multiple matches were allowed for. The authors look at auctions of multiple heterogeneous items, where each bidder can win multiple items. They study FCC spectrum auctions, where complementarities between the geographic territories being auctioned are estimated to be important for the efficient operation of the mobile phone industry. A key methodological challenge is showing how a potentially inefficient, dynamic Nash game could result in equilibria that satisfy pairwise stability. The estimator used is that of Fox (2009a) for matching games with transfers. Fox (2009a) studies the many-to-many matching of automotive suppliers to automotive assemblers, and measures the relative importance of specialization by suppliers in particular corporations, brands and car models. Further, Fox measures a potential benefit of suppliers matching with high-quality Asian assemblers, such as Toyota.

Levine (2008) uses the estimator of Fox (2009a) to explore the matching of biotechnology innovations to marketing firms. She explores whether the returns to scale of marketers might decrease the returns to innovators. Yang, Shi and Goldfarb (2009) use the same estimator to explore the matching of professional athletes to teams, with a focus on the potential marketing complementarities between players and teams from different-sized cities. Akkus and Hortacşu (2007) extend the maximum score estimator to use data on equilibrium transfers. Akkus and Hortacşu investigate geographic complementarities in the market for bank mergers...
after the removal of prohibitions against interstate banks. Mindruta (2009) studies the matching of university researchers and private firms.

**Development, public finance, labour economics and other**

Boyd and colleagues (2003) investigate the matching of teachers to public schools, with a focus on learning how to attract qualified teachers to schools in impoverished areas.

Gordon and Knight (2009) investigate the consolidation decisions of Iowa school districts after the state passed incentives inducing such consolidation.

Ahlin (2009) uses the estimator of Fox (2009a) to study the matching of Thai villagers to other villagers in risk-sharing groups. He investigates whether villagers match by risk type or seek to diversify risk.

Fox (2008) estimates a repeated matching model for the labour market for engineers in Sweden. Each period state variables evolve, a matching model opens, prices are formed to equate supply and demand and workers choose jobs. The model is dynamic in that both firms and workers are forward looking: they consider the effect of the decision to switch today on future outcomes.

Baccara and colleagues (2009) study the matching of professors to offices, and estimate the importance of various types of professional networks in payoffs.

preindustrial inequality

Branko Milanovic
Edited by Steven N. Durlauf and Lawrence E. Blume
Back to top

Abstract

This article considers inequality in preindustrial societies, defined as those prior to the industrial revolution and subsequent non-industrial societies that are not systematically integrated into the advanced world’s economy. Although data on individual incomes and wealth in these societies are limited, increasingly they are becoming available. On the basis of these data, inequality as measured by the Gini coefficient is often on a par with modern industrialized societies, but the income gradient tends to be different, with a mass of people at subsistence level or marginally above, few at the mean, and a small affluent class. More work remains to be done, particularly on the relationship between income inequality and economic progress.

Keywords

Gini coefficient; income distribution; inequality; Kuznets curve; preindustrial societies

Defining preindustrial

We need to circumscribe the scope of preindustrial. At one level, it is easy: preindustrial economies are characterized by low urbanization rates, high share of agriculture in GDP, low literacy rates, and of course low overall GDP per capita. However, many of today’s poor countries share precisely these features. They are however ‘non-industrial’ or ‘non-industrialized’ rather than ‘preindustrial’ economies: this is because they are part of the modern world, systematically included in
trade and voluntary movements of factors of production (‘globalization’) and have social structures which are very different from those of preindustrial societies. The life expectancy of their populations as well as the immunization and school enrolment rates exceed many times those of ‘true’ preindustrial societies. Not the least important is the fact that political compulsion of slave or serf labour, so ubiquitous in all preindustrial societies, is – except in a few pockets – largely absent.

Our definition of preindustrial includes all societies prior to the industrial revolution, and those that have not engaged with the industrial revolution, only up to a point when they began to be integrated systematically, rather than episodically, into the world economy. For many of them, integration coincides with colonization. Thus, broadly speaking – since we are painting with a very broad brush here – we can set limits around the end of the Napoleonic wars for Western Europe and the United States and Canada, and the end of the 19th century for everybody else. Twentieth-century societies, even when poor and hardly industrialized, belong to a different category.

A cut-off date around 1815–20 is convenient for at least three reasons. Politically, it coincides with a ‘rearrangement’ of Europe and, as later emerged, the world. It marks the beginning of the ‘long 19th century’. Economically, it marks, according to the new English wage data series produced by Clark (2005), the beginning of a long-run rise in real wages which is continuing to this day. In terms of history of economic thought, Ricardo’s Principles were published in 1817.

An obvious, but nevertheless important, clarification is that we are concerned here with income inequality: that is, inequality that includes all sources of income and reflects differences in households’ and individuals’ living standards. This, for example, rules out wage or rural–urban inequalities as such. (Wage inequality has meaning only if calculated across all wage-earners; income inequality includes the entire population.)

Implicit theory

We do have an implicit theory about income inequality in preindustrial economies. The Kuznets hypothesis (formulated in 1955), the bread and butter of inequality economics, posits that inequality charts an inverted U shape as economy transforms from predominantly agricultural to predominantly industrialized or modern. In Kuznets’ own words:

One might thus assume a long swing in the inequality characterizing the secular income structure: widening in the early phases of economic growth when the transition from the preindustrial civilization was most rapid, becoming stabilized for a while; and then narrowing in the later phases.
The same hypothesis, albeit without the mechanism that generates the inverted U-shaped curve, was formulated 120 years before Kuznets by Tocqueville:

If one looks closely at what has happened to the world since the beginning of society, it is easy to see that equality is prevalent only at the historical poles of civilization. Savages are equal because they are equally weak and ignorant. Very civilized men can all become equal because they all have at their disposal similar means of attaining comfort and happiness. Between these two extremes is found inequality of condition, wealth, knowledge—the power of the few, the poverty, ignorance, and weakness of all the rest.

(Tocqueville, 1835, pp. 42–3)

From both we should retain the sense that inequality is supposed to emerge only when societies are richer, and thus inequality in preindustrial societies may be expected to be low. But differently, we also have an image of preindustrial societies as combining abject poverty in the bottom with extravagant wealth on the top. For example, in ancient Rome, Goldsmith (1984, p. 287) notes the extraordinarily high income of the rulers relative to Great Britain in the early 19th century. Could both these images be right? As we shall argue below, yes—and this is one of the key features that distinguishes inequality in premodern times from inequality in modern times.

But in order to speak about inequality in preindustrial societies, we must also assume that preindustrial societies were ‘modern’ in the sense that they were (predominantly) market-oriented economies with non-negligible monetized sectors—and when they were non-monetized, goods and services given or received for political or power reasons could be valued at some meaningful ‘market’ prices. This is a position not universally accepted. In a famous debate about the later Roman Empire (and, by extension about all ancient economies) and ‘modernity’, there were two camps: that of ‘primitivists’ led by Polanyi (1944), Finley (1985) and Schiavone (1995), and that of ‘modernists’ (Rostovtzeff, 1926; Walbank, 1946). The first believed that Rome lacked most of the modern concepts that we associate with a market economy. Market relations, even when present, were of peripheral importance, and a market economy, itself a recent phenomenon, is perhaps, in a historical sense, only a brief episode (Polanyi, 1944).

For the ‘modernists’, the links between a preindustrial society like Rome and modern capitalism were obvious. Both Rostovtzeff and Walbank write of Roman ‘bourgeoisie’. Whatever our opinion about the respective merits of ‘primitivists’ and ‘modernists’, it is important to realize that once we attempt to make some tentative estimates of economic inequality in preindustrial societies, we ipso facto accept that, while preindustrial societies might have been poorer and with a different social
structure from modern societies, the differences are of magnitude, not of kind. For if such key concepts of market economy as prices, wage-labour and private property are vague, insufficiently understood by the population, not sanctioned by custom or law, then applying modern economic categories may be meaningless. Every attempt to study preindustrial societies empirically using today’s economists’ tools must assume that ‘ancient’ and ‘modern’ are fundamentally the same – so that that the ‘ancient’ can be described and understood using economic concepts developed from Adam Smith onwards.

Private property must enter the list above with a caveat. No one would deny that socialist societies, where private property was limited, were not modern. Moreover, they regarded themselves as the epitome of modernity. Similarly, societies with largely communal ownership of land (as in Africa) are modern too. Thus, private property of the means of production seems to be less of a requirement for a modern society than for example monetization. Rawls (1971), who can hardly be seen as a non-modernist, allows in his Theory of Justice for both private and non-private ownership of the means of production (see pp. 54, 240–1).

Data for preindustrial inequality

Where do data for preindustrial inequality come from? Since the Second World War, empirical studies of income distribution have been based on household surveys (nationally representative samples of households who are anonymously interviewed about their household characteristics, spending patterns and income). The earliest household surveys are from late 18th-century England. There were a few sporadic surveys in the 19th century (continental Europe, rural Russia) but they spread broadly only after the end of the Second World War, and as far as Africa and China are concerned, surveys became available only more recently, from the early 1980s. Obviously, such surveys were not conducted in any preindustrial society – even if censuses (driven by government tax needs) were. However, there are relatively abundant sources that economists can use to gauge income distribution in preindustrial societies, although the sources are often buried in hard-to-access archives and books, written in languages and alphabets that are not widely known, and requiring large amounts of both money and effort to be brought to light in a usable form. (For example, Ottoman censuses are written in Turkish but using Arabic script, rather than Latin as is used in today’s Turkish. To process them requires knowledge of an often archaic Turkish and an alphabet into which this language is no longer written. See Cosgel, 2002, 2004.) And then lots of heroic assumptions are needed in order for them to be ‘translated’ into modern economic categories. This has severely limited the use of ancient
sources, and this is probably why only a fraction of such sources has been used so far.

The most comprehensive contemporary sources are tax data and government censuses undertaken in order to supply governments with information about taxation and the war-waging capacity of the populace (number of men, houses, horses, grain). Early documentary evidence includes government edicts (such as Diocletian’s edict on maximum prices and wages from 301, recently studied by Allen, 2007), as well as numerous Roman papyri preserved in the dry climate of Egypt. The English Domesday survey of 1086 is perhaps the best known of such sources.

From the Byzantine Empire, we have a few preserved praktika that provide descriptions of household characteristics, inventories of possessions and taxes paid, although they cover only limited areas (towns or ecclesiastical communities). (See the multi-volume Economic History of Byzantium: From the Seventh through the Fifteenth Century edited by Angeliki Laiou, 2002.) Ottoman censuses (defterlar) from approximately the 14th century onward, conducted to assess the wealth and military capacity of newly conquered territories, provide detailed information on settlements (hamlets, villages, small and larger towns) but then present it in average amounts for each settlement (not by individual household). If inequality within settlements is not huge, and the number of settlements included is large, censuses can be used to assess overall income distribution within a country or a region.

A much-used source is the Florentine Catasto from 1427. (The data were originally collated by Herlihy and Klapisch-Zuber, 1985. Currently, they are available on the Internet.) The Spanish Ensenada Cadastre, similar to modern-day household surveys, was carried out in the 1750s for the purposes of a never-implemented fiscal reform. It has recently been used by researchers, and will be no doubt analysed more once it is digitized. Inequalities for the cities of Paris, Amsterdam and London were studied from tax data for respectively 1292–1313 (Sussman, 2005), 1732–42 (McCants, 2007; Soltow, 1989) and 1797–1801 (Schwarz, 1979). However, they refer to wealth inequality (there is no attempted ‘conversion’ to income), cover very truncated data sets, focus either on the rich – those subject to taxation – or the poor (McCants, 2007), and of course include single cities only. Incidentally, all examples but one used by Pareto in the formulation of his famous ‘iron law’ of income distribution come from various European tax data from the end of the 19th century (see Pareto, 1896). The data on Latin America, produced by various Spanish Visitas, which collected detailed information on population, age, land ownership and agricultural output, have been published in numerous volumes but not used for estimates of income distribution. (For Peru, books with detailed notes from Visitas for the years 1562, 1567 and 1604–05 have been published.)
What is common to these sources is that they are in principle surveys of stocks (people and wealth) and require a huge effort of price imputation; first, to ‘transform’ a stock into a meaningful annual yield (income), then to convert produced quantities, expressed in local ‘natural’ units (such as Egyptian *modii* of wheat), into kilograms, and finally to convert all of these into monetary units. Then the researcher needs to resort to even more heroic assumptions to calculate other sources of income, from husbandry, vineyards, honeybee cultivation, fruits and plants, services provided by farmers, and not least, from manufacturing activities like pottery, glass or cloth-making, or provision of urban services from the shoe-maker to the teacher (for which, at least some wage data are generally available). Particularly vexing is the issue of measurement units, volumes or weights with often confusingly similar or identical names, which nevertheless imply different physical amounts from one region to another; or when money units are provided, the issue of silver or gold conversion between them. But such sources, however frustrating, can and do provide very useful evidence about ancient living standards and distribution of income.

The second contemporary evidence is provided by social tables. This is what William Petty termed ‘political arithmetick’. They aim to describe the structure of a society by listing all salient social classes (or professions) and estimating their average incomes (per household, or less often per person). For modern economists, these sources are much easier to use because the classification into presumably socially important groupings and estimates of their money-equivalent incomes provide us with most of what we need to know for the derivation of income distribution. England was the pioneer in the production of social tables, beginning with the famous one of Gregory King for 1688 (which contains 33 social groups with their population sizes and average incomes), and continuing with Massie (1759) and Colquhoun (1801–3). (None of the social tables, or the results obtained from them, is without its critics: for a critique of King’s social table, see Arkell, 2006; for Colquhoun, see Schwarz, 1979; for a critique of Lindert–Williamson’s use of English social tables, see Feinstein, 1988.) Much more recent authors have produced similar social tables for a number of countries (see, for example, Morrisson and Snyder, 2000, for France in 1788, Bértola, Castelnovo, Reis and Willebald, 2006, for Brazil in 1872, van Zanden, 2003, for Java in 1880, Berry, 1990, for Peru in 1876). These new social tables are of course not contemporary sources but they were produced, using bits of dispersed primary or most often secondary sources, by economic historians who specialize in various eras and countries, and they represent our best guess at social structure at remote points in time. The work of Milanovic, Lindert and Williamson (2009; hereafter MLW), who made the first systematic attempt to measure
Empirical evidence

To translate preindustrial inequality into modern economics, we must not only hold that preindustrial societies were largely monetized (and whatever was not monetized could be ultimately expressed in money), but also hold that their inequality can be meaningfully handled by Gini, Theil or any other currently used inequality measure. Otherwise we lack a common yardstick with which to compare past and present.

Using mostly social tables from 30 preindustrial societies, MLW calculated Gini coefficients. They found that the preindustrial Ginis range from the mid-20s to around 65, with a mean of 45 and standard deviation of 11. (Gini is the most commonly used measure of inequality, and ranges from a theoretical zero (everybody has the same income) to a theoretical maximum of 100 (everybody but one person has a zero income, and the richest person takes the entire income of the community).) This is almost the same as the range of Ginis in modern societies. In fact, the modern equivalents of the preindustrial societies included in MLW sample (such as Turkey for Byzantium, Syria for the Levant, today’s United Kingdom for the 1688 England and Wales) have an average inequality of 40 Gini points with a standard deviation of 10. However to make such a simple comparison and leave it at that would be erroneous. Preindustrial and modern societies were very different, even when compared in the language of modern economics.

First, it is very likely that the income gradient (how income increases as we move from poorer to richer income classes) was much flatter in preindustrial that in modern economies (see MLW, 2009). Using Jan Pen’s (1971) metaphor of dwarfs and giants, where people are visualized as marching in a 60-minute parade, from the poorest to the richest, with everyone’s height reflecting their income, preindustrial societies can be seen as societies of dwarfs who would take some 40 to 45 minutes to file past. They contained large groups of people (most of the time, the vast majority of the population) living at, or just above, the subsistence minimum. Percentage differences in income among this vast mass of people were small. The income gradient was flat up to a very high point in income distribution. But then, and quickly, as we approach the very end of the parade, the gradient would suddenly increase, much more so than in modern societies. Thus, unlike a modern parade which would be characterized by a steady increase of the gradient, in preindustrial societies the middle was not much different from the bottom. There was a dearth of people whom we would (using modern terminology) identify with the middle class. (It
is worth pointing out that this ‘middle class’ is not defined in terms of absolute income, or what we would consider today to be middle-class requirements, but entirely in terms of the period average income. We can thus see why both of our preconceived notions - of generalized equality and drastic income disparity among the ancient - are true: they just refer to different parts of income distribution.

This difference in structure implies that the same calculated measures of inequality have different meanings. Gini's, as we have already indicated, were broadly in the same range then and now. But a Gini of 40, estimated independently for the Roman Empire by MLW (2009) and Scheidel and Friesen (2009), had an altogether different meaning from the same Gini in the contemporary United States. (The MLW estimate refers to the year 14 (at the death of Octavian), Scheidel’s estimate to the mid-second century.) The Roman Empire’s mean income was about twice the physiological subsistence level (s). If we require that all members of a society have at least the subsistence minimum - for otherwise the society will tend to shrink and disappear - then a very low level of mean income, regardless of how tiny the upper class is, limits the extent of measured inequality. Simply put, the extent of inequality is limited by the size of average income. That ceiling is more binding when a society is poor. To realize this, assume that society's mean income is just a fraction above s. If all but a tiny elite live merely on s, the elite cannot be extravagantly rich because total income is low, and Gini or Theil indexes, which take into account incomes differences between all individuals, cannot be very high either. This is the idea underlying the Inequality Possibility Frontier (IPF: see Figure 1), defined by MLW (2009) and Milanovic (2006).

Figure 1
The frontier gives a maximum Gini (or Theil) coefficient which is compatible with a given level of mean income and maintenance of society as a going concern. The maximum Gini is equal to \((a-1)/a\) where \(a\) = mean income divided by \(s\), or the number of subsistence minima contained in the mean. As can be seen from the formula, the maximum feasible Gini rises with mean income \((a)\), but at a decreasing rate. If average income is twice the subsistence \((a=2)\), the maximum Gini will be 50. Thus, we see that the Roman inequality of 40 exhausted some 80 per cent of maximum feasible inequality. But for the modern-day United States, where the mean income stands at more than 100 \(s\), the maximum Gini is 99. The actual inequality will have exhausted only 40 per cent of its maximum value. Hence, the social meaning of the same Gini is entirely different. To sustain high inequality, societies must be relatively rich.

We have left the issue of defining the subsistence minimum deliberately vague. Depending on whether we pitch this physiological (note: not social, not relative) minimum higher or lower, the IPF will move down or up, but the same logic will hold.

The difference in the income structure (income gradient) also shows why some other measures, like top-to-bottom ratio or top 1 per cent share, may not be very useful in the preindustrial context. They show the extent of the gap between the richest and the poorest, but they disregard the
entire distribution in-between, which in the past has been much more equal than in today’s societies. IPF imposes a consistency check on our inequality calculations, a fact which is particularly useful for preindustrial societies where the evidence is scant. As illustrated in the figure, once we know the mean income of a society, and estimate its Gini, we know that this estimate must be within, or at the maximum on, the frontier. If it is not, there is something wrong with either the income or the inequality estimate, or the society is doomed to experience a dwindling population and ultimately extinction. It is not surprising that MLW found that all six cases of ancient societies with inequalities close to the frontier were colonies: India in 1750 and 1947, Kenya in 1914 and 1927, Nueva España (Mexico) in 1790, and Maghreb in 1880. Colonizers were clearly much less concerned about the welfare of the populations they ruled than, or did not have to fear them as much as, native rulers.

Preindustrial inequality and modern debates

Empirical evidence on preindustrial inequality has a direct bearing on several contemporary debates. Evidence from the two most advanced economies at the time (England and Holland) paints a picture of increasing inequality from 16th century to the beginning of the Napoleonic wars. (The exception is Soltow, 1968, who found English inequality to have been flat throughout the 18th century.) Premodern growth seem to have exacerbated inequality even in the areas that were characterized by an already high inequality of wealth and income (such as the South Midlands in England, considered by Allen, 1992). Using social tables, Lindert (2000) and Lindert and Williamson (1982, 1983) document the increase of inequality in England between 1750 and 1801. All four observations available for England and Wales in the MLW database (1290 – from Campbell, 2007 – 1688, 1759 and 1801 – 3) show both mean income and inequality rising with time. Similarly, van Zanden (1995), and Soltow and van Zanden (1998) find that income inequality increased in Holland during its ‘Golden age’: between 1561 and 1732: the urban area Gini rose from 53 to 59, and the rural area Gini from 35 to 38. According to a pioneering study by Hoffman and colleagues (2002), ‘real’ European inequality between 1500 and the early 19th century increased even more because the prices of wage-goods, consumed by the poor, rose relative to the prices of ‘luxuries’. The upswing of the Kuznets curve seems to be strongly in evidence in all these cases. But what drove it? Was it a ‘classical explanation’ (as van Zanden, 1995, terms it), namely a shift in the functional distribution of income toward property owners (and their rising concentration) and away from labour – a mechanism that Marx would easily have recognized? (For
Spain, Prados de la Escosura, 2008, uses functional distribution of income, and also finds a clear Kuznets upswing from 1850 to around 1914.) Or was it, as argued by Lindert and Williamson (1985) and Williamson (1982, 1985), caused by the ‘wage-stretching’ which continued well into the 19th century and involved labour-saving technological progress and increased pay-ratios for skilled labour in the presence of demographic pressure from mostly unskilled population? Education responded only very slowly, and the process continued for a couple of centuries until massive European emigration reversed it. The latter is a very neoclassical mechanism familiar to every economist working on poor or rich countries today. The focus is on the functioning of factor markets, not on the division of society into capitalists and workers.

If countries where the industrial revolution originated went through a period of sustained increase in inequality prior to the industrial revolution, does it shed some light on the relationship between higher inequality and the industrial take-off? A number of recent writings (most famously, Pomerantz, 2000; Frank, 1998; and more recently Wen, 2009; Shiue and Keller, 2007) have contrasted China and Western Europe in the 17th and 18th centuries, trying to understand why these two large areas that seemed in many respects similar (for instance in market integration, level of income, technological innovations) charted such different paths in the following three centuries. Does income distribution have to do something with it? Unfortunately, we do not yet have even the intimation of an answer because the historical data for China are not available. However a recent upsurge in archival research on Chinese sources might help throw some new light on this issue.

The work of Engerman and Sokoloff (1997) has profoundly affected our conception of the role of inequality in explaining the economic success of North America and relative decline of Latin America. But while there is little doubt that Latin America was more unequal (particularly in land ownership) that the North, recent historical evidence contrasting Western Europe and Latin America finds no perceptible difference in inequality between the two. Williamson (2009) thus wonders why Western Europe and Latin America have followed different growth trajectories. If the inequality explanation works for one set of regions (the two ‘New Worlds’), why does it seem not to work for another (Europe and Latin America)? Moreover, it is not evident that Latin America was ‘always’ unequal. Prados de la Escosura (2007) and Bértola et al. (2009) argue that strong expansion of inequality occurred during the previous round of globalization (1870–1920). Prados de la Escosura (2007, p. 298) sees the explanation as consistent with the factor–price equalization theorem: opening up Latin America to trade raised land rents, and since land was unequally distributed, increased the concentration of incomes. The data prior to around 1870 are not available (although some estimates for 1870
show inequality in the Southern Cone countries to be at the same level as in Spain: Prados de la Escosura, 2008, Figure 8, p. 307), but we could wonder whether our ‘acquired idea’ of an always high inequality in Latin America is not mistaken – or perhaps it was not inequality, but the inequality extraction ratio that was high. Recasting the issue in this way suggests that the Latin American problem was a low level of income rather than a high Gini.

Conclusion

Studying inequality in its historical context, an area which will doubtlessly loom larger in economics as the search to uncover our economic past progresses, is important not only because it helps us learn about history but because it helps us understand today’s economic problems. Actually, as every historian and politician knows, studying the past is about the future.

Reparations

Kim Oosterlinck
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Reparations for damage caused, paid by the loser following wars, have been known since Antiquity, although much of the literature focuses on the First World War. There has been much debate, both politically and among economists, on the appropriate basis on which to pay.

Article

From time immemorial, wars have led to international financial transfers. During Antiquity, the practice of imposing a payment of a tribute on the vanquished was already common practice (Livy V, pp. 48–9). War indemnities were common during the Middle-Ages. From a legal point of view, few authors questioned the practice, and victory was seen as a sufficient motivation to extract tribute. With the development of theories on international law in the 16th and 17th centuries, the idea of ‘repairing’ the torts done by the war came to be discussed. During the 19th century various legal arguments were invoked to justify war indemnities. The amounts to be paid could, for example, be meant to cover war expenditures incurred by the victor, to make good losses as a result of the war, or to guarantee the victor’s future safety. Most treaties remained silent or at best vague regarding the exact computation of the amounts due, and the final figures were often the result of long negotiations between the parties. To secure payments, occupation of part of the defeated country was common. France had to cope with a German occupation after the Second Treaty of Paris (1815) and as a consequence of the Treaty of Frankfurt (1871) ending the Franco-Prussian war. For both wars, France would eventually pay in full (White, 2001). The amounts
(close to FF1.9 billion for the Napoleonic war and equal to FF5 billion for the Franco-Prussian one) were at the time viewed as exorbitant, and produced heated debates and controversies in France. Devising the means to pay for the reparations also proved to be an arduous task, which has been analysed in detail by economic historians. Loans would eventually provide the bulk of the payment, even though, in 1871, economists such as Louis Wolowsky and bankers such as Henri Germain suggested instead creating a progressive income tax.

The importance of war indemnities before the First World War should not be downplayed. For example, the 230 million silver taels extracted from China after the Sino-Japanese War played a preeminent role in Japan’s decision to join the gold standard (Metzler, 2006, p. 3). The First World War would however act as a real turning point regarding the literature on reparations. Several elements contributed to this change. First, the intensity of the conflict and its huge material and human costs rendered the question of reparations of foremost importance. Second, the Treaty of Versailles (art. 232) directly referred to the notion of reparations. Since the payments were only meant to ‘repair’ the damages done, economists would attempt to evaluate the exact size of this damage. This would raise two questions: which were the losses for which Germany was to pay, and how could one evaluate these? Third, the phrasing of the Treaty of Versailles opened the door to further discussions regarding the amounts due. Indeed, it left the determination of the amounts to be paid to the Reparation Commission, an ad-hoc Inter-Allied Commission, which had to provide an estimate before 1 May 1921. Fourth, the Treaty (art. 232 and art. 234) alluded to the fact that Germany’s capacity to pay had to be taken into account, which meant this capacity had somehow to be estimated. Eventually, the World War reparations would certainly not have been so central in the literature had John Maynard Keynes not attacked them vigorously in his *Economic Consequences of the Peace* (1919). Keynes’s subsequent fame led the broader public to accept his point of view, even though it was firmly contested when first expressed (Bainville, 1920; Ohlin, 1929).

Keynes attacked the treaty on several fronts. First, he suggested a limited interpretation regarding the scope of the damages. During the discussions related to the amounts to be paid, France and Great Britain at first pleaded that Germany should be made to pay all the costs of the war. For the French finance minister, Louis-Lucien Klotz, it was clear that Germany would pay (‘*le boche paiera’*). Eventually however, the position defended by the United States and Belgium would prevail, and the treaty (art 232) would state that reparations were to cover ‘the damage done to the civilian population of the Allied and Associated Powers and to their property’. Keynes defended a narrow interpretation of this article, and considered that only direct damages caused by the war should
be taken into account. To Keynes’s consternation, costs such as pensions and separation allowances were included in the total. Keynes found the terms so harsh that he would qualify the Treaty of Versailles as a ‘Carthaginian Peace’, referring to the extremely hard conditions imposed upon defeated Carthage by Rome after the Second Punic War (218 to 201 bc) (Livy XXX, 16 and 37).

Keynes then proceeded to criticize the first tentative evaluations of the amounts that had been put forward during the Paris Peace Conference. According to him, French estimates regarding reconstruction costs were much too high. Once converted into pounds, they ranged from £2.6 to 5.63 billion, whereas Keynes’s own computation led him to suggest they should be rounded up to £2 billion. Mantoux (1946), probably one of the fiercest critics of Keynes’s estimates, showed that Keynes erroneously used the pre-war exchange rate to convert the French figures into pounds, therefore largely inflating these once converted. He further suggested that the amounts really spent for the reconstruction were actually quite close to the French estimates.

Eventually, the Reparation Commission concluded on 5 May 1921 that Germany would have to pay a total of 132 billion marks (£6.6 billion), and cover Belgium’s war debt, worth the equivalent of 5.6 billion marks. In practice, Germany would pay interest and amortization on two bonds series: the A one representing 12 billion marks and the B one worth 38 billion. The remaining 82 billion would be issued in a third series of bonds (the C one) only if Germany ever became prosperous enough to service them on top of the series A and B. As a matter of fact, most Allied politicians never believed this last issue would ever take place. Furthermore Germany was bound to pay a fixed annuity of 2 billion marks and a variable amount worth 26 per cent of its exports.

According to Keynes, Germany did not have the capacity to pay these amounts. He viewed the requested sums as so high that they would ‘reduce Germany to servitude for a generation, degrade the lives of million of human beings and deprive a whole nation of happiness’ (Keynes, 1929, p. 17). In his eyes, two different issues were to be taken into account when one considered Germany’s capacity to pay: there was both a budgetary problem linked to German capacity to extract the required sums from its citizens and a transfer problem linked to the conversion of the obtained marks into hard currency.

According to Keynes the transfer problem was as important an issue as the budgetary problem (Keynes, 1929). The macroeconomic impact of international transfers had already been addressed before the war. The traditional view was that the transfer-paying country would suffer deterioration in its terms of trade. In the case of the First World War, Keynes believed that creditor countries would not allow Germany to run a huge trade surplus and would thus force Germany to let its terms of trade...
deteriorate. This would in turn reduce Germany’s real income and in a sense add a further burden to the defeated country. Ohlin (1929) attacked this view on the grounds that income effects could induce the recipient countries to buy more German goods and thus improve its terms of trade. The transfer problem in the framework of reparations has since then led to a large literature, and has recently been analysed using recent macroeconomics approaches (Morrison, 1992; White, 2001; Devereux and Smith, 2007 for example).

This transfer problem would partially be addressed in the framework of the Dawes plan. At the end of 1921, Germany started negotiations to get a moratorium on its debts. In exchange for this moratorium, France requested productive pledges, which Great Britain opposed. On 11 January 1923 French and Belgian troops entered the Ruhr to seize part of Germany’s mines and industrial production. German passive resistance to the occupation, its dramatic economic situation characterized by hyperinflation, and geopolitical changes all led to the resumption of negotiations. Eventually, the plan drafted by the former US Director of the Bureau of the Budget, Charles G. Dawes, was agreed upon in August 1924. The Ruhr was to be evacuated, and it was hoped that the transfer problem would be resolved by accepting that Germany pay the annuities either in gold marks or in its German monetary equivalent on a special account of the Reichsbank. The Dawes plan was meant to be a provisional settlement but remained in application for five years. It also opened the door to US investment in Germany, which quickly boomed and rendered the payment of reparations much easier for Germany (Klug, 1990).

Reparations represented but part of the international debts stemming from the war. The sums lent by the United States to its European allies were huge, and had been a major point of contention since the end of the war. Allied European countries wanted them suppressed or reduced. In 1928, they pleaded to link their reimbursement to the reparations. This would lead to a revision of the Dawes plan by a team of experts led by Owen D. Young. The Young report was finalized on 7 June 1929 and adopted shortly afterwards. The amounts due by Germany were reduced to 121 billion marks and were to be administered by the Bank for International Settlements. The Young plan was short lived. The great depression forced Germany to ask for a moratorium, which lead to negotiations and the Lausanne agreements which stated that Germany would pay 3 billion gold marks as final settlement for the reparations. The Lausanne agreements were never formally signed by all parties, but payments nonetheless stopped after 1932. Depending on the sources, the estimation of the amounts paid differs greatly, ranging from close to 21 billion marks by the Reparation Commission to close to 68 billion according to the pre-Second World War German government.
In the 1970s the Keynesian view became the subject of more and more critiques by historians and economists who had access to new archival material. As mentioned by Schuker (1988), however, ‘not only did the Reich entirely avoid paying net reparations to its wartime opponents; it actually extracted the equivalent of reparations from the Allied powers, and principally from the United States’.

In view of the preeminence of the post-First World War German reparations in the literature, many economists still base their views on reparations on this single example, and conclude that reparations are in essence an inefficient mechanism. Contrasting with the German case, history however provides many examples when reparations were paid in full. Table 1 provides a comparison of war reparations for four historical episodes. Even though Germany’s indemnities were higher in percentage of one year’s GDP than the ones imposed on defeated France in 1819 and 1871, they still remained far below the indemnities paid by occupied France during the Second World War. Noteworthy, amounts were paid in full for all the episodes mentioned except the First World War.

Even though the experience of the First World War appeared as negative to most, the Allied countries, anticipating victory, started discussing reparations even before the end of the Second World War. In the framework of the Yalta Conference, which took place on 11 February 1945, the Allied countries agreed to make Germany pay for the ‘losses caused by her to the Allied nations in the course of the war’. The protocol further suggested that reparations in kind should be extracted from Germany (by requesting equipment, machine tools, ships, rolling stock, German investments abroad, and shares of industrial, transport and other enterprises in Germany, or by asking for annual deliveries of goods, or even by using German labour). Exact details were to be determined by a Commission of Damage to be seated in Moscow.

Following Germany’s surrender, the Commission of Damage met to estimate the reparations. Heated debates, fuelled by geopolitical considerations,
animated the discussions. Since the Soviet Union had suffered dramatically from the war, generous reparations would have allowed it to recover quickly, a prospect that did not please countries from the Western bloc. Despite the diverging views, the Commission managed to present a series of principles which were agreed upon at the Potsdam Conference on 2 August 1945. Most importantly, dismantling of German factories was to represent one of the main sources of reparations. The Cold War and Germany's partition would soon lead to a separation of responsibilities regarding the reparations: West Germany would pay reparations to all countries but Poland and the Soviet Union, which were to be covered by East Germany. More than 650 factories (or part of factories) were dismantled from West Germany and transferred for an estimated value of US$130 million, representing 25 per cent of the payment eventually made by West Germany. In East Germany, dismantling was soon abandoned in favor of the transfer of part of its industrial production. Estimates of the magnitude of the transfers are tentative at best, but tend to indicate that they were of large magnitude.

During the Cold War few conflicts led to reparations, most probably because each belligerent could most of the time count on the support of one of the superpowers and therefore avoid a painful settlement (d’Argent, 2002). The practice did not however disappear, and as a consequence of the first Gulf War, a UN Security Council resolution forced Iraq to pay reparations to the victims of its aggression. The first Gulf War case would, on top of the ‘traditional’ questions, raise an additional one. Since payments were expected to come from oil sales, we could wonder, as does Morrison (1992), ‘how to proceed when the guilty nation has the ability to affect world prices – even to the point where it may be able to reduce its reparations burden and inflict real income losses on those seeking compensation’.

Wal-Mart, economics of

Emek Basker

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Wal-Mart is the largest retailer in the world, with stores in 16 countries (including the United States) and annual revenues exceeding $400 billion. Wal-Mart owes its success primarily to its early and persistent investments in technology. Technology has allowed Wal-Mart not only to grow – adding stores in new markets and adding a broad range of products over the past half century – but also to cut its costs, making it a formidable competitor in almost every retail sector. Wal-Mart’s competitive effect lowers prices in local markets, in the process driving some of its competitors to contract or shut down.

Article

Wal-Mart is a discount general-merchandise retail chain based in the United States, and is the largest retailer in the world. As of 2006, Wal-Mart accounted for 28 per cent of Playtex’s sales, 25 per cent of Clorox’s, 21 per cent of Revlon’s, 13 per cent of Kimberly Clark’s, and 17 per cent of Kellogg’s (Weinswig and Tang, 2006).

Started in 1962 by Sam and Bud Walton as a five-and-dime store in Rogers, Arkansas, the chain had 18 stores when it incorporated in 1970, more than 1,700 stores by the end of 1990, and 7,873 stores as of 31 January 2009: 891 US Wal-Mart ‘Discount Stores’ (Wal-Mart’s traditional format, selling apparel, housewares, toys, electronics, prescription drugs, and more), 2,612 US Supercenters (which include a full grocery store in addition to general merchandise), 602 Sam’s Clubs (membership clubs selling a wide range of products), 153 Neighborhood Markets (smaller
formats which sell mostly groceries) and 3,615 international stores in 15 countries: Argentina, Brazil, Canada, Chile, China, Costa Rica, El Salvador, Guatemala, Honduras, India, Japan, Mexico, Nicaragua, Puerto Rico and the United Kingdom. From 1 February 2008 to 31 January 2009, Wal-Mart’s sales exceeded $400 billion; the US divisions alone had revenues exceeding $255 billion, or nearly 1.8 per cent of US GDP. Figure 1 shows the number of stores, by division, at the end of each calendar year (1962–2008).

Figure 1

![Graph showing the number of Wal-Mart stores, 1962-2008.]

Wal-Mart’s main competitors are Target and Kmart, the two largest US discount general merchandisers, but because it sells such a wide range of products it effectively competes with supermarkets, toy stores, electronics stores, apparel stores and much more. Over 99 per cent of Wal-Mart stores have pharmacies; and most Wal-Mart stores, including ‘discount stores’, carry at least some groceries.

Not coincidentally, the first Kmart and Target also date to the early 1960s; Wal-Mart’s rapid expansion has been emblematic of the widespread rise of chain retailing in the 20th century. Chains accounted for less than 30 per cent of all retail sales in 1948 and over 60 per cent of sales by 2002 (Basker, Klimek and Van, 2008). The growth of retail chains owes much to technology, which has made it possible for a single firm to manage complex supplier relationships, personnel, logistics and distribution.

Popular opinion about Wal-Mart is mixed. The criticisms of Wal-Mart tend to vacillate between two contradictory views: that it competes too
aggressively to maximize its profit, for instance by placing extreme conditions on suppliers, aggressively fighting unions, or charging lower prices in markets with heavier competition (see, for example, Norman, 2004); and that it uses its market power in non-profit-maximizing ways, such as to reduce access to birth control or to censor music (Bianco, 2006, pp. 248–50).

Despite widespread claims of negative employment effects and low wages, research has found very small, and generally positive, effects of Wal-Mart on employment. On the other hand, Wal-Mart has either settled or lost a large number of legal challenges by current and former employees alleging they were required to work off the clock, denied breaks, or denied overtime pay.

**Wal-Mart’s advantages: technology and scale**

Wal-Mart invested in computers early and has continued to make large investments in technology, which accounts for much of its success. In 1969, Wal-Mart installed a computer in its first distribution centre, and it later connected all its stores and distribution centres, along with company headquarters, to a computer network. In the 1980s, Wal-Mart was at the forefront of bar-code adoption (Vance and Scott, 1994), just as it is currently a leader in radio frequency identification (RFID) technology, which works by embedding radio transmitters in individual products or cases of products, and reduces much of the cost involved in tracking shipments, inventory and sales. Its Retail Link software, introduced in 1990, connects its stores, distribution centres and suppliers, providing detailed up-to-the-minute inventory data to its suppliers.

These investments have increased Wal-Mart’s productivity and made it a formidable competitor. Basker (2007) offers a back-of-the-envelope calculation of Wal-Mart’s labour productivity growth compared with the productivity growth in the rest of the retail sector from 1982 to 2002. Wal-Mart’s sales per employee grew, in real terms, by 55 per cent over this period; other general merchandisers increased their sales per worker by only 18.5 per cent, and productivity in the rest of the retail sector grew by only 9 per cent.

Economies of scale also play an important role in Wal-Mart’s success and its ability to charge low prices to consumers. There is anecdotal evidence that Wal-Mart asks for, and receives, price discounts from suppliers (see Fishman, 2006). In addition, the benefit that Wal-Mart is able to squeeze from its investments in technology owes much to its size. Tracking purchases alone would not have enabled Wal-Mart to discover that Strawberry Pop Tarts are a popular item consumers stock before hurricanes
A large volume of purchases – from many stores, over a long period of time, in hurricane-prone areas – was also essential. Finally, there is some evidence that Wal-Mart imports disproportionately to its size, which also lowers its costs compared with its smaller competitors. But Wal-Mart was not always a major importer. From 1985 to 1992, Wal-Mart gained popular acclaim with its ‘Buy American’ campaign. This campaign ended abruptly in late 1992 after Dateline NBC aired a segment accusing Wal-Mart of producing private-label goods in Bangladesh, smuggling textiles into the United States in excess of quotas, and placing imported clothes on racks marked ‘Made in the USA’ (Gladstone, 1992). By 2004, Wal-Mart’s imports from China were valued at $18 billion, or 15.4 per cent of US imports of consumer goods from China, more than twice Wal-Mart’s share of retail sales (Basker and Van, 2008).

Local effects

An immediate effect of Wal-Mart’s entry into a local market is increased price competition. Estimates of Wal-Mart’s food prices range from 10 per cent below the competition (Basker and Noel, 2009) to 30 per cent below the competition (Hausman and Leibtag, 2007b). Basker and Noel (2009) estimate that competing supermarkets and grocery stores cut their prices by about 1 per cent on average when a Wal-Mart Supercenter opens in town. Hausman and Leibtag (2007a) calculate that prices paid by consumers fall by 3 per cent on average, accounting for product and outlet substitution. An earlier study focusing on prices of drugstore products such as shampoo and toothpaste found that these also fall (Basker, 2005b).

Increased price competition reduces profits at some incumbent stores and may cause them to contract or exit. On average, almost as many people lose their jobs at other retail establishments as are hired by a new Wal-Mart store. Using publicly available data on Wal-Mart stores’ opening dates to 1999, Basker (2005a) estimated that the number of retail jobs in a county increases by 100 the year Wal-Mart opens a new store (relative to what would have happened had Wal-Mart stayed out of the county), and by 50 after five years. Since the average Wal-Mart store over the period of the study employed about 250 workers, this estimate implies that approximately 200 workers at other stores lose their jobs. In addition, the number of wholesale jobs declines by about 30 in the long run, reflecting the fact that Wal-Mart is vertically integrated: unlike the merchants it replaces, Wal-Mart does not rely on local wholesalers. Drewianka and Johnson (2009) find somewhat larger positive effects on employment in general merchandising. In contrast, Neumark, Zhang and Ciccarella (2008) estimate net job losses of 150 workers per Wal-Mart
store (implying that 400 workers lost their jobs, on average, as a result of a new Wal-Mart store hiring 250 workers). Competitors whose profits fall sufficiently eventually shut down. Basker (2005a) estimates a net closing of about five stores in a county as a result of Wal-Mart’s opening. Jia (2008) finds a net reduction of two or three small general-merchandise stores, such as dollar and variety stores, if Wal-Mart or Kmart enter a market, compared with if either of these large retailers stays out. Drewianka and Johnson (2009) find little effect on the number of competitors. The wide range of estimates of Wal-Mart’s effect on prices, employment and competitors reflects a fundamental problem of identification: that is, disentangling cause and effect. Basker (2005a, 2005b) addresses this problem by exploiting the time lag between Wal-Mart’s initial decision to open a store and its actual opening. Drewianka and Johnson (2009) instead control for pre-existing trends in the outcome variables of interest (employment, wages and so on). Finally, Neumark, Zhang and Ciccarella (2008) use Wal-Mart’s geographic pattern of expansion to predict when Wal-Mart will open in each location. These diverse identification strategies – and the different estimates they produce – are the source of controversy and debate. In the absence of a criticism-proof identification strategy, the precise impact of Wal-Mart on employment and other outcomes remains somewhat uncertain. For a comparison of the store-planning and geographic instruments, see Basker (2006).

Business cycles

Wal-Mart’s low prices are particularly attractive to consumers during economic troughs. Basker (forthcoming) shows that Wal-Mart sells ‘inferior goods’ in the technical sense of the term: goods for which demand increases (relative to trend) when incomes fall. This analysis uses quarterly data on average sales per store at Wal-Mart over a ten-year period; the same analysis shows that Target’s products are ‘normal’, meaning demand for them increases when incomes rise. Using a monthly data set and Granger causality tests, Jantzen, Pescatrice and Braunstein (2009) also find that Wal-Mart’s sales growth falls when the overall economy’s growth rate accelerates.

Conclusion

As the largest, and arguably most efficient, chain retailer in the world, Wal-Mart leads the way in both technological innovation and arousing public opposition. Ultimately, however, Wal-Mart is just one of many
retail chains making these investments, made possible by the same advances in computing technologies that have transformed other sectors of the economy.
