Indeed, if \( C \) causes \( E \) we expect there to be a mechanism running from \( C \) to \( E \). Evidence about a mechanism from \( C \) to \( E \) can thus provide evidence for a causal connection. In turn, according to this view, the mechanism can be used to explain \( E \).

On the other hand, causal explanations that are based on statistical inferences often cite relationships among aggregate factors such as the money stock, the unemployment rate, inflation and so on, and can arguably be said to be somewhat shallow. Perhaps a monetary expansion can be used to explain a subsequent economic expansion because there is statistical evidence that the former is the cause of the latter. In this way one learns at best *that* the monetary change causes the economic change. Describing the transmission mechanism one further learns *how* the monetary change causes the economic change. The explanation is thus arguably more detailed, deeper.
It cannot be said, however, that the mechanistic account wins unequivocally over the probabilistic account on both fronts. In order to meet the empirical adequacy desideratum, a mechanistic explanation must be based on evidence no less than a probabilistic-causal explanation. A mere ‘sketch’ of a mechanism (such as the sketch of the transmission mechanism that follows above quotation by Friedman and Schwartz) does not explain anything. Usually, mechanistic explanations cite relationships among individuals, their preferences and external constraints. The argument that such hypotheses are more readily verifiable (for instance, because they may be verifiable by introspection) goes back at least to the writings of John Stuart Mill (1830). But it is not clear whether it is always easier to provide evidence for causal mechanisms that run at the micro level than for aggregate causal relationships. For instance, the problem of confounding factors is in no way confined to statistical inferences among aggregate variables, and, at the micro level, can only seemingly be alleviated by assuming away the operation of confounders a priori.

Moreover, although with some justification it can be said that mechanistic explanations are deeper than aggregate explanations, there are situations in which information about exactly how some variable influences another is entirely irrelevant. A policymaker, for instance, may be more interested in what is common among expansion episodes rather than in the exact processes that made them happen – which may be different on each occasion.

**How models explain: unificationism**

Let us now move from the applied side to the more theoretical side of economics. Consider the following quotation (Akerlof, 1970):

> From time to time one hears either mention of or surprise at the large price difference between new cars and those which have just left the showroom. The usual lunch table justification for this phenomenon is the pure joy of owning a ‘new’ car. We offer a different explanation.

Akerlof then describes an asymmetric-information model in which low-quality second-hand cars drive higher-quality cars out of the market, which leads to a decrease in average quality and prices. One way to interpret what Akerlof does is to regard the explanatory power of models such as his as consisting in an ability to suggest *schemas* that allow the description of a wide variety of different and seemingly unconnected phenomena. In Akerlof's original article, for instance, the model of the second-hand car market is regarded as a mere ‘finger exercise’ for further application in markets as diverse as insurance, labour, other goods and credit markets. Other economists invoke transaction costs to explain the existence of firms, intergovernmental collaboration, why crime rates are higher among the poor and ‘fair use’ doctrines about the use of copyrighted material among many other phenomena. Many other salient theoretical concepts in economics play a similar unifying role.

Philip Kitcher developed the idea that to explain a phenomenon means to derive a description of the phenomenon from an instance of an argument pattern, instances of which can be used for deriving descriptions of many different kinds of phenomena into a formal account (Kitcher, 1989). Despite its intuitive appeal, however, it is quite clear that unification cannot be all there is to explanation. How
could we tell whether those factors that are salient in a model are the ones that drive the results in the real world? This is a particular problem in economics as many of the concepts that do the alleged explanatory work in models such as Akerlof's are not very discriminatory. There is hardly any market transaction that is not characterized by asymmetric information because it is virtually always the case that one party knows more or something different about a contractually relevant property. Similar observations can be made about other concepts such as human capital or transaction costs or imperfect information. In some situations such factors will be the ones that drive the result, in others they will merely provide a background against which other factors operate. But this is a dominantly qualitative question that should be decided by empirical means, not by means of models alone. Moreover, it seems unlikely that unification is necessary for explanation. Many economic events will be explained with reference to very local and idiosyncratic processes such as wars, innovations and individuals’ decisions that lack the power to unify whole classes of events (for further criticism of the unification model, see Woodward, 2003, ch. 8).

Nevertheless, unification plays at least two important roles in economic explanation. First, models such as Akerlof's suggest factors that may be causes of real phenomena. Unifying model schemas thus have an important heuristic role. Second, unifying explanations are in some sense desirable explanations. Even though the causal role a factor plays in bringing about a phenomenon is that which makes a model that describes the operation of this factor explanatory, it is its ability to systematize our beliefs and to reduce the number of ‘brute facts’ we have to accept as given that makes the explanation attractive to economists.

Equilibrium explanation

Economics is full of equilibrium notions such as the Nash equilibrium, evolutionarily stable equilibrium, sunspot equilibrium, partial and general equilibrium theories. For a variety of reasons, economists tend to downplay explanatory accounts if these accounts do not have a bearing on theory (Heckman, 2000, p. 85):

Applications of this approach [that aims at the statistically analysis of ‘natural experiments’] often run the risk of producing estimates of causal parameters that are difficult to interpret. Like the evidence produced in VAR [vector autoregression] accounting exercises, the evidence produced by this school is difficult to relate to the body of evidence about the basic behavioural elasticities of economics. The lack of a theoretical framework makes it difficult to cumulate findings across studies, or to compare the findings of one study with another. Many applications of this approach produce estimates very similar to biostatistical ‘treatment effects’ without any clear economic interpretation.

Equilibrium explanations, of course, have exactly this virtue: they show how some phenomenon can be systematized in a theoretical framework. Equilibrium explanations obtain at a level in between aggregate probabilistic explanations and causal-mechanical explanations. Unlike aggregate explanations, they are always formulated in terms of micro entities such as preferences, production possibilities and so forth. But, unlike causal-mechanical explanations, they rarely specify the exact details of how an equilibrium
Equilibrium explanations present disjunctions of possible causal scenarios; the actual cause is given by one of the disjuncts, but the explanation doesn't say which.

Because of this, equilibrium explanations are more unifying than explanations that describe the actual causal mechanism that lead to the equilibrium. Nevertheless, equilibrium explanations (at least in economics) tend to cite a lot of information about causes such as preferences, productivity growth, technology and so on. Although abstracting from some causal detail, equilibrium explanations can thus safely be regarded as a species of causal explanation.

The greatest challenge for equilibrium explanations is, however, to meet the desideratum of empirical adequacy. In order to derive any results in an equilibrium model, usually a large number of highly distorting idealizations have to be made: consumers maximize utilities and producers their profits; they operate under perfect information; markets clear instantaneously; goods are infinitely divisible and so on and so forth. Furthermore, results derived from a model making such idealizations tend to be very sensitive to specification changes. There is therefore little reason to believe that those forces that drive the equilibrium results obtain also outside the model. Hence, unless it can be shown that this is the case, equilibrium models should be regarded as mere potential explanations.

Conclusion: the variety of causal explanations

The different types of explanation perform different epistemological roles. Very detailed causal–mechanistic explanations can be contrastive: they can provide information about what is special about the way in which a phenomenon came about, the way in which its causal history differs from the causal histories of other, similar phenomena. Aggregate and unifying explanations, by contrast, are comparative: they provide information about what similar or different phenomena have in common (cf. Pettit, 1993, pp. 253–7). For those who are interested in explanation mostly for the practical goals of prediction and policy, aggregate explanations will often be the relevant type. However, mechanistic knowledge can be used to improve predictions, for instance, because it may provide information about the ways in which aggregate relationships sometimes fail to hold. Those with more purely cognitive goals will often prefer explanations that unify.

exploitation

Abstract

This term ‘exploitation’ is used to characterize social relationships in which one party takes advantage of the attributes or position of another. Used normatively, it conveys the stronger sense that the exploiter takes *inappropriate* or *unfair* advantage of another's condition. While the concept has been invoked in a number of economic contexts, it has been treated most extensively in Marxist analysis of class relations in market economies, featuring in particular *orthodox, neo-Ricardian, and rational-choice Marxist* approaches to the phenomenon. There is ongoing debate concerning both the systemic basis and the normative significance of exploitation.

Article

As applied to social settings, ‘exploitation’ characterizes relationships in which one party takes advantage of the attributes or situation of another. A complete positive account of a given instance of exploitation would include, in addition to the identities of the parties to the relationship, three elements: the process by which one party exploits the other, the nature of advantage taken, and the conditions that make exploitation possible. Used normatively, the term conveys the stronger connotation that the exploiter takes *inappropriate* or *unfair* advantage of another's condition. Understood in this latter sense, exploitation theory thus provides an alternative to the Pareto–utilitarian principle as a basis for assessing social outcomes, inasmuch as a
given relationship may be deemed exploitative even if it improves the welfare of the exploited party. The concept of exploitation has been invoked across a range of distinct economic contexts and paradigms. It has been applied, for example, in mainstream economic analysis of monopsonistic wage practices, and in feminist economics to characterize gender relations within households. The term has been treated most extensively, however, in Marxist political economy, which treatment is therefore the focus of the remaining discussion.

Marxian economic theorizing with respect to this phenomenon can, at some risk of oversimplification, be traced through three stages of development corresponding to distinct systems of analysis brought successively to bear on the question: orthodox Marxist analysis grounded in Karl Marx's reformulation of the classical labour theory of value; Sraffian or neo-Ricardian analysis based on the mathematical properties of linear production systems; and rational-choice Marxist analysis utilizing formal methods of optimization and equilibrium analysis. The ensuing clash in perspectives both within the Marxian framework and between the latter and the liberal tradition undergirding the mainstream paradigm has generated a lively debate on the positive and normative significance of exploitation.

**Marx's account of capitalist exploitation**

Karl Marx analysed societies in terms of relations between classes, defined in terms of ownership and control of alienable productive assets or means of production. In class systems such as feudalism or slavery, Marx held, those who controlled the means of production directly exploited workers by compelling them to expend more labour than that necessary to meet their own consumption needs. Capitalism, in Marx's account, is a specific historical form of class society in which antagonistic class relations are mediated by market transactions. The central analytical problem, in Marx's view, is thus to explain how exploitation of labour might arise in individually voluntary exchanges between traders with formally equal property rights.

Marx's solution to this problem, developed in the first volume of *Capital* (1867), is grounded in the postulate, previously advanced by David Ricardo, that a commodity's value is determined by the labour time necessary to produce it under average production conditions. On the basis of this value framework, Marx advanced three propositions: (a) capitalist profit is based on the extraction of surplus labour, and thus the exploitation of workers; (b) in industrial capitalism, the locus of exploitation is the capitalist-directed production process rather than the marketplace, although exchange relations are the necessary pretext for exploitation to occur; and (c) the systemic basis for exploitation under capitalism is that workers are ‘free in the double sense’, that is, both legally able to offer their services in the labour market and ‘free’ of owning any substantial means of production themselves – a condition Marx saw as the outcome of historical processes of expropriation such as the enclosure movement in pre-industrial Great Britain.

Marx argued the first proposition, which in later formulations has been termed the ‘fundamental Marxian theorem’ (FMT), on the heuristic premise that commodity prices are proportional to their respective labour values. The key to Marx's demonstration is his distinction between labour power, that is, the capacity for productive effort, sold as a commodity in capitalist labour markets, and labour, the exercise of that capacity. If commodities exchange at their respective values, then positive profit is possible if and only if the labour expended by workers in capitalist production exceeds the value of their labour power – that is, workers perform surplus labour for capitalist firm owners.
Marx acknowledged that commodities typically do not exchange at their values, but maintained that prices were nonetheless ‘regulated’ by values, and attempted in the third volume of *Capital* (edited and published in 1894 after Marx’s death by his collaborator Frederick Engels) to demonstrate the aggregate correspondence of profit and surplus labour given competitive market valuation of commodities resulting in economy-wide equalization of profit rates. His treatment of this *transformation problem* is suspect, however, due to an evidently inconsistent ‘transformation’ of value magnitudes in his expressions determining market prices.

Marx’s second proposition emerged as a corollary of his distinction between labour power and labour. Marx argued that what capitalists purchase in the market is not a specified amount of labour time or bundle of labour services, but rather just individuals’ capacity to work for a given period of time. The use value of this capacity must therefore be realized by extracting surplus labour in the process of capitalist-controlled production. It should be noted, however, that Marx did not insist as a matter of *definition* that capitalist exploitation occurs in the arena of production. In earlier drafts of *Capital* (including that which provided the basis for Engels’s edition of the third volume), he frequently alluded to instances of exploitation arising from transactions involving the finance of commodity production without direct capitalist supervision.

With respect to the third proposition, Marx argued in his theory of economic colonization that workers would be unwilling to provide capitalists with surplus value on a regular basis if they were able to produce independently to meet their own needs. Thus, capitalist profit could not in his assessment be systematic unless workers were on the whole divested of substantial ownership in the means of production, such that their livelihoods would be significantly compromised if they chose not to work for wages.

**Neo-Ricardian refinements of the FMT**

The calculation of commodity labour values, necessary for the determination of exploitation status in an exchange economy, is most straightforward in the case of *Leontief* production processes, characterized by fixed input coefficients and the absence of jointly produced goods, a scenario consistent with Marx’s account in the first volume of *Capital* and his treatment of the transformation problem in the third volume. However, even with this basic representation of production conditions, competitively determined commodity prices are typically disproportionate to their values. In light of his problematic ‘transformation’ procedure, Marx’s account raises a question concerning the generality of the FMT. Beginning in the 1960s, this question was taken up by a number of economists who, following a mode of inquiry introduced by Sraffa (1960), applied mathematical results characterizing the formal properties of linear systems understood to represent unit input requirements in a capitalist economy based on Leontief production. This literature is informed by an important theorem due independently to Frobenius and Perron (see Kurz and Salvadori, 1995) which states in effect that, if it is possible to produce a surplus net of physical input requirements and real wages, and if all commodities require the direct or indirect input of other commodities, then there exists a competitive price vector supporting a strictly positive rate of profit. On the basis of this result, one can establish the FMT, framed as the formal equivalence of positive profit and the exploitation of labour given any vector of positive competitively determined commodity prices. This equivalence was subsequently extended to scenarios involving joint production and the presence of multiple alternative Leontief techniques for producing each commodity,
subject to a reformulation of labour values, to be discussed below.

The Sraffian approach prompted a number of debates in the Marxian literature. An overriding concern is methodological in nature, as orthodox Marxists have questioned the relevance of ahistorical mathematical models to Marx's analytical methods and insights. There are, moreover, substantive correlates of their methodological concerns. On the one hand, the neo-Ricardian approach is silent with respect to Marx's second proposition, as the formal representation of production conditions central to the new framework simply takes as given the quantitative translation of labour capacity into productive labour expenditures. Similarly, the question of the systemic conditions enabling the extraction of surplus labour is necessarily begged in this analysis. Consequently, the equivalence between profit and capitalist exploitation established in the new versions of the FMT does not lend itself readily to an assessment of the causal connection between surplus labour and profit; the asserted equivalence might, for example, simply be a reflection of some unspecified underlying condition.

On the other hand, the Sraffian approach challenges the explanatory primacy of labour values, in so far as competitive prices are seen to be calculable directly from production and distribution conditions without any intermediate derivation of labour values. Furthermore, generalization to the case of multiple techniques and joint production introduces an element of ambiguity in the standard calculation of individual commodity values because multiple imputations of labour expenditure are then possible for each individual commodity. Morishima (Morishima and Catephores, 1978) addressed the latter problem by redefining labour values in terms of the minimum possible direct labour required to produce a given bundle of net outputs. This procedure preserves the FMT, but at a potential cost of empirical relevance, as it is at best not obvious that actual capitalists would pursue this objective in selecting among alternative techniques.

While thus casting doubt on Marx's hypothesis that individual commodity prices are somehow regulated by their respective labour values, the Sraffian approach does not directly challenge Marx's labour-based definition of exploitation. Although it provides a basis for calculating economic surplus without reference to labour values, and indicates that the operation of a viable competitive economy is consistent with a range of class distributions of that surplus, this framework establishes no independent basis for judging any such distributive outcome to be the consequence of exploitation.

Rational-choice Marxism and the systemic basis of exploitation

Although the orthodox Marxian account of capitalist exploitation is clearly not methodologically individualist in nature, presumably its exponents understand it to be consistent with the interactions of self-seeking individuals responding intelligently to their available options. Granting the latter possibility raises plausible questions as to why, on the one hand, workers allow themselves to be persistently exploited by capitalists, or on the other, why capitalists choose to exercise direct control over production rather than using simple contractual means for extracting surplus labour. The corresponding normative concern asks how exploitation might be considered morally objectionable if understood to occur in voluntary transactions between rational individuals.

These and similar questions motivate a body of inquiry that has come to be termed ‘rational-choice Marxism’, which utilizes mainstream tools of optimization and equilibrium analysis in investigating the systemic basis and features of exploitation in market economies. A central point of reference for this stage of the Marxian literature is Roemer's *General Theory of Exploitation and Class* (1982), which
poses a cogent and fundamental challenge to the canonical Marxian account. Roemer proposes a re-conceptualization of economic exploitation that dispenses entirely with labour value calculations and makes explicit the systemic basis for moral objections to its existence.

Roemer investigates the traditional labour value-based approach to exploitation in the context of both subsistence and accumulating exchange economies, initially maintaining the standard Leontief specification of production conditions and calculation of commodity values in terms of direct and indirect unit labour requirements. In this sense, his analysis commences where the Sraffian approach leaves off, embedding its representation of production conditions in a general equilibrium framework with optimizing agents.

Roemer expands this framework in two ways. First, in the scenario of subsistence exchange economies, markets for produced commodities are alternatively combined with labour and credit markets facilitating the organization of production activity. Second, in the context of accumulating market economies, he allows for unequal endowments of labour capacity and a more general representation of production possibilities.

Roemer's argument is chiefly organized around three analytical results roughly corresponding to Marx's original propositions. First, the class-exploitation correspondence principle (CECP) reflects Marx's fundamental assessment of the class basis of exploitation: ‘capitalists’, that is, those who hire or extend credit to workers, exploit, while those who work for wages or borrow to finance production activities are exploited. In the strong version of this theorem, class status is furthermore consistently linked to the market value of alienable endowments, such that the sufficiently wealthy become exploiting capitalists and the relatively indigent become exploited workers in market equilibrium.

The CECP deepens and extends the sense of the FMT by linking exploitation status to class position. Roemer demonstrates that the CECP obtains for both subsistence and accumulating economies given Leontief technology and identical preferences and labour endowments, subject only to modifications in the labour-based index of exploitation status to accommodate the distinction between subsistence and surplus economies.

Second, Roemer argues that neither the degree nor the structure of equilibrium exploitation depend in general on whether production activities are supported by labour or credit markets. At first glance, this isomorphism theorem appears to rebut Marx's identification of production as the primary locus of exploitation. However, as in the Sraffian approach, Roemer's framework abstracts from the problem of translating labour capacity into labour performed. Thus the implied rebuttal of Marx's second proposition is contingent: on the assumption that capitalists face no significant obstacles in contracting for given labour services or loan repayments with interest, exchange rather than production relations provide the essential framework for capitalist exploitation. This qualified refutation nonetheless carries theoretical force, in so far as Marx's value-theoretic account of capitalist exploitation in the first volume of Capital does not explicitly feature conditions that would in contemporary terms be described as contracting failures.

Third, Roemer's general equilibrium framework affords a characterization of the systemic conditions for exploitation to occur in either subsistence or accumulating exchange economies. Roemer identifies differential ownership of scarce productive assets (DOSPA) as the necessary and (absent significant contracting failures) sufficient basis for the existence of exploitation. Differential ownership refers to inequality in the market value of individuals’ endowments of productive assets, specifically (given the assumption of identical labour capacities) their endowments of alienable productive assets, that is,
capital’. Significantly, the sense of capital scarcity in Roemer's framework is that of absolute scarcity, such that the market demand for capital assets (either direct or imputed) is positive at the level of total available capital supply. Otherwise, since Roemer’s actors don’t discount future payoffs or demand risk premia, capital goods would not command a positive rate of return.

It is readily seen why wealth inequality and capital scarcity are jointly necessary for exploitation to arise. If productive assets are equally distributed, then even if capital is scarce no agent wishes to supply it because of the resulting sacrifice in increased labour expenditure. If capital is not scarce in the absolute sense, then no agent demands it even if others enjoy greater wealth. This result presumes that individuals are identical except in their endowments of alienable assets.

Realistic generalizations of production and endowment conditions, Roemer argues, undermine the sense and scope of Marx's labour-based theory of exploitation. First, representing production possibilities as a convex cone, which maintains the assumption of constant returns to scale but allows for such practical features as factor substitution, fixed capital and joint production, introduces a tension between the labour-based conceptions of commodity value and capitalist exploitation: even if Morishima’s revised valuation procedure were adopted to accommodate these more inclusive production conditions, the CECP no longer obtains in general.

To address this problem, Roemer suggests a plausible reformulation of labour value in which capitalists, rather than adopting the labour-minimizing technique for given net outputs, are instead understood to choose techniques which minimize costs at going market prices. As he demonstrates, this modification preserves the CECP, but at the necessary cost of rendering commodity values strictly dependent on commodity prices, thus reversing the causal connection asserted by Marx.

The CECP is more fundamentally compromised by quantitative and qualitative variations in individuals’ inalienable endowments of labour capacity. Merely quantitative variations in labour endowments, corresponding for example to the case that some workers are able to work harder or faster than others, weakly preserve the CECP, but eliminate the monotonic relationship between class status and alienable wealth. Thus, from the standpoint of Marx’s canonical account, perversities can arise such as rich but exploited wage workers or poor but exploiting capital suppliers. (A similar difficulty arises, it might be noted, given additional non-produced factors such as ‘land,’ which further disrupt the connection between embodied labour times and individual wealth.)

Heterogeneous labour endowments, reflecting differential abilities across distinct production tasks, raise an even more fundamental problem with respect to defining embodied labour magnitudes, as qualitatively distinct labour expenditures must somehow be aggregated before individuals’ exploitation status can be assessed. But, even if a consistent procedure for aggregating heterogeneous labour inputs were identified, such as weighting them with their respective wage rates, no meaningful and consistent relationship among wealth, class position and exploitation status can thereby be established in general. Thus, the labour value-based conception of exploitation appears to break down entirely in this realistic scenario.

The normative significance of exploitation

These anomalies prompt Roemer to advance a new conception of exploitation that assesses economic outcomes through comparison with some alternative property rights regime reflecting a given distributional norm. Besides sidestepping the inconsistencies arising in the labour-based approach to
exploitation, this formulation offers the advantage of making explicit the grounds for judging given relationships as exploitative. As such it has potential applications beyond the scope of Marxian analysis. Roemer's approach can be represented in terms of a cooperative game with transferable payoffs. Let $N$ denote a set of economic actors with representative subset $C$, called a coalition. Let $(C_i, C_j)$ designate disjoint subsets of $N$ representing distinct coalitions in the larger society. (In Roemer's account, these coalitions are defined more specifically as complements, so that $C_j = N - C_i$.) Suppose that coalitional payoffs in this game are determined by the function $u(C)$, and define a withdrawal rule $\pi (C)$ for the game, interpreted as the payoff to coalition $C$ should it choose to reject the allocation $u(C)$ and freely withdraw with the resources permitted it by the game's rules. Then, given the payoff allocation rule $u(C)$, coalition $C_i$ is said to be exploited by coalition $C_j$ relative to withdrawal rule $\pi (C)$ if (i) $u(C_j) < \pi(C_i)$ ($C_i$ would be made better off by withdrawing), (ii) $u(C_j) > \pi(C_j)$ ($C_j$ would be made worse off by withdrawing), and (iii) $C_j$ dominates $C_i$. Roemer doesn't specify the meaning of 'domination' in the General Theory, and offers alternative formulations in subsequent work without settling on a definitive statement of the condition. A plausible interpretation is that the payoffs $(u(C_i), u(C_j))$ are somehow imposed by $C_j$ in lieu of a feasible alternative payoff rule $\delta(C)$ such that $\delta(C_j) \geq \pi(C_i)$ (coalition $C_i$ isn't made better off by withdrawing, given $\delta$) and $u(C_j) > \delta(C_j)$ (coalition $C_j$ benefits by choosing $u$ over $\delta$).

An allocation $u(C)$ is then called 'non-exploitative' (NE) relative to the game characterized by $\pi (C)$ if no coalition $C \subseteq N$ is exploited. NE allocations are thus related to the well-known concept of the core of a game characterized by $\pi (C)$. All allocations in the core are NE, but not necessarily vice versa, since an allocation may be NE yet Pareto-inefficient. The normative significance of this formulation clearly depends in part on the specification and justification of the withdrawal rule $\pi (C)$. Roemer posits three forms or levels of exploitation corresponding to different types of economic organization. Feudal exploitation is defined relative to a rule allowing individuals to withdraw with the free use of their existing endowments, the interpretation being that this form of exploitation involves coercive or strategic strictures on others’ utilization of their property. Capitalist exploitation is said to exist in the context of a rule allowing actors to withdraw with the per capita share of the economy's alienable productive assets, reflecting the assessment that wealth inequality is a prerequisite for Marxian exploitation in private ownership economies. Finally, socialist exploitation is defined relative to a rule allowing individuals to withdraw with the per capita share of both alienable and inalienable productive assets, including skills and innate abilities.

In subsequent work (for example, Roemer, 1985), Roemer has argued that moral objections to exploitation are most appropriately understood as normative demands for the provision of equal economic opportunities to all. This is a plausible inference, and one that may in any case be compelling to those who characterize capitalist economic relations as exploitative. However, in light of the dominance condition in Roemer's three-part definition, one might with equal justification condemn the relational aspect of exploitation, specifically the acts by which exploiters take advantage of the vulnerable position of others, whatever the material conditions that created this asymmetry.

This point can be illustrated with reference to two strands in the rational-choice Marxist literature subsequent to Roemer's General Theory. One involves the criticism that Roemer's use of the competitive general equilibrium framework abstracts from contracting failures and thus ignores crucial aspects of the
process by which workers are exploited in capitalist economies. In their influential treatment of this issue, Bowles and Gintis (1990) argue that the strategic response of capital suppliers to contracting failures in labour markets creates a situation of *contested exchange* in which a form of unilateral economic power is exercised over workers in capital-owned firms. They argue for the institution of democratically organized firms as a safeguard against the exercise of such power, without qualifications as to the distributional basis for this form of exchange.

A second line of criticism concerns Roemer's use of a static analytical framework in treating the essentially dynamic phenomenon of capital accumulation. This point is developed by Veneziani (2006), who argues that the condition of absolute capital scarcity, necessary for the existence of exploitation in Roemer's models, becomes extremely fragile once embedded in a genuinely intertemporal equilibrium context. On this basis, Veneziani suggests that the competitive model premised on perfect contracting arrangements is not a suitable vehicle for illuminating the Marxian theory of exploitation.

The validity of this claim, and more generally the systemic basis for capital scarcity and profit, remain open theoretical and empirical questions that stand at the boundary distinguishing Marxian and mainstream economic perspectives. In any case, there are distinct senses in which enduring capital scarcity might be deemed consistent with the manifestation of exploitative economic relationships. One possibility is that capital scarcity is somehow preserved by unequal material conditions. If, for example, time or risk preferences were income elastic, then persistent capital scarcity might arise from inequalities of the sort targeted in Roemer's account. However, even if such preferences were innate and generally uncorrelated with wealth, consistent with the standard neoclassical account, exploitation might still be said to arise if capital suppliers used inappropriate means (such as those criticized by Bowles and Gintis) to maximize the advantage derived from their unique position.

External economies and diseconomies nowadays generally mean unpaid side effects of one producer’s output or inputs on other producers. External economies in this sense imply as a rule that market prices in a competitive market economy will not reflect marginal social costs of production, giving rise to a ‘market failure’. But, with technological external economies and diseconomies now most often replaced by the well-defined concept of externality, and with pecuniary external economies and diseconomies being synonymous with general market interdependence, external economies no longer have much of a role to play in economic analysis.

Article
‘The concept of external economies is one of the most elusive in economic literature.’ This is how Tibor Scitovsky began his article ‘Two Concepts of External Economies’ (1954). His statement is still true, and it may be added that there are at least two such concepts.

The meaning of external economies and its counterpart, external diseconomies, has changed over time. Nowadays, it is essentially synonymous with externality or external effects in the sphere of production. That is, external economies (diseconomies) or positive (negative) external effects in production are unpaid side effects of one producer’s output or inputs on other producers. (As an illustrative example, we can take the case where a dam constructed by a hydroelectric power plant eliminates flooding of farmers’ crop fields – external economy – or reduces the catches of fishermen downstream – external diseconomies; a producer’s pollution which increases the costs of, *inter alia*, other producers is perhaps the most important case of externalities.) Sometimes, external economies also refer to unpaid side effects of or on consumption activities, but this meaning is disregarded here.

External economies in this modern sense imply as a rule that market prices in a competitive market economy will not reflect marginal social costs of production. Hence, a ‘market failure’ arises, meaning that the market economy cannot attain a state of efficiency on its own. Specifically, in an otherwise ‘perfect’ market economy, a producer who has external economies (positive external effects) on other producers would not extend his externality generating activity, say, his output, to the point where marginal cost of production equals marginal social benefits of production, which amounts to the market value of his marginal output plus the market value of the side effect on the output of other producers. At an earlier stage, external economies in the meaning now given were called *technological external economies*, reflecting the fact that the effects were transmitted outside the market mechanism and altered the technological relationship between the recipient firm’s output and the inputs under its control. Formally, we have that the output $q_i$, of the $i$th producer is affected not only by changes in his control variables, a vector $x_i$, but also by $e_j$, a variable controlled by some other producer $j$. This gives us the following production function:

$$q_i = f(x_i, e_j).$$
external economies: The New Palgrave Dictionary of Economics

The reason for specifying such effects as technological is that the concept of ‘external economies’ has been given a broad meaning ever since its introduction. During the early part of the 20th century, external economies (diseconomies) were defined so as to include beneficial (detrimental) price effects of producer activities. Thus, in principle, the concept included cases where increases in factor inputs by one firm lowered or raised input prices for other firms. However, much of the discussion centred on the case where increases in industry output lowered or raised input prices for the individual member firm. The case of reduced input prices presupposes that the supply side of the market for inputs is characterized either by imperfect competition (say, a profit-maximizing monopoly producing at decreasing marginal costs, decreasing at a rate sufficient for an increase in demand to lower price) or by a competitive industry having a downward-sloping ‘supply’ curve, which in turn reflects external economies in this industry. Supply conditions in the original industry, as well as in the industry producing inputs for the first industry, are shown in Figure 1. Here, \( \sum s_i(Q_0) \) is the aggregate supply of the firms in the industry when actual industry output is \( Q_0 \). When industry output increases to \( Q_1 \), input prices drop (or technological external economies arise), causing a downward shift in individual cost and supply curves and hence in the aggregate supply \( (\sum s_i(Q_1)) \). The curve \( M \), the downward-sloping ‘supply’ curve, is actually a market equilibrium curve showing the equilibrium price/output combinations at different levels of demand (see Bohm, 1967).

Figure 1

The price effects between firms or between industry and its firms were termed *pecuniary external economies (diseconomies)* by Viner (1931). Before him, A.C. Pigou (1920) had argued (although he phrased it differently) that external economies and diseconomies, both technological and pecuniary, would call for government intervention in order for the industry to attain a socially efficient level of output. Specifically, Pigou argued that, if expansion of a competitive industry would increase prices of inputs sold to the industry, thus
creating pecuniary external diseconomies for the individual firms in the industry, the aggregate ‘supply’ (or market equilibrium) curve would not reflect social marginal costs. Pigou’s argument can be illustrated in Figure 2, where $M$ is the upward-sloping long-run ‘supply’ curve for the industry due to rising input prices as a consequence of increasing industry output. $SMC$ is the curve showing the total marginal outlay on inputs, where the difference to $M$ is the increased outlay for infra-marginal inputs. Pigou contended (but later rescinded this position) that the $SMC$ curve indicated the true social marginal costs and hence, that the price/output combination attained by the market, as shown by the intersection of market ‘supply’ $M$ and market demand $D$, was suboptimal. He argued that the optimal level could not be attained unless a tax were levied on this industry so that, in equilibrium, price and output would be those shown by the intersection of $SMC$ and $D$. (Similarly, a bounty would be required in the case of pecuniary external economies (see Figure 1), where $SMC$ would be downward-sloping and steeper than the $M$ curve.)

Figure 2
It was demonstrated by F.H. Knight (1924) and D.H. Robertson (1924) and further elaborated by Ellis and Fellner (1943) that the total marginal outlay is irrelevant as an indicator of marginal social costs. The effect on outlay for intramarginal units of inputs represents an increment to rent on these units and hence, it is not part of the real costs of increased output; the real marginal costs are only those which have to be paid for the required marginal inputs. In other words, the rising costs for marginal inputs are those shown by the industry ‘supply’ curve $M$. Hence, pecuniary external economies or diseconomies would not call for government intervention. The case is different, however, for technological economies and diseconomies. Assume, for example, that output of a geographically concentrated industry pollutes the area where it is located and hence reduces the productivity of labour inputs of the individual firms in the industry. Here, all effects on input productivity, for marginal as well as intramarginal units, constitute real costs. So if the rising $M$ and $SMC$ reflect such effects only, Pigou’s argument holds.

When the debate had arrived at this point, pecuniary external economies could be dropped as a cause of market failure and, hence, the concept lost its specific economic interest. But, now, what do the technological external economies and diseconomies of industry output on the individual firms in the industry actually represent? Alfred Marshall introduced the term external economies when analysing industry production costs as a function of output:

"We may divide the economies arising from an increase in the scale of production of any kind of goods, into two classes – firstly, those dependent on the general development of the industry; and secondly, those dependent on the resources of individual houses of business engaged in it, on their organization and the efficiency of their management. We may call the former external economies, and the latter internal economies. (Marshall, 1920, p. 266)"

The latter concept is now recognized as economies of scale in the individual firm. Marshall elaborated the meaning of the former concept using scattered examples, the most explicit of which is perhaps the increased knowledge accompanying the expansion of industry output materialized in the publication of trade journals and other forms of improved information about markets and technology in the industry. But, in addition, he argued that industry growth, especially when concentrated to a particular region, might create a market for skilled labour, advance subsidiary industries or give rise to specialized service industries as well as improve railway communication and other infrastructure. Thus, external economies emerged here essentially as cost reductions for individual firms as a consequence of industry growth, that is, as economies external to the firm but internal to the industry. To remain firmly within the framework of static analysis, these economies should be thought of as being reversible. But some of Marshall’s examples alluded to irreversible phenomena and to dynamic effects of industry growth. This was particularly obvious when he at times referred to external economies as being dependent on the ‘general progress of industrial environment’.

Marshall’s claim that external economies were important in the long run – in fact, more important than internal economies – seemed to have little immediate impact on the thinking of his fellow economists. For example, the discussion of ‘empty economic boxes’ in the early 1920s (Clapham, 1922; Pigou, 1922; Robertson, 1924) centred on questioning the relevance of external economies and diseconomies, the latter concept deriving from issues raised by Pigou (1920). Actually, the significance of technological external economies and diseconomies in the static analysis of an industry or among producers in general escaped most economists all the way up to the post-war years when traffic congestion (although already mentioned by Pigou) and the common pool problem of interdependent producers in an oil field or a fishing area became the leading examples of the industry case and environmental pollution the leading example of the general case. Eventually, diseconomies emerged as the important case and economies as the exceptional case, whereas earlier hardly any importance was attached to technological diseconomies (see, for example, Robertson, 1924).

If static external effects turned out to be the most important legacy of Marshall’s original contribution, external economies as a dynamic concept, which seems closer to Marshall’s own ideas, also came to play a role in economic analysis. Dynamic external economies refer to increased division of labour resulting from industry growth, the emergence of firms specializing in new activities, some of which aim at developing capital equipment for, or servicing, other firms. An early elaboration of these ideas was made by Young (1928). Later, the concept of external economies came to play a prominent role in development planning, primarily for underdeveloped countries or regions. The general idea here was hardly at all related to the non-market interdependence of technological external economies, but rather to the market interdependence of which pecuniary external economies were part, now on an economy-wide basis. It was argued, in particular by Rosenstein-Rodan (1943) and – with a somewhat different focus – by Scitovsky (1954), that development must be planned so that supply and demand relationships among different sectors of the economy are taken into account. Specifically, it was pointed out that major investments in industrial capacity in a poor economy risk being a failure unless a required increase in the supply of inputs to meet the need of the expanding industry, as well as a sufficient stimulus of demand for the output of the expanding industry, occur at the same time. This doctrine of ‘balanced growth’ called for a simultaneous expansion of investment in several sectors of the economy, a ‘Big Push’ (Rosenstein-Rodan, 1943) determined by input–output relations or general market interdependence. Scitovsky argued specifically that indivisibilities in capital formation may call for investment criteria, which – in contrast to those of individual firms – take into account the indirect supply and demand effects on profitability elsewhere in the economy. Here, external economies came to be synonymous with what was later called linkage effects (Hirschman, 1958), where backward linkages refer to the supply to the investing sector and forward linkages to the demand for the output of the investing sector. Hirschman’s own analysis led him to recommend a strategy for economic development in poor countries that was opposite to that of a ‘balanced growth’. Focusing on the shortage of entrepreneurial capacity and the small impact of subtle market signals in backward areas, he advocated a
strategy of ‘unbalanced growth’, according to which investments should be undertaken so as to reinforce market signals and create pressure for investments in sectors related to the original investments via strong linkage effects.

That linkage effects offered a more precise terminology than dynamic external economies is one reason why the latter concept now has lost ground. Another is, of course, that this meaning of external economies referred only or primarily to market interdependence, which is a general economic phenomenon. Thus, with technological external economies and diseconomies now most often replaced by the well-defined concept of external effects, and with pecuniary external economies and diseconomies being synonymous with general market interdependence, external economies no longer have much of a role to play in economic analysis. Aside from occasional use as a synonym for external effects, the concept now stands for interdependence that does not clearly fall into any of the categories mentioned here. That is, when firms affect one another in a way not covered by static equilibrium analysis or by interdependence among existing markets in the context of the dynamic analysis of economic development, external economies are still used by economists as a convenient catchall.

Again, one may ask – as did economists in the interwar period – what do these external economies actually stand for? At least some examples can be given. Growth of an industry may create a supply of new skills which turn out to provide a starting point for an altogether new line of business. Or, growth of a technologically advanced industry in a particular region leading to the location of a school of higher learning to this region may in turn stimulate – or reduce – growth of other activities. These cases are awkward to handle in traditional, well-structured economic analysis. So the main characteristic of these external economies, very much like most of those suggested by Marshall, is that we cannot yet say in any systematic way exactly what they represent.

Externalities are *indirect* effects of consumption or production activity, that is, effects on agents other than the originator of such activity which do not work through the price system. In a private competitive economy, equilibria will not be in general Pareto optimal since they will reflect only *private* (direct) effects and not *social* (direct plus indirect) effects of economic activity. This article explains how this outcome arises and considers the policy responses that have been advanced to remedy the market failures stemming from externalities.

**Article**

Competitive equilibria are Pareto optimal when they exist if preferences are locally non-satiated and if externalities are not present in the economy. Why externalities upset the first fundamental theorem of welfare economics and which economic policies can remedy this failure are the major questions addressed below.

**Technological externalities**

Let us call technological externality the indirect effect of a consumption activity or a production activity on the consumption set of a consumer, the utility function of a consumer or the production function of a producer. By ‘indirect’ we mean that the effect concerns an agent other than the one exerting this economic activity and that this effect does not work through the price system.
Externalities may be positive or negative and are quite diverse. Major examples include pollution activities (air pollution, water pollution, noise pollution ...), malevolence and benevolence, positive interaction of production activities. From a practical point of view the most significant are negative pollution activities, so that we can say that the theory of technological externalities is essentially the foundation of environmental economics.

The formalization of technological externalities is achieved in microeconomics by making production sets, utility functions and production sets (or functions) affected by externalities functionally dependent on the activities of the other agents creating these indirect effects.

For example, the utility function of a consumer is made dependent on the level of production of a firm polluting the air breathed by the consumer. This modelling option that we will implicitly adopt here is right as long as the link between production and air pollution is not alterable.

If de-polluting activities are possible the link between the level of pollution and the economic activities generating them must be made explicit. An important difficulty in analysing these activities is due to the non-convexities which they usually introduce.

**Pecuniary externalities**

During the 1930s, a confused debate occurred between economists on the relevance of pecuniary externalities, that is, on externalities which work through the price system. A quite general consensus was that pecuniary externalities are irrelevant for welfare economics: the fact that by increasing my consumption of whisky I affect your welfare through the consequent increase in price does not jeopardize the Pareto optimality of competitive equilibria.

This is true when all the assumptions required for the competitive equilibria to be Pareto optimal are satisfied. In such a framework prices only equate supply and demand and pecuniary externalities do not matter. As soon as we move away from this set of assumptions prices generally play additional roles.

For example, in economies with incomplete contingent markets, prices span the subspace in which consumption plans can be chosen. In economies with asymmetric information, prices transmit information. When agents affect prices, they affect the welfare of the other agents by altering their feasible consumption sets or their information structures. Pecuniary externalities matter for welfare economics.

In what follows we focus only on technological externalities.

**Competitive equilibrium with externalities**

How is the characterization of Pareto optima in convex economies affected by externalities? Very simply, as Pigou early understood. The classical equality of marginal rates of substitution and marginal rates of transformation must now be expressed using *social* marginal rates and not only *private* marginal rates as in an economy without externalities. Social marginal rates must be computed taking into account direct and indirect effects of economic activities. For example, the marginal cost of a polluting activity must include not only the direct marginal cost of production, but also the marginal cost imposed on the environment.

Note that Pareto optima do not exclude polluting activities, but set them at levels such that their social marginal benefit equates their social marginal cost well computed.
It is now easy to understand that in a private competitive economy, equilibria will not be in general Pareto optimal since the private decentralized optimizations of economic agents lead them to the equalization of *private and not social* marginal rates through the price system.

**Markets for pollution rights**

Consider for concreteness a firm polluting a consumer. One potential solution is to create a market for this externality. Before producing, the firm must buy from the consumer the right to pollute. If both actors were behaving competitively with respect to the price of this right, the competitive equilibrium in the economy with an extended price system would be Pareto optimal, since there is no externality left. A number of difficulties exist with this approach. In general we cannot expect agents to behave competitively unless we are in the special case of impersonal externalities. Then, there is a fundamental non-convexity in the case of negative externalities since as a negative externality increases the production set shrinks, but there is a limit to this effect which is the zero production level. Competitive equilibria cannot then exist unless bounds are set on supplies of pollution rights. (For a positive price, a firm would like to offer an infinite amount of pollution rights and close down.)

In the above set-up, the implicit status quo was the absence of externalities. The initial rights are a clean environment: ‘Polluters must pay.’ We can instead give to the polluting firm the right to pollute and then ask the consumer to buy from the firm a decrease of his pollution. This different allocation of initial rights does not upset the Pareto optimality of the competitive equilibrium, but of course has distributional effects.

**Taxation of externalities**

The likely strategic behaviour by agents on markets of pollution rights makes taxation of externalities the most common policy tool. The polluter must then pay for each unit of a polluting activity a tax which equals the marginal cost imposed by this activity on the other agents. The polluter then internalizes the externality and Pareto optimality is restored. If the externality is positive he must be similarly subsidized.

Note that nothing is said about the amount of taxes so obtained by the government. There is no presumption that it is given to the polluters. In fact, the implicit assumption is that it is redistributed through lump-sum transfers which do not affect agents’ behaviours (in the sense of their first-order conditions). From the point of view of Pareto optimality, the important goal is to modify polluters’ behaviours.

If lump-sum transfers are not available, the budget of the government must be balanced and then goods different from the polluting activities must be taxed or subsidized to solve the ensuing second-best problem.

The major difficulty with this solution is informational.

**Imperfect information**

The traditional theory of externalities has proceeded as if the regulators had complete knowledge of the
economy and were therefore able to compute optimal taxes, or as if agents were not behaving strategically with respect to their private information. Very often this is not the case and the problem is to elicit this private information and use it to compute taxes, a more difficult problem. Intuitively, the solution of what is now a second-best problem is to have taxes which depend non-linearly on polluting activities. This non-linearity may sometimes take the extreme form of a zero tax up to a given amount and a very large tax above, a mechanism which is equivalent to a quota.

Planning and externalities

Externalities are not only a problem of market economies with an insufficient number of markets. One way to suppress an externality between two agents is to have them integrate into a single agent. All externalities would be internalized if the whole economy was integrated. If we leave aside imperfect information and the associated strategic behaviours, the planning problem of these integrated agents is more complicated than if externalities were not present. Planning procedures appropriated to externalities have been provided.

Externalities and cooperative game theory

Suppose we attempt to represent the outcome of cooperation in an economy with externalities by the core. The core is the set of allocations which are not blocked by any coalition. A coalition blocks an allocation if it can do better for all its members than this allocation. Externalities introduce a difficulty in the definition of a blocking coalition. When a group of agents envision forming a coalition they must conjecture what will be the behaviour of the complementary coalition since it is affected by the externalities of this complementary coalition. Two extreme notions have been proposed. In the $\alpha$-core a coalition is said to block an allocation if it can do better, whatever the actions of the complementary coalition. This is extremely prudent. In the $\beta$-core a coalition is said to block an allocation if, for any action of the complementary coalition, it can do better. The $\beta$-core is of course included in the $\alpha$-core. Results depend a lot on these conjectures about the actions of the complementary coalition, an unsatisfactory feature. One lesson, however, is that the core may be empty, that is, that externalities introduce an element of instability in economic games.

Historical note

Following the pioneering work by Sidgwick (1887) and Marshall (1890), Pigou (1920) has provided the basic theory of static technological externalities. Coase (1960) has explained how initial rights could be assigned in various ways. Arrow (1969) has explained how externalities could be internalized by the creation of additional markets. Starrett (1972) has pointed out the associated problem of non-convexity. The first theorem of existence of an equilibrium with externalities has been provided by McKenzie (1955). Shapley and Shubik (1969) studied the core with externalities. A large number of authors have studied various second-best problems associated with externalities (Buchanan, 1969; Plott, 1966;

extremal quantiles and value-at-risk

Abstract

This article examines the theory and empirics of extremal quantiles in economics, in particular value-at-risk. The theory of extremes has gone through remarkable developments and produced valuable empirical findings since the late 1980s. We emphasize conditional extremal quantile models and methods, which have applications in many areas of economic analysis. Examples of applications include the analysis of factors of high risk in finance and risk management, the analysis of socio-economic factors that contribute to extremely low infant birthweights, efficiency analysis in industrial organization, the analysis of reservation rules in economic decisions, and inference in structural auction models.

1 Introduction

1.1 Some basics

Let a real random variable $Y$ have a continuous distribution function $F_Y(y) = \text{Prob}[Y \leq y]$. A $\tau$-quantile of $Y$ is the number $F^{-1}_Y(\tau)$ such that $\text{Prob}[Y \leq F^{-1}_Y(\tau)] = \tau$ for some $\tau \in (0,1)$. (More generally, let $F^{-1}_Y(\tau) = \inf \{y; F_Y(y) > \tau\}$.) The quantile function $F^{-1}_Y(\tau)$, viewed as a function of probability index $\tau$, is the inverse of the distribution function $F_Y(y)$. The quantile function is therefore a complete description of the distribution.

Let $X$ be a vector of regressor variables. Let $F_Y(Y|x) = \text{Prob}[Y \leq y|X]$ denote the conditional distribution function of $Y$ given $X=x$. The conditional $\tau$-quantile of a random variable $Y$ with a continuous conditional distribution function is the number $F^{-1}_Y(\tau|x)$ such that $\text{Prob}[Y \leq F^{-1}_Y(\tau|x)|X = x] = \tau$. The conditional quantile function $F^{-1}_Y(\tau|x)$ viewed as a function of $x$ is called the $\tau$-quantile regression function. The main use of the quantile regression function $F^{-1}_Y(\tau|x)$ is to measure the effect of covariates on outcomes, both in the centre and in the upper and lower tails of an outcome distribution. To this effect, a quantile or a conditional $\tau$-quantile will be referred to as extremal whenever the probability index $\tau$ is either low, $\tau < 0.15$, or high, $\tau > 0.85$. Without loss of generality, we focus the discussion on the low quantiles.

1.2 Examples as a motivation

There are many applications of extremal quantiles in economics, particularly of extremal conditional quantiles. Here we give a sample of these applications as a motivation for what follows.
Example 1: Conditional value-at-risk. Value-at-risk analysis seeks to forecast or explain very low conditional quantiles $F^{-1}_Y(\tau | X)$ of an institution’s portfolio return, $Y$, tomorrow, using today’s available information, $X$ (Chernozhukov and Umantsev, 2001). Typically, extremal quantiles $F^{-1}_Y(\tau | X)$ with $\tau = 0.01$ and $\tau = 0.05$ are of interest. Value-at-risk analysis is a daily activity for banking and other financial institutions, as required by the Securities and Exchange Commission and the Basle Committee on Banking Supervision. As a risk measure, value-at-risk is motivated by the safety-first decision principle formalized by Roy (1952), in which one makes optimal decisions subject to the constraint that the probability of the risk of a large loss is kept small. This and similar measures are commonly used in real-life financial management, insurance, and actuarial science (Embrechts, Klüppelberg and Mikosch, 1997).

Example 2: Determinants of very low birthweights. In the analysis of infant birthweights, we may be interested in how smoking, absence of prenatal care, and other types of maternal behaviour affect various birthweights (Abravaya, 2001). Of special interest, however, are the very low quantiles, since low birthweights have been linked to subsequent health problems. Chernozhukov (2006) provides an empirical study of extreme birthweights.

Example 3: Probabilistic production frontiers. An important form of efficiency analysis in the economics industrial organization and regulation is the determination of efficiency or production frontiers (Timmer, 1971). Given cost of production and possibly other factors, $X$, we are interested in the highest production levels that only a small fraction of firms, the most efficient firms, can attain. These (nearly) efficient production levels can be formally described by extremal quantile regression function, $F^{-1}_Y(\tau | X)$ for $\tau \in [1-\varepsilon,1]$ and $\varepsilon > 0$; so only an $\varepsilon$-fraction of firms produce $F^{-1}_Y(\tau | X)$ or more. The models and methods discussed in this article are highly pertinent for inference on the probabilistic frontiers.

Example 4: $(S,s)$-rules and other approximate reservation rules in economic decisions. A related example is that of $(S,s)$-adjustment models, which arise as optimal policies in many economic models (Arrow, Harris and Marschak, 1951). For example, the capital stock $Z$ is adjusted up to the level $S$ once it has depreciated to some low level $s$. In terms of an econometric specification, we may think that the observed capital stock satisfies the equation $Z_t = s(X_t) + v_t$, where $X_t$ is covariates, and $v_t$ is a disturbance that is positive most of the time, that is, $Pr (v_t \geq 0)$ is close to 1. Once the capital stock $Z_t$ reaches the critical level, that is $Z_t \leq s(X_t)$, it is adjusted in the next period. We assume, as in Caballero and Engel (1999), that when the disturbance $v_t = Z_t - s(X_t)$ is negative, it captures unobserved heterogeneity and small decision mistakes that are independent of observed covariates $X_t$. In this example, $Z_t$ could be any monotone transformation of the stock variable. For instance, the log transformation gives an accelerated failure time model for the capital stock. Caballero and Engel, 1999, explore such specifications for empirical $(S,s)$ models in detail. In a given cross-section or time series, adjustment will occur infrequently, so in fact data at or below the lower adjustment band $s(X_t)$ will be observed with a small probability $Pr (v_t \leq 0)$; hence $F^{-1}_Z(\tau | X) = s(X) + F^{-1}_\varepsilon(\tau)$ for $\tau \in (0, Pr (v \leq 0))$. The lower-band function $s(X)$ therefore coincides with the lower conditional quantile function up to an additive constant. A similar argument works for the upper-band function $S(X)$.

Example 5: Structural auction models. In the standard specification of the first-price procurement auction where bidders hold independent valuations, the winning bid, $B$, satisfies the equation $B = C(X) \beta(n) + \epsilon$, $\epsilon \geq 0$, where $C(X)$ is the efficient cost function and $\beta(n) \geq 1$ is a mark-up that approaches 1 as the number of bidders, $n$, approaches infinity (Donald and Paarsch, 2002). By construction, $C(X) \beta(n)$ is the extreme conditional quantile function. In empirical analysis, it is realistic to let the disturbance $\epsilon$ take some small negative value so that, when negative, these disturbances capture small decision mistakes that are independent of included explanatory variables. In this case the quantile function satisfies $F^{-1}_B(\tau | X, n) = C(X) \beta(n) + F^{-1}_\epsilon(\tau)$, for $\tau \in (0, Pr [\epsilon \leq 0])$. Quantile regression methods can be employed to make inference on $C(X)$ and $\beta(n)$.

1.3 Organization of the article

The rest of the article is organized as follows. Section 2 describes the basic model of extremal quantiles and extremal conditional quantiles. Section 3 describes basic estimation theory and inference theory. Section 4 reviews the key empirical applications and provides an illustrative example. Section 5 concludes.

2. Basic models of extremal quantiles

2.1 A basic model of extremal quantiles

Towards discussing inference methods, assume that the distribution function of the response variable $Y$ has Pareto-type tails, which means that tails behave approximately like power functions. Such tails are prevalent in economic data, as discovered by the prominent Italian econometrician Vilfredo Pareto in 1895 (see Pareto, 1964). Pareto-type tails encompass or approximate a rich variety of tail behaviour, including that of thick-tailed and thin-tailed distributions, having either bounded or unbounded support, and their mathematical theory
in connection to extreme value theory has been developed by Gnedenko (1943) and de Haan (1970).

Consider a random variable \( Y \) and define a random variable \( U \) as \( U \equiv Y \), if the lower end-point of the support of \( Y \) is \(-\infty\), and \( U \equiv Y - F_Y^{-1}(0) \), if the lower end-point of the support of \( Y \) is \( F_Y^{-1}(0) > -\infty \). The distribution function of \( U \), denoted by \( F_U \), then has the lower end-point \( F_U^{-1}(0) = -\infty \) or \( F_U^{-1}(0) = 0 \). The assumption that the distribution function \( F_U \) and its quantile function \( F_U^{-1} \) exhibit Pareto-type behaviour in the tails can be formally stated as the following two equivalent conditions (the notation \( a \sim b \) means that \( a/b \to 1 \) as appropriate limits are taken):

\[
F_U(u) \sim \bar{L}(u) \cdot u^{-1/\xi} \text{ as } u \downarrow F_U^{-1}(0),
\]

\[
F_U^{-1}(\tau) \sim L(\tau) \cdot \tau^{-\xi} \text{ as } \tau \downarrow 0,
\]

for some real number \( \xi \neq 0 \), where \( \bar{L}(u) \) is a nonparametric, slowly varying function at \( F^{-1}(0) \), and \( L(\tau) \) is a nonparametric slowly varying function at 0. (A function \( u \mapsto L(u) \) is said to be slowly varying at 0 if \( \lim_{m \to \infty} [L(m) / L(m^m)] = 1 \) for any \( m > 0 \).) The prime examples of slowly varying functions are the constant function \( L(y) = L \) and the logarithmic function.

The number \( \xi \) defined in (2.1) and (2.2) is called the extreme value (EV) index. The absolute value \( |\xi| \) of the EV index \( \xi \) measures heavy tailedness of distributions. A distribution \( FY \) with Pareto-type tails necessarily has a finite lower support point if \( \xi < 0 \) and an infinite lower support point if \( \xi > 0 \). Distributions with \( \xi > 0 \) include stable distributions, Pareto distributions, \( t \) distributions, and many others. For example, the \( t \) distribution with \( \nu \) degrees of freedom has the EV index \( \xi = 1/\nu \) and exhibits a wide range of tail behaviour. In particular, setting \( \nu = 1 \) yields the Cauchy distribution which has heavy tails (with \( \xi = 1 \)), while setting \( \nu = 30 \) yields approximately the normal distribution which has light tails (with \( \xi = 1/30 \)). On the other hand, distributions with \( \xi < 0 \) include the uniform, exponential, Weibull distributions, and others.

The assumption of Pareto-type tails can be equivalently cast in terms of the regular variation assumption, as is commonly done in EV theory. Distribution function \( F_U \) is said to be regularly varying at \( F_U^{-1}(0) \) with index of regular variation \(-1/\xi \) if

\[
\lim_{\nu \downarrow \infty} \nu \cdot F_U^{-1}(\nu m) / F_U(\nu) = m^{-1/\xi}, \text{ for any } m > 0.
\]

for any \( m > 0 \). This condition is equivalent to the regular variation of quantile function \( F_U^{-1} \) at 0 with index \(-\xi \):

\[
\lim_{\tau \downarrow 0} (F_U^{-1}(\tau m) / F_U^{-1}(\tau)) = m^{-\xi}, \text{ for any } m > 0.
\]

It should be mentioned that the case of \( \xi = 0 \) corresponds to the class of rapidly varying distribution functions. These distribution functions have exponentially light tails, with the normal and exponential distributions being the chief examples. To simplify exposition, we do not discuss this case explicitly. However, since the limit distribution of main statistics are continuous in \( \xi \), including at \( \xi = 0 \), inference theory for the case of \( \xi = 0 \) can be adequately approximated by the case of \( \xi \approx 0 \).

2.2 A basic model of extremal conditional quantiles
Consider the classical linear functional form for the conditional quantile function of $Y$ given $X=x$:

$$F_Y^{-1}(\tau|x) = x' \beta(\tau), \text{ for all } \tau \in \mathcal{F} = (0, \eta], \text{ some } \eta \in (0, 1)$$

(2.3)

and for every $x$ in the support of $X$. This linear functional form is flexible in the sense that it has good approximation properties. Given the original regressor $X^*$, the final set of regressors $X$ to be used in estimation can be formed as a vector of approximating functions. For example, $X$ may include power functions, splines, and other transformations of $X^*$. The linear functional form also provides computational convenience.

The following model for the tails and its generalizations were developed in Chernozhukov (2005). The main assumption is that the response variable $Y$, transformed by some auxiliary regression line, has regularly varying tails with EV index $\xi$. Indeed, in addition to (2.3), suppose there exists an auxiliary parameter $\beta_e$ such that the disturbance $U \equiv Y - X' \beta_e$ has conditional end-point 0 or $-\infty$ a.s. and its conditional quantile function $F_U^{-1}(\tau|x)$ satisfies the following tail-equivalence relationship as $\tau \searrow 0$, uniformly for $x$ in the support of $X$:

$$F_U^{-1}(\tau|x) = F_Y^{-1}(\tau|x) - x' \beta_e \sim F_\omega^{-1}(\tau),$$

(2.4)

where $F_\omega^{-1}$ is a quantile function such that

$$F_\omega^{-1}(\tau) \sim L(\tau) \tau^{-\xi},$$

(2.5)

where $L(\tau)$ is a non-parametric slowly varying function at 0. Equation (2.5) imposes Pareto-type behaviour on the conditional law, while equation (2.4) requires this behaviour to hold uniformly across conditioning values. Since this assumption only affects the tails, it allows covariates to impact the extremal quantiles and the central quantiles very differently; the impact of covariates on extremal quantiles is approximated by $\beta_e$, which could differ sharply from, for example, the impact on the median given by $\beta (1/2)$. Chernozhukov (2005) provides further generalizations of this model.

3 Basic estimation methods

3.1 Estimates based on sample quantiles

Given $T$ observations $\{Y_t, t=1, \ldots, T\}$, the $\tau$-sample quantile can be obtained by solving the following optimization problem:

$$\hat{F}_Y^{-1}(\tau) = \arg \min_{\beta \in \mathbb{R}^p} \frac{1}{T} \sum_{t=1}^{T} \rho_\tau(Y_t - \beta),$$

where \( \rho_T(u) = (\tau - 1(\tau < 0))u \) is the asymmetric absolute deviation function of Fox and Rubin (1964).

Sample quantiles are also order statistics, and we will refer to \( \tau/T \) as the order of \( \tau \)-quantile. The sequence of quantile index-sample size pairs \((\tau, T)\) will be said to be an extreme order sequence if \( \tau \gg \Omega \) and \( \tau T \to \infty \), an intermediate order sequence if \( \tau \gg \Omega \) and \( \tau T \to \infty \), and a central order sequence if \( \tau \) is fixed and \( T \to \infty \). Each different type of the sequence leads to different asymptotic approximations to the finite-sample distributions of sample quantiles. Extreme order sequences lead to non-normal (extreme-value) distributions (EV) that approximate the finite sample distributions of extremal (high and low) quantiles much better than the normal distributions do. In particular, EV distributions work much better than the normal distribution if \( \tau T \leq 3\Omega \).

### 3.1.1 Extreme order quantiles

Consider an extreme-order sequence. The following is the classical result on the limit distribution of order statistics: for any integer \( k \geq 1 \) and \( \tau = k/T \), as \( T \to \infty \),

\[
A_T(\hat{F}^{-1}_Y(\tau) - F^{-1}_Y(\tau)) \to \log^{-\xi} \Gamma_k - k^{-\xi}
\]

(3.7)

where

\[
A_T = 1 / F^{-1}_U(1/T), \quad \Gamma_k = \hat{\xi}_1 + \cdots + \hat{\xi}_k
\]

(3.8)

and \((\hat{\xi}_1, \hat{\xi}_2, \ldots)\) is an independent and identically distributed sequence of standard exponential variables.

Result (3.7) was obtained by Gnedenko (1943) under the assumption that \( Y_1, Y_2, \ldots \) is a sequence of independently and identically distributed (i.i.d.) random variables. Result (3.7) continues to hold for stationary weakly dependent series, provided the probability of extreme events occurring in clusters is negligible relative to the probability of a single extreme event (Meyer, 1973). The results have been generalized to more general time series processes (Leadbetter, Lindgren and Rootzén, 1983).

Result (3.7) gives an EV distribution as an approximation to the finite-sample distribution of \( \hat{F}^{-1}_Y(\tau) \). The EV distribution is characterized by the EV index \( \hat{\xi} \), which can be estimated by one of the methods described below. Variables \( \Gamma_k \), entering the definition of the EV distribution, are known as gamma random variables. The limit distribution of the \( k \)th-order statistic is therefore a transformation of a gamma variable. The EV distribution is not symmetric and may have significant (median) bias. The EV distribution has finite moments if \( \hat{\xi} < 0 \) and has finite moments of up to order \( 1/\hat{\xi} \) if \( \hat{\xi} > 0 \).

The classical result is not feasible for purposes of inference on \( \tau \), since the scaling constant \( A_T \) is not easily estimable consistently. One way to overcome this problem is to make additional strong assumptions in order to estimate \( A_T \) consistently. For instance, suppose that \( F^{-1}_U(\tau) \sim L\tau^{-\xi} \), then one can estimate \( \hat{\xi} \) using methods described below and \( L \) by

\[
\hat{L} = (\hat{F}^{-1}_Y(2\tau) - \hat{F}^{-1}_Y(\tau)) / (2^{-\hat{\xi} - 1}) \tau^{-\hat{\xi}}
\]

Another way to overcome the aforementioned infeasibility is to consider the asymptotics of self-normalized extreme order quantiles, as in Chernozhukov (2006):
where for $m > 1$ such that $mk$ is an integer,

$$Z_T(\tau) = A_T \left( \hat{\xi}_Y^{-1}(\tau) - \Gamma_Y^{-1}(\tau) \right) \sim \frac{\sqrt{k(\Gamma_k^{-\xi} - k^{-\xi})}}{\Gamma_{mk}^{-\xi} - \Gamma_k^{-\xi}}$$

(3.9)

Here, the scaling factor $A_T$ is feasible in that it is completely a function of data. The limit distribution only depends on the EV index $\xi$, and its quantiles can be easily calculated analytically or by simulation.

### 3.1.2 Intermediate order quantiles

Consider next an intermediate order sequence. As $\tau \searrow 0$ and $T \to \infty$, under further regularity conditions,

$$Z_T(\tau) = A_T \left( \hat{\xi}_Y^{-1}(\tau) - \xi_Y^{-1}(\tau) \right) \sim \mathcal{N}\left( 0, \frac{\xi^2}{(m^2 - 1)^2} \right),$$

(3.11)

where $A_T$ is defined as in (3.10). This result, obtained by Dekkers and de Haan (1989), gives a normal asymptotic approximation to the finite-sample distribution of sample quantile $\hat{\xi}_Y^{-1}(\tau)$. The main condition for application of this distribution is that $T \to \infty$. In finite samples, we may interpret this as requiring that $T \geq 30$ at the minimum.

The normal approximation (3.11) is convenient, but extreme approximation (3.9) is always better, because it does not fail when $T \to k < \infty$ and it coincides with the normal approximation (3.11) once $k$ is large.

### 3.1.3 Extremal bootstrap

In many cases it is convenient to implement inference using the following approach. Consider the sample of i.i.d. variables:

$$\langle Y_1, \ldots, Y_T \rangle = \left( \frac{\xi_1^{-\xi} - 1}{-\xi}, \ldots, \frac{\xi_T^{-\xi} - 1}{-\xi} \right)$$

(3.12)
where \( \langle \xi_1, \ldots, \xi_T \rangle \) is an i.i.d. sequence of standard exponential variables. \( (Y_t, \text{ defined in this way, follows generalized extreme value distribution, which nests the Frechet, Weibull, and Gumbell distributions. There are other possibilities, for example, } (\xi_1, \ldots, \xi_T) \text{ in (3.13) can be replaced by uniform variables } (U_1, \ldots, U_T), \text{ in which case } Y_t \text{ follows the generalized Pareto distribution.) Variables generated in this way have the quantile function:

\[
F_{Y_t}^{-1}(\tau) = \left[ -\ln (1 - \tau) \right]^{-\xi} - \frac{1}{\xi}.
\]

Observe that \( F_{Y_t}^{-1}(\tau) - 1 / \xi \sim \tau^{-\xi} / \xi \), so condition (2.1) is satisfied. We propose to estimate the finite-sample distributions of \( Z_T(\tau) = A_T(\hat{F}_{Y_t}^{-1}(\tau) - F_{Y_t}^{-1}(\tau)) \) by the finite-sample distribution of \( Z_T(\tau) \) for the case when the data follow (3.13). In this way, we reproduce both the EV limit (3.9) and the normal limit (3.11) under extreme and intermediate sequences, and also guarantee good finite-sample performance for the case when (3.13) holds exactly. The simulation can be done using the following algorithm:

1. For each \( i \leq T \), draw \( (Y_1, \ldots, Y_T) \) as i.i.d. according to (3.13), replacing \( \xi \) with a suitable estimate \( \hat{\xi} \). Compute the statistic \( Z_{T,i}(\tau) = A_T(\hat{F}_{Y_t}^{-1}(\tau) - F_{Y_t}^{-1}(\tau)) \).
2. Use quantiles of the simulated sample \( (Z_{T,i}(\tau), i \leq T) \) for inference purposes.

This scheme could be used to estimate distributions of other statistics, including estimators of the EV index and extrapolation estimators. Another method, developed in Chernozhukov (2006), is based on subsampling the self-normalized quantile statistic. This method is less accurate than the extremal bootstrap. However, it applies under more general conditions. It should be noted that the canonical (nonparametric) bootstrap does not work in these settings (Bickel and Freedman, 1981).

### 3.1.4 Confidence intervals for \( \hat{c} \) and bias correction for \( F_{Y_t}^{-1}(\tau) \)

Let the \( \alpha \) -quantile of \( Z_T(\tau) \) be denoted by \( c(\alpha) \). The estimates of \( c(\alpha) \) can be obtained using either EV approximation, normal approximation, or the extremal bootstrap, also having replaced \( \xi \) with a suitable estimate. Denote the resulting estimates by \( \hat{c}(\alpha) \). Then, the median bias-corrected estimate and \( \alpha \)%-confidence region for \( F_{Y_t}^{-1}(\tau) \) can be constructed as

\[
F_{Y_t}^{-1}(\tau) - \frac{\hat{c}(1/2)}{A_T} \quad \text{and} \quad \left[ \hat{F}_{Y_t}^{-1}(\tau) - \frac{\hat{c}(1 - \alpha/2)}{A_T}, \hat{F}_{Y_t}^{-1}(\tau) - \frac{\hat{c}(\alpha/2)}{A_T} \right].
\]

### 3.1.5 Estimators of the EV index \( \xi \)

There are two principal estimators. The first estimator, due to Pickands (1975), relies on the ratio of sample quantile spacings:
\[ \hat{\xi} = -\ln \left[ \frac{\tilde{F}_Y^{-1}(4\tau) - \tilde{F}_Y^{-1}(2\tau)}{\tilde{F}_Y^{-1}(2\tau) - \tilde{F}_Y^{-1}(\tau)} \right] / \ln 2, \]

such that \( \tau \to 0 \) and \( \tau T \to \infty \) as \( T \to \infty \). Under further regularity conditions,

\[ \sqrt{T \tau} (\hat{\xi} - \xi) \xrightarrow{d} \mathcal{N} \left( 0, \frac{\xi^2 (2^{2\xi+1} + 1)}{2 (2^\xi - 1) \ln 2} \right). \]

Another estimator, developed by Hill (1975), is a moments estimator (notation \((x)_-\) means \((x)_-=x\) if \(x<0\) and \((x)_-=0\) if \(x \geq 0\):)

\[ \hat{\xi} = \frac{\sum_{i=1}^{T} \ln (Y_i / \tilde{F}_Y^{-1}(\tau))}{\tilde{F}_Y^{-1}(\tau)} \]

such that \( \tau \to 0 \) and \( \tau T \to \infty \) as \( T \to \infty \). This estimator is applicable only for the case of \( \xi > 0 \). The estimator can be motivated by a maximum likelihood method that fits an exact power law to the tail data. Under further regularity conditions,

\[ \sqrt{T \tau} (\hat{\xi} - \xi) \xrightarrow{d} \mathcal{N}(0, \xi^2). \]

The methods for choosing \( \tau \) are described in Embrechts, Klüppelberg and Mikosch (1997). The variance of estimators decreases as \( \tau \) increases, but the bias (relative to the true \( \xi \)) goes up. Another view on the choice of \( \tau \) is the following: statistical models are approximations, not literal descriptions of the data. In practice, dependence of \( \hat{\xi} \) on the threshold \( \tau \) reflects that power laws with different values of \( \xi \) fit better different tail regions. Therefore, if the interest lies in making inference on \( \hat{\xi} \) for a particular \( \tau \), it seems reasonable to use \( \hat{\xi} \) constructed using the same \( \tau \) or most similar \( \tau \), subject to the condition that \( \tau T \geq 30 \). (The latter condition requires that a sufficient sample be available to estimate \( \xi \).)

The limit results above can be used for the construction of confidence regions. As an alternative, we can apply extremal bootstrap to statistic \( Z_T = \sqrt{T \tau} (\hat{\xi} - \xi) \) to estimate the quantiles of \( Z_T \). Given the estimated \( \alpha \)-quantiles \( \hat{\xi}(\alpha) \), we can construct the median bias-corrected estimate and \( \alpha \) %-confidence regions for \( \xi \).

### 3.1.6 Extrapolation estimators

When very extreme quantiles cannot be estimated precisely, the following strategy is sensible: estimate less extreme quantiles reliably, and then extrapolate these estimates using the...
assumptions on tail behaviour stated earlier. Dekkers and de Haan (1989) developed the following extrapolation estimator:

\[
\hat{F}_Y^{-1}(\tau \varepsilon) = \frac{(\tau \varepsilon / \tau)^{-\xi} - 1}{\tau^{-\xi} - 1} \left[ \hat{F}_Y^{-1}(2\tau) - \hat{F}_Y^{-1}(\tau) \right] + \hat{F}_Y^{-1}(\tau),
\]

(3.19)

where \( \tau \varepsilon \ll 1 \). Another useful estimator, which is valid only for the case of \( \xi > 0 \), is the following:

\[
\hat{F}_Y^{-1}(\tau \varepsilon) = (\tau \varepsilon / \tau)^{-\xi} \cdot \hat{F}_Y^{-1}(\tau),
\]

(3.20)

where \( \tau \varepsilon \ll 1 \). The above estimators have good properties provided the quantities on the right-hand side of (3.19) and (3.20) are well estimated, which requires that \( \tau \ T \) be large, and that the tail model be a good approximation of the underlying true tail.

3.2 Estimates based on sample regression quantiles

Given \( T \) observations \( \{Y_t, X_t, t = 1, \ldots, T\} \), the quantile regression estimate of \( \beta \) is given by:

\[
\hat{\beta}(\tau) = \underset{\beta \in \mathbb{R}^d}{\arg \min} \sum_{t=1}^{T} \rho_\tau(Y_t - X_t \beta),
\]

(3.21)

where \( \rho_\tau(u) = (\tau - 1(u < 0))u \). Quantile regression was introduced by Laplace (1818) for the median case. Koenker and Bassett (1978) extended this formulation to other quantiles.

3.2.1 Extreme order asymptotics

Chernozhukov (2005) derives asymptotic distributions of regression quantiles under extreme-order sequences. Consider the canonically normalized QR statistic

\[
\hat{Z}_T(k) = A_T(\hat{\beta}(\tau) - \beta(\tau)), \text{ where } A_T = 1 / F_0^{-1}(1 / T),
\]

(3.22)

and the self-normalized QR statistic

\[
\hat{Z}_T(k) = \frac{1}{\hat{F}_Y^{-1}(1 / T)} \left[ \hat{F}_Y^{-1}(\tau) - \hat{F}_Y^{-1}(\tau \varepsilon) \right],
\]

(3.23)
where \( T(m-1) > d \). The first statistic uses an infeasible canonical normalization, while the second statistic uses a feasible normalization. Then as \( \tau T \to k > 0 \) and \( T \to \infty \)

\[
\zeta_{\tau T} \to \mathcal{N}(0, \tau^2)
\]

\[
\zeta_{\infty}(k) = \arg \min_{\xi \in \mathbb{R}} \left[ -kE(X_i')z + \sum_{i=1}^{\infty} \left[ X_i'z - \Gamma_i^{-1/2}(\xi) \right]^2 \right] \quad (\xi < 0)
\]

\[
\zeta_{\infty}(k) = \arg \min_{\xi \in \mathbb{R}} \left[ -kE(X_i')z + \sum_{i=1}^{\infty} \left[ X_i'z + \Gamma_i^{-1/2}(\xi) \right]^2 \right] \quad (\xi > 0)
\]

where \( \{\Gamma_1, \Gamma_2, \ldots\} = \{\xi_1, \xi_1 + \xi_2, \ldots\} \) and \( \{\xi_1, \xi_2, \ldots\} \) is an i.i.d. sequence of exponential variables that is independent of \( \{X_1, X_2, \ldots\} \). Further, for any \( m \) such that \( k(m-1) > d \),

\[
Z_{\tau T} \to \mathcal{N}\left(0, \sqrt{\frac{k\zeta_{\infty}(k)}{E[X'_i]} (Z_{\infty}(mk) - Z_{\infty}(k))} \right)
\]

The results hold under the assumption that the data come from either an i.i.d. sequence or a stationary weakly dependent sequence with extreme events satisfying a non-clustering condition.

Related results for canonically normalized statistics for the case where \( \tau T \to 0 \) as \( T \to \infty \) have been obtained by Knight (2001) and Portnoy and Jureková (1999).

3.2.2 Intermediate order asymptotics

Chernozhukov (2005) shows that under intermediate order sequences, as \( \tau \to 0 \) and \( \tau T \to \infty \),

\[
Z_{\tau T} = \mathcal{N}\left(0, \frac{\zeta_{\infty}^2}{m^{-1/2} - 1} \right)
\]
where $A_T$ is defined as in (3.23). Like the result under extreme order sequences, this result holds under the assumption that the data come either from an i.i.d. sequence or from a stationary weakly dependent sequence with extreme events satisfying a non-clustering condition.

3.2.3 Extremal bootstrap

In practice, it is convenient to implement inference by constructing a bootstrap model that approximates the tail features of the true conditional quantile model under the assumptions of Section 2.2; then using this model to simulate the distributions of estimators of extreme quantiles and tail parameters.

Consider the sample

$$((Y_1, X_1), \ldots, (Y_T, X_T)) = \left(\left(\frac{\xi^{-\xi} - 1}{-\xi}, X_1\right), \ldots, \left(\frac{\xi^{-\xi} - 1}{-\xi}, X_T\right)\right),$$

(3.27)

where $(\xi_1, \ldots, \xi_T)$ is an i.i.d. sequence of standard exponential variables and $(X_1, \ldots, X_T)$ is a fixed set of observations on regressors that we have. Variable $Y_t$ generated in this way has the conditional quantile function

$$F_Y^{-1}(t|X_t) = X_t \beta(t),$$

(3.28)

where $\beta(t) = \left(\frac{[\ln(1 - \tau)]^{-\xi} - 1}{-\xi}, 0, \ldots, 0\right)'$.

Observe that $F_Y^{-1}(t|X_t) - 1 / \xi - \tau^{-\xi} / \xi$, so the model satisfies conditions (2.4) and (2.5), as does the true conditional quantile model under our assumptions. Hence we can estimate the finite-sample distributions of $Z_T(t) = A_T(\hat{\beta}(t) - \beta(t))$ by the finite-sample distribution of $Z_T(t)$ in the case when data follows (3.27). In this simple way, we can replicate both the EV approximation (3.26) and the normal approximation (3.24) and also guarantee good finite-sample performance for the case when the model (3.27) holds. The simulation can be done using the following algorithm:

1. For each $i \leq \xi$, draw data according to (3.27), replacing $\xi$ with a suitable estimate $\hat{\xi}$. Compute the statistic $Z_{T,i}(t) = A_T(\hat{\beta}(t) - \beta(t))$.
2. Use the empirical distribution of the simulated sample $(Z_{T,i}(t)), i \leq \xi$ for inference.

This method can also be used to estimate distributions of estimators of the EV index and extrapolation estimators described below.

3.2.4 Confidence intervals and bias corrected estimates

Suppose we are interested in the parameter $\psi' \beta(\tau)$ for some non-zero vector $\psi$. Let the $\alpha$-quantile of $\psi' Z_T(\tau)$ be denoted by $c(\alpha)$. Having replaced $\xi$ with a suitable estimate, the estimates of $c(\alpha)$ can be obtained using either the EV approximation, normal approximation or the extremal bootstrap. Denote the resulting estimates by $\hat{c}(\alpha)$. The
median-bias corrected estimator and the $\alpha$ %-confidence interval for $\psi' \beta (\tau)$ can be constructed as

$$
\psi' \hat{\beta} (\tau) - \frac{\hat{\xi}(1/2)}{A_T} \quad \text{and} \quad \left[ \psi' \hat{\beta} (\tau) - \frac{\hat{\xi}(\alpha/2)}{A_T}, \psi' \hat{\beta} (\tau) - \frac{\hat{\xi}(1 - \alpha/2)}{A_T} \right].
$$

(3.29)

3.2.5 Estimators of the EV index $\xi$

The following estimators are regression analogs of the Pickands and Hill estimators. The first estimator takes the form

$$
\hat{\xi} = -\ln \left[ \frac{\hat{F}_Y^{-1}(2\eta \bar{X}) - \hat{F}_Y^{-1}(2\tau \bar{X})}{\hat{F}_Y^{-1}(2\eta \bar{X}) - \hat{F}_Y^{-1}(\eta \bar{X})} \right] / \ln 2,
$$

(3.30)

where $\bar{X}$ is the average value of $X_t$. Under additional regularity conditions, as $\tau \downarrow 0$ and $\tau T \to \infty$

$$
\sqrt{T} (\hat{\xi} - \xi) \to \sigma N \left( 0, \frac{\xi^2 (2^{2\xi+1} + 1)}{(2 (\xi - 1) \ln 2)^2} \right).
$$

(3.31)

The second estimator, which is applicable when $\xi > 0$, takes the form:

$$
\hat{\xi} = -\frac{\sum_{t=1}^{T} \ln (Y_t / \hat{F}_Y^{-1}(\eta X_t)) -}{T}.
$$

(3.32)

Under additional regularity conditions, as $\tau \downarrow 0$ and $\tau T \to \infty$

$$
\sqrt{T} (\hat{\xi} - \xi) \to \sigma N (0, \xi^2).
$$

(3.33)
The limit results above can be used for the construction of confidence regions. An alternative approach is to apply the extremal bootstrap to statistic $Z_T = \sqrt{T} (\hat{\xi} - \xi)$ to estimate the quantiles of this statistic. Then we can use estimated $\alpha$-quantiles $\hat{\xi}(\alpha)$ for constructing the median bias-corrected estimate and $\alpha$%-confidence regions for $\xi$:

\[
\hat{\xi} - \frac{\hat{\xi}(1/2)}{\sqrt{T}} \quad \text{and} \quad \left[ \hat{\xi} - \frac{\hat{\xi}(1 - \alpha/2)}{\sqrt{T}}, \hat{\xi} - \frac{\hat{\xi}(1 + \alpha/2)}{\sqrt{T}} \right].
\]

### 3.2.6 Extrapolation estimators

By analogy with the unconditional case, the extrapolation estimators for $\hat{F}^{-1}_Y (\tau \ell | x)$, where $\tau \ell$ is a very low value, can be constructed as

\[
\hat{F}^{-1}_Y (\tau \ell | x) = \frac{\tau \ell / \tau}{m^{-\hat{\xi}} - 1}[\hat{F}^{-1}_Y (m\ell | x) - \hat{F}^{-1}_Y (\ell | x)] + \hat{F}^{-1}_Y (\ell | x),
\]

\[
(3.35)
\]

\[
\hat{F}^{-1}_Y (\tau \ell | x) = (\tau \ell / \tau)^{-\frac{\hat{\xi}}{m}} \hat{F}^{-1}_Y (\ell | x) (\xi > 0),
\]

\[
(3.36)
\]

where $\tau \ell \ll \tau$. Note that the estimator (3.36) is valid only in the case $\hat{\xi} > 0$. The comments given for the unconditional case apply here as well. Also, we can construct confidence regions for $\hat{F}^{-1}_Y (\tau \ell | x)$ based on extrapolation estimators. This can be done by applying the extremal bootstrap to statistic $Z_T = A_T [\hat{F}^{-1}_Y (\tau \ell | x) - \hat{F}^{-1}_Y (\ell | x)]$ where $A_T = \sqrt{T} / \hat{\xi} \cdot (\hat{\xi}(2\tau) - \hat{\xi}(\tau))$.

### 4 Empirical applications: an overview and an illustration

#### 4.1 A simple overview

The following review is not exhaustive by any means; it aims to provide only a few quintessential references.

#### 4.1.1 Extremal unconditional quantiles
As mentioned in Section 2, Pareto analysed income and wealth data in 1895 and suggested that power laws accurately describe the tail data. Pareto's discovery, although remarkably simple, had a profound effect on both empirics and the theory of extremes. Zipf (1949), Mandelbrot (1963), Fama (1965), Praetz (1972), Sen (1973), Jansen and de Vries (1991), and Longin (1996), among others, gave further empirical evidence on the nature and prevalence of Pareto-type laws in economic data, including city sizes, incomes, and financial returns. It should be mentioned that many of the early studies were highly informal in nature. The theoretical work in extreme value theory has opened paths for better analysis. From this aspect, the study of Jansen and de Vries (1991) can be singled out as it gave, to our knowledge, the first highly rigorous analysis of the tail properties of financial returns. Jansen and de Vries (1991) estimate the EV indices for various primary US stocks to be between $\xi = 1/5$ and $\xi = 1/3$. Using quantile extrapolation estimators to estimate value-at-risk, they also conclude that the 1987 market crash was not an outlier. Rather it was a rare event, the magnitude of which could have been predicted using prior data. This study stimulated numerous other studies that rigorously document the tail properties of economic data (Embrechts, Klüppelberg and Mikosch, 1997).

4.1.2 Extremal conditional quantiles

There has been considerably less work on conditional methods. However, following recent theoretical advances we expect that this area will see active development in the near future. In what follows, we merely highlight some of the topics and directions.

In what might be the earliest example of conditional quantile analysis, Quetelet (1871) fitted various conditional quantile curves to age–height data. Remarkably, Quetelet's work included tabulations of very high and very low quantiles of heights as a function of age. There is a great potential for the applications of extremal quantile regression methods in similar problems. In a recent study, Chernozhukov (2006) estimates the impact of smoking and maternal behaviour on extremely low birthweights in the United States, focusing on black mothers. He finds that the impact of these variables on birthweights in the ranges between 250 and 1,500 grams sharply differs from their impact on the central birthweights. For instance, smoking is not correlated with extremal birthweights, while quality of prenatal medical care is strongly linked to extremal birthweights. Aigner and Chu (1968), Timmer (1971), and Aigner, Amemiya and Poirier (1976) pioneered a large empirical literature on production frontiers. A major problem of the subsequent empirical literature has been the lack of statistical methods for construction of reliable estimates and confidence regions. The new methods discussed in Section 3 solve the problem, and should improve the rigour of the empirical work in this area.

There is a considerable appeal for the use of extremal conditional quantile methods in auction models. An important study that illustrates the potential is by Donald and Paarsch (2002), who analyse an empirical structural auction model. They estimate the conditional support function of bids using extreme order statistics for each covariate cell, then project the estimated function onto a lower dimensional structural function implied by the model via a minimum-distance method. A generalization of this approach is to employ extremal quantile regression for estimation of the (approximate) support function in the first stage. (The use of near-extreme quantile regression for estimation of approximate support functions allows the researcher to discard some outliers that do not conform the model, in the spirit of the discussion given in Section 1.) Value-at-risk is another potentially important area of applications of the extremal quantile regression. Chernozhukov and Umantsev (2001) apply these methods to the problem of forecasting value-at-risk of a major US oil company. They estimate extremal conditional quantiles, using both ordinary and extrapolation methods, and implement confidence regions, using subsampling methods described in Chernozhukov (2006). The section below briefly revisits some of the main qsts of this study.

4.2 An illustrative example

Here we consider a problem of forecasting conditional value-at-risk. We revisit some of the qsts asked in Chernozhukov and Umantsev (2001) with an improved methodology. To implement the analysis, we use algorithms written in R language that rely on Koenker's (2006) quantreg package as the basic platform. The algorithms as well as the data-set can be downloaded from http://www.mit.edu/~vchern/EQR (accessed 23 April 2007). A detailed description of the data-set is given in Chernozhukov and Umantsev (2001).

We estimate the following conditional quantile function for various low values of $\tau$ :

$$F_{Y_t}^{-1}(\tau | X_t) = X_{t,1}^\beta(\tau) + \beta_0(\tau)X_{t,2} + \beta_{12}(\tau)X_{t,2}X_{t,3},$$

(4.37)

where $Y_t$ is the daily (log) return on the stock of Occidental Petroleum, $X_{t,1}$ is the lagged return on spot oil price, $X_{t,2}=Y_{t-1}$ is the lagged own return, and $X_{t,3}$ is the lagged return on the
Dow Jones Industrial Index. There are 2527 observations in the sample.

We first estimate and plot the function \((\tau, t) \mapsto X(t\tau)\) in \((\tau, t)\) space, with \(\tau \leq 0.25\). The graph of this function, shown in Figure 1, gives a good picture of the evolution of risk over time, indicating dates where the predicted risk is especially high. Let us next determine what causes these risk fluctuations.

Figure 1

Table 1 reports the estimates of the coefficients of the model \((4.37)\). The table also reports median bias-corrected estimates and 90 per cent confidence regions, which were obtained using the extremal bootstrap approach described in Section 3. The results show that the primary determinant of the high-risk levels is the market. The further in the tail we go, the larger is the magnitude of the point estimate of the coefficient on the DJI return. Moreover, the confidence region for this coefficient excludes zero even at \(\tau = 0.001\).

We next characterize the tail properties of the conditional quantile model. Table 2 reports the estimates of the EV index \(\xi\) obtained using estimator \((3.32)\). The table also reports median bias-corrected estimates, and 90 per cent confidence regions, which were obtained using the nested approach described in Sections 3.2.3 and 3.2.5. The bias-corrected estimates tend to be stable with respect to the start of the tail determined by probability index \(\tau\). On the basis of Table 2, we take \(\xi = 1/4\) to be the estimate of the EV index.

Having characterized the EV index, we can now estimate very extreme quantiles using extrapolation methods. We set the risk level at \(\tau = 0.0001\), so that the return falls below \(\tilde{F}_{\tau}^{-1}(0.0001|X_i)\) only once per about 30 years, a very rare, extreme event. The extrapolated estimates of 0.0001-quantile are obtained using equation \((3.36)\) with \(\tau = 0.05\) and \(\tilde{\xi} = 1/4\). The resulting extrapolation fit \(\tilde{F}_{\tau}^{-1}(0.0001|X_i)\) sharply differs from the ordinary fit \(\hat{X}_{\tau}(\tau)\) obtained by quantile regression. The reason for this is simple: the ordinary fit uses sample data that likely contains no observations on the extreme events defined above. In sharp contrast, the extrapolated fit uses the tail model and a reliably estimated conditional 0.05-quantile to predict the magnitude of such events. The quality of this prediction clearly depends on whether the tail model is accurate. Figure 2

5 Conclusion

This article examines the theory and empirics of extremal quantiles in economics. The theory of extremes provides a set of applicable methods that have generated numerous valuable empirical findings. There is equally promising scope for the use of the extremal conditional quantile methods. The latter methods are new – there are great opportunities for further empirical and theoretical developments.

extreme bounds analysis

Edward E. Leamer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Extreme bounds analysis is a global sensitivity analysis that applies to the choice of variables in a linear regression. Rather than a discrete search over models that include or exclude subsets of the variables, this sensitivity analysis answers the question: how extreme can the estimates be if any linear homogenous restrictions on a selected subset of the coefficients are allowed? When these bounds are too wide to be useful, narrower bounds can be found by restricting the set of prior distributions that underlie the sensitivity analysis.

Article

The analysis of economic data necessarily depends on assumptions that our weak data-sets do not allow us to test. We are forced to choose a limited number of variables in a multivariate analysis, to restrict the functional form, to limit the considered interdependence among observations to special forms, and to make special distributional assumptions. We make these assumptions, not because we believe them, but because we have to. Absent assumptions, our data-sets are utterly useless.

We sometimes put aside the discomfort that our choice of assumptions entails by doing what is conventional, like using a normal distribution, a linear functional form and the same limited set of variables studied by almost everyone else.

We sometimes pretend to treat the problem of choice of assumptions by using ‘nonparametric’ methods that masquerade as assumption-free. These methods are assumption-free only in Asymptopia, the land where all data-sets are unlimited. To get to the happy land of Asymptopia, we need only let the number of tested assumptions grow in the future more slowly than the number of observations. Then we can be sure to test all assumptions during our journey into the future. But here on Earth we have limited data-sets, and inevitably the way we analyse these data works well for some sets of assumptions and not so well for others. We cannot really know what we are doing unless we can draw some kind of line between the assumptions for which our inferences are valid and the assumptions for which our inferences are not valid. Thus, for example, ‘heteroscedasticity-consistent’ standard errors are now commonly deployed as if they were corrections for any form of heteroscedasticity. But these corrections of the standard errors, which leave the point estimates unchanged, are an appropriate treatment given the actual limited data only for some forms of heteroscedasticity, not for all. Unfortunately, with these ‘nonparametric’ methods, the border between the do-it-with assumptions for which the method works and the not-do-it-with assumptions is impossible to draw. Incidentally, these ‘heteroscedasticity-consistent’ standard errors are often called White-corrected standard errors, to which I respond rhetorically by calling the method ‘White-washing’. If conventions and nonparametric methods are not enough to soften the discomfort with the assumptions we make, we can always fantasize that the choice of assumptions doesn't really matter. We ‘know’ the methods we use work well under conditions that are ‘close’ to the assumptions that underlie them but not well if the departures are great. We hope that the neighbourhood in which the assumptions work is wide enough to encompass the problem at hand. For example, we don’t really think the distribution is normal, but how much could that matter for linear regression? Isn’t it enough to have symmetric unimodal distributions, shaped ‘sort of like’ a normal distribution?

Neither conventions, nor nonparametric sleight-of-hand, nor hope that it doesn’t really matter form an adequate scientific response to doubt about the assumptions that underlie a data analysis. The correct way to deal with ambiguity in the choice of assumptions that are beyond the range of statistical tests is a sensitivity analysis that demonstrates that our assumptions do not in fact matter much. The most common sensitivity analysis involves the choice of variables in linear regression. Rather than reporting just one regression, many researchers offer a table of results, all based on different subsets of the variables. Typically, all the reported regressions have a common set of ‘core’ variables but differ depending on whether or not the regressions include selected ‘doubtful’ variables.

Although it can be comforting to discover that the coefficients of the core variables do not change much when doubtful variables are excluded, this kind of sensitivity analysis leaves open the possibility that there is some combination of doubtful variables that would radically change the result. Has the analyst worked hard enough to find the oddball estimates that these data allow? ‘Extreme bounds analysis’ answers this question. In an extreme bounds analysis, the computer chooses the linear combinations of doubtful variables that, when included in the regressions along with the core variables, produce the most extreme (minimum and maximum) estimates for the coefficient on a selected core variable. There is no way of fudging with the doubtful variables that can produce an estimate outside the extreme bounds. If the extreme bounds interval is small enough to be useful, that is the end of the story, and the result is reported to be ‘sturdy’. This would occur, for example, when the core variables and the doubtful variables are ‘independent’, in which case the effects of the core variables don’t change at all when doubtful variables are excluded. But quite often with highly correlated economics data these extreme bounds can be uncomfortably wide, and we are forced either to retreat in dismay or to seek some way to make the bounds narrower.

One way of restricting the range of alternative models is to allow only inclusion/exclusion options, not the all linear combinations embodied in the extreme bounds. These inclusion/exclusion restrictions are the basis for the tables of alternative results that are commonly offered as evidence of inferential stubbedness, and the set of alternative estimates thus presented is smaller than the extreme bounds set.

Another way to restrict inclusion/exclusion options is to consider the estimates of the coefficients of the doubtful variables. But why? Why restrict to inclusion/exclusion options? Classical inference is not well suited to respond to this ‘why?’ question since the answer depends on the state of mind of the analyst and since classical inference presumes a researcher and an audience with a ‘blank slate’. Moreover, the effect on the inferences of setting a regression coefficient to zero depends on the assumptions along which the regression is run. If you use $x$ and $z$ as explanatory variables, and I use $x + z$ and $x - z$, we get different answers.) Indeed, the extreme bounds are formed by setting coefficients to zero in an appropriately defined coordinate system, and therefore restriction to inclusion/exclusion restrictions is a meaningless restriction absent advice on how to define the coordinate system.

A Bayesian analysis can help to choose a coordinate system and can be a basis for a sensitivity analysis with a set of models that is sensibly smaller than the set of models underlying the extreme bounds. Bayesians allow the state of mind to influence the analysis by letting a researcher act as if the vector of regression coefficients on the doubtful variables, $\theta$, comes from a normal distribution with a mean vector $\theta$ and covariance matrix $V_0$, selected by the researcher. The smaller is the covariance matrix $V_0$, the more likely are the coefficients $\theta$ to hug close to zero and the more doubtful are the doubtful variables.

To parallel the decision always to include the core variables in the equation, it is natural to deploy a prior probability distribution for the core coefficients with an infinite variance – the blank-slate initial-ignorance option. Then, corresponding to each choice of covariance matrix for the coefficients of the doubtful variables are estimates of the coefficients of the core variables, $\hat{\beta}|\mathcal{V}_2$. If, for example, the covariance matrix $V_0$ is set to zero, this is equivalent to assuming the coefficients of the doubtful variables are all zero, and we should be running the regression with all these doubtful variables omitted. Conversely, if the covariance matrix $V_0$ is set to an ‘infinitely large’ matrix (unlimited variances), then this is the ignorance option for the doubtful

variables, and the way to do the estimation is simply to include all the doubtful variables along with the core variables in the regression.

A 'global' sensitivity analysis in this setting is carried out by building a correspondence between sets of prior covariance matrices for the doubtful variables, $V_0$, and the corresponding sets of estimates of the coefficients on the core variables, $\hat{\beta}(V_0)$. Three possibilities are discussed in Leamer (1978) and Leamer and Chamberlain (1976): (a) $V_0$ unrestricted, (b) $V_0$ diagonal, (c) $V_0$ diagonal with all diagonal elements the same.

1. The extreme bounds apply when the covariance $V_0$ is any positive semi-definite matrix.
2. The 2p regressions, found by including different subsets of the p doubtful variables, define the bound when $V_0$ is a (non-negative) diagonal matrix. (Thus the 'right' coordinate system is the one in which the regression coefficients are a priori independent of each other in the sense that knowledge about one doesn't affect your thinking about the others.)
3. A still narrower set of bounds is found by estimating the p+1 'principal component' regressions with the principal component restrictions ordered by their eigenvalues. This applies when $V_0$ is proportional to the identity matrix.

Each of these three sets of prior covariance matrices includes the dogmatic priors that set certain linear combinations of the coefficients exactly to zero and also complete ignorance priors that allow certain linear combinations to be completely free. Neither of these two extremes is sensible in practice, since in the first case the data evidence is completely ignored (the restriction is imposed without testing) and in the second case the prior information is completely ignored. These can be excluded to restricting the prior covariance matrix from above and below: $V_L < V_0 < V_U$ where $A < B$ means that the matrix $B - A$ is positive definite. The theorem that then applies comes from Leamer (1981, 1982) as is reported below. First, a statement about the posterior mean of the regression coefficient vector.

**Theorem (Bayes estimate):** Let the conditional on the observable matrix $X$, and the unobservable parameters $\beta$ and $\sigma^2$, an observable vector $y$ is normally distributed with mean $X\beta$ and covariance matrix $\sigma^2I$, and if the coefficient vector $\beta$ comes from a normal distribution with mean $b_0$ and covariance matrix $V_0$, then the conditional mean of $\beta$ given $y$ is approximately

$$b_2 = \left( X'X / s^2 + V_0^{-1} \right) ( X' \hat{y} / s^2 + V_0^{-1} b_0)$$

where $s^2$ is the sample estimate of $\sigma^2$:

$$s^2 = y'(I - X(X'X)^{-1} X')y / (n-k),$$

where $n$ is the number of observations and $k$ is the number or regression coefficients and where $b$ is the ordinary least squares estimator (a solution to the normal equations $X'Xb = X'y$).

**Theorem (posterior bounds):** Given $V_L < V_0 < V_U$ with $V_L$ and $V_U$ positive definite and with $V_L < V_0$ signifying that $V_0 - V_L$ is positive definite, then the posterior mean $b_2$ lies in the ellipsoid

$$[b_2 - f]^{\prime} H (b_2 - f) < c$$

where

$$H = (X'X / s^2 + V_0^{-1}) + (X'X / s^2 + V_0^{-1})(V_L^{-1} - V_0^{-1} - (X'X / s^2 + V_0^{-1}))^{-1} (X'X / s^2 + V_0^{-1}) = \left[ (X'X / s^2 + V_0^{-1}) - \frac{1}{2} [X'X / s^2 + V_0^{-1}]^{-1} (X'X / s^2 + V_0^{-1})^{-1} X'X / s^2 \right] c = \left[ b'X'X / s^2 + V_0^{-1} - (V_L^{-1} - V_0^{-1}) (X'X / s^2 + V_0^{-1})^{-1} X'X / s^2 \right] c = \left[ b'X'X / s^2 + V_0^{-1} - (V_L^{-1} - V_0^{-1}) (X'X / s^2 + V_0^{-1})^{-1} X'X / s^2 \right] c$$

Households living in extreme poverty face deprivations that cost millions of lives annually. Ending extreme poverty requires an understanding of poverty traps, including the effects of adverse biophysical and geographical factors, a lack of resources required for the investments needed to escape poverty, and poor governance. Policies must focus both on promoting market-oriented economic growth and on directly addressing the needs of the poor. Foreign aid will be required to finance interventions that poor countries cannot finance themselves, and aid to well-governed poor countries should be increased, consistent with the rich-country promise of 0.7 per cent of GNP as official development assistance.

Article

There are many definitions of poverty, as well as intense debates about the exact numbers of the poor, where they live and how their numbers are changing over time. As a matter of definition, it is useful to distinguish between three degrees of poverty. Extreme (or absolute) poverty, moderate poverty and relative poverty. Extreme poverty can be thought of as ‘poverty that kills’, meaning that households cannot reliably meet basic needs for survival. Households living in extreme poverty are chronically...
undernourished, unable to access health care, lacking the amenities of safe drinking water and sanitation, unable to afford education for some or all of the children, and perhaps lacking rudimentary shelter – a roof to keep the rain out of the hut, a chimney to remove the smoke from the cooking stove – and basic articles of clothing such as shoes. Such deprivations cost lives, by the millions, every year. Life expectancy is considerably lower and mortality rates are considerably higher in countries in which large proportions of the population live in extreme poverty.

Unlike moderate and relative poverty, extreme poverty currently occurs only in developing countries. Moderate poverty generally refers to the conditions of life in which basic needs are met, but only barely. Relative poverty is generally construed as a household income level below a given proportion of average national income. The relatively poor, in high-income countries, lack access to cultural goods, entertainment, recreation, and to quality health care, education, and other perquisites of social mobility. They may also live outside of the ‘mainstream’ of social life, and thus without dignity and social respect.

In order to estimate the number of extreme poor, most analysts use a poverty line – a level of income below which the person is ‘extremely poor’ by some definition. Most countries set their own poverty lines, based on the per capita cost of a consumption basket that attempts to measure basic needs. Since the poorest people in poor countries spend most of their money on food, most of the basket used for national poverty lines consists of food, usually in terms of meeting a minimum intake of 2,000 calories (Deaton, 2004). These poverty lines are surely imperfect: they suffer from the measurement error inherent in household surveys; they are rarely updated with regards to spending on nutrition; they do not account for differences in rural versus urban calorie consumption; and they do not capture all dimensions of extreme poverty (for example, access to health care, safe water, sanitation, education or political voice).

Moreover, they can lead to undesirable policy results (a person just below the poverty lines could be treated very differently from someone just above the line, despite having almost equal incomes). Governments judged solely according to the number of people below the poverty line could choose to focus only on those closest to the line and ignore the poorest of the poor. Finally, as Nobel Laureate Amartya Sen has emphasized, poverty should be defined more broadly than having a low income; rather, it is the absence of basic capabilities to function in society. This could include not only income poverty (involving a lack of food, clothing, or shelter), but also lack of access to public goods, social standing, and political participation. Despite these shortcomings, most dimensions of extreme poverty that people would like to improve are correlated with household income, thus making a poverty line a helpful, though rough, first approximation of poverty rates. Measures that combined household income with provisions of public goods (disease control, public health, primary education) would surely be preferable.

In the late 1980s, and especially with the 1990 World Development Report, the World Bank introduced a single measure of extreme poverty – an income of one dollar per day or less (in 1985 purchasing power parity, PPP, dollars) – in order to compare rates of extreme poverty across countries and to track extreme poverty over time. The one dollar per day number was chosen since it corresponds roughly to the highest national poverty rate among low-income countries (around 360 dollars per year). In 2000, the World Bank used improved PPP estimates to adjust its global poverty line to 1.08 dollars per person per day (in 1993 PPP dollars). This global extreme poverty line has been criticized by some for not being high enough and thus undervaluing the needs of the poor (Pritchett, 2003) and by others for being too arbitrary and detached from the country-specific needs of the poor (Srinivasan, 2004). Nevertheless, it provides a useful, albeit highly imperfect, measuring tool to look at extreme poverty around the world.
Another important indicator for poverty is the Human Development Index (HDI), published by the United Nations Development Programme (UNDP) since 1990. The UNDP sought to incorporate the multidimensional aspects of poverty into a new indicator, and to emphasize that development should expand human capabilities, particularly those that are universally valued and basic to life: the capability to lead a long and healthy life, to be knowledgeable, and to have access to the resources needed for a decent standard of living (UNDP, 2004). The result was the HDI, which averages normalized 0–1 indexes for income per capita, life expectancy, and education school enrolment and literacy. Countries classified as ‘low human development’ have a very strong overlap with those countries that have a high proportion of the population living under one dollar per day according to the World Bank.

Where are the poor?

The most recent estimates of extreme poverty around the world (using the one dollar per day estimate) were made by Shaohua Chen and Martin Ravallion at the World Bank (see Table 1). They estimated that roughly 1.1 billion people were living in extreme poverty in 2001, down from 1.5 billion in 1981 (Chen and Ravallion, 2004). The overwhelming share of the world's extreme poor, 93 per cent in 2001, live in three regions, East Asia, South Asia and Sub-Saharan Africa. Since 1981, the absolute numbers of extreme poor have risen in Sub-Saharan Africa, but have fallen in East Asia and South Asia. In terms of proportions, nearly half Africa's population is judged to live in extreme poverty, and that proportion has risen slightly over the period. The proportion of the extreme poor in East Asia has plummeted, from 58 per cent in 1981 to 15 per cent in 2001; in South Asia the progress has also been marked, although slightly less dramatically, from 52 per cent to 31 per cent. Latin America's extreme poverty rate is around ten per cent, and relatively unchanged; Eastern Europe's rose from a negligible level in 1981 to around four per cent in 2001, the results of the upheavals of Communist collapse and economic transition to a market economy. It is worth noting that these numbers are debated heatedly; other researchers have relied on national income accounts, which tend to show somewhat faster progress in the reduction of Asian poverty, and sometimes very different estimates for the total amount of people living in extreme poverty (Sala-i-Martin, 2002; Bhalla, 2002). The general picture, however, remains true in all these studies: extreme poverty is concentrated in East Asia, South Asia and Sub-Saharan Africa. It is rising in Africa in absolute numbers and as a share of the population, while it is falling both in absolute numbers and as a proportion of the population in the Asian regions.

There are some defining circumstances specific to the poorest of the poor. They are found mainly in rural areas (though with a growing proportion in the cities); the rural poor tend to have fewer opportunities to earn income, have less access to education and health care, and are often more vulnerable to the forces of nature. The extreme poor face challenges almost unknown in the rich world today – malaria, famines, lack of roads and motor vehicles, great distances to regional and world markets, lack of electricity and modern cooking fuels. Women tend to be at a disadvantage compared with men, since they often have less access to property rights (land ownership, inheritance), and since they bear the physical burden of lack of infrastructure (collecting water and fuel wood at great distances). Girls have historically received less primary and secondary education than boys. Labour markets often discriminate against women, and women tend to work longer when one counts unpaid labour at home. Domestic violence continues to burden the lives of millions of women around the world (World Bank, 2001). Finally, large pockets of poverty exist within many countries due to racial and ethnic discrimination, or low social (for example, caste) status.

Consequences of extreme poverty

When individuals suffer from extreme poverty and lack the meagre income needed to cover even basic needs, a single episode of disease, a drought, or a pest that destroys a harvest can be the difference between life and death. In households suffering from extreme poverty, life expectancy is often around half that in the high-income world, 40 years instead of 80 years. It is common that, in the poorest countries of Sub-Saharan Africa, of every 1,000 children born more than 100 die before their fifth birthday, compared with fewer than ten in the high-income world. An infant born in Sub-Saharan Africa today has only a one-in-three chance of surviving to age 65. At the most basic level, the poorest of the poor lack the minimum amount of capital necessary to get a foothold on the first rung of the ladder of economic development. The extreme poor tend to lack six major kinds of capital:

- Human capital: health, nutrition, and skills – education – needed for each person to be economically productive.
- Business capital: the machinery, facilities, motorized transport used in agriculture, industry and services.
- Infrastructure: roads, power, water and sanitation, airport and seaports, and telecommunications systems, which are critical inputs into business productivity.
- Natural capital: arable land, healthy soils, biodiversity, and well-functioning ecosystems that provide the environmental services needed by human society.
- Public institutional capital: commercial law, judicial systems, government services and policing that underpin the peaceful and prosperous division of labour.
Knowledge capital: the scientific and technological know-how that raises productivity in business output and the promotion of physical and natural capital.

Importantly, the poorest of the poor tend to have higher fertility rates, for several reasons. Infant mortality rates are high when there are inadequate health services, so high fertility provides ‘insurance’ to parents that they will succeed in raising a child who will survive to adulthood. In rural areas, children are often perceived as economic assets who provide supplementary labour for the farm household. Poor and illiterate women have few job opportunities away from the farm, and so may place a low value on the opportunity (time) costs of bringing up children. In addition, women are frequently unaware of their reproductive rights (including the right to plan their families) and lack access to reproductive health information, services, and facilities, leading to high unmet demands for contraception in low-income countries and among poorer members of all developing countries. Finally, poor households lack the income to purchase contraceptives and family planning, even when they are available. For these reasons, high fertility rates are prevalent among families living in extreme poverty, resulting in very low investments in the health and education of each child (what is known as the quantity–quality trade-off). Poor and hungry societies are much more likely than high-income societies to fall into violent conflicts over scarce vital resources, such as watering holes and arable land – and over scarce natural resources, such as oil, diamonds and timber (United Nations, 2004). This relationship between violence and high rates of extreme poverty holds with a high degree of statistical significance. A country with a civil war within its borders typically has only one-third of the per capita income of a country with similar characteristics but at peace. Moreover, poor countries – even those not in conflict – risk conflict in the future. A country with a per capita income of 500 dollars is about twice as likely to have a major conflict within five years as a country with an income of about 4,000 dollars per capita (UN Millennium Project, 2005). In addition, low economic growth rates are associated with higher risks of new conflict; one study finds that a negative growth shock of five per cent increases the risk of civil war by 50 per cent in the following year, and that economic conditions are probably the most important determinants of civil conflict in Sub-Saharan Africa (Miguel, Satyanath and Sergenti, 2004). The most comprehensive study of state failure, carried out by the State Failure Task Force established by the Central Intelligence Agency in 1994, confirms the importance of the economic roots of state failure (defined as revolutionary war, ethnic war, genocide, politicide, or adverse or disruptive regime change). The Task Force studied all 113 cases of state failure between 1957 and 1994 in countries of half a million people or more, and found that the most significant variables explaining these conflicts were the infant mortality rate (suggesting that overall low levels of material well-being are a significant contributor to state failure), openness of the economy (more economic linkages with the rest of the world diminish the chances of state failure), and democracy (democratic countries show less propensity to state failure than authoritarian regimes). The linkage to democracy also has a strong economic dimension, however, because research has shown repeatedly that the probability of a country’s being democratic rises significantly with its per capita income level. In refinements of the basic study, the Task Force found that in Sub-Saharan Africa, where many societies live on the edge of subsistence, temporary economic setbacks (measured as a decline in gross domestic product per capita) were significant predictors of state failure (State Failure Task Force, 1999). Similar conclusions have been reached in studies on African conflict, which find that poverty and slow economic growth raise the probability of conflict.
Theories of extreme poverty

For decades, observers have tried to explain why extreme poverty persists. Many theories have looked for single-factor explanations for a lack of economic growth, often grounded in racist beliefs (poor countries do not grow because their cultures, races, or religions fail to promote economic growth). The increasing number of success stories of growth proved all these theories to be wrong. However, despite the complexity of an economy and the number of things that can go wrong, single-factor explanations persist. The most common is that poverty is a result of corrupt leadership, which impedes modern development.

Governance is indeed important: economic development stalls when governments do not uphold the rule of law, pursue sound economic policy, make appropriate public investments, manage a public administration, protect basic human rights, and support civil society organizations – including those representing poor people – in national decision-making. Importantly, long-term poverty reduction in developing countries will not happen without sustained economic growth, which requires a vibrant private sector. Government, therefore, needs to provide the economic policy framework and the support that the private sector needs to grow. However, many well-governed poor countries may be too poor to help themselves out of extreme poverty. Many well-intentioned governments lack the fiscal resources to invest in infrastructure, social services, environmental management, and even the public administration necessary to improve governance. Further, dozens of heavily indebted poor and middle-income countries have been forced by creditor governments to spend large proportions of their limited tax receipts on debt service, undermining their ability to finance vital investments in human capital and infrastructure. The reason these poor countries cannot grow is not poor governance, but a poverty trap. They lack the basic infrastructure, human capital, and public administration – the foundations for economic development and private sector-led growth. Without roads, soil nutrients, electricity, safe cooking fuels, clinics, schools, and adequate and affordable shelter, people are chronically hungry, burdened by disease and unable to save. As mentioned above, fertility rates tend to be high, preventing families from investing enough in each child. Without adequate public sector salaries and information technologies, public management is chronically weak. For all of these interlocking reasons, these countries are then unable to attract private investment flows or retain their skilled workers, and can therefore find themselves with low or negative growth. In short, they are stuck in a poverty trap.

The concept of a low-level poverty trap is a long-standing hypothesis in the theories of economic growth and development. The earliest mathematical formalization was by Nelson (1956), who put emphasis on demography. The theoretical possibility of poverty traps in the neoclassical growth model is covered briefly in the economic growth textbook by Barro and Sala-i-Martin (1998), which also discusses briefly the possible case for large-scale development assistance to overcome such traps. The connection of a low-level trap to subsistence consumption needs is spelled out in Ben-David (1998), and connections to agriculture and education are described in the World Economic and Social Survey (UN, 2000). Two recent empirical studies claiming that such poverty traps exist in poor countries are UNCTAD (2002) and Bloom, Canning and Sevilla (2003). A close look at a poverty trap in Sub-Saharan Africa is in Sachs et al. (2004).

An often overlooked characteristic of poverty is that some countries and regions are clearly more
vulnerable than others to falling into a poverty trap. While a history of violence of colonial rule or poor governance can leave any country bereft of basic infrastructure and human capital, physical geography plays special havoc with certain regions. Some regions need more basic infrastructure than others simply to compensate for a difficult physical environment. Some of the barriers that must be offset by investments include adverse transport conditions (landlocked economies, small island economies far from major markets, inland populations far from coasts and navigable rivers, populations living in mountains, long distances from major world markets, very low population densities); adverse agro-climatic conditions (low and highly variable rainfall, lack of suitable conditions for irrigation, nutrient-poor and nutrient-depleted soils, vulnerability to pests and other post-harvest losses, susceptibility to the effects of climate change); adverse health conditions (high ecological vulnerability to malaria and other tropical diseases, high AIDS prevalence); and other adverse conditions (lack of domestic energy sources, small internal market and lack of regional integration, vulnerability to natural hazards, artificial borders that cut across cultural and ethnic groups, proximity to countries in conflict). Adam Smith was acutely aware of the role of geography in hindering economic development. He stressed, in particular, the advantages of proximity to low-cost, sea-based trade as critical, noting that remote economies would be the last regions to achieve economic development. More recent studies have found statistical significance of these relationships between geography and economic outcome (Gallup, Sachs and Mellinger, 1999; Mellinger, Sachs and Gallup, 2000; Sachs and Gallup, 2001).

In the rich countries of North America, Western Europe and East Asia, the process of massive investment in research and development, leading to sales of patent-protected products to a large market, stands at the core of economic growth. Advanced countries are typically investing two per cent or more of their gross national product directly into the research and development process, and sometimes more than three per cent. That investment is very sizeable, with hundreds of billions of dollars invested each year in research and development activities. Moreover, these investments are not simply left to the market. Governments invest heavily, especially in the early stages of R&D. In most poor countries, especially smaller ones, the innovation process usually never gets started. Potential inventors do not invent because they know that they will not be able to recoup the large, fixed costs of developing a new product. Impoverished governments cannot afford to back the basic sciences in government laboratories and in universities. The result is an inequality of innovative activity that magnifies the inequality of global incomes. While the innovation gap is reduced in the case of some poor countries through technological diffusion, even diffusion is limited in the poorest countries, because they face distinctive ecological problems not addressed by ‘rich-world science’ (for example, tropical diseases and tropical farming systems), because they cannot afford high-tech capital goods and because they fail to attract foreign businesses that would bring the technology with them.

**Policy responses**

Theories on how to tackle extreme poverty are varied and controversial. For the most part, they can be divided into two camps: strategies that focus on promoting market-oriented economic growth, and strategies that focus on directly addressing the needs of the poor. Of course the two approaches can be combined. The Washington Consensus, a set of policy recommendations especially prevalent from 1980 to the late 1990s, embodies the first type, with its focus on macroeconomic stability, greater economic openness to trade and investment, and improved environment for private business. The idea was that
these policies would lead growth of the private sector, thus increasing demand for labour and thereby improving the welfare of the poor.

A second set of strategies focuses instead on providing what the poor need in order to increase their productivity. These investments in ‘human development’ argued for directing health and education investments towards the poor, and providing social safety nets. Many of these strategies became popular in the 1990s as a reaction to the Washington Consensus. There were three kinds of critiques. One held that growth would not be achieved with market reforms alone, because of the poverty trap. A second held that growth must in any event be combined with increased public investments, for example for health and education. A third, and more extreme position, held that growth per se would have adverse effects on the poorest of the poor. For example, the 1996 Human Development Report warned that in some cases growth can fail to create jobs and provide benefits, and can even increase empowerment of the rich, wreck cultural identities and destroy the environment (UNDP, 1996).

Numerous studies have shown that growth does, in fact, tend to be good for the poor (Dollar and Kraay, 2002; Roemer and Gugerty, 1997; Gallup, Radelet and Warner, 1999). Yet growth may not be achievable for countries trapped in poverty, and growth may not be sufficient to enable the poorest of the poor to meet their basic needs. The emerging consensus is that both economic growth and direct investments for the poor are necessary, in order to break the poverty trap and to provide vital public goods. International institutions are paying more attention than before to the possibility of poverty traps, and to the non-income dimensions of extreme poverty (for example, health and education). Five of the eight Millennium Development Goals (the world’s time-bound and quantified targets for addressing extreme poverty, discussed below) are about promoting health and education, and individual countries are giving more priority to these broader measures than ever before.

Another dimension of the fight against extreme poverty is referred to as the rights-based approach. The guarantee that all people can live in dignity and meet their basic needs is also a basic human right – the right of each person on the planet to health, education, shelter and security as pledged in the Universal Declaration of Human Rights and various UN covenants, treaties and inter-governmental documents (such as the UN Millennium Declaration). The human rights approach seeks to use national and international human rights accountability mechanisms to monitor action on behalf of a human right rather than a development target. Economic evaluations often measure whether a given policy action contributes to reaching a target. Conceived in terms of rights, the same evaluation would measure not only those reached by a given action, but several other considerations as well: (a) the numbers not being reached; (b) the empowerment of the poor to achieve their rights; (c) the protection of these rights in legislation; and so forth. To date, there has been insufficient effort to integrate development planning with a human rights framework, even though such integration has tremendous potential and relevance. Since the creation of the United Nations in 1945, the international system has been working to reduce poverty around the world, but often with results that fall short of laudable rhetoric. In January 1961, the United Nations resolved that the decade of the 1960s would be the Decade of Development. US President Kennedy launched the decade at the UN in New York. Earlier, in his inaugural address as President, he had signalled a new sense of purpose in international affairs. He declared: ‘To those peoples in the huts and villages of half the globe struggling to break the bonds of mass misery, we pledge our best efforts to help them help themselves’ (History Place, 2007). The second Development Decade resolved to emphasize measures deliberately targeted at the poor – to help them meet their basic needs for food, water, housing, health and education. The UN held a series of international conferences:
on environment (Stockholm, 1972); population (Bucharest, 1974); food (Rome, 1974); women (Mexico City, 1975); human settlements (Vancouver, 1976); employment (Geneva, 1976); water (Mar del Plata, 1977); and desertification (Nairobi, 1977). In 1978, the governments of the world came together to sign the Alma Ata Declaration that promised ‘Health for All by 2000’, a promise the world failed miserably in delivering. The 1980s – the third Development Decade – were very difficult for developing countries as they suffered from a worldwide recession that hit the developing world and debtor countries with special force. Nevertheless, important improvements were made in some areas, such as nutrition, access to safe drinking water, and reductions in child mortality. One result was the international conference held in 1990 under the auspices of UNDP, UNESCO, UNICEF and the World Bank in Jomtien (Thailand), which set the target of ‘Education for All by the Year 2000’, another goal not met. The 1990s also became a decade in which the response of the UN system to the flagging development movement was to embark on a series of global conferences. The UN Conference on Environment and Development (Rio de Janeiro, 1992) was followed by conferences on nutrition (Rome, 1992); human rights (Vienna, 1993); population and development (Cairo, 1994); social development (Copenhagen, 1995); women (Beijing, 1995), human settlements (Istanbul, 1996). The decade ended with the landmark Millennium Summit in 2000, which resulted in the Millennium Development Goals (MDGs), and the Financing for Development Conference in Monterrey in 2002, where rich countries renewed their pledge to provide 0.7 per cent of their GDP in foreign aid. Also relevant was the Brussels Programme of Action for the Least Developed Countries, which suggests that they require greatly increased official development assistance, since private capital flows will not finance needed public investments. The programme outlines several priority areas for cooperation including human and institutional resource development, removing supply side constraints and enhancing productive capacity, protecting the environment, and attaining food security and reducing malnutrition. As the UN Millennium Project has pointed out, the Millennium Development Goals are the most broadly supported, comprehensive, and specific poverty reduction targets the world has ever established, so their importance is manifold. For the international political system, they are the fulcrum on which development policy is currently based. For the billion-plus people living in extreme poverty, they represent the means to a productive life (UN Millennium Project, 2005). Besides aiming to reduce the 1990 proportion of people in extreme poverty by half by 2015, the MDGs tackle poverty in its many dimensions – income poverty, hunger, disease, lack of adequate shelter, and exclusion – while promoting gender equality, education and environmental sustainability. Thus, while supporting the need for economic growth, the MDGs emphasize that the growth needs to be pro-poor. In 2005, the UN Millennium Project presented the Secretary General with ‘A Practical Plan to Achieve the Millennium Development Goals’, which outlined specific interventions to address the multiple causes of poverty traps in poor countries around the world (UN Millennium Project, 2005). Moreover, it emphasized that foreign aid will be needed to finance the interventions that the poor countries cannot finance themselves. In the case of well-governed poor countries, the report recommended that foreign assistance should be scaled up immediately, significantly, and on a sustained basis, consistent with the promise of 0.7 per cent of GNP as official development assistance.

Prospects

There are reasons to be optimistic about the elimination of extreme poverty on the planet. Economic
development has lifted more than 100 million people out of extreme poverty since the mid-1990s, and the pace is probably accelerating in Asia. While the population of developing countries rose from about four billion people to about five billion, average per capita incomes rose by more than 21 per cent. With 130 million fewer people in extreme poverty in 2001 than a decade before, the proportion of people living on less than one dollar a day declined by seven percentage points, from 28 to 21 per cent. Despite the good news, however, Africa remains mired in seemingly intractable extreme poverty. Africa faces difficult structural challenges (very high transport costs and small markets, low-productivity agriculture, very high disease burden, a history of adverse geopolitics, and slow diffusion of technology from abroad), but, in countries where governments are committed, these challenges can be overcome if addressed through an intensive programme that directly confronts them (Sachs et al., 2004). Ending the poverty trap in Africa and meeting the MDGs will require a comprehensive strategy for public investment in conjunction with improved governance. The good news is that the amount of investment required, although out of reach of African governments alone, is within the amount already promised in foreign aid by the rich countries (UN Millennium Project, 2005).

One final point is that a sustained reduction in extreme poverty requires tackling long-term challenges that the human family faces, in particular environmental challenges. Raising the incomes of billions of people around the world is surely desirable. Nevertheless, the increased income will come with increased demand for food, energy, and consumer goods, which may push our planet's already stressed ecosystems beyond what they can support. As the world works towards eliminating extreme poverty, it must do so with a conscious plan to limit the environmental burden that humanity places on the planet. Moreover, in many cases, the environmental challenges (such as water stress) may prove to be the biggest barriers to poverty reduction even in the short term.

Despite the Webbs’ disdain for abstract economics (‘sheer waste of time’), economic arguments have always held a central place in the Fabian case for socialism. As in most matters the Fabian Society has approached the dismal science eclectically. Some members have accepted market economics, others have rejected it; some embraced the Keynesian Revolution, others remained sceptical; some have believed in market pricing, others have been convinced that controls are essential for centralized planning. There is no consistent body of thought which could properly be described as Fabian economics. There is nonetheless a distinctive Fabian approach to economics, which this essay identifies while tracing the significant shifts in its key elements.

The Fabians and the marginal revolution

When the small group including Sydney Olivier, Bernard Shaw and Sidney Webb first started to meet at Mrs Charlotte Wilson's house in Hampstead, they set themselves the task of reading Marx's Das Kapital chapter by chapter. Graham Wallas, who joined the group in February 1885, later recalled how they were astonished to find ‘that we did not believe in Karl Marx at all’ (Wallas, 1923). Webb, Wallas and Shaw were also members of the Economic Circle, an offshoot of the Bedford Chapel Debating Society, where Professor Edgeworth helped to expound the principles of the new marginal economics with
another economist, Philip Wicksteed. Thus, according to Wallas, under Webb's leadership the group thrashed out ‘the Jevonian anti-Marx value theory as the basis of our socialism’. Shaw apparently needed more convincing than others. In the *Fabian Essays* he later described how he had been converted from his earlier Marxist faith that the working class revolution would take place in Britain by 1889 ‘at latest’ (Shaw, 1908, pp. 218–19). Instead of manning the barricades that year, Shaw was busily explicating the new Fabian economic basis for socialism.

In his preface to the essays, Shaw explained that the writers were all social democrats, ‘with a common conviction of the necessity of vesting the organisation of industry and the material of production in a State identified with the whole people by complete Democracy’. In his contributions he propounded the theory of marginal productivity, demonstrating that Ricardian economic rent, or ‘surplus value’, can accrue to all the factors of production, to land and to labour, and not just to capital as in the Marxist version. Similarly, he rejected the labour theory of value, and advanced the neoclassical version, which he called ‘exchange value’; in other words value was determined by the interaction of supply and demand in the marketplace. Shaw concluded:

> What the achievement of Socialism involves economically, is the transfer of rent from the class which now appropriates it to the whole people. Rent being that part of the produce which is individually unearned, this is the only equitable method of disposing of it. (1908, p. 220)

The method proposed to accomplish the transition was the common ownership of property, or as Webb put it: ‘the gradual substitution of organized operation for the anarchy of competitive struggle’ (p. 62). The original essayists all shared Marx's moral outrage at the evils of capitalism, particularly as a cause of hopeless poverty, inhuman working conditions and excessive inequality, and they also identified the institution of private property as its prime motivating force. However, they did not share the Marxist belief that capitalism must inevitably collapse. Although they recognized that periodic slumps were endemic to the system, they were more struck by its spectacular long-run growth and saw no reason to suppose that it would not continue to reap the benefits of technological change. Thus, as Schumpeter later explained, they were the kind of socialists who believed in the productive success of capitalism while they deplored its distributive results (Schumpeter, 1942, pp. 61–2). They thought that through the gradual extension of public property socialism would evolve from democratic efforts to mitigate the effects of industrialization. Indeed, Webb provided an extraordinary two-page catalogue of socialism's accomplishments to date, which ranged from the army and navy to public baths and cow meadows (Shaw, 1908, pp. 66–7). William Clarke described the growth of joint stock companies, and more recently of ‘rings’ and ‘trusts’, through which ownership became ever more divorced from entrepreneurial function and ‘capitalism ever more inconsistent with democracy and the public interest’. These changes provided the other main Fabian justifications for the public ownership of industry. Their views on the actual operations of a socialist system were hazy. Shaw and Webb both imply that socialism will have arrived when the entire market operation is administered through nationalization, municipalization and government regulation. Shaw described the aim of social democracy:

> to gather the whole people into the state, so that the state may be trusted with the rent of
the country, and finally with the land, the capital, and the organisation of the national industry—with all sources of production, in short, which are now abandoned to the cupidty of irresponsible private individuals. (1908, p. 224)

Yet, in other Fabian tracts, Shaw extolled the virtues of competition and of individual freedom, asserting that the latter was ‘as highly valued by the Fabian Society as Freedom of Speech, Freedom of Press, or any other article in the charter of popular liberties’ (Shaw, 1896, p. 327).

Later, of course, the Webbs provided a far more detailed view of their ideas for the organization of a Social Parliament to decide economic policy and to administer public enterprises. Beatrice herself remained ambivalent as to whether unemployment was caused by personal failings or ‘the disease of industry’; their apparently countercyclical unemployment scheme only shifted existing projects without requiring fundamental changes in government policy (Harris, 1972, pp. 42–3). The Webbs’ ideas about state planning were based on administrative principles, not economic science.

In the next Fabian generation, Hugh Dalton, a student of Pigou, used Pigou's revised version of neoclassical theory to demonstrate the critical differences between factor incomes and personal incomes. He introduced and defined the nature of inheritance and its role in maintaining wealth differentials; he broadened its concept to include educational opportunity, access to public services and institutional customs (Dalton, 1920). According to Gaitskell's later assessment of the British tradition, Dalton's work was a decisive influence in shifting socialist thought from the ‘sterile, out-of-date, somewhat academic arguments of earlier writers’ to the practical issues of progressive taxation and educational reform (Gaitskell, 1955, pp. 936–7). Although still grounded in neoclassical criteria of allocative efficiency, Dalton's analysis dealt directly with income equality, opening up ways to achieve socialism other than through Webbian public ownership. Thus, Gaitskell believed that the case for socialist equality could be stated on ‘straightforward ethical principles’, rather than on ‘complicated arguments about economic abstractions’.

The Fabians, the Keynesian revolution and economic planning in the 1930s

The Great Depression threatened both the political and economic stability of capitalist systems. Inspired by the Russian Revolution and its apparent success in replacing capitalism and avoiding mass unemployment, many leftist sympathisers turned to Marxism. They struggled through *Das Kapital*, they visited the Soviet Union, and they recommended the Soviet political philosophy and economic system. The Webbs fell in love with Russia; in their last major work, *Soviet Communism: A New Civilization?*, they advocated a totally controlled economy, visualising Soviet planning as the ultimate Fabian collective. In *New Fabian Essays* Crossman argued that they had simply superimposed Marxism on their basic utilitarianism; he believed that only John Strachey successfully re-thought the entire system ‘in Anglo-Saxon terms’ (Crossman, 1970, p. 5).

It fell to the younger generation to restate the traditional Fabian case against Marxist economic thought and revolutionary methods and to redefine the democratic socialist alternative. Hugh Gaitskell and Evan Durbin organized the Economic Section of the New Fabian Research Bureau, which had been founded by G.D.H. Cole in March 1931 and merged with the parent Fabians in 1938; their purpose was to explore the implications of the theoretical economic controversies for socialism and to make policy...
recommendations to the Labour Party (Durbin, 1985). At the same time the obvious failures of the market system were challenging economists to rethink the role of government intervention and to redesign their toolkit. Keynesian macroeconomics, the economics of imperfect competition and the principles of economic planning embodied in the new ‘market socialism’ were first developed during the 1930s. After the war they were incorporated into the orthodox case for the mixed economy.

In pointed contrast to official policy, Keynes had begun pressing British governments to expand, not to contract, public expenditure to cope with unemployment. In the early 1930s his position was largely intuitive; *The General Theory* published in 1936 was the first systematic exposition of his theoretical case. Until then the most fundamental cleavage on the unemployment issue was between those who advocated government intervention in the market and those who did not. Socialists were naturally allied with the interventionists on social and political grounds, as well as economic, and thus were sympathetic to Keynes's policy efforts: but they were suspicious of his political ties to the Liberal Party, and some of the professional; economists were sceptical about his expansionist policies. James Meade and Colin Clark, who were working alongside Keynes, were convinced expansionists by August 1931. Together they were responsible for converting the New Fabians well before 1936. Amongst the sceptics were Gaitskell and Durbin, who were strongly influenced by Hayek's trade cycle theories and who were deeply concerned to demolish ‘treasured dogma’ within the Labour party, namely the myths that capitalism was collapsing and that socialism could easily replace it and automatically solve the unemployment problem. As early as 1932 Gaitskell explained why, although ‘prosperity’ was an important socialist goal, it was not ‘the distinguishing characteristic of the Socialist ideal’ (Gaitskell, 1932).

Meade also played an important role in converting Douglas Jay, whose influential book, *The Socialist Case*, published in 1937, was the first to propose that Keynesian fiscal and monetary measures to control output and employment be explicitly incorporated as part of socialist planning methods. Cole, who thought that the *General Theory* was the most important economics book published since Marx's *Das Kapital* and Ricardo's *Principles*, was quick to point out that because Jay gave such a low priority to nationalization his book contained very little of ‘what most people habitually think of as socialism’ (Cole, 1935). Thus, the introduction of Keynesian methods also served to weaken the case for public ownership as the basis of the socialist economic alternative.

By the late 1930s most democratic socialists in Britain had recognized the importance of the Keynesian message for socialism, and by the end of the war the Labour Party had officially adopted a Keynesian full employment policy. The new macroeconomic analysis provided an obvious answer to the problem of dealing with capitalist collapse. It also reinforced distributive goals, since lower-income families had a higher propensity to consume, and it underscored the importance of central planning to control the economy, since only the government had the power to offset insufficient private spending. So compelling were these arguments that they also converted at least one influential Marxist, John Strachey, to the Fabian cause.

Yet Fabian acceptance of Keynes's economics and of Keynes's basic individualism is often overstated, particularly in the pre-war context. Anthony Wright (in Pimlott, 1984) has suggested that the Tawney approach to equality is fundamentally different from the liberal philosophy behind Beveridge's welfare state. A similar contrast can be made between Fabian conceptions about economic planning in the 1930s and Keynesian macroeconomic management. Fabians were explicit about their opposition to the capitalist system, which Keynes wanted to repair, but which they wanted to replace. They were emphatic
about the need for major reform of Britain's financial institutions and for substantial growth of the public sector; indeed, they believed that both were essential to implement a successful full employment policy. At least one Fabian economist, Evan Durbin, never accepted The General Theory model as the solution to all macroeconomic problems; he believed that it failed to explain the trade cycle, and was therefore unsuitable for the long-term growth problems which the socialist state must solve in order to improve upon capitalism's record.

The principles of market socialism grew out of work initiated by Durbin and Gaitskell, who undertook a systematic reconsideration of the Marshallian microeconomic grounds for intervention and the implications for socialist planning. Together with H.D. Dickinson they demonstrated that the market system by definition could neither price collective goods nor reflect the true social value of externalities, and, therefore, that it could not determine the appropriate allocation of resources for their production. They also incorporated the new economics of imperfect competition associated with Joan Robinson to restate the objections to the existing system, which they termed 'monopoly capitalism'. A planning authority would be able to correct these deficiencies and use the principles of optimal allocation to guide its decisions; in other words, neoclassical criteria should serve as the handmaiden to collective decision-making. In the 1930s and 1940s, many Fabians contributed to the further elaboration of these ideas into a socialist economic system based on free choices in the labour market, consumers’ sovereignty through market pricing and marginal cost pricing in nationalized industries. The importance of this analysis was that it added strong theoretical arguments for a mixed economy as an explicit complement to the macroeconomic Keynesian ones.

There were, however, other Fabians who found such arguments hard to take and/or to follow. Barbara Wootton, whose planning schemes were an updated version of the Webbian administrative structure, was clear that prices would have to be controlled in the public interest. Even Dalton, who recognized that planning was not necessarily socialist, still maintained the early Fabian belief that ‘Socialism is primarily a question of ownership’ (Dalton, 1935, p. 247). With more appreciation for the problems of allocative efficiency under socialism, Cole attempted to fashion a different socialist economics, one which was neither Marxist nor neoclassical (Cole, 1935). Although his own system remained a rather sketchy attempt to incorporate socialist distributional goals into decisions about production, he had some telling arguments against his neoclassical comrades, pointing out that market prices reflected the existing income distribution, and thus could not provide the proper signals for socialist allocation. His efforts are particularly interesting for the light they throw on the need to mesh social policy with economic planning, and on the problem of applying neoclassical analysis to meet essentially political goals.

By the end of the 1930s, most Fabians had come to accept the necessity for a mixed economy, if only on practical grounds, because the legislation necessary to secure socialism by parliamentary methods could not be accomplished by one Labour government. Government planning was necessary to ensure aggregative and allocative efficiency and to redistribute income and wealth. Control of what were later known as ‘the commanding heights’ of the economy was essential to implement the planning alternative, and a central authority was required to make sure that sectional interests, such as bankers, business and trade unionists, did not subvert the public good. However, in an important change of emphasis, Durbin and Gaitskell were explicit that their objections to capitalism and to the Marxist alternative were social and political, not economic (Gaitskell, 1935; Durbin, 1940). The essence of their socialism was social justice as Tawney defined it. In short, the mixed economy was not simply politically expedient, it was
central to the economic operation of the democratic socialist state.

The Fabians and the mixed economy in practice

As authors in the *New Fabian Essays* later pointed out, the war substantially altered the balance of power between the government and the private sector. And in comprehensive plans for recovery, the wartime coalition laid the foundations for bipartisan support of full employment, a unified system of social services and educational reform. Thus, when the Labour government took over in 1945, there was not much resistance to its programme or to its Fabian philosophy.

In 1948 the Fabian Society commissioned W. Arthur Lewis to write a pamphlet on ‘the economic perplexities of the moment’. These turned out to be so numerous that Lewis ended up writing a short book, *The Principles of Economic Planning* (1949), an influential statement of the revised conception of market socialism. Like Meade in *Planning and the Price Mechanism*, published in the same year, he argued the case for planning on general interventionist grounds, implicitly rejecting the Durbin–Gaitskell notion that only a socialist government could run the economy efficiently, although one might still believe only a socialist government would. To paraphrase Lewis, socialism was not about the state, any more than it was about property; ‘socialism is about equality’. There could be many ways to handle property and to plan the economy, which were not inconsistent with socialism (Lewis, 1949, pp. 10–11).

Lewis argued that the crucial issue was whether the state should operate ‘through the price mechanism or in supersession of it’; the real choice was ‘between planning by inducement, and planning by direction’. Lewis himself was neutral on the issue, believing that Britain needed some of both. Although insistent that there must be free consumer goods and labour markets, he argued that demand was not sacred and that it should be manipulated in specific markets and in the aggregate to achieve policy goals. Similarly, he did not believe that nationalization should be taken on its merits. Lewis wanted ‘more than we have already got’ (steel, banking and chemicals were his candidates), but in no circumstances the whole economy; ‘a country whose people love freedom will not wish the state to become the sole employer’ (p. 104).

Shortly after this book was published in 1949, Cole as chairman of the Society organized a conference to begin to rethink the way forward now that the main components of the first Fabian stage to socialism were in place. *New Fabian Essays* published in 1952 was the end result of this effort to take account of important societal changes and the Keynesian Revolution. The essayists were all agreed that the British version of the mixed economy was a permanent Fabian accomplishment, and that the Tories would not dismantle the welfare state nor renege on full employment. Yet, despite the enormous gains, substantial inequities remained and new problems emerged: in particular, the great concentrations of bureaucratic power in the public and private sectors which threatened individual freedom. In general terms the way forward was to continue to pursue equality, to improve labour–management relations and to disperse power as much as possible.

However, the Fabians were still united in their dissatisfaction with that system. Although they were clear that the postwar version of welfare capitalism did not meet their conception of socialism, many of the essayists were vague about what they did want. Writing about equality in *New Fabian Essays*, Roy Jenkins explained that a classless society was one ‘in which men will be separated from each other less sharply by variations in wealth and origin than by differences in character’, but it was impossible to describe ‘the exact shape of the goal’. Of contributors to *New Fabian Essays*, only Crosland was willing...
to be explicit in the negative sense that he specified four policies which would not achieve equality; the continued extension of free social services, more nationalization, the proliferation of controls and further redistribution of income by direct taxation. In an important shift, many Fabians had come not only to believe in the mixed economy, but also to accept its current structural form.

Crosland outlined the main features of what he called ‘post-capitalist society’: he concluded that it was more equal and more planned than before, but that it was still based on unacceptable class divisions. While individual property rights were no longer the essential basis of economic and social power, they still affected the distribution of wealth. He felt that the power of the state had been expanded sufficiently to exert control over the economy: if anything, physical controls should be reduced as they were unpopular and inefficient. Similarly, nationalization had secured government power in the central sectors of the economy, social legislation had ensured a national minimum welfare level, and full employment policies had removed insecurity and demonstrated that central planning could be directed to meet social ends. Keynesian policies were crucial to maintaining this system, but as these were now well understood, Crosland argued that ‘the new society may prove to be a very enduring one’. In The Future of Socialism (1956), Crosland spelled out his ideas on planning in more detail; he believed its ‘essential role’ was Keynesian economic management, that the techniques were no longer controversial nor the preserve of any one party, and that political will, not planning theory, were required to plan effectively; ‘if socialists want bolder planning, they must choose bolder ministers.’

One lone dissenter from the general Fabian romance with Keynes was G.D.H. Cole. Although enthusiastic about the General Theory when it was published, he had become increasingly concerned about these new directions after the war. Indeed, this was precisely why he had initiated the process of rethinking, and why, as the discussions progressed, he resigned his position as chairman of the Fabian Society. In 1950 he published a short book, Socialist Economics, which spelled out his disagreements with the new Fabian approach. First, he thought that Keynesian economics was too involved with aggregates and not sufficiently concerned with the structural problems necessary for a socialist economy to replace the capitalist system. As far as he was concerned the new direction provided a diluted form of socialism, which was ‘little more than Keynesian Liberalism with frills’. Second, although Cole had advocated using a wide range of industry controls as early as 1929 and was opposed to total public ownership, he was also explicit in rejecting the current version of the mixed economy ‘as a permanent resting place’.

factor content of trade

Donald R. Davis
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Trade in goods is also implicitly trade in the services of the factors used to produce those goods. This insight underlies the Heckscher–Ohlin–Vanek model of factor service trade, and provides a laboratory to test our theories concerning world general equilibrium. In recent years this theory has undergone close empirical scrutiny. Early tests strongly rejected the simplest variants of the theory. More recent tests have imposed a modest number of additional restrictions suggested by the data. These involve cross-country heterogeneity in productivity, factor prices, consumption patterns, and the incorporation of non-traded goods. With these restrictions, the model fares well.

Article

International trade is the cross-border exchange of goods (and services), both final and intermediate. These goods are produced with factors of production located in specific countries, hence the trade in these goods is implicitly also trade in the services of the factors used to produce them. This converts the standard Heckscher–Ohlin model of trade in goods into the Heckscher–Ohlin–Vanek (HOV) model of the factor content of trade.

The most important reason to study the factor content of trade is that it provides a laboratory to test our understanding of world general equilibrium. Countries have specific endowments, technologies, tastes, locations, and distributions of incomes (among other characteristics). The simplest statement of general equilibrium is that these elements are supposed to ‘hang together’ in a coherent way. Tests of the factor content of trade thus become a first test of the adequacy of our understanding of this world general equilibrium. If we should fail to correctly predict the factor content of trade, then we know that our theory seriously misunderstands at least one element of the underlying reality. If our theory does a good...
The job of making sense of the factor content of trade, then this is a suggestion that the main thrust of our
theory is working well. This would give us more confidence, then, in using the theory in policy
applications.

The canonical Heckscher–Ohlin–Vanek model of factor service trade can be described simply (see
Vanek, 1968). Assume that there are \( G \) goods, each produced under perfect competition with constant
returns to scale. Assume as well that there are \( F \) primary factors of production with factor markets
competitive. Let \( A \) be an input–output matrix that links net output \( Y \) to gross output \( X \) via
\[
Y = (I - A)X
\]
Let \( B \) be a matrix of direct factor inputs, with dimension \( F \times G \), where columns denote factor inputs
required to produce a unit output of a single good and rows show factor inputs for a single factor across
all goods. Let \( \bar{B} = B(I - A)^{-1} \) be the corresponding matrix of direct plus indirect factor inputs, where
both primary and intermediate usage represent cost-minimizing choices. Let \( c \) be an index for countries,
and \( W \) represent the aggregate for the world as a whole.

Let technologies for all goods and quality of all factors be common for all countries of the world, and let
there be at least as many goods as factors, so that \( G \geq F \). Assume that trade between countries is free, so
that goods prices are equalized. Assume that the distribution of world endowments among countries
satisfies the requirements to replicate what has been termed the ‘integrated equilibrium’ (see Helpman
and Krugman, 1985). In such a case, the division of world endowments between the countries is of no
economic consequence, since outputs adjust across countries so that the countries jointly produce
exactly the same output and use the same input ratios as they would if the factors were perfectly mobile
across countries. Then factor prices will be equalized (FPE), and for all countries \( c \in C \), there are
common technology matrices: \( B = B^c \), and \( \bar{B} = \bar{B}^c \). For country \( c \) with gross output vector \( X^c \) and
primary input vector \( V^c \), \( BX^c = V^c \). We further assume that demand is identical across countries and
homothetic. Let \( D^c \) be country \( c \)'s vector of final goods demand, \( Y^W \) be the world net output vector, and
\( s^c \) be country \( c \)'s share of world spending. Then, with free trade equalizing goods prices, \( D^c = s^c Y^W \).
This identifies the demand for goods, and, by pre-multiplying by the common technology matrix \( \bar{B} \), we
can convert this to a statement about the factor content of consumption. \( \bar{B}D^c = s^c V^W \). Net trade is
\( T^c = Y^c - D^c \). Hence the prediction of the net factor content of trade is:

\[
\langle HOV \rangle \bar{B}T^c = V^c - s^c V^W.
\]

Early empirical work, such as Bowen, Leamer and Leo (1987) and Trefler (1995), examined this under
the assumption that all countries use the technology matrices of the United States. Without reservation,
the conclusion of these papers was that the simplest version of the model is an utter failure. Trefler
characterized the central failing as the ‘mystery of the missing trade’. If we term \( \bar{B}T^c \) the measured
factor content of trade and \( V^c - s^c V^W \) the predicted factor content of trade, then the mystery is that the
measured factor content of trade is much smaller than that predicted. Much of the subsequent literature
has focused on identifying reasons for the mystery of the missing trade and finding solutions for it.
Virtually every assumption underlying the Heckscher–Ohlin–Vanek model is in principle open to
question. The strategic issue has been to bring more data to bear on the question in order to identify which of the assumptions is violated most seriously and what amendments to the theory and data work are needed to fit the pieces of the puzzle together.

Various approaches have been considered. Trefler (1993) develops a model that assumes net factor trade is correctly measured, and calibrates factor quality differences across countries that would rationalize the measured trade. This can be thought of as a model of adjusted factor price equalization. While the theoretical model of quality-adjusted factor service trade is an important addition to the toolkit of researchers, this proposed resolution has not fared well empirically (Davis and Weinstein, 2003).

Increasingly, researchers moved to a wider set of departures from the standard Heckscher–Ohlin–Vanek model. These include differences across countries in total factor productivity (TFP); a breakdown in factor price equalization, even adjusted for the TFP differences; specialization in different traded goods within industries; differences in factor input ratios in both traded and non-traded sectors; and costly trade. Davis et al. (1997) examined the adequacy of assuming a common technology matrix (in this case, that of Japan) for a set of OECD countries. Instead of looking directly at the factor content of trade, they looked at the factor content of production for these countries, that is, 

$$\mathbf{B}^{-1} \mathbf{a}_{\text{paran}} \mathbf{T}^c = \mathbf{V}^c - \Delta \mathbf{V}^W,$$

they looked at the factor content of production for these countries, that is,

$$\mathbf{B}^{-1} \mathbf{a}_{\text{paran}} \mathbf{X}^c = \mathbf{V}^c.$$ This is such a poor fit in the data that they conclude that much of the problem lies in cross-country differences in technology matrices. They went on to develop a theory to predict the factor content of Japanese regions under the assumption that these share FPE, even though Japan does not share FPE with the world as a whole. In this sample, this largely eliminated the mystery of the missing trade.

This left open the larger question of why technologies differed, how they differed, and whether a parsimonious set of departures from the HOV theory could get the model of factor service trade to work well. Davis and Weinstein (2001a) brought a great deal more data to bear on the problem, developing technology matrices for ten rich OECD countries and a composite rest of the world. Technologies differed systematically, even among these rich OECD countries, so that more capital-abundant countries use more capital-intensive methods industry by industry. As it turned out, this happened in both traded and non-traded goods sectors, the latter being important in identifying a breakdown in relative FPE (because there is less likelihood of aggregation issues impinging). Moreover, recognizing that non-traded sectors in different countries use systematically different input coefficients has a large impact on predicted factor contents. For example, a capital-abundant country uses more capital per worker than would be suggested in an FPE model. For this reason, and because non-traded sectors are large, the capital-abundant country has less ‘excess’ capital to export through factor services. All told, the adjustments made allow the measured factor content of trade to be approximately 60–80 per cent of that predicted.

The subsequent literature has focused on a number of elaborations and challenges to this work. Feenstra and Hanson (2000) explore in more detail issues of aggregation bias in measurements of net factor service trade. In related work, Davis and Weinstein (2001b) have developed a more elaborate model of gross trade in factor services that helps to understand even North–North trade. In effect, they argue that much of the mystery of the missing trade arose because the focus on net goods trade ignored the fact that when factor intensities are not identical even intra-industry goods trade conveys net factor content. Choi and Krishna (2004) implement alternative tests, based on Helpman (1984), of the net factor content of trade which has the advantage of being robust to breakdowns in FPE, but the disadvantage of needing to
have confidence that we can adequately measure the differences in factor prices, including returns to capital. For the sample of bilateral predictions they consider, the model performs well. Reimer (2006) has aimed to incorporate a more elaborate model of trade in intermediates and argues that this diminishes when measured against predicted factor contents.

Research on the factor content of trade is important because it represents the greatest effort on the part of trade economists to assemble all of the pieces of general equilibrium into a single coherent framework relating underlying endowments, production, technology, consumption and trade. The early theoretical and empirical work provided a starting place and a number of anomalies, such as the mystery of the missing trade, that motivated ongoing research. Subsequent literature has gone a long way towards resolving the mystery of the missing trade. But new questions continue to arise, particularly related to trade in intermediates and issues of aggregation. No doubt these will invite further investigation.

factor models

Jushan Bai

Abstract

Factor models explain correlations among a set of variables. By postulating that the variables are linked with a small number of latent components, factor models imply a particular structure for the correlation matrix. This article discusses the model’s identification and estimation as well as their applications in economics.

Article

The primary objective of factor analysis is to explain, in a parsimonious way, the correlation among a set of variables. For example, cross-sectional correlation of asset returns may be explained by a single factor, according to capital asset pricing theory (Sharpe, 1964; Lintner, 1965). The correlation among a large number of macroeconomic variables could be explained by some common shocks (Sargent and Sims, 1977; Bernanke and Boivin, 2003). Historically, factor models were used by psychologists to examine correlations among a set of test scores. Students’ performance across different subjects (maths, philosophy, history, and so on) may potentially be accounted for by a single factor (for example, overall intelligence) (see Lawley and Maxwell, 1971). In these examples, a common theme is that a large number of variables are linked with a small number of unobservable variables which give rise to the cross correlations.

While sample correlation matrix may serve the same purpose in describing the linkage of variables, it is neither parsimonious nor reliable when the number of variables is large relative to the number of observations. Suppose there are $N$ variables, each with $T$ observations. The sample correlation matrix
estimates $N(N - 1)/2$ parameters without any restriction. When the number of variables exceeds the number of observations ($N > T$), the sample correlation matrix is not of full rank, even though the underlying true correlation matrix is positive definite. A factor model with, say, a single factor attempts to explain the correlation with far fewer parameters, and the resulting correlation matrix will be positive definite. If a factor structure truly (or approximately) characterizes the data generating process, the estimated correlation matrix implied by the factor model constitutes a better estimate than the sample correlation matrix. Even if the data generating process does not follow a factor model, under large $N$, shrinking the sample correlation matrix towards a correlation matrix with a factor structure may be desirable, in light of Ledoit and Wolf (2003). Most importantly, sample correlation is purely statistical, but factor models have structural interpretations.

In this article, we first present the mathematical form of the factor model, then we state the assumptions employed by classical factor analysis, in which the statistical theory is developed under a fixed $N$. We then go on to discuss modern factor analysis in which both $N$ and $T$ are large, and in particular, the number of variables ($N$) can be much larger than the number of observations ($T$). In each case, we discuss issues related to identification and estimation, and the determination of number of factors. More attention is paid to modern factor analysis. We also present a few applications of factor models in economics, including diffusion index forecasting, panel unit root and cointegration analysis. Finally, we briefly highlight the difference between principal component analysis and factor analysis.

**The Model**

A factor model takes the form

$$X_{it} = \mu_i + \lambda_i^T f_t + e_{it}; \ i = 1, 2, ..., N; \ t = 1, 2, ..., T$$

where $X_{it}$ is the observation on variable $i$ at period $t$; $\mu_i$ is the mean of $X_{it}$, $\lambda_i (r \times 1)$ is vector of factor loadings, $f_t (r \times 1)$ is vector of factor processes, and $e_{it}$ is the idiosyncratic error term. For example, $X_{it}$ may represent the output growth rate for country $i$ in quarter $t$, $\mu_i$ is the mean growth rate, $f_t$ is a vector of common shocks (technology shocks, financial crises, oil price shocks, and so on) that influence output, $\lambda_i$ represents the impact of shocks on country $i$, and $e_{it}$ is the country-specific growth rate. As a further example, $X_{it}$ is the return of asset $i$ in period $t$, $\mu_i$ is the mean return, $f_t$ is a vector of factor returns with zero mean (risk premia adjusted), $\lambda_i$ is a vector of factor loadings, and $e_{it}$ is the idiosyncratic return. The arbitrage pricing theory of Ross (1976) implies restrictions between $\mu_i$ and $\lambda_i$. Introducing the following notation
factor models: The New Palgrave Dictionary of Economics

The factor model can be rewritten as

\[
X_t = \mu + \Lambda f_t + \epsilon_t; \quad t = 1, 2, ..., T.
\]  

Below we separately discuss classical factor analysis and modern factor analysis; they are based on different assumptions and inferential theory also differs.

**Classical factor analysis**

The main assumptions under classical factor analysis are: (i) \(f_t\) and \(\epsilon_t\) are i.i.d. random variables with zero means; (ii) for normalization purposes, \(Ef_t f_t' = I_r\), an identity matrix; (iii) \(f_t\) and \(\epsilon_t\) are uncorrelated; (iv) \(\Lambda\) is a matrix of fixed constants. Let \(\Sigma = E((X_t - \mu)(X_t - \mu)')\), the covariance of \(X_t\) and let \(\Phi = E\epsilon_t \epsilon_t'\), the covariance of \(\epsilon_t\). It follows that

\[
\Sigma = \Lambda \Lambda' + \Phi.
\]

Another key assumption under classical factor analysis is that \(N\) is fixed. This assumption appears to be at odds with the essence of factor analysis because this analysis was motivated by large \(N\) problems. Nevertheless, traditional applications had been on problems of relatively small \(N\). Furthermore, fixed \(N\) assumption makes the statistical inference more tractable. For example, \(\Sigma\) is consistently estimable under fixed \(N\) (for example, by the sample covariance matrix) as \(T\) goes to infinity. Thus for identification purposes, \(\Sigma\) is assumed to be known.

Without further restrictions, the parameter matrices \(\Lambda\) and \(\Phi\) are not identifiable since \(\Phi\) alone would have the same number of parameters as the number of equations in (2). Classical factor analysis thus
assumes that $\Phi$ is a diagonal matrix. This assumption is not too restrictive since correlation among the variables is supposedly explained by the common factors $f_t$. In addition, a rotational indeterminacy exists for $\Lambda$ since $\Lambda G (\Lambda G) = \Lambda \Lambda'$, where $G$ is such that $GG' = lr$. To remove this rotational indeterminacy, it is often assumed that $\Lambda' \Phi^{-1} \Lambda$ is a diagonal matrix. A diagonal matrix imposes $r(r-1)/2$ number of restrictions. Thus the number of parameters on the right hand side (2) is $N + Nr - r(r-1)/2$. The number of equations in (2) is $N(N+1)/2$. Thus in order to identify the parameters, we must have

$$s = \frac{N(N+1)}{2} - N - Nr + \frac{r(r-1)}{2} = \frac{(N-r)^2 - (N+r)}{2} \geq 0.$$ 

This is known as the order restriction, meaning that the number of equations must be no smaller than the number of parameters. This implies that for a factor model to be identifiable, $N$ cannot be smaller than three. When $N$ is exactly three, there can only be one factor ($r = 1$). In this case, $s = 0$ and the number of parameters in the factor model coincides with the number of elements in $\Sigma$. When this occurs, no simplification is achieved via factor analysis. Nevertheless, structural interpretation of the model is still of interest since it indicates that the three variables are related to a single common component.

Even for $s = 0$, there may not exist solutions for $\Lambda$ and $\Phi$ to satisfy (2) because factor models further restrict non-negativity for the diagonal elements of $\Phi$; see examples in Lawley and Maxwell (1971, pp. 10–11).

For a larger $N$ and small $r$, we usually have $s > 0$. In this case, overidentification occurs. Model estimation entails finding $\Lambda$ and $\Phi$ to make the distance between $S$ and $\Lambda \Lambda' + \Phi$ small, where $S$ is the sample covariance matrix. The model is usually estimated by the principal-factor analysis or the maximum-likelihood method (see Mardia, Kent and Bibby, 1979; Anderson, 1984).

A special case is that $\Phi = \sigma^2 I_N$, a scalar multiple of an identity matrix. In this case, the smallest $N$ that permits identification is $N = 2$, with $r = 1$. To see this, consider

$$\Sigma = \lambda \lambda' + \sigma^2 I_2$$

where $\lambda = \langle \lambda_1, \lambda_2 \rangle'$ is a vector. Reparameterize $\lambda \lambda' = \tau^2 \delta \delta'$ with $\|\delta\|^2 = \delta' \delta = 1$, where $\tau^2 = \|\lambda\|^2 = \lambda' \lambda$. The two eigenvalues of the matrix on the right hand side are $\sigma^2$ and $\sigma^2 + \tau^2$. The eigenvector associated with the larger eigenvalue is simply $\delta$. Thus we can identify $\sigma^2$ as the smaller eigenvalue, and $\tau^2$ as the difference between the two eigenvalues. Moreover, $\delta$ is the eigenvector associated with the larger eigenvalue of $\Sigma$.

On the assumption that the model is identifiable, the estimated factor loadings will be consistent, the limiting distribution can be found in Anderson (1984) under the assumption of fixed $N$ and large $T$. 

Given $\Lambda$ and $\Phi$, the factor scores $f_t$ can also be estimated by either the generalized least squares (GLS) or the Bayesian method. For example, the GLS estimator of $f_t$ is

$$\hat{f}_t = (\Lambda' \Phi^{-1} \Lambda)^{-1} \Lambda' \Phi^{-1} \chi_t \ (t = 1, 2, \ldots, T).$$

While $f_t$ is unbiased for $f_t$, it is not consistent since $N$ is fixed, even if $\Lambda$ and $\Phi$ are known. Finally, the number of factors $r$ is determined via hypothesis testing.

**Modern factor analysis**

Modern factor analysis takes model (1) as the starting point, but then proceeds under different assumptions. First, the number of variables $N$ is assumed to be large, and the limit theory is developed under the assumption that both $N$ and $T$ go to infinity. In particular, $N$ can be much larger than the number of observations $T$. Second, both $f_t$ and $e_t$ can be serially correlated. Third, $\Phi$ needs not to be a diagonal matrix, and in fact, none of the off-diagonal elements needs to be zero. Thus the number of parameters in $\Phi$ can be as many as the equations. This is called ‘approximate factor model’ by Chamberlain and Rothschild (1983). The main interest of this large dimensional factor analysis is to estimate $r, \Lambda$, and $F$. One key assumption of the approximate factor model is that the largest eigenvalue of $\Phi$ is bounded uniformly in $N$. This implies that cross-correlations in the idiosyncratic errors must be weak.

**Identification and estimation**

Let $X = (X_{it})$ be the $N \times T$ data matrix and $\varepsilon = (\varepsilon_{it})$ be the error matrix of the same dimension. Then

$$X = \Lambda F' + \varepsilon.$$

Here we assume the constant vector $\mu$ to be zero, but without assuming $F$ to have zero mean. If $\mu \neq 0$, the demeaned data matrix should be used in the following discussion, and zero mean for $F$ should also be imposed. Now both $\Lambda$ and $F$ are to be estimated. Since $\Lambda F' = \Lambda A A^{-1} F'$ for an arbitrary invertible matrix $A (r \times r)$. As an arbitrary $r \times r$ invertible matrix has $r^2$ free parameters, we need to impose $r^2$ restrictions. We may impose $\frac{1}{T} F' F = \frac{1}{T} \sum_{t=1}^{T} f_t f_t' = 1$ together with $\Lambda' \Lambda$ being diagonal. Alternatively, we may impose $\frac{1}{N} \Lambda' \Lambda = 1_r$ together with $F' F$ being diagonal. Either way, it will uniquely fix $\Lambda$ and $F$ (up to a column sign change) given the product $\Lambda F'$.

Under the least squares objective function $S(\Lambda, F) = \sigma^2 \left[ (X - \Lambda F') (X - \Lambda F')' \right]$, the optimal solution $(\hat{F}, \hat{\Lambda})$ is simply the principal-components estimator. More specifically, under the first set of normalization restrictions, $\hat{F}$ is the $T \times r$ matrix consisting of the first $r$ eigenvectors (multiplied by $\sqrt{T}$) associated with the first $r$ largest eigenvalues of the $T \times T$ matrix $\chi' \chi$, and $\hat{\Lambda} = \frac{1}{T} \chi' \hat{F}$. Under the second
set of identification restrictions, the optimal solution \((\tilde{F}, \tilde{\Lambda})\) is also an eigenvalue problem associated with the matrix of \(XX'\), which is \(N \times N\). That is, \(\tilde{\Lambda}\) is the matrix of the first \(r\) eigenvectors (multiplied by \(\sqrt{N}\)) of the matrix \(XX'\) and \(\tilde{F} = XX'/N\) (see Connor and Korajczyk, 1986; Stock and Watson, 2002a). The relationships between the two sets of solutions are given by \(\tilde{F} = \hat{F}V^{-1/2}\) and \(\tilde{\Lambda} = \hat{\Lambda}V^{1/2}\), where \(V\) is an \(r \times r\) diagonal matrix consisting of the eigenvalues of the matrix \(\frac{1}{NT}XX'\). The statistical properties of \(\tilde{F}\) and \(\tilde{\Lambda}\) are analysed by Bai (2003).

The number of factors

The number of factors \(r\) can be consistently estimated using the information criterion approach of Bai and Ng (2002). Let \(\hat{\sigma}^2(k)\) denote the sum of squares residuals (divided by \(NT\)) when \(k\) factors are allowed, that is, \(\hat{\sigma}^2(k) = S(\tilde{\Lambda}^k, \tilde{F}^k) / (TN)\). Consider the following criterion

\[
IC(k) = \log \hat{\sigma}^2(k)^2 + kg(N, T).
\]

If \(g(N, T)\) is such that \(g(N, T) \to 0\) and \(\min [N, T]g(N, T) \to \infty\), then \(P(\hat{k} = r) \to 1\), where \(\hat{k}\) minimizes the information criterion. For example, \(g(N, T) = (N + T) \log (NT) / (NT)\) satisfies the above condition.

Nonstationary factor analysis

When the factor process \(f_i\) is a vector of I(1) or integrated processes such that \(f_t = f_{t-1} + \eta_t\), \(X_{it}\) is nonstationary. Examples include nominal exchange rates series (see Banerjee, Marcellino and Osbat, 2005). When the idiosyncratic process \(e_{it}\) is I(0) both \(\Lambda\) and \(F\), as well as \(r\) can be consistently estimated, as shown by Bai (2004). Since \(X_{it}\) (for all \(i\)) share the same common stochastic trends \(f_i\), \(X_{it}\) are cointegrated among themselves.

When the idiosyncratic process \(e_{it}\) is I(1) for all \(i\) such that \(e_{it} = e_{i,t-1} + \varepsilon_{it}\), there is no cointegration among the observable \(X_{it}\). But still, the common stochastic trends are well defined and can be estimated consistently up to a rotation, a striking contrast with a fixed \(N\) spurious system. In a small \(N\) system, common stochastic trends and cointegration are synonymous. A spurious system has no common trends or at least cannot be discerned. To see how large \(N\) makes a difference, consider the system in differenced form...
\[ \Delta X_{it} = \lambda_i' \eta_t + \varepsilon_{it} \]

where \( \eta_t = \Delta f_t \) and \( \varepsilon_{it} = \Delta e_{it} \). This is a standard factor model, and \( \eta_t \) can be estimated under large \( N \) and large \( T \). Recumulating \( \eta_t \) will obtain \( f_t \) up to a location (unless \( f 1 = 0 \)) and scale shift. When the initial observation \( X_{i1} = \lambda_i' f 1 + \varepsilon_{i1} \) is included in estimation, there is only a scale shift in the estimated \( f_t \).

The above idea is implemented in Bai and Ng (2004) for testing panel unit roots. The process \( X_{it} \) will have a unit root if either \( f_t \) or \( e_{it} \) has a unit root. The key is to consistently estimate \( f_t \) and \( e_{it} \) without knowing a priori their integration orders. Bai and Ng propose to test separately the nonstationarity property for the common component and the idiosyncratic components. This permits us to trace the source of a nonstationary property arising from a common or idiosyncratic component.

**Diffusion-index forecasting**

Large-dimensional factor models have proven useful in forecasting macroeconomic variables. Let \( y_t \) be the variable to be forecasted, say inflation. Consider the \( h \)-period-ahead forecasting equation,

\[ y_{t+h} = \alpha' w_t + \beta' f_t + \varepsilon_{t+h} \]

where \( w_t \) is a set of observable predictors, such as the lags of \( y_t \) and the unemployment rate under the Philips curve model. Here, \( f_t \) is not observable, but it captures the co-movement among a large number of macroeconomic variables \( X_{it} \), which links to \( f_t \) according to (1). Stock and Watson (2002a; 2002b) suggest that \( f_t \) be extracted from \( X_{it} \) to obtain \( \hat{f}_t \), and then use \( \hat{f}_t \) in place of \( f_t \) in the forecasting equation. This method is referred to as diffusion index forecasting, which outperforms many competing methods. Bai and Ng (2006a) analyse the statistical properties of this method. A modified diffusion index approach is proposed in Bai and Ng (2006b). The modified approach consists of two steps. The first step selects a subset of \( X_{it} \) that is relevant to \( y_t \) based on certain criteria. The second step proceeds as the usual diffusion approach using the selected subset of \( X_{it} \) only.
A large dimensional covariance matrix is useful in financial risk management and portfolio construction. For \( N > T \), the sample covariance matrix \( S(N \times N) \) as an estimator for \( \Sigma \) is not full rank. Thus we consider factor-model based estimator. For this purpose, we use a demeaned data matrix, denoted by \( X_c \) (remove the time series mean for each series). Note that the sample covariance matrix is \( S = \frac{1}{T-1} X_c X_c' \).

Estimate the factor \( \tilde{\xi} \) in the same manner as above using \( X_c' X_c \), then \( \tilde{\Lambda} = X_c \tilde{\xi} / T \), and \( \tilde{\varepsilon} = X_c - \tilde{\Lambda} \tilde{\xi}' \). Given these estimates, a factor-model based covariance matrix is then defined as

\[
\hat{\Sigma} = \alpha \tilde{\Lambda} \tilde{\Lambda}' + D
\]

where \( D \) is a diagonal matrix with typical element \( \hat{d}_i = \frac{1}{T-1} \sum_{t=1}^{T} \hat{\varepsilon}_t^2 \) \((i = 1, 2, \ldots, N)\), \( \alpha = T / (T - 1) \).

The diagonal elements of \( \hat{\Sigma} \) coincide with the corresponding elements of the sample covariance matrix \( S \). In essence, \( \hat{\Sigma} \) is an estimator that shrinks the off-diagonal elements of \( S \) towards zero. Also the inverse of this matrix is quite easy to compute, it is given by

\[
\hat{\Sigma}^{-1} = D^{-1} - \alpha D^{-1} \tilde{\Lambda} (I_r + \alpha \tilde{\Lambda}' D^{-1} \tilde{\Lambda})^{-1} \tilde{\Lambda}' D^{-1},
\]

which only requires the inverse of a diagonal matrix and that of an \( r \times r \) matrix. Other covariance estimators are discussed by Ledoit and Wolf (2003; 2004), and Fan, Fan, and Lv (2006).

**Dynamic factor models**

In model (1), the factor process \( f_t \) is allowed to be a general dynamic process. However, the relationship between \( X_{it} \) and \( f_t \) is static. A general dynamic factor model is defined as

\[
X_{it} = \mu_i + \gamma_i(L) u_t + \varepsilon_{it}
\]

where \( u_t \) are i.i.d. random vectors, and \( \gamma_i(L) = \sum_{k=0}^{\infty} \gamma_{ik} L^k \) with \( L \) being the lag operator. Sargent and Sims (1977), Quah and Sargent (1993) and Geweke and Singleton (1981) are among the early researchers who have studied the dynamic factor models in economics. Identification and estimation of the general dynamic factor model is studied by Forni et al. (2000), who extend the dynamic principal...
components analysis of Brillinger (1981) to large $N$. If $\gamma_i(L)$ is a finite order polynomial such that

$$\gamma_i(L)'u_t = \gamma_{i0}'u_t + \ldots + \gamma_{ip}'u_{t-p}$$

(a finite order moving average) then the dynamic factor model can be written as a static factor model by defining $f_t = (u_t', ..., u_{t-p}'),$ and $\lambda_i = (\gamma_{i0}', ..., \gamma_{ip}')'$ so that $\gamma_i(L)'u_t = \lambda_i'^{}f_t.$ The usual principal components method is still applicable. In general, when the coefficients in $\gamma_i(L)$ decays to zero quickly, $\gamma_i(L)u_t$ can be approximated by a finite order moving average.

Relationship with principal components analysis

Principal components analysis (PCA) seeks linear combinations of the observable variables that give rise to maximum variations. The aim is to summarize the data with as few components as possible without losing too much information. In doing so, it imposes no restrictions on the covariance matrix, as does factor analysis. As such, PCA is a pure dimension-reduction technique.

Factor analysis aims to explain the correlations or co-movements among the observable variables. It assumes that observable variables are linked with a small number of unobservable variables (factors), which are responsible for the correlation. Thus factor analysis is conducted based on a model. In contrast, PCA can be considered as a model-absence method.

Factor models can be estimated by the principal components method. The so-called principal-factor analysis is an iterated principal components method (see Mardia, Kent and Bibby, 1979). There are three situations in which the principal components method (without iteration) will give either identical or similar results as other factor estimation methods: (i) the idiosyncratic covariance is a scalar multiple of an identity matrix, that is, $\Phi = \sigma^2 I_N$; (ii) the idiosyncratic error variance is small, that is, $\Phi$ is close to zero; (iii) the number of variables of $N$ is large.

Summary

Factor analysis is a model for correlations, postulating that correlations be induced by a few unobservable common components. The model implies a structure on the covariance matrix, which has far fewer free parameters than unrestricted covariance matrix. Therefore, factor models are employed in problems where a reduction in the number of parameters is desired. Applications in economics include modelling cross-sectional correlation, capturing co-movements, forecasting, panel unit root and cointegration analysis, as well as financial risk management and optimal portfolio construction.

factor price equalization (historical trends)

Kevin H. O'Rourke
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Heckscher–Ohlin prediction that international trade should lead to relative factor prices converging internationally is one that receives abundant empirical support for the period that was the focus of interest for these two economists, namely the ‘long 19th century’. In labour-abundant regions, wage–rental ratios increased, whereas they declined in land-abundant countries.

Article

When 21st-century undergraduate economists are taught trade theory, they inevitably encounter the standard Heckscher–Ohlin trade theory, which was for many years, and perhaps still is, the workhorse of international trade theory. The ‘2×2×2’ version of the theory which they first study surely strikes many of them as unrealistic in the extreme, with its strong predictions of factor price equalization, which logically follows when both countries produce both goods using the same technology. However, the origins of the theory lie in the attempts of two Swedish economists, Eli Heckscher (who was an economic historian) and Bertil Ohlin, to understand the world around them, and in particular to make sense of the global economy of the late 19th century. Not surprisingly, perhaps, their theoretical predictions find ample empirical support in the historical records of that time.

Bertil Ohlin presented the theory as follows:

Australia has a small population and an abundant supply of land, much of it not very fertile. Land is consequently cheap and wages high, in relation to most other countries. It would therefore seem profitable to produce goods requiring large areas of less fertile land but relatively little labour. Such is the case, for example, in wool production … Similarly, regions well endowed with technically trained labor and capital will specialize in industrial production … Exports from one region to the other will on the whole consist of goods that are intensive in those factors with which this region is abundantly endowed and the prices of which are therefore low … In short, commodities that embody large quantities of particularly scarce factors are imported, and commodities intensive in relatively abundant factors are exported. … Australia exchanges wool and wheat for industrial products since the former embody much land and little labour while the opposite is true of industrial products. Australian land is thus exchanged for European labor. (Flam and Flanders, 1991, p. 90)

He then argued that the level of trade integration helped determine factor prices in both regions:

If, for example, Australia produced its own industrial products rather than importing them from Europe and America in exchange for agricultural products, then, on the one hand, the demand for labor would be greater and wages consequently higher, and on the other the demand for land, and therefore rent, lower than at present. At the same time, in Europe the scarcity of land would be greater and that of labor less than at present if the countries of Europe were constrained to produce for themselves all
their agricultural products instead of importing some of them from abroad. Thus trade increases the price of land in Australia and lowers it in Europe, while tending to keep wages down in Australia and up in Europe. The tendency, in other words, is to approach an equalization of the prices of productive factors. (Flam and Flanders, 1991, pp. 91–2)

Three points should be noted about these quotations. First, Ohlin presented the theory using an example that seems to lend itself more easily to formalization via a three-factor, two-good model (in which land, labour and capital produce agricultural and industrial products) than to formalization via the 2x2 framework that is often associated with Heckscher–Ohlin theory today. Second, he speaks of a ‘tendency’ to ‘approach an equalization’ of factor prices, but not of factor price equality per se. That is, his prediction is that there would be factor price convergence. Third, the metaphor that motivated him was one that reflected the international economy of the late 19th century, in which intercontinental trade flows for the most part reflected an exchange of resource-intensive products coming from the New World, but also from resource-abundant regions in Asia and Africa, for labour-intensive (and also capital-intensive) manufactured goods produced in western Europe and parts of North America (Findlay and O’Rourke, 2007, ch. 7).

The 19th century, and particularly the period from roughly 1840 onwards, offers the perfect context in which to study the empirical relevance of such a theory, for it was a period that saw a dramatic, worldwide decline in transport costs (O’Rourke and Williamson, 1999, ch. 3). For example, Knick Harley’s (1988) index of British ocean freight rates declines by about 70 per cent between 1840 and 1910, after having remained roughly constant for a century or so. Table 1 presents freight factors (that is to say, transport costs as a percentage of either the import or the export price of a commodity) for several commodities and routes, and the picture which emerges is one of sharply falling transport costs on many routes. The implication is that the relative prices of imported goods should have been steadily declining across continents, as commodity market integration lowered intercontinental price gaps. Furthermore, these declining transport costs were linking continents with very different factor endowments, implying that there should have been scope for trade to have had the sort of impact on factor prices that Heckscher and Ohlin said it should.

In this historical context, one key prediction of the theory is as follows. In labour-abundant regions, such as the crowded countries of Europe, declining transport costs should have led to the relative price of agricultural commodities falling, as they were imported from land-abundant regions, and thus to the ratio of wages to land rents rising. In land-abundant countries, such as the frontier societies of the New World, declining transport costs should have led to the rise of relative price of agricultural commodities, and thus to a fall in wage-
rental ratios. Economic historians have examined this prediction at great length. O’Rourke, Taylor and Williamson (1996) presented evidence for seven affluent ‘Atlantic economy’ economies, while more recently Jeffrey Williamson, in a series of papers summarized in Williamson (2002), has expanded the work to include data for several developing economies. By and large, the Heckscher–Ohlin predictions hold good for the late 19th century, both for western Europe and the New World, and for those Third World countries that participated in the late 19th-century global economy (O’Rourke and Williamson, 1999, ch. 4; Williamson 2002, Table 3, p. 73). In land-scarce economies such as those of Japan, Korea, Taiwan or the United Kingdom, the wage–rental ratio increased substantially; while it fell sharply in land-abundant food exporting nations and regions such as Argentina, Uruguay, Burma, Siam, Egypt, the United States, Canada, Australia and the Punjab (see Table 2).

**Source:** Williamson (2002, Tables 3 and 4, pp. 73–4).

Of course, the fact that wage–rental ratios were systematically trending upwards in labour-abundant economies, and downwards in land-abundant economies, cannot be taken as proof that the Heckscher–Ohlin theory was at work, any more than rising skill premia in many Organisation for Economic Co-operation and Development (OECD) economies can be taken as evidence of factor price equalization today, in 2007. As today’s debate about ‘trade and wages’ suggests, other forces might be at work driving up the ratio of skilled to unskilled wages in skill-abundant economies, most notably perhaps technological change biased in favour of skilled workers. (Recent contributions to the literature on this controversy include Collins, 1998; Feenstra, 2000; and Feenstra and Hanson, 2004.) For the late 19th century, both econometrics and simulation exercises indicate that the wage–rental ratio trends documented in Table 2 were indeed in part due to Heckscher–Ohlin forces. That is to say, the price of agricultural products relative to manufactured products was negatively related to the wage–rental ratio during this period (O’Rourke and Williamson, 1994; 1999; O’Rourke, Taylor and Williamson, 1996). It is noticeable that wage–rental ratios increased by less in protectionist economies such as those of France and Germany than in the free-trading United Kingdom. Further evidence in favour of this Heckscher–Ohlin interpretation of 19th-century distributional trends comes from a comparison of the pre-1800 and 19th-century periods (O’Rourke and Williamson, 2005). Before 1800, British land–labour ratios were trending downwards, as population expanded but land supplies remained relatively constant. In a closed economy setting, this would be expected to lead to an increase in the relative price of agricultural commodities, and to a decline in wage–rental ratios; and this is indeed what happened (Figure 1, Panel A). From 1840 onwards, by contrast, relative agricultural...
prices stopped rising, and eventually started falling, while the wage–rental ratio stopped falling and started rising (Panel B). This switch occurred despite an acceleration in British population growth, and is consistent with a British economy opening up to trade and becoming more exposed to the factor price convergence forces identified by Heckscher and Ohlin.

Factor prices were certainly not equalized during the late 19th century, any more than they have been equalized today. But they converged between continents, in precisely the manner envisaged by Heckscher and Ohlin.

The constraint binding changes in the distributive variables, in particular the real wage rate \( (w) \) and the rate of profit \( (r) \), was discovered (though not consistently demonstrated) by Ricardo: ‘The greater the portion of the result of labour that is given to the labourer, the smaller must be the rate of profits, and vice versa’ (Ricardo, 1971, p. 194). He was thus able to dispel the idea, generated by Adam Smith's notion of price as a sum of wages and profits, that the wage and the rate of profit are determined independently of each other. Ever since the inverse relationship between the distributive variables played an important role in long-period analysis of both classical and neoclassical descent. In more recent times it was referred to by Samuelson (1957), who later dubbed it ‘factor price frontier’ (cf. Samuelson, 1962). Hicks (1965, p. 140, n.1) objected that this term is unfortunate, since it is the earnings (quasi-rents) of the (proprietors of) capital goods rather than the rate of profit which is to be considered the ‘factor price’ of capital (services). A comprehensive treatment of the problem under consideration within a classical framework of the analysis, including joint production proper, fixed capital and scarce natural resources, such as land, was provided by Sraffa (1960). The relationship is also known as the ‘wage frontier’ (Hicks, 1965), the ‘optimal transformation frontier’ (Bruno, 1969) and the ‘efficiency curve’ (Hicks, 1973).

The duality of the \( w-r \) relationship and the \( c-g \) relationship, that is, the relationship between the level of consumption output per worker \( (c) \) and the rate of growth \( (g) \) in steady-state capital theory has been demonstrated by the latter two authors and in more general terms by Burmeister and Kuga (1970); for a detailed account, see Craven (1979).

To begin with, suppose for simplicity that there are only single-product industries with labour as the only primary input and that only one (indecomposable) system of production is known (cf. Sraffa, 1960, Part I). Then, with gross outputs of the different products all measured in physical terms and made equal to unity by choice of units and with wages paid at the end of the uniform production period, we have the price system.

\[
p = (1 + r) a p + w a_0,
\]

where \( p \) is the column vector of normal prices, \( a \) is the square matrix of material inputs, which is assumed to be productive, and \( a_0 \) is the column vector of direct labour inputs. Using the consumption basket \( d \) as standard of value or numéraire,

\[
d p = 1,
\]

we can derive from (1) and (2) the \( w-r \) relationship for system \((a, a_0)\).
The relationship is illustrated in Figure 1. At $r=0$ the real wage in terms of $d$ is at its maximum value $W$; it falls monotonically with increases in $r$, approaching zero as $r$ approaches its maximum value $R$. (The $w-r$ relationship can be shown to be a straight line if Sraffa's Standard commodity $s$ is used as *numéraire*, where $s$ is a row vector such that $s=(1+R)s_0$; cf. Sraffa, 1960, chap. IV.)

Figure 1

\[ w = \left( d \left[ 1 - (1 + r)g \right]^{-1} \right)^{-1} \]
Let us now assume that several systems are available for the production of the different commodities and that all the production processes exhibit constant returns to scale. We call the set of all the alternative methods (or processes) of production known the technology of the economic system. From this set a series of alternative techniques can be formed by grouping together these methods of production, one for each commodity. Hence there is the question of the choice of technique. Under competitive conditions this choice will be exclusively grounded on cheapness, that is, the criterion of choice is that of cost-minimization. In the case depicted, it can be shown that the competitive tendency of entrepreneurs to adopt whichever technique is cheapest in the existing price situation, will for a given $w$ (or, alternatively, $r$) lead to the technique yielding the highest $r(w)$, whereas techniques yielding the same $r(w)$ for the same $w(r)$ are equiprofitable and can co-exist (cf. Garegnani, 1970, p. 411).

What has just been said is illustrated in Figure 2. It is assumed that only three alternative techniques, $\alpha$, $\beta$, and $\gamma$, are available, each of which is represented by the associated $w-r$ relationship; since $w$ is always measured in terms of the consumption basket $d$, all three relationships can be drawn in the same diagram. Obviously, technique $\gamma$ is inferior and will not be adopted. Technique $\alpha$ will be chosen for $0 < w < w_1$ and $w_2 < w < w_\alpha$, while technique dominates at $w_1 < w < w_2$; there are two switch points (at $w=w_1$ and $w=w_2$, respectively) at which both techniques are equiprofitable. The heavy line represents the economy's $w-r$ frontier (or 'factor price frontier') and is the outer envelope of the $w-r$ relationships. At a level of the wage rate $w^*$, for example, technique $\beta$ will be adopted giving a rate of profit $r^*$. (For a discussion of more general cases of single production, see Pasinetti, 1977, ch. VI; for a reformulation of some results in capital theory in terms of the so-called ‘dual’ cost and profit functions, see Salvadori and Steedman, 1985; on the maximum number of switch points between two production systems, see Bharadwaj, 1970.)

Figure 2
Figure 2 shows that the same technique (\(\alpha\)) may be costminimizing at more than one level of the wage rate (rate of profit) even though other techniques (here \(\beta\)) dominate at wage rates in between. The implication of this possibility of the *reswitching* of techniques (and of the related possibility of *reverse capital deepening*) is that the direction of change of input proportions cannot be related unambiguously to changes in the distributive variables. This can be demonstrated by making use of the duality between the \(w-r\) and the \(c-g\) frontier.

Denoting the value of net output per labour unit by \(y\) and the value of capital per labour unit by \(k\), we have in steady-state equilibrium

\[
y = w + rk = c + gk.
\]

Solving for \(k\) we get

\[
k = (c - w) / (r - g)
\]

except in golden rule equilibrium (\(g=r\)), where \(k\) can be shown to be (minus) the slope of the golden rule \(w-r\) relationship at the going level of \(r\). In Figure 3(a) the frontier built of two techniques, \(\alpha\) and \(\beta\), is depicted. The rate of growth is fixed at the level \(\bar{g}\), to which correspond \(c_\alpha\), and \(c_\beta\). For values of \(r \geq \bar{g}\), that is, on the right side of the golden rule, Fig. 3(b) gives the corresponding value of \(k (r, \bar{g})\). For example, at \(\bar{w}\) technique \(\beta\) will be chosen, yielding a rate of profit \(\bar{r}\) the associated capital intensity is given by

\[
\tan \theta = (c_\beta - \bar{w}) / (\bar{r} - \bar{g}) = \bar{k}.
\]
Figure 3(b) shows that the capital–labour ratio need not be inversely related to the rate of profit as neoclassical long-period theory maintained. In more general terms, it cannot be presumed that input uses, per unit of output, are related to the corresponding ‘factor prices’ in the conventional way (see Metcalfe and Steedman, 1972, and Steedman, 1985). This result calls in question the validity of the traditional demand and supply approach to the determination of quantities, prices and income distribution.

The results stated above essentially carry over to the more general case with fixed capital, pure joint production and several primary inputs, such as land and labour of different qualities, provided the formalization of the problem is appropriately adapted to the specific case under consideration. Here it suffices to point out a few additional aspects of the choice of technique problem.

With fixed capital there is always such a problem to be solved. This concerns both the choice of the system of operation of plant and equipment, that is, for example, whether a single or a double-shift system is to be adopted; and the choice of the economic lifetimes of fixed capital goods. During the capital theory debates of the 1960s and early 1970s attention focussed on the latter aspect of the use of capital. It was shown that with decreasing or changing efficiency of the durable capital good, cost minimization implies that for a given level of the rate of profit, premature truncation is advantageous as soon as the price (book value) of the partly worn out item becomes negative. While the $w-r$ relationship for a given truncation may slope upwards over some range of $r$, the $w-r$ frontier consists only of those parts of the $w-r$ relationships that are downward-sloping. Moreover, it was demonstrated that the frontier can display the return of the same truncation (cf., for example, Hagemann and Kurz, 1976). As to the other aspect of capital utilization, a similar possibility can be
shown to exist: the *return of the same system of operation of plant and equipment* (cf. Kurz, 1986). Both phenomena are of course variants of the reswitching of techniques. In systems with pure joint production a choice of technique is inherent, even where the number of processes available does not exceed the number of products. Sraffa's approach to joint production is in terms of 'square' systems of production, that is, systems where the number of processes operated is equal to the number of commodities (i.e. positively-priced products). However, as Salvadori (1982) has shown, in such a framework a cost-minimizing system does not need to exist. A way out of this impasse may be seen in a formalization of joint production that is similar to von Neumann's. In such a formalization the free disposal assumption plays a crucial role. It can be shown that the $w-r$ frontier is downward-sloping, even though individual $w-r$ relationships may have positive ranges.

factor prices in general equilibrium

Michael Mandler
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In general equilibrium models with linear or nonlinear activities, factor prices can be indeterminate and agents will have an incentive to non-competitively manipulate prices even if they are small relative to the market. The indeterminacy cannot occur at generic endowments, but the non-generic endowments where it does occur will arise endogenously as an equilibrium outcome when some factors, such as capital goods, are produced. This endogenous indeterminacy creates a hold-up problem since investors need not earn the rate of return that obtains in an intertemporal competitive equilibrium. Unlike the classical hold-up problem, factor-price indeterminacy is not attributable to there being few agents or bilateral monopoly.

1 Introduction

At first glance, the Walrasian general equilibrium model does not offer a theory of factor prices. Factors are goods supplied by agents to firms which then use them to produce outputs. In the general equilibrium model, there is no such class of goods: one and the same good can simultaneously be used as an input by some firms, produced as an output by other firms, sold by some consumers, and purchased and consumed by other consumers. Indeed, the general equilibrium model’s abstraction from
the minutiae of how particular goods are used is one of the theory's great advantages. For many of the classical concerns of the Walrasian tradition – the existence of equilibrium, optimality – these details are irrelevant.

Even if there is a category of factors that consumers sell and firms buy, it is hard to see any distinctive properties of these goods. While factor supply functions can exhibit perverse responses to price changes, so can output demand functions. The responses of firms to price changes are better behaved, and firm factor demands may seem to be governed by a distinctive principle: a firm's demand for a factor diminishes in its own price while a firm's supply of an output increases in its own price. While correct, these two fundamental rules of producer comparative statics are really reflections of a single law, as Samuelson (1947) showed long ago. Suppose in an $n$-good economy that a profit-maximizing firm with production set $\mathcal{Y} \subset \mathbb{R}^n$ chooses $y = (y_1, \ldots, y_n) \in \mathcal{Y}$ when facing prices $p = (p_1, \ldots, p_n)$ and $\hat{y} \in \mathcal{Y}$ when facing $\hat{p}$. Since each decision is profit-maximizing, $p \cdot y \geq p \cdot \hat{y}$ and $\hat{p} \cdot \hat{y} \geq p \cdot y$ and hence $(\hat{p} - p) \cdot (\hat{y} - y) \geq 0$. If only one price differs at $p$ compared to $\hat{p}$, say the first, then $(\hat{p}_1 - p_1)(\hat{y}_1 - y_1) \geq 0$. So if $\hat{p}_1 > p_1$ then $\hat{y}_1 \geq y_1$. Both of the comparative statics rules now follow from the appropriate sign restrictions on $y_1$ and $\hat{y}_1$: when both are positive we conclude that the output of good 1 supplied by the firm must be weakly increasing in its price, while if both are negative we conclude that the factor demand for good 1 must be weakly decreasing in its price (since $\hat{y}_1 \geq y_1$ and $(\hat{y}_1, y_1) \leq 0$ imply $|\hat{y}_1| \leq |y_1|$). It is tempting to conclude that there is no special general equilibrium principle of factor demands, just a specific application that follows when the sign convention for factors is inserted.

2 Factor-price indeterminacy

The demand for and supply of factors can nevertheless exhibit distinctive properties, although they are consistent with the generalities pointed out in the previous section. These properties do not matter for the most of the classical results of general equilibrium theory, but they can undermine one result, the generic determinacy (local uniqueness) of equilibria.

The first distinguishing trait of factors is that sometimes they do not provide any direct utility and are useful only as inputs in production. Consumers will supply to the market their entire endowment of such 'pure' factors and hence supply will be inelastic with respect to price changes. As we will see, what matters is local unresponsiveness to prices. Perhaps when a factor such as iron ore is sufficiently cheap in terms of consumption goods consumers will find some direct use for it and hence have an excess demand that locally varies as a function of prices. But above some minimum price, consumers will not consume any iron ore and in this range consumers' excess demand will be inelastic. Second, technology can restrict the number of ways in which factors can be productively combined. The extreme case occurs with fixed coefficients – the Leontiev production function – where to produce one unit of a good just one combination of factors will do. More flexible is the linear activities model where finitely many constant-return-to-scale techniques are available to produce one or more goods. Factors then may be combined in various configurations but some factor proportions cannot be used productively (that is, without disposing of some of the factors). Nonlinear activities are qualitatively similar but do not require constant returns to scale. In all these cases, production sets have a kinked rather than smooth
Consequently factor prices can be adjusted at least slightly from one equilibrium configuration without changing the quantity of factors that profit-maximizing producers will demand when producing a given quantity of output (or vector of outputs). In the Leontiev case, picture the multiple price lines that can support the model's L-shaped isoquants. Of course, production sets do not have to exhibit kinks; for example, they will be smooth when each output is a differentiable function of factor inputs. Any change in relative factor prices will then lead to a change in factor demand.

Factors of production thus are distinctive in that both demand and supply can be unresponsive to certain types of price changes. Factor demand and supply do not have to display this unresponsiveness, but under plausible circumstances permitted by the general equilibrium model they will. Inelastic factor demand and supply in turn can lead to an indeterminacy of factor prices. For a simple example, suppose an economy has one consumption good, produced by a single linear activity that requires $a_1$ units of one factor and $a_2$ units of a second factor to yield one unit of output. Set the price of consumption equal to 1, let $w_1$ and $w_2$ be the two factor prices, let the endowments of the two inelastically supplied factors be $e_1 \geq 0$ and $e_2 \geq 0$, and let $y$ be the sole activity usage level. An equilibrium $(w_1, w_2, y) \geq 0$ where the consumption good is produced and has a positive price must satisfy three conditions: (i) $a_1 w_1 + a_2 w_2 = 1$ (the activity breaks even), (ii) $a_i y \leq e_i$ for $i = 1, 2$ (market-clearing for factors), and (iii) $a_i y < e_i \Rightarrow w_i = 0$ for $i = 1, 2$ (factors in excess supply have a 0 price). On the assumption that the demand for output equals factor income, which is a form of Walras's law, (i)–(iii) imply that the market for output clears.

Evidently equilibrium must satisfy $y = \min \left( \frac{e_1}{a_1}, \frac{e_2}{a_2} \right)$. By (iii), the two factors will both have a strictly positive price only if

$$\frac{e_1}{a_1} = \frac{e_2}{a_2},$$

in which case any $w = (w_1, w_2) \geq 0$ that satisfies (i) will be an equilibrium $w$: indeterminacy therefore obtains when (1) holds. We defer for a little while the question of whether this knife-edge condition is likely to be satisfied.

Fixed coefficients and inelastic factor supply do not always lead to indeterminate factor prices. Prior to the invention of the differentiable production function and for a while thereafter, the standard cure for factor-price indeterminacy was to argue that, even if each industry uses factors in fixed proportions, those proportions will differ across industries; variations in factor prices will then lead to changes in relative output prices, and thus to changes in output demand that feedback to changes in factor demand (Cassel, 1924; Wieser, 1927). Substitution in consumption can thereby play the same equilibrating role as the technological substitution of inputs in production. For the simplest example, suppose we supplement the above single-sector economy with a new sector that uses $b_1$ units of the first factor and $b_2$ units of the second factor to produce one unit of a second consumption good. If we keep the price of the first consumption good equal to 1, and let $p_b$ be the price of the second consumption good, then when both activities break even the equalities
must be satisfied. As long as \( a_1 / a_2 \neq b_1 / b_2 \), it will not be possible to adjust \( w \) without also changing the relative price of the consumption goods \( p_b \). When \( w_1 / w_2 \) increases, the consumption good that uses factor 1 more intensively will rise in price, presumably diminishing demand for that good and thus diminishing the demand for factor 1. Even if demand for consumption is a perverse function of prices, this two output–two factor model will still typically have determinate prices as long as both activities break even.

A general linear activity analysis model will clarify when the determinate and indeterminate cases arise. The linearity of the activities serves only to simplify the model's equilibrium conditions. There will be two types of goods: factors, which give no utility and are inelastically supplied, and consumption goods, which do give utility. Despite their name, consumption goods can be used as inputs and nonproducible but they must provide utility to some agents. We now adopt the standard sign convention and define an activity to be a vector, with as many coordinates as there are commodities, whose positive coordinates give the quantities of goods produced and negative coordinates give the quantities of goods used when the activity is operated at the unit level. In equilibrium the excess demand for each good must be non-positive, each good in excess supply must have a 0 price, each activity must earn non-positive profits, and each activity in use must earn 0 profits. Since determinacy and indeterminacy are purely local events, a search for equilibrium prices and activity near a reference equilibrium can ignore the 'slack' equilibrium conditions, the market-clearing condition for any good in excess supply and the no-positive-profits condition for any activity that either makes strictly negative profits or utilizes and produces only goods in excess supply: for small adjustments of prices and activity levels, the excluded goods will remain in excess supply and the excluded activities will continue to make negative profits or continue to use and produce only goods in excess supply (and hence continue to break even). Call any good not in excess supply and any activity that breaks even and that uses or produces at least one good not in excess supply ‘operative’. Given some reference equilibrium with \( \mathcal{E} \) operative consumption goods, \( m \) operative factors, and \( n \) operative activities, let \( A \) be the \((\mathcal{E} + m) \times n\) activity analysis matrix whose rows and columns correspond to the operative goods and activities, let \( y \) be the \( n \)-vector of operative activity levels, let \( p \) be the \( \mathcal{E} \)-vector of prices for the operative consumption goods, let \( w \) be the \( m \)-vector of prices for the operative factors, let \( z(p, w) \) be the excess demand function for the operative consumption goods, which we assume is homogeneous of degree 0 in \((p, w)\), and finally let \( e \) be the \( m \)-vector of inelastic supplies of the operative factors. Walras's law then states that \( p \cdot z(p, w) = w \cdot e \). Equilibria \((p, w, y) \succeq 0\) are locally characterized by the equalities

\[
(z(p, w), -e) = Ay, \quad (p, w)'A = 0.
\]
factor prices in general equilibrium: The New Palgrave Dictionary of Economics

(All vectors are column vectors and \( \prime \) denotes transposition.) Bear in mind that the market-clearing and no-positive-profit inequalities excluded from (2) vary by equilibrium; the activities and goods operative in one equilibrium need not be operative in another. We assume henceforth that, at any equilibrium, each of the operative activities is used at a strictly positive level and that each operative good has a strictly positive price, \( (p, w, y) \gg 0 \). As usual, the homogeneity of demand allows us to set one of the positively priced goods to be the numéraire and Walras's law implies that one of market-clearing conditions is redundant. So we set the price of the first consumption good not in excess supply to equal 1 and put aside the market-clearing condition for this good. Letting \( \bar{z}(p, w) \) denote \( z(p, w) \) without the first coordinate, \( \bar{A} \) denote \( A \) without the first row, and \( \bar{p} \) denote \( p \) with the first coordinate set equal to 1, (2) can be written

\[
(\bar{z}(\bar{p}, w), -\varepsilon) = \bar{A}y
\]

(3)

\[
(\bar{p}, w)\prime A = 0.
\]

(4)

Any small change in \( (\bar{p}, w, y) \) that satisfies (3)–(4) will then continue be an equilibrium: the variables \( (\bar{p}, w, y) \) will remain positive, all excluded goods will remain in excess supply, and all excluded activities will continue to make negative profits or continue to use and produce only goods in excess supply.

The most conspicuous case of factor-price indeterminacy occurs when \( m>n \), that is, when there are more operative factors than operative activities. If, beginning at some reference equilibrium, we fix \( y \) at its equilibrium value, then as \( (\bar{p}, w) \) varies the market-clearing conditions for factors in (3) will continue to be satisfied. But the remaining equilibrium conditions – (4) and the market-clearing conditions for consumption goods in (3) – comprise \( n + \varepsilon - 1 \) equations in the \( \varepsilon - 1 + m \) variables \( (\bar{p}, w) \). Hence, if \( m>n \) and as long these remaining equilibrium conditions satisfy a rank condition, which allows the implicit function theorem to be applied, indeterminacy will occur. The economy considered earlier where two factors are used by one activity qualifies as an example of the \( m>n \) type of indeterminacy, while the economy where two factors are used to produce two goods does not. A slight variation of this argument applies to a subset of factors. Suppose that \( \hat{m} \) of the \( m \) operative factors are used by only \( \hat{n} \) of the \( n \) operative activities, and that \( \hat{m} > \hat{n} \). Thus the remaining \( n - \hat{n} \)
operative activities have 0 entries in the rows of $A$ that correspond to these $\hat{m}$ factors. If we fix the $\hat{n}$ coordinates of $y$ for the activities that do use these $\hat{m}$ factors, then, as the remaining endogenous variables (the other $n - \hat{n}$ activity levels, $\vec{p}$, and $w$) change, the market-clearing conditions for the $\hat{m}$ factors will continue to be satisfied. Moreover, the number of remaining endogenous variables is $n - \hat{n} + \ell - 1 + m$ while the number of remaining equilibrium conditions is $\ell - 1 + m - \hat{m} + n$. The difference between the number of remaining variables and remaining equilibrium conditions is therefore $\hat{m} - \hat{n}$ and so there are more variables than equilibrium conditions. Indeterminacy therefore obtains (again, given a rank condition).

Factor-price indeterminacy, whether for an economy as a whole or for a subset of an economy's factors, depends critically on production sets that exhibit kinks. By fixing a set of activity levels, the above indeterminacy argument fixes a vector of factor demands and finds a multiplicity of prices at which firms will demand exactly those quantities. If the aggregate production set were smooth, a fixed vector of firm factor demands would be supported by only one vector of relative factor prices.

Factor-price indeterminacy brings dramatic behavioural consequences: agents have a strong incentive to manipulate factor prices and hence markets cannot function competitively. In the two factor–one activity example, where the endowments satisfy (1), the tiniest withdrawal of either factor $i=1$ or $i=2$ from the market will lead the other factor to be in excess supply and have price 0 and hence cause factor $i$'s price to jump to $1/a_i$. No matter how small an owner of factor $i$ is as a proportion of the market, it will be in his or her interest to remove a small amount of $i$ from the market. Agents therefore will not behave like price-takers. When more activities are present, the jump in factor prices need not be as large, but a jump will still occur for an arbitrarily small withdrawal of a factor, and hence the incentive to manipulate will remain. The distinctive mathematical feature of factor-price indeterminacy that drives this conclusion is that the equilibrium correspondence fails to be lower hemicontinuous. (The equilibrium correspondence is the correspondence from the parameters of the model, such as the endowments $e$, to the endogenous variables $(\vec{p}, w, y)$.) When the endowments of factors lead to an indeterminate equilibrium, it will usually be impossible at nearby endowment levels to find equilibrium prices near to the prices of the indeterminate equilibrium. Other varieties of indeterminacy in the general equilibrium model, such as the indeterminacy of the overlapping generations model, do not suffer from such a failure of lower hemicontinuity and therefore do not invite market manipulation (see Mandler, 2002).

3 The emergence of factor-price indeterminacy through time

We saw in the two factor–one activity example that indeterminacy occurs only if a knife-edge condition on endowments is satisfied. This observation applies to the broader species of factor-price indeterminacy as well. Suppose again that at some reference equilibrium $\hat{m}$ operative factors are used by $\hat{n} < \hat{m}$ operative activities, let $\hat{e}$ be the endowments of these $\hat{m}$ factors, let $\hat{y}$ be the activity levels for the $\hat{n}$ activities, and let $\hat{A}$ be the $\hat{m} \times \hat{n}$ submatrix of $A$ formed by the rows for the $\hat{m}$ factors and the columns for the $\hat{n}$ activities. Then $\hat{A}\hat{y} = \hat{e}$. But since $\hat{A}$ has more rows than columns, for almost every value of $\hat{e}$, $\hat{A}\hat{y} = \hat{e}$ will have no solution. Hence, for most levels of an economy's endowments, there will be no equilibrium at which $\hat{m}$ operative factors are used by fewer than $\hat{m}$ operative activities. While the failure
in these so-called generic cases of the indeterminacy arguments we have given does not show that equilibria are generically locally unique, the literature on regular economies (see in particular Mas-Colell, 1975; 1985; and Kehoe 1980; 1982) has shown that, for generic endowments and preferences, general equilibrium models with linear or nonlinear production activities do have locally unique equilibria.

The determinacy quest, however, does not end here. An economy’s endowments of produced inputs – capital goods – are in any long-term view endogenous variables not parameters. Consequently, even though factor-price indeterminacy does not arise for generic endowments, it is conceivable that those special endowments that lead to indeterminacy will systematically arise as the equilibrium activity of an economy unfolds through time. To see that this can indeed happen, we partition an intertemporal economy’s dates into two periods, a first period where goods are either consumed or invested in the production of factors, and a second period where the factors produced by first-period activities and natural endowments are used to create consumption goods (possibly also with the aid of intermediate inputs produced within the second period). To test whether the nongeneric factor endowments that lead to indeterminacy are likely to appear, we consider intertemporal economies where the endogenous equilibrium production of second-period factors leads the total stock of these factors to assume the nongeneric values where indeterminacy arises. If this endogenous second-period indeterminacy obtains for a robust family of equilibria (the equilibria of a nonempty open set of economies), then sequential indeterminacy occurs (Mandler, 1995).

In the Arrow–Debreu view of an intertemporal economy, agents trade just once at the beginning of economic time; after these initial contracts are signed, no further trade occurs, goods are just delivered. To allow for trade at multiple dates, and thus give indeterminacy in later time periods a chance to appear, we assume instead that agents transfer wealth between periods by borrowing or lending assets. Agents then will typically trade every period, and the economies that appear in later periods will have endowments that are endogenously determined by trade in the initial periods. Moreover any indeterminacy of prices in later periods will change the quantities of goods exchanged and hence change agents’ utilities. In our setting, with just two periods, we can let the activities that produce second-period factors serve as assets: agents in the first period will buy or sell rights to the outputs of the activities that produce the second-period factors and then in the second period receive or deliver the second-period factors they contracted for in the first period and use their income to trade for consumption. The allocation achieved by a two-period Arrow–Debreu intertemporal equilibrium will occur in an equilibrium with two sequential periods of trade if (a) agents in the first period unanimously anticipate a second-period price vector, (b) given those expectations, goods and asset markets in the first period clear, and (c) given asset deliveries, second-period markets clear at the anticipated prices. We omit the routine details of how to decompose an intertemporal equilibrium into a sequential-trading equilibrium (see Radner, 1972) and will just write one equilibrium condition explicitly, the market-clearing equality for second-period factors.

As usual, we consider some reference equilibrium and ignore those goods in excess supply and those activities that make strictly negative profits or that use and produce only goods in excess supply. If there are $k$ operative goods in period 1, and $\ell$ operative consumption goods and $m$ operative factors in period 2, the activity analysis matrix for the operative goods and activities takes the form
where the subscript $c$ or $f$ indicates whether the rows are for consumption goods or factors and the subscript 1 or 2 indicates the time activities begin operation. Since presumably the second-period factors are the outputs of time 1 activities and the inputs of time 2 activities, it makes sense to suppose $A_{f1} \geq 0$ and $A_{f2} \leq 0$. If we let $y_i$ denote the activity levels for operative activities that begin in period $i$ and $e$ the endowment of operative second-period factors, the market-clearing equality for operative second-period factors is

$A_{f1}y_1 + A_{f2}y_2 + e = 0.$

(5)

In the background lie the remaining equilibrium conditions: market-clearing conditions for excess-supply factors and for all consumption goods, and nonpositive profit conditions for activities. Consider the restrictions that (5) places on the number of operative factors. If the number of operative activities in the two periods that produce or use the $m$ operative second-period factors is less than $m$, then, for almost every $e$, (5) will have no solution $y = (y_1, y_2) \succeq 0$. Similarly if there is a subset of $\tilde{m}$ operative second-period factors where the number of operative activities in the two periods that produce or use these factors is less than $\tilde{m}$, then again (5) will usually have no solution. We may therefore dismiss these cases as unlikely, in line with the literature on regular economies. In the remaining cases, where for each subset of $\tilde{m}$ operative second-period factors the number of operative activities in the two periods that produce or use these factors is greater than or equal to $\tilde{m}$, then (5) can have a solution $y \succeq 0$ for a robust (open) choice of endowment levels $e$. But in these latter cases it could well be that some subset of operative second-period factors – say the entire set of all $m$ of these factors – is used by fewer than $m$ operative second-period activities. For an example, let $m=2$, suppose that the first factor has no endowment but is produced by an activity with factor output coefficient $c_1$ while the second factor has a positive endowment in the second period and is not produced. In the second period, both factors are used by one activity with factor usage coefficients $a_1$ and $a_2$. Then (5) consists of the two equalities

$e_1 y_1 + a_1 y_2 = 0,$

$e_2 y_2 + a_2 = 0.$

(6)
Evidently if $a_1 < 0$, $a_2 < 0$, $c_1 > 0$, and $e_2 > 0$, then a solution $y \gg 0$ to (6) exists and is robust: for a small variation in the production coefficients or the endowment, a solution $y \gg 0$ will continue to exist. In this equilibrium, factor 2 is produced in just the quantity necessary to ensure that neither factor 1 nor factor 2 is in excess supply. For a second example, suppose that factor 2 is produced as well and also has no endowment, and let $y_{1i}$ denote the usage level of the activity that produces factor $i$. Then (6) is replaced by $c_1 y_{11} + a_1 y_{22} = 0$ and $c_2 y_{12} + a_2 y_{22} = 0$. Now efficiency and hence equilibrium will usually require that the two factors are produced in quantities that leave neither in excess supply in period 2; if, say, factor 1 were in excess supply and if $y_{11}$ could be lowered, thereby increasing the output of some first-period consumption good, an inefficiency would exist, which is impossible in equilibrium.

Once agents arrive at period 2, they trade again but now the factor outputs produced by the activities that began in period 1 are exogenously given. So in the example given by (6) the endowment of factor 1 in period 2 equals $c_1 y_1$ and one may readily check that this quantity along with $e_2$ of factor 2 satisfies the knife-edge condition (1). Thus, despite seeming to be unlikely at a given point in time, the endowments that lead to indeterminacy can endogenously arise.

Intertemporal general equilibrium economies therefore can be sequentially indeterminate. Moreover, factor-price indeterminacy is typically the only source of endogenous indeterminacy. Let us call the equilibria that occur in the later periods of operation of a sequential-trading equilibrium and that confirm the expectations formed in the initial period ‘continuation equilibria’. A continuation equilibrium is indeterminate if it sits amid a continuum of other (usually non-continuation) equilibria.

**Sequential indeterminacy th:** (Mandler, 1995). For a generic set of intertemporal economies with linear activities, a continuation equilibrium is indeterminate at some date $t$ if and only if there is a set of operative factors appearing at $t$ or later that are used or produced by fewer than $m$ operative activities that begin at $t$ or later.

In contrast, when production sets are smooth, endogenous endowments do not lead to indeterminacy; typically continuation equilibria are locally unique (Mandler, 1997).

### 4 Factor price indeterminacy and the hold-up problem

The endogenous factor-price indeterminacy of the previous section is not an indeterminacy of the equilibria of the entire intertemporal economy or of the corresponding sequential-trading equilibria. As long as the non-produced endowments of every period of an intertemporal economy avoid certain nongeneric values, and barring flukes in preference or technology coefficients, only a finite number of intertemporal equilibria will exist. It follows that in a two-period model that displays sequential indeterminacy, almost all of the infinite multiplicity of equilibria of the second-period economy could not form part of a two-period sequential-trading equilibrium: if the prices of almost any of the second-period equilibria were anticipated in period 1, they would be inconsistent with market clearing. Specifically, if anticipated second-period prices were to vary slightly from the values that hold in a sequential-trading equilibrium, then either assets would no longer share the same rate of return or the common rate of return on assets would change, and hence typically markets would not clear. But
bygones are bygones: once period 1 is past, even the second-period equilibria that violate the requirements of an intertemporal equilibrium are equilibria nonetheless when the economy arrives at its second period. Moreover second-period indeterminacy will prevent sequential-trading equilibria from proceeding smoothly through time: they will be virtually certain to unravel. Since factor prices are indeterminate in the second period, rational agents will predict that an investment in an activity producing a second-period factor will not except by chance earn the rate of return anticipated in the first period of a sequential-trading equilibrium. Investments will therefore differ from their Walrasian levels. The predictions of the general equilibrium model thus become untenable when agents trade repeatedly through time and factor-price indeterminacy is present, even though all the classical presuppositions of the model – price-taking agents, no distortions and so on – obtain. The inability of second-period markets to ensure that assets earn the rate of return necessary for efficiency amounts to a hold-up problem, but the cause of the problem differs from the conventional diagnosis. In the classical hold-up problem, the owners of two complementary factors Nash bargain over the revenue they jointly earn; hence, if the owner of one of the factors invests to improve the quality of his factor, the owner recoups only a fraction of the increment to revenue, and consequently investment is inefficiently low (Hart, 1995). The problem, it would seem, is that the factor owners form a bilateral monopoly and cannot purchase each other's services on a competitive market. What we have seen, however, is that a hold-up problem can arise with perfectly competitive markets. Even if factor owners can purchase all complementary factors on competitive markets, factor-price indeterminacy can prevent investments in factors from earning the rate of return required in intertemporal equilibrium (and hence the rate necessary for efficiency): an unguided market has no means to select from the continuum of equilibrium factor prices the specific prices that deliver intertemporal efficiency. Factor markets moreover will not operate competitively in the presence of factor-price indeterminacy, which is another cause for the rate of return to deviate from its competitive equilibrium value. For both reasons, the efficient Walrasian levels of investment need not occur. Just as in the classical hold-up problem, long-term contracts can mitigate the troubles that factor-price indeterminacy brings. If labour is among the factors in an economy displaying factor-price indeterminacy, then a labour contract may be able to force trading at prices that allow intertemporal efficiency and prevent labourers or capital goods owners from manipulating factor prices by withdrawing their services from the market. Of course, as in the classical hold-up problem, the incompleteness of contracts may hamper the ability of this solution to deliver first-best efficiency. Alternatively, when a set of complementary factors displays factor-price indeterminacy and consists solely of produced goods, then a bundling of the complementary factors in an asset portfolio – that is, in a ‘firm’ – can eliminate the incentive to manipulate prices. From the vantage point of factor-price indeterminacy, unions and labour contracts and the firm as an institution emerge as devices to enforce competitive equilibria, not as consequences of imperfect competition in factor markets.

5 Conclusion: factor-price indeterminacy past and present

Prior to the Arrow–Debreu transformation of general-equilibrium theory, economists were well aware that linear activities could lead to an indeterminacy of factor prices. The problem was considered from a long-run perspective: a change in a factor price was presumed to persist for many periods, and, although
such a change might not lead to an instantaneous change in either the supply or demand for the factor, arguments were deployed for why demand and supply responses would eventually kick in. For example, in response to a wage increase, although existing capital equipment might have fixed labour requirements, newly constructed capital equipment could be built to use labour less intensively. In addition, a wage increase would eventually lead the price of labour-intensive consumption goods to rise, diminishing the demand for these goods and therefore ultimately for labour as well. This effect does not operate immediately since a wage increase will lead to an offsetting fall in the prices of existing stocks of complementary capital inputs. But the prices of newly produced capital inputs are constrained by break-even requirements; hence, given enough time, the prices of labour-intensive consumption goods will increase. (Robertson, 1931, and Hicks, 1932, offered the most detailed long-run theories. See Mandler, 1999, ch. 2.) Although pre-modern explanations of factor prices faced the indeterminacy problem explicitly, and marshalled a rich array of counter-arguments for why the problem normally will not be severe, the long-run perspective had its drawbacks: the attention to persistent changes in factor prices masked an inability to explain why factor prices cannot temporarily change. The older long-run theories simply assumed that, in the absence of demand or supply shocks, factor prices will be maintained at their long-run equilibrium values. This presumption amounts to a rudimentary version of the rule that in an intertemporal equilibrium prices should fulfill the expectations that agents formed in earlier periods. As we have seen, the market mechanism will not enforce this rule; a supplementary theory of contracts and institutions is necessary. The Arrow–Debreu treatment of factors (and other goods) at different dates as fully distinct goods naturally raises the question of whether prices can deviate from previously anticipated values even in the absence of shocks, and curiously, therefore, the Arrow–Debreu account of markets points to the need for a theory of non-market institutions. Unfortunately, the Arrow–Debreu tradition also took the model of trading at a single point in time as its benchmark. It is only with the combination of goods rigorously distinguished by date, sequential trading, and production sets with kinks that factor-price indeterminacy will appear.

fair allocation

Abstract

We survey the theory of equity in a variety of concretely specified resource allocation models: classical economies with private goods, economies with production, economies with indivisible goods, when monetary compensations are feasible and when they are not, economies with single-peaked preferences, and economies in which the dividend is a non-homogeneous continuum. We present the central fairness punctual notions, no-envy, egalitarian-equivalence, concepts of equal or equivalent opportunities and the relational principles of monotonicity and consistency.

Article

We survey the theory of equity in concretely specified economic environments. The literature concerns the existence of allocation rules satisfying various requirements of fairness expressed in terms of resources and opportunities understood in their physical sense (and not in terms of abstract entities such as utilities or functionings). For lack of space, we often give only representative references. Detailed treatments of the subject are Young (1994), Brams and Taylor (1996), Moulin (1995; 2003), and Thomson (1995b; 2006c).

1 Concepts

We introduce concepts central to the classical problem of fair division. These have much broader applicability, but for other models they sometimes have to be reformulated. Also, as models vary in their
mathematical structures, the implications of a given concept may differ significantly from one to the other.

In an economy, there is a social endowment of resources to be distributed among a group of agents who are collectively entitled to them. For what we call a classical problem of fair division, the resources are infinitely divisible private goods, and preferences are continuous, usually monotonic (sometimes strictly so), and convex. In an economy with individual endowments, each agent starts out with a share of society's resources; the issue in this case is to redistribute endowments. In a generalized economy, some resources are initially owned collectively and others are individual endowments (Thomson, 1992; Dagan, 1995). A solution associates with each economy a non-empty subset of its set of feasible allocations. A rule is a single-valued solution.

An axiomatic study begins with the formulation of requirements on solutions (or rules). Their logical relations are clarified and their implications, when imposed in various combinations, are explored. For each combination of the requirements, do solutions exist that satisfy all of them? If the answer is ‘yes’, can one characterize the class of admissible solutions?

A punctual requirement applies to each economy separately. The main question then is the existence, for each economy in the domain under consideration, of allocations satisfying the requirement. First are bounds on welfares defined agent-by-agent, in an intra-personal way. Some are lower bounds, offering agents welfare guarantees. Others are upper bounds, specifying ceilings on their welfares. An allocation satisfies no-domination of, or by, equal division, if no agent receives a bundle that contains at least as much as an equal share of the social endowment of each good, and more than an equal share of the social endowment of at least one good, or a bundle that contains at most as much as an equal share of the social endowment of each good, and less than an equal share of the social endowment of at least one good (Thomson, 1995b). It satisfies the equal-division lower bound if each agent finds his bundle at least as desirable as equal division (Kolm, 1972; Pazner, 1977; and many others).

Second are requirements based on interpersonal comparisons of bundles, or more generally, ‘opportunities’, involving exchanges of, or other operations performed on, these objects. An allocation satisfies no domination across agents if no agent receives at least as much of all goods as, and more of at least one good than, some other agent (Thomson, 1983a). It satisfies no-envy if each agent finds his bundle at least as desirable as that of each other agent (Foley, 1967; Kolm, 1973, proposes a definition that encompasses many variants of the concept). The final definition is quite different in spirit: an allocation is egalitarian-equivalent if there is a reference bundle that each agent finds indifferent to his own bundle (Pazner and Schmeidler, 1978). Given a direction \( r \) in commodity space, it is \( r \)-egalitarian-equivalent if it is egalitarian-equivalent with a reference bundle proportional to \( r \). Of particular interest is when \( r \) is the social endowment.

A relational requirement prescribes how a rule should respond to changes in some parameter(s) of the economy. The idea of solidarity is central: if the environment changes, and whether or not the change is desirable, but no one in particular is responsible for the change, that is, no one deserves any credit or blame for it (or no one in a particular group of agents is responsible for the change), the welfares of all agents (or all agents in this particular group), should be affected in the same direction: all ‘relevant’ agents should end up at least as well off as they were initially, or they should all end up at most as well off. In implementing this idea, the focus is usually on a particular parameter. When the parameter belongs to a space that has an order structure, as is frequent, one can speak of the parameter being given
a ‘greater’ or ‘smaller’ value in that order. Then, together with efficiency, the solidarity idea often implies a specific direction in which welfares should be affected: when a Pareto improvement is possible, all relevant agents should end up at least as well off as they were initially; otherwise, all should end up at most as well off. Thus, solidarity takes the form of a ‘monotonicity’ requirement. Examples are *resource monotonicity*: if the social endowment increases, all agents should end up at least as well off as they were initially (Thomson, 1978; Roemer, 1986a; 1986b; Chun and Thomson, 1988); *technology monotonicity*, a similar requirement when technology expands (Roemer, 1986a; Moulin and Roemer, 1989); *population monotonicity*: if population expands, all agents initially present should end up at most as well off as they were initially (Thomson, 1983b; Chichilnisky and Thomson, 1987; for a survey, see Thomson, 2006a).

When the parameter that varies does not belong to a space equipped with an order structure, solidarity retains its general form. For example, *welfare domination under preference replacement* says that if the preferences of some agents change, all agents whose preferences have not changed should end up at least as well off as they were initially, or that all should all end up at most as well off (Moulin, 1987b; for a survey, see Thomson, 1999). Whether or not the parameter belongs to a space with an order structure, one can imagine simply replacing the initial value taken by the parameter with another value (to which, if there is an order, it may or may not be comparable in the order), and still require that the welfares of all relevant agents should be affected in the same direction.

Another application of the idea is to situations where some agents leave with the resources assigned to them. The requirement that the welfares of all remaining agents should be affected in the same direction, when imposed on efficient rules, often means that these agents should be assigned the same bundles as initially. It can be expressed more simply as *consistency*: given an allocation chosen by a solution for some economy, let us imagine the departure of some agents with their components of it. In the resulting ‘reduced economy’, the remaining agents should receive the same bundles as initially (for a survey, see Thomson, 2006b).

Requirements relative to private endowments, when such exist, may be imposed on rules. For instance, the *individual-endowments lower bound* is the punctual requirement that each agent should end up with a bundle that he finds at least as desirable as his endowment; *individual-endowment monotonicity* is the relational requirement that if an agent's endowment increases, he should end up with a bundle that he finds at least as desirable as the one he got initially (Aumann and Peleg, 1974).

*Logical relations; existence.* Under standard assumptions, efficient allocations meeting the equal-division lower bound exist, and so do envy-free and efficient allocations. If preferences are strictly monotonic, no envy implies no-domination. An allocation meeting the equal-division lower bound is not necessarily envy-free. *Equal-division Walrasian allocations* are both envy-free and efficient, and under standard assumptions, they exist. In an economy with an infinite population of agents modelled as a continuum, and if preferences are sufficiently diverse, a partial converse holds: if an allocation is envy-free and efficient, it is an equal-income Walrasian allocation (Varian, 1974; Kleinberg, 1980; Champsaur and Laroque, 1981; Mas-Colell, 1987; Zhou, 1992). If preferences are not convex, the existence of envy-free and efficient allocations can be derived from certain assumptions about the structure of the efficient set itself (Varian, 1974; Svensson, 1983a; 1994b; Diamantaras, 1992). In the absence of such assumptions, efficient allocations satisfying no envy, even no domination, may not exist (Maniquet, 1999).
An egalitarian-equivalent and efficient allocation may violate no domination. When $|N| > 2$, and if the reference bundle is proportional to the social endowment, then obviously the equal-division lower bound is met, although not no domination. In fact, for some economies, all egalitarian-equivalent and efficient allocations violate no domination (Daniel, 1978). An equal-division Walrasian allocation may not be egalitarian-equivalent.

The existence of $r$-egalitarian-equivalent and efficient allocations holds under weak assumptions (Pazner and Schmeidler, 1978; Sprumont and Zhou, 1999, offer a proof for economies with a continuum of agents).

**Variants: extensions.** Some solutions are based on comparing across agents the number of agents whom each agent envies and the number of agents who envy him. Envy is balanced if, for each agent, these two numbers are equal (Daniel, 1975). The existence of allocations with balanced envy holds more generally than is common for other concepts. Other natural ideas are to require of an allocation that all agents should envy the same number of agents, or that all agents should be envied by the same number of agents. But neither definition will do, as soon as efficiency is imposed, because in any economy whose set of feasible allocations is closed under permutations, at an efficient allocation, at least one agent envies no one, and at least one agent is envied by no one (Varian, 1974; Feldman and Kirman, 1974).

**Selections.** When envy-free allocations exist, there may be a large number of them and the question of selection arises. A variety of proposals have been made. Some are based on quantifying the extent to which the no envy constraints are exceeded. Conversely, when envy-free allocations do not exist, the extent to which they are violated can also be measured. Measures based on counts of envy relations, or on the adjustments in commodity bundles required to eliminate envy have been proposed (Feldman and Kirman, 1974; Varian, 1976; Chaudhuri, 1985; 1986; Diamantaras and Thomson, 1990; Kolpin, 1991a). These operations can be adapted so as to extend, or select from, other equity notions, and in a second step, rankings of allocations can be derived (Chaudhuri, 1986; Thomson, 1995c).

**Group fairness.** Most of the concepts of the previous pages can be applied to compare the welfares of groups of agents. Central among them are the equal-division core, whose definition is straightforward, and group no envy: no group should be able to improve the welfares of all of its members if given access to the resources assigned to some other group of the same size. The definition can be adapted to handle groups of different sizes (Kolm, 1972; Feldman and Kirman, 1974; Green, 1972; Khan and Polemarchakis, 1978). Under replication, there is a sense in which the set of efficient allocations that are group envy-free converges to the set of equal-division Walrasian allocations (Varian, 1974; Kolpin, 1991b).

**Fairness of trades.** The concepts formulated above for allocations can be adapted in various ways to assess the fairness of individual trades when agents are individually endowed (Kolm, 1972; Schmeidler and Vind, 1972), and to assess the fairness of the trades of groups (Jaskold-Gabszewicz, 1975; Yannelis, 1983). Walrasian trades satisfy most of the definitions that have been proposed and under weak assumptions on preferences, for several of the definitions, a converse inclusion holds (Schmeidler and Vind, 1972; Shitovitz, 1992).

Interesting conceptual issues arise in relating the fairness of allocations and the fairness of trades (Goldman and Sussangkarn, 1980; Thomson, 1983a).
2 Economies with production

A fundamental issue is fair allocation when agents have contributed differently to production, because they have supplied unequal amounts of their time or because they are unequally productive. A first way to extend the notion of an envy-free allocation to such situations is by having each agent \( i \in N \) compare his complete consumption bundle (including his consumption of leisure) to those of the other agents. Unfortunately, and even if preferences are quite well-behaved, envy-free and efficient allocations may not exist (Pazner and Schmeidler, 1974). Limited exceptions are when all abilities or all preferences are the same (Varian, 1974). Another exception is in the two-good case, under a ‘single-crossing’ assumption on preferences and when the technology is linear (Piketty, 1994).

Egalitarian-equivalent and efficient allocations exist quite generally (Pazner and Schmeidler, 1978). Also, under appropriate convexity assumptions, existence still holds if the reference bundle in the definition of egalitarian-equivalence is required to be proportional to the average consumption bundle. An alternative proposal is to recognize the envy of agent \( j \in N \) by agent \( i \in N \) only after agent \( i \)'s consumption of leisure is adjusted for him to produce what agent \( j \) produces (Varian, 1976; Otsuki, 1980). The concept is well defined only if the production set is additive. A proof of the existence of such productivity-adjusted envy-free and efficient allocations can be given along the lines of the ‘Walrasian’ proof of existence of envy-free and efficient allocations in exchange economies and under similar assumptions (Varian, 1974). Some have objected to the definition because it lets agents with high productivity appropriate the benefits of their greater skills. Alternative concepts have been defined that attempt to distribute across agents these benefits (Pazner and Schmeidler, 1978; Varian, 1974; Pazner, 1977). The main proposal here has been to take advantage of the instrumental value of the Walrasian solution in delivering envy-free allocations when there is no production and in providing equal opportunities: here, one operates the Walrasian solution from equal division of all goods, including time endowments. Svensson (1994b) states an existence result for allocations at which implicit incomes are equal.

Non-convexities in technologies present another difficulty for the existence of envy-free and efficient allocations (Vohra, 1992). Vohra proposes to weaken no envy by imposing a certain symmetry among all agents with respect to possible occurrences of envy (see also Varian, 1974). Existence holds without any convexity assumption on either preferences or technologies. A critical one, however, is that there be no agent-specific input (Vohra, 1992).

Next, we turn to criteria that, by contrast with the previous ones, can be evaluated agent-by-agent, just like the equal-division lower bound. First, for each agent, we imagine an economy composed of agents having the same preferences as his, and we identify their common welfare under efficiency and equal treatment of equals. We take this welfare as a bound, thereby defining the identical-preferences lower bound. For nowhere-increasing returns-to-scale, it can be met (Gevers, 1986; Moulin, 1990d).

Alternatively, we could imagine each agent in turn controlling an equal share of the social endowment and the technology, obtaining the equal-division free-access upper bound (Moulin, 1990d; Yoshihara, 1998). This definition can be generalized by imagining each group of agents in turn controlling a proportion of the social endowment equal to its relative size in the economy and the technology (Foley,
This yields the equal-division free-access core. There are economies with a concave production function in which no allocation is envy-free, efficient, and meets the equal-division free-access upper bound (Moulin, 1990c). However, the bound is met on that domain by selections from the Pareto solution, in particular by the constant-returns-to-scale-equivalent solution defined later (Mas-Colell, 1980; Moulin, 1987b). For nowhere-decreasing returns-to-scale, the equal-division free-access bound becomes a lower bound: here, no sub-solution of the Pareto solution satisfies no envy for trades and meets the bound (Moulin, 1987b). Systematic studies of lower and upper bounds are Moulin (1990a; 1990e; 1991; 1992b).

For one-input one-output production economies, an allocation is proportional if there are prices such that each agent, facing these prices, maximizes his preferences at his component of the allocation. These allocations can be used to define another lower bound on welfares (Maniquet, 1996b; 2002; see also Roemer and Silvestre, 1993).

The constant-returns-to-scale lower bound is defined, for each agent, by reference to the best bundle he could achieve if given access to a constant-returns-to-scale technology, the same for all agents; the work-alone lower bound is defined for each agent, by reference to the best bundle he could obtain if given access to the actual technology but under the obligation to provide bundles to the other agents to which he would not prefer his own (Fleurbaey and Maniquet, 1996a; 1999).

Another study relating bounds in a class of two-good economies with convex production sets, the identical preferences lower bound and the free-access upper bound is due to Watts (1999).

### 3 Equal opportunities as equal, or equivalent, choice sets

The notion of ‘equal opportunities’ is of course central in the theory of economic justice (for a general discussion, see Fleurbaey, 1995c). The expression has been given a variety of meanings. In economies affected by uncertainty, it may mean ‘equal treatment ex ante’. Uncertainty may also be endogenously generated by an allocation rule. Consider the problem of allocating an indivisible good. A lottery giving all agents equal chances might be deemed equitable ex ante although the final allocation may well appear inequitable. Alternatively, if agents’ opportunities today are determined by decisions they made yesterday, equal opportunities may mean that they all had access to the same set of decisions. It is often argued that, because of incentive considerations, we should not attempt to equalize end results but instead should limit ourselves to giving people equal chances to develop their potential. If we do so, equal opportunities are provided by the mechanism that converts the choices agents make into a final outcome.

Another way to give substance to the idea of equal opportunities is to let each agent choose his consumption bundle from a common choice set (for example, see Kolm, 1973). For the list of choices they make to constitute a feasible allocation, one should have access to a ‘rich enough’ family of choice sets. In addition, one would prefer efficiency to hold whenever feasibility does. Let be a family of choice sets. An allocation is an equal-opportunity allocation relative to if there is a member of on which each agent maximizes his preferences at his component of the allocation. Such an allocation is of course envy-free. The family is satisfactory on a domain if the resulting equal-opportunity allocations are always efficient. Under standard assumptions on preferences, the equal-

income Walrasian family is satisfactory.

Another concept, equal-opportunity-equivalence relative to a family $\mathcal{B}$ of choice sets, generalizes the reasoning underlying egalitarian-equivalence. Check, whether, for some member of $\mathcal{B}$, each agent is indifferent between what he receives and the bundle he prefers in that set (Thomson, 1994a). For the family of linear choice sets, and adding efficiency, we obtain any efficient allocation such that each agent finds his component of it indifferent to the best bundle he could achieve if endowed with an equal share of the social endowment and given access to a constant-returns-to-scale technology, the same for all agents (Mas-Colell, 1980). Such an allocation is a constant returns-to-scale equivalent allocation.

Other solutions are obtained by having all agents face a hypothetical technology obtained from the actual one by imagining the productivity of one specific factor of production (alternatively, of some subset of the factors of production) to be multiplied by some number, or by introducing a fixed cost of some factor of production (alternatively, introducing a fixed cost proportional to some fixed vector). Radial expansions and contractions of the production set can also be considered. An application of the concept is by Nicolò and Perea (2005).

The next definition generalizes proposals by Archibald and Donaldson (1979) and Varian (1976). An allocation exhibits no envy of opportunities relative to a family $\mathcal{B}$ of choice sets if for each agent, there is a member of $\mathcal{B}$ that contains the agent's maximizer on the union of everyone's sets (Thomson, 1994a).

For the family of linear choice sets, the resulting solution coincides with the equal-income Walrasian solution. If $\mathcal{B}$ is the family of $|N|$-lists of bundles, we obtain a concept that generalizes both no envy and egalitarian-equivalence. An allocation is envy-free-equivalent if there is a list of reference bundles, one for each agent, such that each agent is indifferent between his component of the allocation and his reference bundle and he finds his reference bundle at least as desirable as anyone else's reference bundle (Pazner, 1977).

4 Monotonicity

Monotonicity properties are quite strong when imposed in conjunction with no envy and even no domination. Indeed, (a) no selection from the no-domination and Pareto solution is resource-monotonic (Moulin and Thomson, 1988); (b) no selection from the no envy and Pareto solution is population-monotonic (Kim, 2004); (c) no selection from the no domination and Pareto solution satisfies welfare-domination under preference-replacement (Thomson, 1996). Other versions of these results are available, some of which involving significantly weaker distributional requirements (Geanakoplos and Nalebuff, 1988; Moulin and Thomson, 1988; Maniquet and Sprumont, 2000; Kim, 2001). However, if preferences satisfy gross substitutability and all goods are normal, the equal-division Walrasian solution is an example of a selection from the no envy and Pareto solution that is resource-monotonic and population-monotonic (Moulin and Thomson, 1988; Fleurbaey, 1995c).

On the other hand, no special assumptions are required for the existence of selections from the egalitarian-equivalence and Pareto solution that are resource-monotonic, or population monotonic, or satisfy welfare-domination under preference-replacement. Other rules based on the notion of equal-opportunity equivalence have these properties as well (Thomson, 1987).

For economies with quasi-linear preferences satisfying certain additional assumptions, the Shapley value
can provide the basis for a solution that is resource-monotonic (Moulin, 1992a). The Shapley value has in fact proved useful on other domains to obtain this and other desirable properties of rules, although at the price of no envy, egalitarian-equivalence, and their variants.

The solidarity requirement can be applied to the joint replacement of resources and preferences (Sprumont, 1996).

Technology-monotonicity is satisfied by certain selections from the egalitarian-equivalence and Pareto solution. For two goods, a characterization of a particular one is obtained by imposing it together with a few other minimal requirements. Suppose first that good 1 is used to produce good 2 according to a nowhere-decreasing-returns-to-scale technology. Given a group \( N \) of agents with preferences defined on \( \mathbb{R}^2 \), given some social endowment of good 1, which can be consumed as such or used as input in the production of good 2, the equal-division free-access lower bound solution selects the set of allocations such that each agent finds his bundle at least as desirable as the best bundle he could achieve if endowed with an equal share of the social endowment and given access to the technology.

Under alternative assumptions on technologies, \((a)\) the only selection from the equal-division free-access lower bound and Pareto solution satisfying Pareto-indifference and technology-monotonicity is the constant-returns-to-scale–equivalence solution; \((b)\) parallel characterizations hold for selections from the equal-division free-access upper bound (Moulin, 1987b; 1990d).

Although in \((a)\), the bounds on welfares are individual bounds, the solution that emerges happens to satisfy the requirement that no group of agents should be able to make each of its members at least as well off, and at least one of them better off, if each of its members is endowed with an equal share of the social endowment and the group is given access to the technology. A similar strengthening holds for \((b)\). Suppose now that resources and technologies both change. Dutta and Vohra (1993) require of a solution that if the set of feasible profiles of welfare levels enlarges, each allocation chosen initially should be welfare-dominated by some allocation chosen after the change, and that each allocation chosen after the change should welfare dominate some allocation chosen initially. Let us refer to this requirement as opportunity-monotonicity. The requirement of \( r \)-equity is that in an exchange economy in which there is only some amount of good \( r \) to divide, equal division should be chosen. Dutta and Vohra consider an invariance requirement that also depends on the choice of a good, say \( r \), so we call it \( r \)-invariance. It is not motivated by normative considerations, so we only note that it is a weak version of an invariance requirement that has been important in the theory of implementation. The results are: up to Pareto-indifference, \((a)\) the \( r \)-egalitarian equivalence and Pareto solution is the only selection from the Pareto solution satisfying \( r \)-equity and opportunity-monotonicity; \((b)\) on the sub-domain of exchange economies, it is the only selection from the Pareto solution satisfying \( r \)-equity, \( r \)-invariance and opportunity-monotonicity.

Economies with production. In situations where agents are differentiated by their input contributions, a first monotonicity requirement is that if the contribution of an agent increases, he should end up at least as well off as he was initially. In situations in which agents differ in their productivities, a corresponding requirement is that if an agent's productivity increases, then again, he should end up at least as well off as he was initially.

The solidarity requirement, applied to the joint replacement of preferences and population in conjunction with the self-explanatory replication-invariance, leads to the selection from the egalitarian-equivalence solution for which the reference bundle is proportional to the social endowment (Sprumont and Zhou, 2009-1-1 23:10:38)
1999; these authors also prove a version of this result for a model with infinitely many agents modelled as a continuum).

Economies with individual endowments. If the issue is that of allocating gains from trade, an appealing requirement is that when an agent's endowment increases, he should end up at least as well off as he was initially, *endowment monotonicity*. Another is that under the same hypotheses, nobody else should be made worse off than he was initially, *no negative effects on others*.

It is easy to define selections from the individual-endowments lower-bound and Pareto solution that are *own-endowment monotonic*. However, there are impossibilities too: (a) no selection from the no envy in trades and Pareto solution satisfies either *endowment monotonicity* or *no negative effect on others* (Thomson, 1987); (b) no selection from the egalitarian-equivalence and Pareto solution satisfies *no negative effect on others* (Thomson, 1987).

The appropriate expression of *population-monotonicity* here is that the welfares of all agents who are present before and after the change should be affected in the same direction. The Walrasian solution violates the property. However, the selections from the egalitarian-equivalence in trades and Pareto solution obtained by requiring the reference trade to lie on a monotone path satisfy the requirement. They also meet the individual-endowments lower bound (Thomson, 1995a).

### 5 Consistency and related properties

Here, we also consider situations in which both the population of agents and the resources may vary, but this time, our focus is on a variety of invariance properties. These properties can be interpreted as formalizing trade-offs between equity and efficiency objectives with objectives of informational simplicity.

A converse of *replication-invariance*, *division-invariance*, says that if an allocation that is chosen for a replica economy happens to be a replica allocation (of the same order), then the model allocation should be chosen for the model economy.

The central notion, *consistency*, was defined in Section 1. Conversely, given some allocation that is feasible for some economy, check whether the restriction of the allocation to each subgroup of two agents is chosen for the problem of allocating between them what they have received in total. If the answer is always yes, then one can say that each agent is treated fairly in relation to each other agent; then, *converse consistency* requires that the allocation itself should be chosen for the initial economy. The Pareto solution is *consistent*. If preferences are smooth and corners excluded, it is also *conversely consistent* (Goldman and Starr, 1982). The no-envy solution is both *consistent* and *conversely consistent*. The egalitarian-equivalence solution is *consistent* but not *conversely consistent*. This is also true for the equal-division Walrasian solution although, if preferences are smooth and corners excluded, this solution is *conversely consistent*.

We have the following characterizations: (a) if a sub-solution of the equal-division core is *replication-invariant*, then it is a sub-solution of the equal-division Walrasian solution (this is because under replication, the core ‘shrinks’ to the set of Walrasian allocations; Debreu and Scarf, 1963; Thomson, 1988; Nagahisa, 1994, gives full characterizations of the Walrasian solution); (b) if a sub-solution of the group no-envy solution is *replication-invariant*, then it is a sub-solution of the equal-division Walrasian solution (Varian, 1974); (c) under smoothness, if a sub-solution of the equal-division lower bound and
Pareto solution is replication-invariant and consistent, then it is a sub-solution of the equal-division Walrasian solution (Thomson, 1988); (d) under smoothness, if a sub-solution of the equal-division lower bound and Pareto solution is anonymous and conversely consistent, then on the sub-domain of two-agent economies, it is a sub-solution of the equal-division Walrasian solution; if in fact coincidence occurs on that sub-domain, then it contains the equal-division Walrasian solution for all other cardinalities (Thomson, 1995b).

Consistency has been studied in economies with a large number of agents modelled as a continuum (Zhou, 1992). For economies with possibly satiated preferences, a characterization of the ‘equal-slab Walrasian solution’ (Mas-Colell, 1992) is available (Thomson and Zhou, 1993). This solution differs from the standard Walrasian notion in that each agent's income is the sum of the value of his endowment at the prices announced by the auctioneer (they may have negative or 0 components) and a supplement, the same for all agents, which, like prices, is determined endogenously. Economies with both atoms and an atomless sector have also been studied (Zhou, 1992; Shitovitz, 1992).

Juxtaposition-invariance says that if an efficient allocation happens to be obtained by juxtaposing two allocations that are chosen for two sub-economies with equal per-capita social endowments, then it should be chosen (Thomson, 1988). Under smoothness of preferences, the equal-division Walrasian solution is the only sub-solution of the Pareto solution satisfying a weak symmetry property, juxtaposition-invariance, and consistency (Maniquet, 1996a).

In formulating consistency for a production economy, the issue arises of how to define the opportunities open to a group of agents after the members of the complementary group leave with their bundles. The simplest idea is to translate the production set by the sum of the bundles the departing agents took with them. Standard classes of technologies are not closed under this operation however, and adjustments have to be made to ensure that the ‘reduced’ production set is admissible. For economies with one-input one-output and inelastic demands, characterizations of proportional cost sharing and serial cost sharing (which can be understood as an extension of the Shapley value) are available (Moulin and Shenker, 1994).

The equal-wage-equivalent and Pareto solution selects the efficient allocations for which there is a reference wage such that each agent finds his bundle indifferent to the best bundle he could achieve by maximizing his preferences on a budget set defined by this wage. The output-egalitarian-equivalence and Pareto solution selects the efficient allocations that each agent finds indifferent to a common consumption consisting of only some amount of the output.

Under appropriate assumptions on technologies, (a) the former is the only essentially single-valued selection from the constant-returns-to-scale lower bound solution satisfying Pareto indifference, equal welfares for equal preferences (self-explanatory), contraction independence (as in bargaining theory), and consistency; (b) the latter is the only essentially single-valued selection from the work-alone lower bound solution satisfying Pareto indifference, equal welfares for equal preferences, and consistency (Fleurbaey and Maniquet, 1999).

Roemer (1986a; 1986b; 1988) formulates consistency requirements with respect to changes in the number of goods.

When a solution is not consistent, it has a minimal consistent enlargement (Thomson, 1994d). For instance, the minimal consistent enlargement of the equal-division lower bound and Pareto solution is ‘essentially’ the Pareto solution. That of the Ω -egalitarian-equivalence and Pareto solution is
essentially the egalitarian-equivalence and Pareto solution. The maximal consistent sub-solution of a solution can be defined in a symmetric way provided the solution contains at least one consistent solution.

Notions of consistency have been proposed for economies with individual endowments (Thomson, 1992; van den Nouweland, Peleg and Tijs, 1996; Serrano and Volij, 1998; Korthues, 2000).

6 Indivisible goods

Estate or divorce settlements often involve items that cannot be divided (houses, family heirlooms), or can only be divided at a cost that would make the division undesirable (silverware). Other examples are positions in schools or organs for transplant patients. We call such goods ‘objects’. We consider situations in which the social endowment also contains some amount of an infinitely divisible good, ‘money’. We focus on situations in which each agent can consume at most one object. An illustration is the problem of allocating rooms to students in the house they share, and specifying how much each of them should contribute to the rent.

Let $A$ be a set of objects. Each agent has preferences defined over $\mathbb{R} \times A$ (or over $\mathbb{R}^+ \times A$). They are continuous and strictly monotonic with respect to money, and such that the switch from any object to any other object can be compensated by an appropriate adjustment in the consumption of money. The simplest case is when there are as many objects as agents. Situations where there are fewer objects than agents are accommodated by introducing a ‘null object’; there are always enough copies of the null object for each agent to end up with one (real or null) object. If there are fewer agents than objects, some objects are unassigned. In some applications, it is natural to require that the null object should not be assigned until all real objects are, even if these objects are undesirable, or undesirable for some agents. They could be tasks to be assigned to housemates that none of them enjoys performing; alternatively, some of them may find a given task enjoyable and the others not (cooking).

Punctual requirements. It is clear that if consumptions of money have to be non-negative, envy-free allocations may not exist. Otherwise, or if the social endowment of money is large enough, existence holds (Svensson, 1983a; Maskin, 1987; Alkan, Demange and Gale, 1991; Tadenuma and Thomson, 1993; Ichiishi and Idzik, 1999; Su, 1999). For quasi-linear preferences, several algorithms leading to envy-free allocations are available (Aragones, 1995; Klijn, 2000; Ünver, 2003; Abdulkadiroğlu, Sönmez and Ünver, 2004). Remarkably, envy-free allocations are always efficient (Svensson, 1983b). A variety of selections from the no-envy solution have been proposed (Tadenuma, 1989; 1994; Alkan, Demange and Gale, 1991; Aragones, 1995; Tadenuma and Thomson, 1995).

Egalitarian-equivalent and efficient allocations exist very generally, when preferences are defined over $\mathbb{R} \times A$ and the compensation assumption holds. When preferences are defined over $\mathbb{R}^+ \times A$, existence holds under similar assumptions as the ones guaranteeing that of envy-free allocations. Just as in the classical case, there are economies in which all egalitarian-equivalent and efficient allocations violate no-envy. The case of one object is special, and the solution that selects the envy-free allocation at which the winner receives the least amount of money has a number of interesting properties and has been characterized on the basis of these properties. This allocation is egalitarian-equivalent, with the losers’
bundle serving as reference bundle (Tadenuma and Thomson, 1993; Thomson, 1998). The Walrasian solution can easily be adapted to the present model but here, an allocation is an equal-income Walrasian allocations if and only if it is envy-free and efficient, and if and only if it is group envy-free (Svensson, 1983b).

Another requirement is that each agent should be made at least as well off as he would be at the (essentially) unique envy-free allocation of the hypothetical economy in which everyone had his preferences. If $|N| = 2$, meeting this identical-preferences lower bound is equivalent to no-envy, but if $|N| > 2$, the identical-preferences lower bound is weaker (Bevia, 1996a). Thus, this concept gives us another chance of obtaining positive results when no-envy is too demanding. Unfortunately, there are quasi-linear economies with equal numbers of objects and agents in which all egalitarian-equivalent and efficient allocations violate not only no-envy, as already noted, but in fact the identical-preferences lower bound. When there are more objects than agents, an allocation may be envy-free and efficient without meeting the identical-preferences lower bound, but it does meet the variant of the lower bound obtained by using only the objects that are assigned. No-envy remains incompatible with this bound however (Thomson, 2003).

Relational requirements. Selections from the no-envy solution exist that satisfy a form of money-monotonicity (Alkan, Demange and Gale, 1991). Any selection from the egalitarian-equivalence and Pareto solution obtained by fixing the reference object is money-monotonic. Object-monotonicity, the requirement that when additional objects become available, all agents should end up at least as well off as they were initially, makes sense if the objects are desirable or when there are undesirable objects, they do not have to be assigned. To study it, in specifying an economy, we now have to allow the numbers of objects and agents to differ. Then, an envy-free allocation is not necessarily efficient and we explicitly impose efficiency. Unfortunately, no selection from the no-envy and Pareto solution is object-monotonic, even if preferences are quasi-linear (Alkan, 1994).

Suppose now that all real objects have to be assigned before any null object is, independently of whether they are desirable. For instance, objects may be activities that some agents enjoy and others do not, but these activities have to be carried out if there are enough agents for that, an example mentioned earlier. Even if preferences are quasi-linear, no selection from a natural weakening of the identical-preferences lower bound and Pareto solution is weakly object monotonic, that is, such that the welfares of all agents should be affected in the same direction by an enlargement of the set of objects (Thomson, 2003). Even if preferences are quasi-linear, no selection from the no-envy solution satisfies welfare-domination under preference-replacement (Thomson, 1998).

A first requirement in the context of a variable population is that if the social endowment of money is non-negative and the objects are all desirable, none of the agents initially present should benefit from the arrival of additional agents. Even if preferences are quasi-linear, population-monotonicity is incompatible with no-envy (Alkan, 1994; Moulin, 1990b). In fact, an agent could be better off at any envy-free allocation than if he were alone, so that the free-access upper bound is incompatible with no-envy.

If there is a single object, which is desirable, and the social endowment of money is zero, a population-monotonic selection from the identical-preferences lower bound and Pareto solution can be defined, based on the Shapley value (Moulin, 1990b; Bevia, 1996c). Other positive results can be obtained for that case.
The selection from the egalitarian-equivalence and Pareto solution obtained by requiring the reference bundle to contain a fixed object is weakly population-monotonic (the arrival of new agents affects the welfares of all existing agents in the same direction), but it is not guaranteed to be a selection from the no-envy solution any more. In fact, no selection from the no-envy solution is weakly population-monotonic (Tadenuma and Thomson, 1995). Weaker requirements pertaining to changes in resources or population are defined and investigated by Alkan (1994).

Turning to consistency, we have the following result: if a sub-solution of the no-envy solution is neutral (that is, invariant under exchanges of bundles that leave all agents indifferent) and consistent, then in fact, it coincides with the no-envy solution (Tadenuma and Thomson, 1991). As always, the no-envy solution is conversely consistent, but many proper sub-solutions of it are too (as well as neutral). On the other hand, the Pareto solution is not (unless the objects are identical). However, if a sub-solution of the no-envy solution is neutral, bilaterally consistent, and conversely consistent, then in fact it coincides with the no-envy solution (Tadenuma and Thomson, 1991).

The identical-preferences lower bound solution is conversely consistent but not consistent. The minimal consistent enlargement of its intersection with the Pareto solution is the Pareto solution itself. This is true when there is at most one object, when there are multiple identical objects, and when there are multiple and possibly different objects. The maximal consistent sub-solution of the identical-preferences lower bound and Pareto solution is the no-envy solution (Bevia, 1996a).

Related models. When each agent can consume several objects (in addition to the infinitely divisible good), the situation is quite different from what it is in the one-object-per-agent case, unless severe additional restrictions are imposed on preferences. In fact, many of the special relations that exist in the one-object-per-agent case disappear, and the situation resembles the classical situation (Tadenuma, 1996; Haake, Raith and Su, 2002).

For preferences that have additive representations, a rule proposed by Knaster (1946) is generalized by Steinhaus (1949) and advocated by Samuelson (1980). An alternative is the selection from the egalitarian-equivalence and Pareto solution obtained by choosing the null object as reference object. Interestingly, it is a selection from the no-envy solution (Willson, 2003). Each is money-monotonic and satisfies a form of object-monotonicity.

Even if preferences are quasi-linear and no other fairness requirement is imposed, no selection from the Pareto solution is population-monotonic (Bevia, 1996b). In contrast to the one-object-per-person case, there are consistent sub-solutions of the no-envy and Pareto solution, and converse consistency becomes a much stronger requirement. Characterizations have been obtained under an additional invariance requirement on solutions (Bevia, 1998). The population-monotonicity of rules that select lotteries is examined by Ehlers and Klaus (2003b).

When monetary compensations are not possible. This situation has recently been much studied, mainly in the one-object-per-agent case when preferences are strict. It is clear that punctual requirements of fairness such as no-envy and egalitarian-equivalence are not generally achievable here (think of situations where all agents have the same preferences). However, most of our relational requirements remain meaningful. The main lesson of the literature is that they can be satisfied, but in a rather limited way, by sequential priority rules and variants. If the objective is to respect an exogenously given priority order of agents, then of course more positive results can be obtained (Svensson, 1994a; Balinski and
Now, imagine that agents can consume several objects. Herreiner and Puppe (2002) propose a maximin-type criterion, and define an iterative procedure that produces, among the efficient allocations, the one that is best according to this criterion (see also Ramaekers, 2006). In that situation, no selection from the Pareto solution satisfies welfare-domination under preference replacement (Klaus and Miyagawa, 2001). Brams and Fishburn (2000) for $|\mathcal{N}|=2$ and Edelman and Fishburn (2001) for $|\mathcal{N}|>2$ examine the special case when agents have the same preferences over individual objects but possibly different preferences over sets of objects. Brams, Edelman and Fishburn (2003) drop the assumption that preferences over individual objects are the same, and propose, in addition to requirements related to no-envy, some that are based on comparing the numbers of objects received by the various agents.

The possibility that agents are endowed with objects is considered by Shapley and Scarf (1974), and situations when some objects are initially individually owned and others are commonly owned (residential housing on a university campus being an illustrative example; kidney exchange is another application) are discussed by Roth, Sönmez and Ünver (2004) and Sönmez and Ünver (2005).

Various notions of efficiency for rules that select lotteries are examined by Hylland and Zeckhauser (1979), Demko and Hill (1988), Abdulkadiroğlu and Sönmez (1998; 1999), and Bogomolnaia and Moulin (2001; 2002).

When objects cannot be transferred. Consider the problem of allocating a single infinitely divisible good, ‘money’, among agents characterized by variables that cannot be transferred (talent or handicaps for examples), and thus can be thought of ‘objects’. How should money be divided to compensate agents for possible differences in these variables? This question, formulated by Fleurbaey (1994; 1995a), has given rise to a large literature. For a detailed survey, see Fleurbaey and Maniquet (2008).

7 Single-peaked preferences

Consider the problem of allocating a social endowment of an infinitely divisible and non-disposable commodity among a group of agents whose preferences over $\mathbb{R}^+$ are single-peaked: up to some critical level, his peak amount, an increase in an agent’s consumption increases his welfare but beyond that level, the opposite holds. Since there is no possibility of disposal, the social endowment has to be fully distributed. If the sum of the peak amounts is greater than the social endowment, ‘there is not enough’, and for efficiency, no agent should consume more than his peak amount. If the inequality goes the other way, ‘there is too much’; here, for efficiency, no agent should consume less than his peak amount (Sprumont, 1991).

Punctual requirements. Efficient allocations meeting the equal-division lower bound, or no-envy, in fact both, always exist. The equal-division core and the group-no-envy solution may be empty, but natural variants of these solutions are not.

A number of interesting rules can be defined: the commodity can be divided proportionally to the peak amounts, or so that all agents’ consumptions are at the same distance from their peak amounts subject to non-negativity, or so that the sizes of their upper contour sets at their assigned consumptions are equal, or as equal as possible. The following rule, called the uniform rule, will be central: if there is not enough, and given $\lambda \geq 0$, assign to each agent the amount he prefers in $[0, \lambda]$; choose $\lambda$ so that the sum
of these assignments is equal to the social endowment; if there is too much, given \( \lambda \geq 0 \), assign to each agent the amount he prefers in \([\lambda, \infty]\); here too, choose \( \lambda \) so that the sum of these assignments is equal to the social endowment.

The uniform rule depends only on the profile of peak amounts – it satisfies the peak-only requirement – and it is the only subsolution of the no-envy and Pareto solution to do so (Thomson, 1994c). Also, it is the only selection from the Pareto solution minimizing (a) the difference between the smallest amount anyone receives and the greatest amount anyone receives; (b) alternatively, the variance of the amounts they all receive (Schummer and Thomson, 1997).

Relational requirements. Here, the natural expression of the idea of solidarity when the social endowment varies is that all agents should be made at least as well off as they were initially or that they should all be made at most as well off. This requirement is incompatible with no-envy (or with the equal-division lower bound). This is because a change in the social endowment can be so disruptive that it turns an economy in which there is not enough to one in which there is too much, or converse. This suggests limiting its application to situations in which no such switches occur, yielding one-sided resource-monotonicity. This property is much less demanding. Solidarity requirements with respect to changes in population or preferences can similarly be modified by limiting their application to situations in which the direction of the inequality between the sum of the peak amounts and the social endowment is not reversed by the change under consideration. We add the suffix ‘one-sided’ to indicate the weaker versions so defined. We also consider separability, which says that given two economies having a group of agents in common, if the agents in this group receive the same aggregate amount in both, then each of them should receive the same amount in both.

We have the following characterizations, some of which require that each preference relation be such that if its peak amount is positive, there is an amount greater than the peak amount that is indifferent to 0. The uniform rule is (a) the only selection from the no-envy and Pareto solution to be one-sided resource-monotonic (Thomson, 1994b); (b) the only selection from the no-envy and Pareto solution to satisfy replication-invariance and one-sided welfare-domination under preference-replacement (Thomson, 1997); (c) the only selection from the no-envy and Pareto solution to be replication-invariant and one-sided population-monotonic (Thomson, 1995a); (d) the only selection from the no-envy and Pareto solution to be resource-continuous and separable (Chun, 2003; 2006). (d) the smallest (in terms of inclusion) subsolution of the no-envy and Pareto solution to be resource upper hemi-continuous and consistent (Thomson, 1994c); (e) the only single-valued selection from the equal-division lower bound and Pareto solution to be replication-invariant and consistent, or to be anonymous and conversely consistent (Thomson, 1995c).

Many refinements and variants of these results are available (Sönmez, 1994; Klaus, 1997; 1999; 2006; Dagan, 1996; Moulin, 1999; Herrero and Villar, 1998; 2000; Ehlers, 2002a; 2002b; Kesten, 2004b). An application to a pollution problem is by K•br•s (2003).

Related models. Fairness issues have been analysed for the variant of the model obtained by introducing individual endowments (Thomson, 1995c; Klaus, 1997; 2001; Klaus, Peters and Storcken, 1997; Moreno, 2002).

For economies with both individual endowments and a social endowment, different ways of adapting the punctual fairness requirements have been proposed, and issues of monotonicity, with respect to the individual endowments and the social endowment, in addition to consistency and population-
monotonicity, have been addressed (Thomson, 1995c; Klaus, 1997; Herrero, 2002). In these studies, a rule that is the natural extension of the uniform rule most frequently emerges. A multi-commodity version of the single-peaked assumption is easily defined. For such a model, a generalization of the equal-slacks Walrasian solution (Mas-Colell, 1992) is axiomatized along the lines of Schummer and Thomson's (1997) axiomatization of the uniform rule (Amoros, 1999). A probabilistic version of the uniform rule is characterized by Sasaki (1997).

8 Non-homogeneous continuum

Here, we consider the problem of dividing a heterogeneous commodity modelled as measure space, each agent having preferences defined over the measurable subsets, and the question being how to select partitions consisting of measurable subsets, one for each agent. Think of a cake on which frosting and decorations are distributed unevenly. Often, this commodity is embedded in a finite-dimensional Euclidean space: an example is land.

Punctual requirements. In such situations, equal division has no economic meaning, even when it can be defined in physical terms (surface area, say, or weight). However, our central criteria (no-envy; egalitarian-equivalence) remain applicable. A large literature concerns preferences that can be represented by atomless measures, a somewhat restrictive assumption that precludes complementarities between different parts of the dividend. Additional topological and geometric criteria are sometimes meaningful (Hill, 1983). The construction of iterative procedures leading to partitions satisfying some fairness requirement, exactly or in some approximate sense, has been important in the literature, but until recently, efficiency had often been ignored.

If no restrictions are imposed on preferences apart from continuity and monotonicity with respect to set inclusion, envy-free and efficient partitions may not exist (Berliant, Dunz and Thomson, 1992). However, when preferences are representable by atomless measures, they do (Weller, 1985). An existence result for group envy-free partitions is also available (Berliant, Dunz and Thomson, 1992).

An interesting special case is the one-dimensional case when the dividend is an interval that has to be partitioned into subintervals, one for each agent. It has many applications: division of an interval of time, a length of road, and so on. When preferences are represented by atomless measures, envy-free partitions exist (Woodall, 1980), but in fact existence then holds under much weaker assumptions (Stromquist, 1980; Su, 1999). In the case of a closed curve, the situation is much less satisfactory (Barbanel and Brams, 2005; Thomson, 2007). Under monotonicity of preferences, no-envy implies efficiency (Berliant, Dunz and Thomson, 1992). Under continuity and strict monotonicity of preferences, egalitarian-equivalent and efficient allocations exist (Berliant, Dunz and Thomson, 1992).

When preferences are represented by atomless measures, the \( \frac{1}{n} \) – lower-bound is that for each agent, the value to him of his assignment should be at least \( \frac{1}{n} \) times his value of the dividend. Some of the early literature searched for partitions such that for each agent, this bound is met as an equality. Given a list \( \alpha \in \Delta^N \) of ‘shares’, the \( \alpha \) – lower-bound is that for each \( i \in N \), the value to agent \( i \) of his assignment should be at least \( \alpha_i \) times his value of the dividend. Partitions satisfying these notions and generalizations exist (Berliant, Dunz and Thomson, 1992; Barbanel and Zwicker, 2001; Reijnierse and...
An existence result is available when preferences are representable by atomless concave capacities (Maccheroni and Marinacci, 2003). The existence of envy-free partitions is also known for a more general notion of a partition, where agents receive ‘fractional’ consumptions of each point of the dividend (Akin, 1995).

A succession of attempts at generalizing to more than two agents the classical two-person divide-and-choose scheme (one agent divides and the other chooses one of the two pieces; the divider receives the other), have been made over the years that generate partitions that are either envy-free or meet the $\frac{1}{n}$ lower-bound. It took many years until an algorithm that produces an envy-free partition in the $n$-person case, for arbitrary $n$, was discovered (Brams and Taylor, 1995). None of the solutions proposed necessarily attains efficiency.

Brams and Taylor (1996) survey the literature. Robertson and Webb (1998) focus on algorithms and pay little attention to efficiency. On the other hand, Barbanel (2005) provides an in-depth analysis of the shape of the image of the set of feasible partitions in a Euclidean space of dimension equal to the number of agents, using their measures as representations of their preferences. It offers characterizations of its subset of efficient points. It also gives existence results for efficient and envy-free partitions.

Many economists would emphasize that scientific claims must be capable of falsification. According to Milton Friedman, an hypothesis ‘is rejected if its predictions are contradicted…. Factual evidence can never “prove” a hypothesis; it can only fail to disprove it …’ (1953, p. 9). These claims echo Karl Popper's philosophy of science, which, on one interpretation, maintains that what distinguishes scientific theories from theories that are not scientific is that scientific theories are falsifiable. A theory is falsifiable if it is logically inconsistent with some finite set of ‘basic statements’ – that is, true or false reports of observation. A true theory will not be inconsistent with any set of true basic statements, but it will still be falsifiable because it is inconsistent with (or ‘forbids’) some observation reports. In other words, logic and observation can force one to give up falsifiable theories. Popper notes that there is an asymmetry between falsification and verification: basic statements can be logically inconsistent with universal generalizations and can thereby disprove them, but they do not imply that any universal generalizations are true. In his view scientific knowledge grows exclusively from falsification. Verification and even confirmation are impossible.

Although Popper distinguishes theories that are falsifiable from theories that are not falsifiable, he is also distinguishes the ‘critical’ attitudes and norms that characterize scientists – who are willing to test theories harshly and to give up claims that do not pass the test – from the dogmatic attitudes of non-scientists, who seek supporting evidence and explain away apparently disconfirming evidence. It is this latter methodological distinction between science and non-science that is Popper's more important contribution.

To maintain that scientific theories are falsifiable is problematic, because, with very few exceptions, scientific theories are not testable or falsifiable by themselves. Observing an increase in demand for some commodity after a rise in its price does not falsify the law of demand if there has been a change in tastes, an even greater increase in the price of a close substitute, a general rise in the price level and
hence a drop in the real price, or some other complicating factor. To say that an hypothesis ‘is rejected if its predictions are contradicted’ is misleading, because hypotheses rarely have predictions of their own. Significant scientific hypotheses imply predictions only when combined with other statements. So, if one insists that scientific claims have to be testable all by themselves, virtually nothing in science counts as science. On the other hand, if one insists only that, like the law of demand, scientific claims must be falsifiable in combination with other claims, then one cannot rule out even the most blatant pseudo-sciences. When Popper criticizes the scientific credentials of Freudian psychology, he does not maintain that, coupled with other statements, it makes no predictions. His criticism is instead that, when those predictions fail, psychoanalysts never cast blame on Freud's theory.

What distinguishes sciences from pseudo-sciences is methodology: when amalgams of theories and various auxiliary hypotheses make false predictions, scientists, unlike practitioners of pseudo-science, are willing to modify or even discard their theories. However, it is difficult to specify exactly how willing scientists should be to surrender their theories. Deciding whether observations give one good reason to reject an hypothesis, like deciding whether observations give one good reason to accept an hypothesis, requires weighing alternative explanations of the data. There is no simple asymmetry between falsification and confirmation.

The significance of falsification is methodological rather than logical or linguistic – a question of the norms that should govern science. The message of falsification is that science treats its findings as subject to criticism and revision. How can one make this platitude concrete? As even Popper and his followers have recognized, some dogmatism may be a good thing. Theories are hard to come by and should not be surrendered too easily. What characterizes successful sciences is on the one hand a mixture of attitudes on the part of individual scientists, with some much more critical than others, and on the other hand an institutional structure in which criticism is not too risky to individuals, and successful criticisms are strongly rewarded.

Those commentators on economic methodology who have been most influenced by Popper have generally been critical of economists. Mark Blaug, for example, argues that economists practise ‘innocuous falsificationism’ (1976, pp. 159–60), paying lip service to the importance of falsification while in fact showing little interest in criticism.

family decision making

Shelly Lundberg and Robert A. Pollak

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The classic unitary model assumes that households maximize a household utility function and implies resource ‘pooling’ – household behaviour does not depend on individuals’ control over resources within the household. Since the 1980s, economists have modified the unitary model in ways that have theoretical, empirical and practical implications. Non-unitary alternatives based on joint decision-making by individual family members with distinct preferences broaden the range of observable behaviour consistent with economic rationality. Many non-unitary models imply that both individuals’ control over resources and ‘environmental factors’ can affect intra-household allocation. Empirical evidence has consistently rejected income pooling and, hence, the unitary model.

Article

Economic models of consumer demand and labour supply begin with an individual economic agent choosing actions that maximize his or her utility subject to a budget constraint. How can we reconcile this individualistic theory of the consumer with the reality that people tend to live, eat, work and play in families? Economists have dealt with a possible multiplicity of decision-makers in the family in two ways. The first, in ascendancy until the 1980s, was the unitary approach – treating the family as though it were a single decision-making agent, with a single pooled budget constraint and a single utility function that includes the consumption and leisure time of every family member. The second approach, pioneered in the early 1980s by Manser and Brown and by McElroy and Horney, was to model family behaviour as the solution to a cooperative bargaining game. Other non-unitary approaches have subsequently been developed, including the ‘collective’ model of Chiappori, extensions of the cooperative models of Manser–Brown and McElroy–Horney, and various non-cooperative models.

Most non-unitary models of family behaviour allow two decision makers – the husband and the wife; children are customarily excluded from the set of decision-making agents, though they may be recognized as consumers of goods chosen and provided by loving or dutiful parents. Bargaining models have also been used to analyse interactions between parents and adolescent or young adult children, and between elderly parents and adult children. These interactions may involve family members living in different households, and, in many of these models, who lives with whom is endogenous. As a class, non-unitary models are consistent with a wider range of behaviour than unitary models. The empirical implications of specific non-unitary models of the family depend upon their assumptions about preferences, opportunities, and the form of the game.

Unitary models

Two models provide the theoretical underpinning of the unitary, or common preference, approach to family behaviour: Samuelson's (1956) consensus model and Becker's (1974;
1981) altruist model. The consensus model was introduced by Samuelson to exhibit the conditions under which family behaviour can be rationalized as the outcome of maximizing a single utility function. Consider a two-member family consisting of a husband and a wife. Each partner has an individual utility function that depends on his or her private consumption of goods, but, by consensus, they agree to maximize a social welfare function incorporating their individual utilities, subject to a joint budget constraint that pools the income received by the two spouses. Then we can analyse the household’s observed aggregate expenditure pattern as though the family were a single agent maximizing a utility function (that is, the consensus social welfare function). That is, the household maximizes $U(c^h, c^w)$, where $c^h$ and $c^w$ are the private consumptions of husband ($h$) and wife ($w$), subject to the budget constraint $P(c^h + c^w) = v = y^h + y^w$ which pools the individual incomes of husband and wife. This problem generates demand functions $c^i = f^i(p, v)$ that depend only on prices and total family income and that have standard properties provided the utility functions are well behaved. Thus, the comparative statics of traditional consumer demand theory apply directly to family behaviour under the consensus model. Samuelson did not, however, purport to explain how the family achieves a consensus regarding the joint welfare function, or how this consensus is maintained.

Becker's (1974; 1981) altruist model addresses these questions, and also provides an account of how resources are distributed within the family. In Becker's model, the family consists of a group of purely selfish but rational 'kids' and one altruistic parent whose utility function reflects his concern for the well-being of other family members. Becker argues that the presence of an altruistic parent who makes positive transfers to each member of the family is sufficient to induce the selfish kids to act in an apparently unselfish way. The altruistic parent will adjust transfers so that each 'rotten kid' finds it in his interest to choose actions that maximize family income. The resulting distribution is the one that maximizes the altruist's utility function subject to the family's resource constraint, so the implications of the altruist model for family demands coincide with those of the consensus model (see Bergstrom, 1989 for a discussion of the conditions under which the rotten kid theorem holds and does not hold).

Unitary models provide a simple, powerful mechanism for generating demand functions and establishing their comparative statics for use in applied problems. Since the introduction of the bargaining paradigm however, these models have been criticized on both empirical and theoretical grounds. We first discuss the theoretical criticisms, and then turn to the accumulating empirical evidence inconsistent with the unitary model.

Dissatisfaction with unitary models on theoretical grounds has been the product of serious study of marriage and divorce. Models of marriage and divorce require a theoretical framework in which agents compare their expected utilities inside marriage with their expected utilities outside marriage, but the individual utilities of husband and wife outside marriage cannot be recovered from the social welfare function that generates consumption, labour supply, fertility, and other behaviour within marriage. If the analysis of marriage and divorce is awkward, the analysis of marital decisions in the shadow of divorce is even more so. If unilateral divorce is possible, individual rationality implies that marital decisions cannot leave either husband or wife worse off than they would be outside the marriage. This individual rationality requirement, however, alters the comparative statics of the model, and destroys the correspondence between the behaviour of a single utility maximizing agent and the behaviour of a family.

### Non-unitary models

#### Cooperative bargaining models

A viable alternative to unitary models of the family must recognize, in a non-trivial fashion, the involvement of two or more agents in determining family consumption. Bargaining models from cooperative game theory, first applied to marriage by Manser and Brown (1980) and by McElroy and Horney (1981), satisfy these conditions. A typical cooperative bargaining model of marriage begins with a family that consists of only two members, a husband and a wife. Each has a utility function that depends on his or her consumption of private goods ($U^h(c^h)$ for the husband and $U^w(c^w)$ for the wife). If agreement is not reached, then the payoff received is represented by the ‘threat point’, $(\tau^h(Z), \tau^w(Z))$ – the utilities associated with a default outcome of divorce or, in the ‘separate spheres’ model of Lundberg and Pollak (1993), a non-cooperative equilibrium within the marriage. The threat point depends, in turn, upon a set of exogenous distribution factors $Z$ that influence individual well-being in the default outcome.

The Nash bargaining model provides the leading solution concept in bargaining models of marriage. Nash bargaining implies that the couple maximizes the Nash product function $N = [U^h(c^h) - \tau^h(Z)] [U^w(c^w) - \tau^w(Z)]$ subject to a pooled budget constraint, and this results in demand functions of the form $c^i = f^i(p, v, Z)$. Thus demands and individual utilities depend upon the distribution factors $Z$, which may include individual incomes $v^h$ and $v^w$. This solution can be illustrated by a diagram in utility space (Figure 1), where AB is the utility-possibility frontier. Nash (1950) shows that a set of four axioms, including Pareto efficiency – which ensures that the solution lies on the utility-possibility frontier – uniquely characterize the Nash bargaining solution.

**Figure 1**

The Nash bargaining solution
The utility received by husband or wife in the Nash bargaining solution depends upon the threat point: the higher one’s utility at the threat point, the higher one’s utility in the Nash bargaining solution. This dependence is the critical empirical implication of Nash bargaining models: family demands depend, not only on prices and total family income, but also on determinants of the threat point.

In divorce-threat bargaining models, the threat point is the maximal level of utility attainable outside the marriage. Hence, the threat point depends on wage rates and on the assets each spouse would take if the marriage were to end in divorce. The divorce threat point is also likely to depend on environmental factors (extra-household environmental parameters, or EEPs, in McElroy’s, 1990, terminology) that do not directly affect marital utility, such as conditions in the remarriage market and the income available to divorced men and women. The family demands that result from divorce-threat marital bargaining will therefore depend upon these parameters as well.

In the separate spheres bargaining model of Lundberg and Pollak (1993), the threat point is internal to the marriage, not external as in divorce-threat bargaining models. The husband and wife settle their differences by Nash bargaining, but the alternative to agreement is an inefficient non-cooperative equilibrium within marriage. In this non-cooperative equilibrium, each spouse voluntarily provides household public goods, choosing actions that are utility-maximizing, given the actions of their partner. Divorce may be the ultimate threat available to marital partners in disagreement, but a non-cooperative marriage in which the spouses receive some benefits due to joint consumption of public goods may be a more plausible threat in day-to-day marital bargaining.

The introduction of this internal threat point has important implications, because the separate spheres model generates family demands that, under some circumstances, depend not on who receives income after divorce, but on who receives (or controls) income within the marriage. Lundberg and Pollak assume gender specialization in the non-cooperative provision of household public goods, with the husband providing one good out of his own resources, and the wife providing a separate good from her individual resources. This specialization occurs because socially prescribed gender roles provide a focal point for non-cooperative bargaining. The individual reaction functions in this game determine a Cournot–Nash equilibrium in which the public goods contributions may be insufficiently low, and may depend upon the distribution of individual incomes within the family.

As the divorce-threat and separate spheres models show, cooperative bargaining does not necessarily imply income pooling, that is, the property that demands depend only on total household income, rather than its separate components. Bargained outcomes depend upon the threat point, and the income controlled by husband and wife will affect family behaviour (and the relative well-being of men and women within marriage) if this control influences the threat point. This dependence implies that public policy (for example, taxes and transfers) need not be neutral in their effects on distribution within the family. Also, the absence of pooling and the presence of extra-household environmental parameters in family demands yield a model that can be tested against the unitary alternative. For example, changes in the welfare payments available to divorced mothers, or in the laws defining marital property and regulating its division upon divorce, should affect distribution between men and women in two-parent families through their effect on the threat point.

The ‘collective’ approach

Most models of the family either assume or conclude that family behaviour is Pareto efficient. Unitary models ensure Pareto efficiency by assuming a family social welfare function that is increasing in the utilities of all family members: when such a utility function is maximized, no member can be made better off without making another worse off. Cooperative bargaining models characterize the equilibrium distribution by means of a set of axioms, one of which is Pareto efficiency.

Pareto efficiency is the defining property of the ‘collective model’ of Chiappori (1988; 1992). Rather than applying a particular cooperative or non-cooperative bargaining model to the household allocation process, Chiappori assumes only that equilibrium allocations are Pareto efficient. He demonstrates that, given a set of assumptions including weak separability of public goods and the private consumption of each family member, Pareto efficiency implies, and is implied by, the existence of a ‘sharing rule’. Under a sharing rule, the family acts as though decisions were made in two stages: first total family income is divided between public goods and the private expenditures of each individual, and then each individual allocates his or her share among private goods. The collective model implies a set of testable restrictions on the response of household demands to ‘distribution factors’ that affect the household’s sharing rule.

Non-cooperative bargaining models

The use of models that assume Pareto efficiency of outcomes relies on the judgement that information within families is relatively good (or at least not asymmetric) and that members are able to make binding, costlessly enforceable agreements. Since legal institutions do not provide for external enforcement of contracts regarding consumption, labour supply, and allocation within marriage, however, the binding-agreement assumption is unappealing.
Non-cooperative game theory focuses on self-enforcing agreements. It is possible for non-cooperative bargaining to yield Pareto efficient outcomes under certain conditions. For example, repeated non-cooperative games have multiple equilibria which are sustained by credible threats of punishment, and some of these equilibria are Pareto efficient. One of the benefits of modelling distribution within marriage as a non-cooperative game is the opportunity to treat efficiency as endogenous, potentially dependent upon the institutions and social context of marriage in a particular society and upon the characteristics of the marital partners.

The prevalence of destructive or wasteful phenomena such as domestic violence and child abuse, as well as the demand for marriage counselling and family therapy, suggests that we consider the possibility that family behaviour is sometimes inefficient. Other researchers have pointed to gender segmentation in the management of businesses or agricultural plots in many countries as evidence of an essentially non-cooperative, and possibly inefficient, family environment. One piece of evidence is provided by Udry (1996), who finds that in Burkina Faso the marginal product of land controlled by women is below the marginal product of land controlled by men and concludes that the household allocation of inputs to male- and female-controlled agricultural plots is inefficient.

**Intertemporal models**

In dynamic bargaining models, decisions made in one period can alter the relative bargaining power of individual family members in future periods. If family members cannot agree on rules for sharing household resources in the future, and make credible promises to obey such rules, then inefficiencies of the standard ‘hold-up’ variety will result. Lundberg and Pollak (2003) model the two-earner couple location problem as a two-stage game in which a couple must decide where to live and whether to stay together without being able to make binding commitments about allocation in the new location. Lundberg and Pollak show that the equilibrium of this two-stage game need not be efficient even if the second-stage game is conditionally efficient (that is, efficient given the location determined at the first stage).

Even if prospective spouses can make binding agreements in the marriage market, they cannot make agreements with potential spouses they have not yet met. Konrad and Lommerud (2000) show that individuals will over-invest in education prior to marriage to increase their marital bargaining power, even if they expect to bargain cooperatively once they find and marry a spouse. Models of limited commitment in marriage can also be applied to decisions about childbearing, career choice and work effort.

**Empirical evidence**

Recent empirical evidence suggests that the restrictions imposed on demand functions by unitary models are not well supported. Rejections of the family income pooling hypothesis, in particular, have been most influential in weakening economists’ attachment to unitary models. Unitary models imply that the fraction of income received or controlled by one family member should not influence demands, given total family income. A large number of recent empirical studies have rejected pooling, finding that earned and unearned income received by the husband or wife significantly affect demand patterns when total income or expenditure is held constant. Some studies find that children appear to do better when their mothers control a larger fraction of family resources (Thomas, 1990; Haddad and Hoddinott, 1994). These results are inconsistent with the unitary framework, but consistent with both bargaining models (provided individual incomes affect the threat point) and with the collective model (provided individual incomes are included among the ‘distribution factors’ that influence the household’s sharing rule).

The collective model imposes, in addition, a proportionality restriction on the influence of distribution factors on demands. The ratio of the marginal propensities to consume any two goods must be the same for all sources of income, for example, because individual incomes affect consumption only through the sharing rule. A generalization of Slutsky symmetry in price effects can also be derived (Browning and Chiappori, 1998). A series of empirical tests have found that consumption expenditures in households reject the unitary framework but are generally consistent with the collective model (for example, Bourguignon et al., 1993; Browning and Chiappori, 1998).

Tests of the unitary model against non-unitary alternatives require a measure of husband’s and wife’s relative control over resources. Relative earnings would seem to be an attractive candidate for this measure, since labour income is by far the largest component of family income, and earnings data are readily available and reliably measured. Also, the earnings of wives relative to husbands have increased dramatically in the United States and many other countries, and we would like to assess the distributional consequences, if any, of this change. The difficulty with this approach is that earnings are clearly endogenous with respect to household time-allocation decisions. Earnings are the product of hours worked, a choice variable, and hourly wage rates, which measure the prices of time for husband and wife and therefore enter demand functions directly in the unitary model. This implies that households with different ratios of wife’s earnings to husband’s earnings are likely to face different prices and may have different preferences.

One might try to avoid these problems by testing the pooling of unearned income rather than earnings. Unearned income is not contaminated by price effects, but most unearned income sources are not entirely exogenous with respect to past or present household behaviour. Schultz (1990), who like Thomas (1990) uses unearned income to test the pooling hypothesis, points out that variations in unearned income over a cross-section are likely to be correlated with other (possibly unobservable) determinants of consumption. For example, property income reflects, to a considerable extent, accumulated savings and is therefore correlated with past labour supply and, if those who worked a lot in the past continue to do so, with current labour supply. Public and private transfers may be responsive to household distress due to unemployment or bad health, and may be related to...
expenditures through the events that prompted them. *Unexpected* transfers such as lottery winnings, unexpected gifts or unexpected bequests will affect resources controlled by individuals without affecting prices, but are likely to be sporadic and unimportant for most families. Other standard empirical proxies for the relative bargaining power of husbands and wives (or, in the terminology of the collective model, distribution factors) include the relative ages, educations, or measures of family background of husband and wife. The interpretation of these factors, however, is contaminated by assortative mating on unobserved characteristics. It would be unwise to assume that a highly educated woman married to a man with less education has relatively more control over the allocation of household resources without controlling for other personal characteristics that affected the decision of this couple to marry in the first place. The same critique applies to measures of relative assets brought to the marriage by the husband and wife, even when they maintain separate ownership of these assets during marriage and divorce.

The ideal test of the pooling hypothesis, and therefore of the unitary family model, would be based on an experiment in which some husbands and some wives were randomly selected to receive income transfers. A less-than-ideal test could be based on a ‘natural experiment’ in which some family members receive an exogenous income change, and one can study a constant population of families before and after the change. Several studies exploiting such policy changes have found evidence against income pooling, and have also supported the hypothesis that women have a greater propensity, on average, to spend on children's goods. Lundberg, Pollak and Wales (1997) examine the effects of a policy change in the United Kingdom that transferred a substantial child allowance from husbands to wives in the late 1970s. They find strong evidence that a shift towards relatively greater expenditures on women's goods and children's goods coincided with this income redistribution, and interpret this as a rejection of the pooling hypothesis. Duflo (2000) studied the effect of an extension of the South African Old Age Pension on children's health and nutrition, and found that payments to grandmothers had a substantial effect on these outcomes, especially for girls, while payments to grandfathers had no effect. These results both reject a unitary framework for multi-generation families, and support the hypothesis that children benefit from female control of household resources. Tests of pooling using PROGRESA, a public cash transfer programme in Mexico directed at women, have been more complicated. A random assignment social experiment, PROGRESA had a substantial income effect and benefits were conditional on child school enrolment. Attanasio and Lechene (2002) reject household pooling using PRORESA data, and Rubalcava, Teruel, and Thomas (2004) find that these transfers to women were more likely to be spent on child goods, improved nutrition, and investments in small livestock than other household income.

One important implication of non-unitary models of the household is that government programmes targeted to particular individuals within households may affect the intra-household allocation. Even if, as rejections of the unitary model suggest, targeted transfers are effective in the short run, we cannot conclude that targeted transfers will be effective in the long run. Lundberg and Pollak (1993) show that the long-term effects of such policy changes on intra-household allocation may be very different from the short-term effects, as adjustments occur in the marriage market of subsequent cohorts. If prospective couples can make binding agreements when they marry, then the distributional effects of policy can be offset by subsequent generations of families. Even if such marital agreements are not possible, changes in the expected gains to marriage will affect who marries whom and who marries at all, and this will also affect the long-run distributional effects of policy. Cross-sectional studies of intra-household allocation that use state variation in policy or laws (such as divorce laws or property settlement rules) will be estimating the equilibrium effects of long-standing differences in policy, including any marital sorting effects.

**Conclusion**

The classic unitary model assumes that households maximize a household utility function subject to household resource and technology constraints. Unitary models imply income or resource ‘pooling’ – household behaviour does not depend on individual control over resources within the household. Since the 1980s, economists have modified the unitary model in ways that have theoretical, empirical and practical implications. Non-unitary alternatives based on joint decision-making by individual family members with distinct preferences broaden the range of observed behaviour consistent with economic rationality. Non-unitary models also permit the analysis of marriage and divorce within the same framework as household demands and the labour supply of household members. Unlike unitary models, many non-unitary models imply that both individual control over resources and ‘environmental factors’, such as divorce laws, that affect the well-being of individuals outside the household can affect intrahousehold allocation. Empirical evidence has consistently rejected income pooling and, hence, the unitary model.

Abstract

Family economics is the application of the analytical methods of microeconomics to family behaviour. It aims to improve our understanding of resource allocation and the distribution of welfare within the family, investment in children and inter-generational transfers, family formation and dissolution and how families and markets interact. In family economics, non-market interactions are crucial for family behaviour and individual welfare.

Article

Family economics is the application of the analytical methods of microeconomics to family behaviour. It aims to improve our understanding of resource allocation and the distribution of welfare within the family, investment in children and inter-generational transfers, family formation and dissolution, and how families and markets interact. Family economics lifts the lid on the ‘black box’ of the family, within which non-market interactions are crucial for family behaviour and individual welfare. It analyses how markets affect family behaviour and on how family context affects market behaviour, such as labour supply and consumer demand, thereby linking family economics with traditional fields of economics. Medical and social sciences indicate the importance of nutritional, cognitive and emotional development during childhood for a person's lifetime health and prosperity, and these developments are a product of parents’ actions, including family break-up. Acquiring a better understanding of family formation and
dissolution and of decisions within the family, particularly as these are affected by elements of people's budget constraints, is an important prerequisite for understanding how public policy can influence the family.

In a broad sense, family economics has been around for over two hundred years. Thomas Malthus believed that human fertility was determined by the age at marriage and frequency of coition during marriage. He contended that an increase in people's income would encourage them to marry earlier and have sexual intercourse more often. Modern economic theories of fertility generalized the Malthusian theory (starting with Becker, 1960), and Gary Becker subsequently developed a broader economic analysis of the family (Becker, 1981), which forms the foundation for today's family economics (Ermisch, 2003).

**What influences family decisions?**

Individualism needs to be the foundation of family economics if we are to analyse the impacts of public policies and technological developments on the welfare of *individuals*. In particular, decisions about marriage and divorce must make comparisons between *individual* welfare within and outside a couple. The family is best viewed as a 'governance structure' for organizing its activities rather than as a preference ordering augmented by home production technology, or as a set of long-term contracts (Pollak, 1985). This suggests that bargaining models, in which alternatives and ‘threat points’ affect intra-family allocation and distribution, provide a useful framework for analysing family behaviour. A bargaining approach naturally focuses on the structure of family membership and its internal organization (for example, comparing an intact nuclear family with divorced parents), and allows decisions to evolve in a flexible way.

A fruitful starting point is to assume that all individuals act to maximize their welfare as they evaluate it, given the predicted behaviour of others in the family. Some authors have adopted this non-cooperative approach to studying family choices (for example, Konrad and Lommerud, 1995). But, in many circumstances (for example, the co-resident family), cooperative behaviour is a better representation of family behaviour because of repeated interaction between family members, which facilitates information flows and monitoring. Nevertheless, family members must obtain welfare from cooperation that is at least as great as they would achieve from a non-cooperative outcome, although in some circumstances divorce may be a credible threat affecting decisions within the family (Bergstrom, 1996).

Cooperation achieves an efficient allocation of resources within the family. Individual welfare depends, in general, on individual incomes and prices and possibly other ‘distribution factors’ like marriage market conditions, divorce laws and other institutions (Browning and Chiappori, 1998), whose influence reflects bargaining between family members. For example, an increase in the mother's income may have two effects on family choices. It increases family resources, expanding welfare-enhancing opportunities for all family members. It also may increase her threat point (bargaining power), which pushes family choices in her favour, thereby increasing her welfare relative to the father's. Put differently, her income affects the position of the family's utility possibility frontier and also the position on it. If, for example, mothers’ preferences put more weight on children than fathers’ preferences do, then an increase in her share of family income would increase expenditure on children. If this is the case, then children do better when mothers control more of family resources, developments which improve women's earning
opportunities affect the distribution of welfare within families, and it is possible to target policies on individuals within families. In a dynamic setting, in which current decisions affect future bargaining power, efficiency is harder to sustain because of the difficulty of making binding commitments, but individual incomes and distribution factors still affect intra-family allocation.

One particular decision-making rule has been an important part of family economics: the family maximizes the welfare of an 'effective altruist'. It is in fact a special case of the cooperative (efficient outcomes) framework just discussed. A person is said to be altruistic toward someone if his or her welfare depends on the welfare of that person. Altruism is usually defined more narrowly, by what have been called 'caring' preferences: the altruist's ‘social’ utility takes the form \( W^A[U^A(x_A, G), U^B(x_B, G)] \), where \( x_A \) and \( x_B \) are vectors of private goods consumed by persons \( A \) and \( B \) respectively, \( G \) is a vector of public goods and \( U^A(\cdot) \) and \( U^B(\cdot) \) are 'private' utility indices for each person. The altruist \( A \) does not care how (in terms of \( x_B \) and \( G \)) a given level of private utility is obtained by his/her beneficiary \( B \).

Caring preferences limit only the relevant range of the utility possibility frontier expressed in terms of private preferences. Some family decision rule is still needed to determine the point on the frontier that is chosen, but there are circumstances in which caring preferences can produce distinctive predictions. Suppose that a wife and her husband care for each other, and her share of joint income is sufficiently large that she is making transfers to him to ensure that his welfare is not too low. To use Becker's (1981) term, she is an effective altruist. Only joint income matters for family decisions in these circumstances. Thus, effective altruism provides partial insurance for family members and insulates the family from targeted changes in taxes and benefits. Becker's (1981) claim that effective altruism also provides incentives for the beneficiary to act in the best interests of the family and reduces intra-family conflict – the so-called Rotten Kid Theorem – is, however, valid only with very restrictive preferences (Bergstrom, 1989).

If, however, the couple's incomes are relatively similar, then neither spouse is rich enough relative to the other to make transfers to the other, and individual incomes are likely to affect family decisions. In either case, non-market interactions between family members are important for determining individual welfare, through either bargaining or intra-family transfers motivated by altruism, and these also affect market behaviour like consumer demand and labour supply.

**Fertility, investments in children and security in old age**

The primary reason that most men and women enter a long-term relationship is to bear and raise children. In addition to the number of children, parents’ welfare is likely to depend on the lifetime well-being of each child – 'child quality' for short. That is, parents receive more satisfaction from having children who are better off throughout their life, and they make monetary transfers and human capital investments to influence their children's lifetime standard of living.

If parents view child quantity and quality as substitutes and treat all their children equally, their budget constraint contains the product between the number of children and quality per child (Willis, 1973). This implies that the ‘shadow price’ of an additional child is proportional to the level of child quality, and the shadow price of raising child quality is proportional to the number of children. As a consequence, there is an important interaction between family size and child quality. For example, a higher return to human
capital increases investment per child. This raises the shadow price of children, which lowers family size and the price of child quality, thereby raising child quality further, and so on. Thus, increases in the returns to human capital investment associated with technical change may lead to simultaneous large reductions in fertility and increases in human capital investment in children. This is consistent with important stylized facts of economic development and links family economics with the study of economic growth and development (Rosenzweig, 1990).

The quantity–quality interaction may also produce a ‘high fertility–low child investment trap’, in which low quality produces a low price of children, high fertility and a high shadow price of child quality. Higher parents’ income increases fertility and the price of child quality, keeping child investment low. It may take some policy or technological development that alters the prices of quantity or quality independently, such as a family planning intervention or a large change in the return to human capital investment, to ‘spring the trap’. Once sprung, if the quality income elasticity exceeds the one for quantity, then the ratio of quality to the number of children rises with higher income, thereby increasing the shadow price of an additional child relative to the shadow price of child quality. The substitution effect induced by this increase may be sufficiently large to produce a decline in fertility when income increases, even though children are normal goods.

The ultimate manifestation of low child quality is a child not surviving to adulthood. Scientific advance or a policy intervention, such as better water supply or public health, increases the probability of child survival, but it has conflicting impacts on fertility. On the one hand, it reduces the price of a surviving birth, thereby encouraging higher fertility. But if parents can influence the chances that their own children survive to become adults by spending more on each child, then it is possible that exogenous improvements in child survival reduce fertility, provided that improvements in child survival substitute for parents’ expenditure on child health (Cigno, 1998). Such a relationship may help account for the ‘demographic transition’ – the change from a high fertility-high ‘child mortality environment to a low fertility-low mortality one.

The factors affecting the cost of children (including investment in them) are closely associated with the key role of parental time in the rearing of and investment in children. The rearing of children is usually presumed to be time-intensive relative to other home production activities, and mothers provide a disproportionate share of parental time in the production of child quality. Thus, the cost of children relative to the cost of the parents’ living standard is directly related to the mother's cost of time (Willis, 1973). This links the cost of children with women's educational and earning opportunities, with implications for their effects on fertility, women's labour supply and investment in children.

Fertility and child investment may also be motivated by the need for support in old age. If people do not have access to a capital market, an extended family network including three generations at different stages of life could substitute for a capital market (Cigno, 2000). In effect, it arranges ‘loans’ to its young members from its middle-aged ones and enforces repayment later when the young borrowers have become middle-aged and the middle-aged lenders have become old. People may have children only because they are needed to transfer resources through time. The opening of a capital market with a sufficiently high interest rate offers the middle-aged an alternative to this family transfer system. A threat of no support from the family in old age is no longer a deterrent, because they can make their own provision for old age through the market. In broad terms, this prediction is consistent with the observation that the growth of the financial sector, or the introduction of a state pension system, tends to coincide with a sharp decline in private transfers from the middle-aged to their elderly parents and a fall
in fertility. The fact that childbearing does not cease suggests that the demand for children is not entirely derived from the need for transfers from them to finance consumption in old age. Again we see the important role of institutions in shaping family behaviour.

In countries with well-developed capital markets and pension systems, it is often observed that financial transfers from adult children to parents are rare, but transfers in the other direction are more common. Also, children are often observed providing ‘services’ to their parents that do not have clear market substitutes, such as companionship, attention and adapting their behaviour to their parents’ wishes. Such services come at a cost to the children, and so transfers from parents to their child may be an exchange for these services (Cox, 1987). Parents may also want to help their children financially when they need it, but they want them to behave responsibly in the sense of expending sufficient effort to support themselves. How transfers from parents respond to an adult child’s income depends on the balance of altruistic motives, parents’ intention to provide an incentive for high effort and the effects of parent–child bargaining on the provision of child-services.

Marriage and divorce

In addition to love and companionship, marriage offers two people the opportunity to share household public goods and benefit from the division of labour, and it facilitates risk sharing. Whom a person marries influences family behaviour (for example, fertility) and individual welfare through family resources, bargaining and costs (for example, of children). But the process of finding a spouse is one in which information is scarce, and it takes time to gather it. These market frictions affect who marries whom, the gains from each marriage and the distribution of gains between spouses (Burdett and Coles, 1999). The positive correlation between spouses in desirable attributes like education is expected to be weaker when frictions are larger. The chances of divorce, and therefore divorce laws, also affect matching in the marriage market. A higher divorce rate makes people less choosy when selecting a spouse, because it reduces the perceived benefits from waiting for a better match by making it more likely that a person will return to the single state. Poorer matches ensue, and these have a higher probability of dissolving.

Marriage market frictions may also be responsible for childbearing outside marriage. A woman who has a relationship with a man she does not wish to marry, or who will not marry her, would choose to have a child by the man if the short-run gain exceeds the long-term costs in terms of damage to her marriage prospects (Ermisch, 2003, ch. 7). Those women who expect to obtain a significant increase in welfare when they marry suffer a greater long-term cost by having a child while single than women whose marriage prospects are such that they expect to gain little from marriage. Thus, women with poorer marriage prospects are more likely to have children outside marriage.

Parents are likely to continue to care about the welfare of their children after they divorce, and so expenditure on children, such as investment in their human capital, is a public good to the parents. When living together, they choose the efficient level of this public good. But after breaking up, the mother usually obtains custody of the children and she decides the level of expenditure on children (Weiss and Willis, 1985). The father can influence it only by making transfers to the mother, and he must transfer more than a dollar to obtain a dollar's more expenditure on children, because the mother spends part of the transfer on herself. The higher effective price for child expenditure when divorced encourages him to
spend less on children after divorce (perhaps nothing), resulting in a lower, inefficient level of expenditure on children overall. This is likely to have implications for the lifetime welfare of children. The probability that a couple divorces is inversely related to this efficiency loss from divorce. Behaviour within marriage is likely to be affected by exogenous variation in the probability of divorce (for example, through legal changes). If, for example, more participation in paid employment raises future wages, the risk of divorce can encourage more paid employment by the mother during marriage and, by raising the cost of child quality, lower expenditure on children and lower fertility. These ‘defensive investments’ are undertaken to increase welfare later, when outcomes are uncertain because of the possibility of divorce. Thus, the probability of divorce affects women's wages and labour supply in the economy.

Examples have illustrated the distinctive aspects of family economics: how market prices and personal incomes affect non-market interactions between individuals in the family (through altruistic motives and bargaining), fertility and investment in children. These channels link family economics to traditional fields like growth and development, labour economics, consumer demand, savings and inter-generational transfers.

Abstract

Today the ultimate Malthusian check of ‘gigantic, inevitable famine’ is confined to the very poorest pockets of the globe. Economic development, medical technology and the globalization of disaster relief have reduced the size and duration of famines in the recent past. On the other hand, totalitarianism and the enhanced role of human agency produced in the 20th century some of the biggest famines ever. Topics discussed include the demography and long-run impact of famine, the role of public and private action in relieving those at risk, and how markets function during famines.

‘Famine’ is defined narrowly here as a food shortage leading directly to excess mortality from starvation or hunger-induced illnesses (compare Howe and Devereux, 2004). By this definition, the 20th century presents a paradox in the history of famines. On the one hand, it witnessed in China in 1959–61 the greatest famine in world history. On the other, it saw the virtual elimination of famine across most of the globe. Economic growth in the 19th century led to the disappearance of famine in Europe in peacetime and, after the 1870s, a reduction in famine intensity throughout Asia.

Today's high-profile famines are, relatively speaking, small and confined to poverty-stricken and often war-torn corners of Africa. In principle, famine prevention should be ‘easy’. Better communications, better understanding of nutritional requirements and medical remedies, and the globalization of disaster relief mean that the risks faced by the world's most underdeveloped economies should be far fewer than
those faced by equally poor countries in the past.

‘Malthusian’ famines

Famines and economic backwardness are closely related. Malthus would not have been surprised to hear of famine in Niger, probably the world’s poorest economy, in 2005, or that the cross-sectional correlation between excess mortality and poverty was strong within Ireland in the 1840s and Bengal in the 1940s. And he would have deemed the extreme backwardness of the Chinese economy in the mid-1950s a contributory factor to the Great Leap Forward famine of 1959–61: Chinese real GDP per head then was less than half the African average in 2006 (Maddison 2006).

Most famine victims succumb to infectious diseases rather than to actual starvation. Poverty prevents proper medical care because the associated remedies are costly and difficult to implement in crisis conditions. Sub-Saharan Africa has yet to complete the ‘epidemiological transition’, mainly because the resources and the political capabilities to put what is available locally or obtainable from abroad to most effective use are lacking. Famines are the exception where the transition has been completed, but when they occur, as in Nazi-occupied Leningrad, Greece, and the western Netherlands during the Second World War, the diseases mainly responsible for excess mortality were very different. In these relatively developed societies, public health structures that prevented the spread of infectious disease had become part of daily routine, and continued to be so during the war (Mokyr and Ó Gráda, 2002; Maharatna, 1996, pp. 159–61; Hionidou, 2006).

Most famines strike in the wake of major crop failures, although crop failure is neither a necessary nor a sufficient condition for famine. Even the most backward economies often have the resilience to cope with once-off harvest shortfalls, so that in the past the worst famines have been the product of back-to-back shortfalls of the staple crop. Thus, the probability of back-to-back poor harvests should provide some sense of the likelihood of famine in the past. Agricultural and meteorological data imply that such back-to-back events were uncommon (Ó Gráda, 2007).

Entitlements and governance

Civil unrest and bad government can also lead to famine by limiting production and trade or failing to prevent the spread of epidemic disease. The impact of war on the supply of shipping and grain imports from abroad was an important contributory factor to famine in Bengal in 1943–44. Panics about the food supply and poorly performing food markets may exacerbate famine. In such instances factors other than crop shortfalls reduce the purchasing power or ‘entitlements’ of vulnerable sections of the population: the size of the loaf matters less than its distribution. Claims that even during famines there is adequate food for everyone are not new. Such claims, which invert the relative importance of food supply on the one hand, and human action and distribution on the other, had a particular resonance for the 20th century. On several occasions between the 1930s and the 1950s, not only did totalitarian regimes engage in policies that placed millions at risk, but they also managed to keep the consequences largely hidden from the outside world. Analyses of 20th-century famines accordingly have tended to dwell less on economic factors such as the background level of development and the extent of the crop shortfall than on the role of human agency – be it the ruthlessness of dictators or the incompetence of officialdom. Yet closer
inspections suggest that even the most notorious ‘man-made’ famines of the 20th century in the Soviet Union in 1932–33, in China in 1959–61, and even in Bengal in 1943–44, entailed what Amartya Sen (1981) has dubbed ‘food availability declines’ (FADs) (Davies and Wheatcroft, 2004: ch. 5; Tauger, 2006; Ó Gráda, 2007). The paucity of evidence for ‘pure’ entitlement famines – famines where there was no food availability decline – suggests that modern scholarship may underestimate the role of food supply in the relatively recent past.

Sen’s claim that famine and democracy are incompatible (Sen, 2001) is a special case of the more general claim that democratic institutions promote economic justice and reduce inequality. Exceptions to this rule seem few: Banik's analysis of press reports of starvation deaths in Orissa in the 1990s confirms it in so far as famines are concerned, but highlights the inability of a free press and collective action to prevent mass malnutrition and ‘many, many deaths’ (Banik, 2002). It also bears noting that in poverty-stricken, ethnically divided, low-literacy economies democracy may not be sustainable. Nonetheless, the exogenous element in democratic institutions surely matters.

Markets and famines

Economists have long argued that, since crop failures are subject to spatial variation and rarely occur two years in succession, spatial and intertemporal arbitrage in food markets should help mitigate the cost of famines (Persson, 1999). However, natural obstacles (poor communications) and artificial obstacles (war, civil unrest, trade restrictions and price controls) have often impeded the scope for arbitrage. Research on Bengal in 1942–44 and Bangladesh in 1974–75 claims that food markets worked poorly in these instances, in the double sense of inadequate inter-regional trade and ‘excessive’ hoarding on the part of producers and traders (Sen, 1981; Ravallion, 1987, pp. 19, 111–13; 1997, pp. 1219–21). Formal studies of market performance during pre-20th century famines are few, although evidence from pre-industrial Europe suggests that they functioned no worse than in normal times (Ó Gráda, 2005). The asymmetry in speculators’ expectations implied by the findings of Sen and Ravallion – over-pessimism in the event of a harvest shortfall – is absent in the earlier data. That does not mean that markets worked like clockwork in pre-industrial Europe, but merely that their responses to spatial and intertemporal disequilibria were no weaker than in non-crisis times. In practice, markets may adjust too slowly to prevent famine: in the mid-19th century, for example, before the telegraph and long-distance bulk carriage by steamship could have made the difference, global grain markets could not have prevented mass mortality in Ireland and India. Nor does this mean that well-functioning, integrated markets always benefit the poor: as Sen emphasizes, they might allow inhabitants of less affected areas, endowed with the requisite purchasing power, to attract food away from famine-threatened areas. Much depends on whether such exports are used to finance cheaper imported substitutes, and on the speed with which food markets adjust. Dogmatic generalizations are not warranted.

Free markets can mitigate the impact of famines in two other respects. First, migration arguably limits the damage wrought by poor harvests, since the migrants reduce the pressure on scarce food and medical resources where the crisis is deepest. This is probably true even when the poorest lack the resources to migrate. Although migration undoubtedly exacts a cost in terms of the spread of infectious disease in host countries, on balance it saves lives.

Second, regional specialization increases aggregate output, with a resultant reduction in the risks
attendant on any proportionate harvest shortfall. Increasing commercialization also makes for more effective arbitrage in food markets. For example, the implied reduction in the cost of holding carry-over stocks and of transport greatly reduced the vulnerability of the Italian and the English poor in the early modern era (Persson, 1999; Ó Gráda, 2007).

Public and private action

Throughout history, whether out of fear or compassion, ruling elites have accepted a degree of responsibility for those at risk during famines. Most analytical attention has focused on the management rather than the extent of relief allocation. Since human interventions almost always give rise to principal–agent problems, choosing the appropriate yardstick for effective famine relief is an abiding issue. In the past, because governing elites were remote from those at risk, they often relied on sub-bureaucracies and landowners to identify deserving recipients of relief. History is full of examples of trade-offs between the degree of delegation on the one hand, and corruption and red tape on the other (see, for example, Shiue, 2004).

The choice of appropriate public action in the presence of such agency problems during famines is discussed in Drèze and Sen (1989), Besley and Coate (1992), Ravallion (1997), and elsewhere. Transfers of food at subsidized prices may risk corruption and hoarding; hence the frequent focus on the provision of non-tradable and highly perishable food rations. Income transfers (for example, through wages paid on public work schemes) are less likely to distort food markets, though if linked to work performance they may well discriminate against those in most need. Public works schemes also risk spreading infectious diseases. A further problem with public works is that fiscal stringency or fears of distorting labour markets, as in Ireland in the 1840s and in southern India in the 1870s, may entail below-subistence wages and consequent excess mortality.

Private charity can mitigate famine but is rarely adequate during big crises. Since the 1950s famine relief has been globalized through non-governmental organizations (NGOs) such as Oxfam. NGOs have been effective at highlighting the link between Third World poverty and the risk of famine, and at fundraising in the wake of highly publicized crises. Nonetheless, their record in mitigating and averting famine raises several issues.

First, agencies originally founded as famine relief agencies tend to reinvent themselves as bureaucracies. Such organizations must balance the public's wish to relieve disasters as they happen with their own need for bureaucratic sustainability. This has entailed focusing more on development than on famine relief per se. Budgetary pressures have also tempted NGOs to exaggerate the risks or gravity of famine, or to claim the credit when the crisis is ‘averted’ (De Waal, 1997). Given the likely long-term costs of such tactics, and the recent increasing dependence of NGOs on public funding, independent monitoring of their activities is essential. Moreover, NGO interventions typically lag, rather than lead, media reports; instead of drawing on previously accumulated reserves, they rely on crises to solicit aid, and their over-reliance on emergency-generated funding has led them to locations where they lack the detailed expertise and connections essential for effective famine relief. Most NGOs continue to spread themselves too thin, and are too small to offer the insurance required for a rapid response against famine.

Measuring the demographic cost
Soaring food prices and poor harvests are often harbingers of famine, but are neither necessary nor sufficient conditions for one. On the one hand, appropriate relief policies may prevent famine; on the other, not all famines result from aggregate food deficits or inflated food prices. An abnormal jump in mortality is a surer signal of famine, and is usually regarded as its defining feature. For most historical famines, however, establishing excess mortality with any precision is impossible, and inferences derived from incomplete data are often controversial. Much hinges on assumptions about the under-registration of deaths at the time. Controversy still surrounds the true tolls in the Soviet Union in 1931–33, China in 1959–61, Cambodia in 1975–79, and North Korea in 1995–99. Nonetheless, it is clear that modern famines are, relatively speaking, far less costly in terms of human lives than earlier famines. Although non-crisis death rates in Africa remain high, excess mortality from famines in recent decades has been low. In Devereux's useful listing of major 20th-century famines only two – Nigeria in 1968–70 and Ethiopia in 1983–85 – are accorded tolls nearing one million (Devereux, 2000). Elsewhere, deaths were far fewer.

Although famine had virtually disappeared from Europe by the mid-19th century, 30 million is a conservative estimate of famine mortality in India and China alone between 1870 and about 1900, and ‘fifty million might not be unrealistic’ (Davis, 2001, p. 7). One hundred million would be a conservative guess at global famine mortality during the 19th century as a whole. Given that global population rose from about 1.3 billion in 1870 to 2.5 billion in 1950, in relative terms famines were much more lethal in the 19th century than in the 20th. The late 19th century saw a reduction in famine intensity in India, due to a combination of better communications and improvements in relief policy; in Russia, too, famines became more localized. Japan, where famines were common in the 17th century, and less so in the 18th, experienced its last true famine in the 1830s.

As noted earlier, infectious diseases usually account for most famine deaths. These include deaths due to diet-related diseases brought on by impaired immunity, or to poisoning from inferior or unfamiliar foods. They also include deaths stemming from the disruption of personal life and societal breakdown attendant on famine. Disease spreads with the increased mobility of the poor and the inevitable deterioration in sanitary conditions. Famines also are associated with outbreaks of seemingly unrelated diseases such as cholera, influenza, and malaria (Mokyr and Ó Gráda, 2002).

The implications of focusing on relative rather than absolute mortality are also worth noting. In relative terms, excess mortality in China in 1959–61 was modest compared, for example, with Ireland in the 1840s or Finland in 1867–68. The lower rate matters to the extent that it affected the characteristics of the famine. But such comparisons beg the question of the appropriate denominator. Most of these famines were regionally concentrated, but the denominators refer to larger political or geographical units. Finally, most famines last a year or two at most. Ireland in the 1840s, Cambodia in the 1970s, and North Korea in the 1990s are exceptional in this respect.

Although in the past non-crisis male life expectancy usually exceeded female, the evidence for a female advantage during famines is overwhelming (for example, Hionidou, 2006, p. 165; Maharatna 1996, pp. 231–4). The main reason for this is physiological. Whether the female advantage has changed over time remains a moot point, but there is some presumption that the female advantage is greater when the main cause of death is literal starvation. Most famine victims tend to be the very young and those beyond middle age, although the greatest proportional increases in death rates are at ages in between. In cases where population growth of two or three per cent per annum is the norm, such age and gender biases are
unlikely to have much impact, and population growth may be expected to quickly fill the resultant demographic vacuum. Where non-crisis growth is slow, these biases may matter more, and post-famine recovery is likely to be slower.

For several reasons, the demographic consequences of famine are more complex than implied by the standard measure of excess mortality. First, that measure ignores the drop in births that usually accompanies famine. Famines almost invariably entail significant reductions in births and marriages (for example, Maharatna 1996, pp. 179–83; Hionidou, 2006, pp. 178–89). There is a case for including the births deficit in the demographic reckoning. Births lost due to the Great Irish Famine numbered about 0.4 million in a population of eight million, whereas estimates for China in the wake of the 1959–61 famine run as high as 30 million in a population of 650 million (Yao, 1999). There are several reasons for such declines in the birth rate, including lower libido, spousal separation, and weaker reproductive functioning. Famines also usually entail fewer marriages although, clearly, in most situations marriage reductions have implications only for first births.

Second, the excess mortality measure omits both the rebound in the birth rate and the decline in the death rate that sometimes follow once the crisis has passed. Births in China in 1962 exceeded those in any year since 1951, and in the following three years the birth rate was also higher than in any other year in the 1950s and 1960s. Therefore, to some extent at least, births ‘lost’ during the famine seem to have been merely postponed.

Third, it leaves out of account any longer-run impact on mortality and morbidity. Famines hasten the deaths of some ill and elderly people who would have died soon in any case. The ensuing impact on the demographic structure entails a reduction in the death rate in the wake of famines.

**Long-term health effects**

Recent medical-historical research has revealed a close link between health and nutrition in utero and in early childhood on the one hand, and adult health and longevity on the other (Barker, 1992). The implications for the long-term demographic and health effects of famines are obvious. Research on Russian, Dutch and Chinese data links foetal exposure to famine to increased risks in later life of diseases as varied as schizophrenia, breast cancer, arteriosclerosis, and antisocial personality disorders (Khoroshinina, 2005, p. 208). There is evidence from Leningrad that being born just before or during famines reduces expected adult height (for example, Kozlov and Samsonova, 2005, pp. 178–89; Khoroshinina, 2005, pp. 198–200). Such evidence suggests that the human cost of famines has been underestimated in the past, although it is too soon to say by how much. Finally, there is the further disturbing possibility – still unexplored – that famine-induced malnutrition in utero or early childhood adversely affects the mental development of those at risk.

**Conclusion**

Famine's range has been narrowing since Malthus's time. By 1900 Europe and its industrialized extensions, Latin America, and Japan were virtually famine-free, and today major, prolonged famine anywhere is conceivable only in contexts of endemic warfare or self-enforced isolation. Compared with the persistent effects of HIV/AIDS on the population of sub-Saharan Africa, the damage wrought by
famine is minimal. Moreover, given that throughout most of history land hunger has been a powerful predictor of famine, recent trends in the balance between population and food production offer room for cautious optimism about the near future. In both Asia and Latin America, food production has grown much faster than population since the 1960s. In sub-Saharan Africa the balance has been much closer, although the problem there has been very rapid population growth rather than sluggish food output growth. Moreover, some African countries such as Burkina Faso and Niger have walked a high demographic tightrope while others (such as Malawi and Zimbabwe) have performed poorly despite slower population growth.

The few remaining places still vulnerable to textbook Malthusian famine are those yet to undergo the fertility decline of the demographic transition. Those countries have experienced considerable mortality improvement in recent decades, but they lag behind in terms of fertility decline. A key issue is how fertility decline, scarcely yet under way, unfolds in such vulnerable economies. The experience of post-fertility transition economies worldwide strongly mirrors the historical pattern whereby declines in fertility were preceded by declines in mortality. However, the length of the lag and the extent of the fertility decline are clearly crucial. A guarded historical lesson for countries like Niger is that the transition, once under way, has been more rapid in latecomers than in pioneers. Africa's sluggish fertility transition, itself a function of economic underdevelopment, has increased its share of global population from only 8.8 per cent in 1950 to 14 per cent today; it is set to reach 21.7 per cent by 2050. Even though a drop in the annual growth rate from 2.5 per cent during the second half of the 20th century to 1.4 per cent during the first half of the 21st in Africa as a whole is implied, population is predicted to treble by 2050 in famine-prone countries such as Niger, Uganda and Mali. When coupled with the problem of global warming, which is likely to impact disproportionately on the productivity of arid lands limited to a short growing season, the implied threat to living standards is clear.

William Farr, born in Kenley, Shropshire on 30 November 1807, died in London on 14 April 1883, was a statistician in the General Register Office who had been appointed in 1840 as ‘compiler of abstracts’ and was two years later made Statistical Superintendent, a post he held until his retirement in 1880. He pioneered the quantitative study of morbidity and mortality and in the process became one of Victorian England's most prominent figures in the public health and reform movements (Cullen, 1975). He made major contributions in the fields of data collection, being largely responsible for the introduction of a cause of death classification which was linked with his derivation of the ‘zymotic’ theory of epidemic disease (Eyler, 1979; Pelling, 1978). As an Assistant Census Commissioner for each of the censuses of 1851, 1861 and 1871, he was largely responsible for the development of reliable procedures for the recording of occupations (McDowall, 1983). He is, however, best known as a statistical analyst, for in 1843 he constructed the first English Life Table based on deaths in 1841 linked to the census of that year. At the same time he established the formula for deriving from a rate of mortality by age $m$ the probability of survival $p$ at the initial age. In 1850 and 1864 Farr produced his second and third English Life Tables, the last mentioned being used as the actuarial basis for the life insurance scheme set up by the Post Office for its employees. Farr in his work on occupational mortality was the first to make extensive use of the standard mortality rate, allowing comparisons of the mortality of different groups by means of a summary statistic which took account of differences in the age structure of the groups being compared. A recurring theme in his work was the identification of variation in mortality in different urban areas of the country. Such differential mortality was viewed as an index of human welfare. For example, in 1850 one-tenth of the registration districts, those he named ‘healthy districts’, had average mortality rates not exceeding 17 per 1,000, a rate he thought indicative of the ‘natural’ mortality which, when exceeded, would indicate those deaths attributable to unnatural and preventable diseases. An underlying aim in much of his work was to discover statistical laws or numerical expressions of
regularities such as he proposed in the laws of recovery and death in smallpox, the elevation law for cholera mortality in London (Lewes, 1983) and the law of the relation between population density and mortality. He was also an early contributor to human-capital theory (Kiker, 1968) arguing, in particular, that the economic value of men varied with age as well as social class, and this he used as powerful publicity for urban reform by drawing attention to the financial losses that followed from diseases that were the causes of death and illness in society at large.

M.J. Farrell was born in 1926 and read Politics, Philosophy and Economics at New College, Oxford, graduating with First Class Honours. He moved to Cambridge in 1949 to work with Richard Stone at the Department of Applied Economics. He became a Fellow of Gonville and Caius College and the University made him Lecturer in Economics and eventually Reader. He was Editor of the *Review of Economic Studies* and a Fellow of the Econometric Society. In 1957 Farrell contracted poliomyelitis which left him dependent on crutches to get about. He died in 1975.

The bibliography of Farrell's work provided by Fisher (1976) lists 25 journal papers, about one a year in a cruelly shortened academic life. The quality of these papers is remarkable. They reveal the clarity of their author's mind and an outstanding creativity. Farrell often answered questions that others had hardly considered.

As a young man Farrell was influenced by Phillip Andrews, the author of *Manufacturing Business*, and they shared a dissatisfaction concerning the prevailing theory of the firm: ‘They [economists in the 1920s and 1930s] reduced the theory of the firm to a maximization problem soluble by the most elementary application of the differential calculus …’ and ‘Unfortunately these conclusions did not fit the regrettably complex facts well …’ (Farrell, 1971, p. 10). Farrell's work on the theory of the firm displayed an acute understanding of the subtlety of profit maximization as a strategy. In (1954) he provided one of the first applications of linear programming to this field. Farrell believed that the case for profit maximization eventually depended in part on the operation of a selection process. His (1970) paper remains to this day one of the best papers ever written on that topic.

Farrell wrote on the measurement of productive efficiency, on the consumption function, and on welfare economics. On some topics he produced a single paper – his last was on social choice theory.
In (1959) Farrell made two observations which were important innovations at the time. First, he exposed what he called ‘the fallacy’. This is a confusion between sufficient and necessary conditions for competitive equilibrium to be efficient. Convexity, as Farrell neatly demonstrated, is sufficient for existence of equilibrium but is necessary neither for existence nor for efficiency. Second, ‘… concavities in individual indifference maps disappear when one aggregates over a large enough number of individuals’ (1959, p. 381).

This deep aggregation result, which gave rise to an extensive literature (see, for example, Arrow and Hahn, 1971, chs 7 and 8), is based on a simple point. To illustrate it consider consumers and let them all have the same tastes, which may be represented by $U(x)$, where $x$ is a vector of consumptions. Suppose that $U(x_1) = U(x_2)$ and let there be $N$ consumers. We now wish to see whether a convex combination of $N \cdot x_1$ and $N \cdot x_2$, that is $\lambda \cdot N \cdot x_1 + (1 - \lambda) \cdot N \cdot x_2$, can be distributed so as to make each consumer at least as well off as with $x_1$ or $x_2$. If it can, community indifference curves will be convex even if those derived from $U(\cdot)$ are not.

If consumers were indefinitely divisible we could achieve this result by giving $x_1$ to $\lambda \cdot N$ consumers and $x_2$ to $(1 - \lambda) \cdot N$ consumers. However, as $\lambda \cdot N$ may not be an integer this exact procedure is inadmissable. Nevertheless, as $N$ becomes large an integer $M < N$ will eventually emerge such that $M/N$ approximates $\lambda$ to any desired degree of accuracy. Hence Farrell's result follows.

Farrell treated the often sloppily discussed question whether speculation could be destabilizing and still profitable, in (1966). His demonstration within a very general framework that linearity of demand functions is required to exclude this possibility greatly advanced the general understanding of this problem.

In (1962) Farrell considered the well-known problem of the yield gap, the observation that equities at certain times show a different rate of return from that obtained from bonds. He provided some calculations which showed that there had been yield gaps in the past even when returns were corrected for capital gains. In considering what light these ex post observations throw on investors’ ex ante decisions, Farrell asked ‘… what do we mean by perfect knowledge in a market where uncertainty is present?’ (1962, p. 835). This led him to analyse what he called ‘accurate’ expectations: ‘… an individual’s expectation is “accurate” if his subjective probability distribution is the same as the hypothetical frequency distribution by which we represent the real world’ (1962, p. 836). Long before the idea of rational expectations became fashionable, Farrell saw its relevance to the analysis of securities markets. However the careful student of profit maximization and selection processes found no reason to assume that expectations would necessarily be ‘accurate’.

Article

Fasiani was born in Turin and died in Genoa. Clearly the most important Italian scholar of fiscal theory to emerge in the interwar period (Buchanan, 1960, p. 36), he taught public finance in Turin, Sassari, Trieste and, from 1934, in Genoa. His career was rapid and exclusively academic. Despite his untimely death, he left important works on fiscal theory, and also on economic theory, economic policy and the history of economic thought.

Following Pareto's theory of the ruling class and Puviani's idea of fiscal illusion, which he rediscovered, Fasiani asserts that fiscal activity is to be explained on the basis of the nature of the political entity and not in terms of economic calculus or by sacrifice theories or by the ability-to-pay principle (1932a, 1941). As taxation and public expenditure are political phenomena, it is impossible to know the laws of fiscal activity. Fiscal theory can only be built through static models reflecting the different types of political societies. To De Viti de Marco's models of the ‘monopolistic’ state, where the ruling class governs only in its own interest, and of the ‘cooperative’ state, where the ruling class governs in the interest of every member of the community, Fasiani adds the model of the ‘modern, nationalistic or corporative’ state, in which the ruling class governs in the interest of the collectivity, considered as a whole (1941).

He dealt with the duration of the process of tax shifting (1934) and with the characteristics of intermediate positions in the transition from one state of equilibrium to another (1932b); with tax shifting in conditions of constant, increasing and decreasing costs in competition and in monopoly (1941, App. I and II) and with the effects of an excise tax under conditions of industrial concentration (1942a). He analysed the different elements determining the ‘quantity of labour’ and proved the...
impossibility of understanding the effects of taxation on labour supply assuming as variables only working hours and income (1942c). He devoted much research to the problem of the double taxation of saving (1926), confirming the validity of J.S. Mill's thesis in opposition to the theories of Einaudi and of Fisher. Fasiani also wrote important notes on the application of the Paretian indifference curve apparatus to the classical problem of the relative burden of income tax and consumption tax (1930) and on the analysis of the relationship between taxation and risk-taking (1935b).

In order to study the effects of taxation in a state of equilibrium, Fasiani re-examined and criticized some problems of economic theory. Among other things, he reasserted the hypothesis of production at constant costs and redefined the variables of the labour supply. Specifically he dealt with business cycles and stabilization policy, giving a decisive role to monetary policy (1935a; 1937a; 1942b).

His most important work in the history of economic thought is a very long essay on fiscal theory in Italy (1932c). In this work Fasiani critically examined the general theories of public finance formulated in Italy between 1880 and 1930, that is to say the economic theory, the political theory, the sociological theory, and also the theses on the effects of taxation and public debt on tax shifting and tax incidence. Finally, the essays on fiscal theory in the 18th century (1936) and on Francesco Fuoco (1774–1841), a forerunner of mathematical economics (1937b), are worthy of note.

Faustmann, Martin (1822–1876)

Article

Faustmann was a German forester who spent much of his life working on the grand-ducal forests of Hesse. Between 1849 and 1865 he entered into controversies with other foresters concerning methods of forest valuations, his ideas eventually prevailing among that minority of forest economists who accepted the discipline of a positive rate of interest in making forest calculations. Although it has been said that his work was approved by such ‘national economists’ as Wagner and Roscher (Allgemeine Deutsche Biographie, 1877), it was evidently quite unknown to the more theoretically oriented German and Austrian specialists in capital and interest. Incorrect solutions to the optimum forest rotation problem were subsequently offered by such economists as Jevons, J.B. Clark and Irving Fisher, in the course of simplified expositions of the idea of the production period of a single investment. Not until the 1950s did economists working outside forestry realize that Faustmann's approach as explained to generations of resistant forestry school students contained a correct approach to the forestry question. The economists’ discovery was sparked by F. and V. Lutz, M. Gaffney, P.H. Pearse and, a few years later, Paul Samuelson. (The literature suggests that some Scandinavian and German economists, notably Ohlin, either knew of Faustmann's formula or worked it out for themselves.)

Faustmann's formula is derived from his investigations into forest values, needed at that time to guide the allocation of landowners’ acres between trees and agriculture. His predecessors had consequently attempted to value the soil and the forest separately. In this they failed, partly because they confused stocks and flows. Faustmann cleared this up in 1849 by providing a single forward-looking approach for the present value of the next and future forest crops. As his professional readership required, his formulation also made it possible to take account of expected planting, husbanding, thinning and harvesting net costs during the life of each subsequent stand. He was able to solve his predecessors’ problem by showing that the soil value (with which agricultural values are to be compared) is the value of the forest enterprise when it is still bare land, before a crop rotation has been commenced.
Faustmann is known today by resource economists for two by-products of his original perception. First, he showed correctly how to calculate the rotation age that is optimal for the owner in the presence of all expected costs and expected subsequent harvests. Second, by including the expected net discounted returns from subsequent rotations in his value and rotation-age formulae, he took the step that later eluded 20th-century economists, such as Fisher. He included the implicit forgone rent or shadow price of the land. He showed that the effect of doing this is that a given growth-and-harvest cycle will be shorter than economists’ analyses would have predicted. Shorter rotations advance the date on which the next and all subsequent rotations will be harvested, thus reducing the effect of waiting on calculated soil values.

Faustmann made subsequent contributions to professional forestry, but they are of little interest today.

Federal Reserve System

Donald D. Hester
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Federal Reserve System was established in 1913 to provide the United States with an elastic currency. It managed security offerings to finance the First World War, and evolved from a set of 12 semi-autonomous banks to a centralized institution in the 1920s. Having failed to prevent the Depression of the early 1930s, it was substantially reorganized in 1933 and 1935. After the Second World War and a 1951 accord reached with the Treasury, it started on an odyssey of monetary policy interventions, employing many policy instruments, indicators, and powers with varying degrees of success to the present day.

Article

The Federal Reserve System of the United States was established on 23 December 1913, when President Woodrow Wilson signed the Federal Reserve Act. The need for a new federal banking institution became clear when a severe crisis occurred in 1907. In May 1908 the Aldrich–Vreeland Act established a bipartisan National Monetary Commission that proposed establishing a National Reserve Association with 15 locally controlled branches that would ‘provide an elastic note issue based on gold and
commercial paper’ (Warburg, 1930, p. 59). The proposal was not enacted, nor was a subsequent proposal for a central bank with about 20 branches that would be controlled by a centralized Federal Reserve Board, consisting largely of commercial bankers. In the debate preceding the Federal Reserve Act, banking industry domination was rejected in favour of a board that had five members appointed by the President and two ex officio members, the Secretary of the Treasury and the Comptroller of the Currency. The appointed members had staggered terms and were to represent different commercial, industrial, and geographic constituencies. A sixth appointed member representing agriculture was added in 1923. The composition of the Board and its relation to Federal Reserve banks were drastically changed in 1935. Partly because of continuing disagreements about public versus commercial bank control, the new Board's powers were left ambiguous in the act.

The act mandated that all national banks become members of the new system and stockholders of Federal Reserve banks. Because reserves were to be concentrated in 12 Federal Reserve banks, the act substantially reduced reserve requirements at national banks. State chartered banks could join if they chose to and were judged to be financially strong. The first Board was sworn in on 10 August 1914 and the system opened for business on 16 November 1914. Federal Reserve notes that were backed 100 per cent by ‘eligible paper’ and, additionally, 40 per cent by gold began to circulate. Eligible paper was self-liquidating, short-term paper that arose in commerce and industry. The rationalization for eligible paper was the real bills doctrine, which held that credit extended for financing only the production and distribution of goods would not lead to inflation. The doctrine is invalid because of fungibility; there is no relation between paper acquired by Federal Reserve banks and loans the commercial banks are extending. In addition, all deposits at Federal Reserve banks had to be backed at least 35 per cent by gold. Subsequent amendments to the act effectively eliminated the supra-100 per cent collateralization of notes. A June 1917 amendment to the act forced all member banks to pool required reserves at Federal Reserve banks and further reduced reserve requirements to decrease the burden of membership on national banks and attract more state-chartered banks to the system.

The early years

The early years of the Federal Reserve System were marked by struggles to define the distribution of power between Federal Reserve banks and the Board, in the context of growing US involvement in the First World War. The Board gradually assumed more powers, but was unsuccessful in controlling open-market trading, which inevitably was concentrated in New York. Benjamin Strong, the New York bank governor, managed system trading. (Until 1935 the chief executives of Federal Reserve banks were called ‘governors’. After 1935 their title was changed to ‘president’ and members of the Board were called ‘governors’.) The Federal Reserve System was made fiscal agent for the Treasury in 1920, but the Treasury dealt directly with Federal Reserve banks, not the Board. Until 1922 the Board's statistical research office was located in New York, and arguably the Board was less informed than the New York bank about money market conditions.

Federal Reserve banks immediately sought earning assets in order to pay expenses and the six per cent required dividends on member bank capital subscriptions. As they expanded their portfolios of bills, US securities, discounted commercial paper, and acceptances, the breadth and liquidity of these markets increased. In early 1915 the New York bank was buying and selling for other Federal Reserve banks. Discount rates charged by reserve banks varied across Federal Reserve districts.
In anticipation of the US declaration of war on Germany in 1917, Federal Reserve banks became responsible for issuing and redeeming short-term Treasury debt certificates before and during Liberty Loan drives. There would be four large Liberty Loans and a Victory Loan in 1919 that required extensive Federal Reserve involvement. US bonds were sold to the public on an instalment plan by member banks; the interest rate banks charged on the unpaid balance on a bond was equal to the coupon rate on the bond. Member banks, in turn, discounted short-term US debt at Federal Reserve banks at an interest rate below the yield on the debt, which allowed them to recover their costs of instalment lending. US government interest-bearing debt rose from $1.0 billion at the end of 1916 to $25.5 billion at the end of 1919, and would never again fall below $15 billion. This huge increase, and the fact that Federal Reserve banks offered preferentially low interest rates when member banks discounted government debt, had important lasting consequences on the money market. Before the war, Federal Reserve banks had schedules of discount rates that varied across the quality and maturity of discounted paper and the amount of borrowing by a member bank. Because of the low discount rate on government debt, member banks almost exclusively offered it as collateral when borrowing. The discount rate effectively became the rate charged on government debt. By 1922 each reserve bank effectively had a single discount rate, but rates still varied across Federal Reserve districts.

The November 1918 armistice brought new challenges. Continuing shortages of food and other goods in Europe and large increases in the stock of money led to inflation in the United States. The rate of inflation peaked in May 1920 and was followed by a sharp deflation in the following year of about 45 per cent in wholesale prices. In that year industrial production fell by about 30 per cent and unemployment soared. Until October 1919 Federal Reserve banks were obliged to keep the low wartime discount rates in order to allow banks and the public to absorb the 1919 Victory Loan. In November, Federal Reserve banks began raising their discount rates in an effort to combat inflation. In June 1920 four banks raised the rate to seven per cent. Amplifying the effects of the interest rate increases was an outflow of gold to Europe and a sharp reduction in discount window borrowing as Federal Reserve banks cut back on subsidizing the public’s instalment purchases of US bonds.

The Boston bank lowered its rate from seven per cent to six per cent in April 1921, and was gradually followed by other reserve banks in an effort to respond to the slowdown. Deposits at all member banks reached a local maximum of $26.1 billion in the December 1919 call report and then fell to $22.8 billion in the April 1921 report. Discount window borrowings reached a year end high of $2.7 billion in December 1920 and then fell to $0.6 billion at the end of 1922 as gold flows turned positive. As gold flowed in, reserve banks lowered their discount rates to 4.5 per cent in 1923 and early 1924. While gold inflows slackened after 1923, it became apparent that new operating guidelines were needed. Governor Strong understood that the real bills doctrine was invalid and that many countries were not acting according to the old gold-standard rules. As interest rates fell, most reserve banks were again acquiring securities to augment their income. Strong, on the other hand, had begun to sterilize the New York bank’s holdings of gold by selling its securities in the open market. The Treasury was concerned that reserve bank trading was upsetting securities markets when it was buying or selling debt. In May 1922 the reserve banks established the Governors Executive Committee consisting of the governors of the Boston, Chicago, Cleveland, New York, and Philadelphia banks to manage transactions for all 12 banks. The committee executed orders on behalf of the banks in the light of Treasury plans and made recommendations, but acted only as agents and had no executive power. In April 1923 it was renamed the Open Market Investment Committee (OMIC), which had the same membership as its predecessor.
but was required

to come under the general supervision of the Federal Reserve Board; and that it be the
duty of this committee to devise and recommend plans for the purchase, sale and
distribution of open-market purchases of the Federal Reserve Banks in accordance with …
principles and such regulations as may from time to time be laid down by the Federal
Reserve Board. (Chandler, 1958: 227–8)

Strong dominated the OMIC and began to understand the way open-market operations worked. He noted
in particular that the sum of reserve bank open-market purchases and gold inflows almost equalled
negative changes in member bank borrowing. He developed a case for active monetary policy and
argued that restrictive monetary policy should be initiated with open-market sales and followed by
increases in the discount rate. This was the likely origin of member bank borrowings and nominal
interest rates as indicators of monetary policy. Policy instruments were open-market operations and the
discount rate. While proposals to change discount rates originated with Federal Reserve banks, they
required Board approval, which may explain why Strong preferred to lead with open-market operations.
Strong was sensitive to the effects of monetary policy on prices, but objected to any legislated targeting
of prices. His analysis was seriously incomplete when banks were not net borrowers from the Federal
Reserve, and in such circumstances so were his policy tactics. Tragically, beginning in 1916 Strong
suffered from recurrent attacks of tuberculosis and would die in October 1928, before such
circumstances arose.

The 1923 Board Annual Report advocated an activist policy, but continued to support the real bills
doctrine. In response to pressure from the Treasury and the Board, Federal Reserve banks sold most of
their government securities in 1923; yearend holdings fell from $436 million to $134 million between
1922 and 1923. Federal Reserve notes and member bank reserves backed by such assets were
unjustifiable under the doctrine, and the Treasury objected to Federal Reserve banks profiting from such
assets. However, at the end of 1924 the banks held $540 million, and the banks’ portfolio of government
securities fluctuated considerably in the following years in response to changes in the volume of
discounted bills and gold flows. Discount rates at Federal Reserve banks were lowered in the latter half
of 1924 and 1925 before converging on four per cent at the beginning of 1926, largely following short-
term interest rates in New York. Short-term market rates fell because of a sharp recession; the Federal
Reserve index of industrial production (1997=100) fell from 7.84 in May 1923 to 6.43 in July 1924.
Clearly policy was active, but not because of the real bills doctrine!

The discount rate was four per cent in June, when Federal Reserve banks began to cut the rate to 3.5 per
cent and to make open-market purchases. At the beginning of 1928 discount rates were increased
because of developing speculation in the stock market and continued to rise to as much as six per cent in
October 1929, when the stock market crashed. In part, Federal Reserve discount rates were again
responding to changes in industrial production, which had been quite sluggish until the end of 1927 and
then began to grow rapidly until July 1929. In part, the 1927 rate cut reflected Federal Reserve efforts to
help the United Kingdom maintain sales of gold at the pre-war sterling price, which had been restored in
1925. Governor Strong and Montagu Norman, the Governor of the Bank of England, were working to re-
establish a gold standard that could restore order to international finance. To help the United Kingdom in
1925, the New York bank extended the Bank of England a $200 million gold credit and attempted to
keep interest rates low in New York relative to those in London. By reopening gold sales at the pre-war price, Britain had effectively revalued the pound upward in 1925 by about ten per cent, with devastating consequences for its economy.

As Strong's health failed in 1928, a leadership vacuum developed. In an attempt to coordinate policy among all 12 reserve banks and the Board, the Board proposed in August 1928 that the five member OMIC be replaced by a new Open Market Policy Committee (OMPC) that included all 12 reserve bank governors and was chaired by the Governor of the Federal Reserve Board. This proposal was rejected by bank governors, but a modified form was adopted in January 1930. Strong had been aware of growing stock market speculation and did not object to Federal Reserve open-market sales and the increase in the discount rate. These actions were reinforced by outflows of gold. In mid-1928 gold flows reversed, apparently attracted by high and rising short-term interest rates. Federal Reserve banks continued to sell bills and government debt, forcing member banks into the discount window to the extent of about $1 billion in the second half of 1928 and in the middle of 1929. At the end, Strong was aware of the danger of restrictive monetary policy actions over an extended period on the real economy, but remained reasonably optimistic that the situation could be controlled (Chandler, 1958: 460–3). After his death the struggle for control continued between his successor at the New York bank, George L. Harrison, and the Board; the latter argued that the real bills doctrine was not dead and that reserve banks should take direct action to penalize member banks making loans that supported security speculation. The Federal Reserve index of industrial production peaked in July 1929, Bureau of Labor Statistics (BLS) wholesale and consumer price indices had been slowly falling since 1926, and in October the stock market collapsed.

The Great Depression

Led by the New York bank, the Federal Reserve flooded the money market with cash by aggressively buying government securities. Discount window borrowing by member banks fell from $1,037 million in June 1929 to $632 million in December and to $271 million in June 1930. Further, discount rates at reserve banks were rapidly reduced; at the New York bank the rate was lowered from six per cent in October to 2.5 per cent in June 1930. The monthly average Standard and Poor common stock index (1935–1939=100) began to stabilize; it was 195.6 in January 1929, 237.8 in September, 159.6 in November, and 191.1 in April 1930. However, the index of industrial production continued to fall after the open-market purchases, and the BLS index of wholesale prices was ten per cent lower in 1930 than in 1929.

In mid-1930 reserve banks sharply reduced their purchases of government securities in the belief that monetary policy was adequately expansionary. The OMPC seems to have been guided by what Meltzer (2003: 164) calls the Riefler–Burgess Doctrine: ‘If [discount window] borrowing and interest rates were low, policy was easy; if the two were high policy was tight.’ An interpretation is that if member banks wanted to lend they could have inexpensive and relatively easy access to funds; if not, there was little more that the Federal Reserve could do. While total member bank discount window borrowing was positive, many banks were holding excess reserves. Conventional wisdom has it that the reserve banks should have continued buying securities. However, it is unclear even today whether continued large open-market purchases by the Federal Reserve would have had much of an impact on real economic activity in late 1930; the experiment was never tried. Rapid expansion of reserves and member bank deposits did occur in the late 1930s, with little effect on real economic activity.
On average about 600 bank failures a year occurred between 1920 and 1930; most failing banks were small and not members of the Federal Reserve System. The number of failing banks doubled in 1930 and increased by another 70 per cent in 1931. The total deposits of failing banks between 1920 and 1930 averaged less than $200 million a year, but more than quadrupled in 1930 and doubled again in 1931. Total deposits and currency had begun to fall after December 1928 and continued to fall after the stock market crash. Currency in circulation began to rise in November 1930, as bank failures increased. Industrial production and wholesale prices were falling at an accelerating rate. The directors of the New York bank counselled Governor Harrison to continue open-market purchases in 1930, but he encountered opposition in the OMPC and little was done. Net gold inflows were offset by open-market sales because the OMPC collectively believed monetary policy was expansionary. Reserve bank discount rates and money market interest rates trended down until 21 September 1931, when the United Kingdom suspended gold payments.

The British abandonment of gold led to very large withdrawals of gold and currency from the United States that were initially partially offset by open-market purchases of bills and increased discount window borrowing, which occurred at sharply higher interest rates as recommended by Bagehot (1873). However, Federal Reserve bank credit fell from $2.2 billion in October 1931 to $1.6 billion in March 1932. During this period of rising bank failures, rapidly declining economic activity, and falling prices, Harrison argued against open-market purchases for a number of reasons, but primarily because of the possibility of a shortage of ‘free gold’, that is, gold that was not required as collateral for Federal Reserve notes and reserves. The Glass–Steagall Act of 1932 authorized the Federal Reserve banks temporarily to use US government securities as collateral for Federal Reserve notes and thus largely solved the problem of a lack of free gold. In February 1932 Federal Reserve banks began aggressive open-market purchases of government securities that more than offset continuing gold losses and allowed member bank borrowings to fall about 50 per cent by August 1932. Discount rates at the New York and Chicago banks were lowered to 2.5 per cent in June 1932, but all other banks kept their rates at 3.5 per cent until the national banking ‘holiday’ that began on 5 March 1933 when President Roosevelt closed all US banks. Net free reserves (excess reserves minus discount window borrowing) had turned positive in September and thus signalled excessive ease to some individuals on the OMPC.

Restructuring the Federal Reserve System

It was obvious that the Federal Reserve had been ineffective in combating the collapse of the banking system and responding to the Great Depression. The banking system and the Federal Reserve needed to be restructured and strengthened. The Emergency Banking Act of 9 March 1933 authorized the Treasury to license and reopen national banks that were judged to be sound; state chartered banks that were sound would receive licences from state banking commissioners. Many reopening banks received capital injections by selling preferred stock to the Reconstruction Finance Corporation. At year end 1929 there were 24,026 commercial banks of which 8,522 were members of the Federal Reserve System; at year end 1933 there were 14,440 commercial banks of which 6,011 were member banks. For a period of one year all banks, whether members or not, could borrow on acceptable collateral from Federal Reserve banks.

Many of the reforms that were adopted would survive at least until late in the 20th century. Because of a belief that the collapse lay in undisciplined stock market trading, the Glass–Steagall Act of 1933
required that commercial banks divest themselves of investment banking activities. This act introduced deposit insurance that became effective in January 1934. It also banned interest payments on demand deposits and allowed the Board to impose ceilings on interest rates that banks could pay on time and savings deposits. Finally, the act renamed the OMPC the ‘Federal Open Market Committee’ (FOMC), but as in earlier incarnations its executive committee remained the same. The Securities Exchange Act of 1934 authorized the Board to impose margin requirements on stock market trades. Federal Reserve banks were authorized to make commercial and industrial loans to non-financial firms.

Having failed to expand reserve bank credit between July 1932 and February 1933, the Board found itself under extraordinary political pressure to expand resources to the banking system. As Meltzer (2003: 435–41) explains, President Roosevelt threatened to have the Treasury issue currency in the form of greenbacks if the FOMC failed to expand sufficiently. Net free reserves turned positive in May 1933 and rose to more than $3.0 billion by January 1936. The revaluation of gold in February 1934 together with subsequent large gold inflows from Europe and hesitancy to lend by member banks contributed to this surge in excess reserves.

The reconstruction of the Federal Reserve System continued with Roosevelt's nomination of Marriner Eccles to become Governor of the Federal Reserve Board in November 1934. Eccles had argued that system power should be concentrated in the Board and that reserve banks be prevented from undertaking open-market operations on their own accounts. Eccles's initiatives were opposed by Senator Carter Glass, many reserve bank governors, and the banking industry, but he largely succeeded in achieving his goals. The reforms were in the Banking Act of 1935, which restructured the Board to consist of seven appointed governors, each with a staggered 14-year term. The FOMC was restructured to consist of the seven governors and five reserve bank presidents. Two of the governors were to be appointed for four-year terms as chairman and vice-chairman of the Board by the president, with the advice and consent of the Senate. Eligible paper was no longer restricted to being short-term paper that originated in commerce and industry. The Board was empowered to vary reserve requirements; the upper limit was twice the percentages that were specified in the 1917 amendments to the Federal Reserve Act.

Members of the renamed Board of Governors of the Federal Reserve System took office in February 1936, with Eccles as chairman. For some time the FOMC had expressed concern about the inflationary potential of large excess reserves. In particular, because excess reserves exceeded reserve bank credit, the FOMC would not be able to absorb them without an increase in reserve requirements. Employing its new policy instrument, on 14 July 1936 the Board announced an increase in reserve requirements on August 15 of 50 per cent on all deposits at member banks. The increase was expected to absorb less than half of system excess reserves and was not expected to impinge on member bank lending or the economic recovery. In part because of continuing gold inflows, excess reserves were $3.0 billion at the end of July 1936, and averaged about $2.0 billion through the end of February 1937. Because excess reserves continued to be large, the Treasury began to sterilize gold inflows in December 1936, but not to the extent desired by the Board. At the end of January the Board announced a further two-step increase in reserve requirements of one-third to take place in March and May 1937. These actions took reserve requirements to their legal maxima and reduced excess reserves to below $800 million in summer months. In August and September reserve banks reduced their discount rates to one per cent or 1.5 per cent, levels that would last until December 1941. Coinciding with the May increase, the industrial production index (1997=100) reached a high of 10.4 and then decreased to 7.0 in May 1938. Continuing gold inflows and the Treasury's February 1938 abandonment of gold sterilization allowed excess...
reserves to increase to $1.5 billion in March 1938. Beginning after the Board's reduction in reserve requirements of more than ten per cent in April 1938, excess reserves began a rise to nearly $7 billion in late 1940; however, industrial production did not pass its 1937 peak until October 1939, after the Second World War had begun in Europe.

Second World War and recovery

As the war approached gold flowed into the United States, and the FOMC allowed its security holdings to fall and their maturity to lengthen. In response to inflationary pressures, the Board introduced consumer credit controls in September 1941 and again raised reserve requirements to their legal maxima in November. After the United States declared war, monetary policy was constrained to facilitate war finance. In April 1942 the FOMC set interest rate ceilings on treasury bills at 0.375 per cent and on long-term bonds at 2.5 per cent. The yield curve was upward-sloping and effectively ‘pegged’ by these two boundary conditions into the post-war period. Because capital gains could be earned by buying high coupon securities and selling as they approached maturity, the cost of intermediate term debt was higher than rates shown on the yield curve. Discount rates were lowered to one per cent by all reserve banks and were not raised again until 1948. A preferential discount rate of 0.5 per cent was charged for loans collateralized by short-term US debt. Reserve requirements for central reserve city member banks were lowered in 1942, causing interest-free reserves to disappear into interest-bearing US securities. Finally, a variety of selective credit controls were imposed during and after the war, which ended in August 1945. Yearend deposits and government securities of member banks had risen from $61.7 billion and $19.5 billion in 1941 to $129.7 billion and $78.3 billion respectively in 1945. Because of the pegging of the yield curve, Federal Reserve bank yearend ownership of US securities rose from $2.3 billion in 1941 to $24.3 billion in 1945; treasury bills were $10 million in 1941 and $14.4 billion in 1946. The preferential discount rate was eliminated in the spring of 1946. In July 1947 the FOMC relaxed the rate ceiling on treasury bills and the rate rose to about one per cent by yearend. Reserve banks raised the discount rate to 1.25 per cent in early 1948. Eccles's long term as chairman ended in February 1948, but he continued as a member of the Board. Reserve requirements were increased in 1948 as the Board sought to control inflation, although prices were actually falling at yearend when a recession occurred. Indeed, the reserve requirement policy instrument was used many times between April 1948 and February 1951 because it was perceived not to have a direct effect on treasury interest rates. A continuing struggle between the Board and the Treasury for an independent monetary policy would not be resolved until a spurt of inflation after the start of the Korean War led to an accord signed on 4 March 1951. It effectively freed the Board from pegging interest rates. Partly because of frictions leading to the accord, a new chairman, William McChesney Martin, Jr., was appointed in April.

Resumption of discretionary monetary policy

In the Martin era of discretionary monetary policy, new operating techniques were needed. In 1953 the FOMC settled on a policy of ‘bills only’, which meant that open-market operations would be largely confined to the market for treasury bills, because it was recognized that large policy actions in thin markets could impair market efficiency. Indicators of monetary policy continued to be net free reserves and market interest rates. Because evidence was lacking that interest rates had much effect on private
sector investment, a new paradigm, the ‘availability of credit’ doctrine, was used to rationalize the transmission of policy actions to the real economy. It argued that banks rationed credit to marginal borrowers when restrictive policy led to rising interest rates or indebtedness at the discount window. With these adjustments the FOMC vigorously and unsuccessfully pursued goals of lowering inflation and combating unemployment in the turbulent decade of the 1950s. In that decade there were three business cycles, which were marked by successively rising peaks of interest rates, inflation, and unemployment. The reason for this failure was thought to be inflation-induced rising marginal rates of taxation, which were addressed by large tax cuts in the following decade.

As interest rates rose, the opportunity cost of holding excess reserves rose, which led to the reappearance of a federal funds market in which banks traded reserves. Because banks paid no interest on demand deposits, there was also rapid expansion of the market for commercial paper in which large firms with good credit ratings traded idle funds without the direct intervention of banks. Both markets had atrophied after the 1920s because of low interest rates, and served to change the relation between open-market operations and real economic activity. They were precursors of a wave of innovations that would have similar effects in the coming decade. These included large-denomination negotiable certificates of deposit, one-bank holding companies, offshore ‘shell’ branches, the Eurodollar market, and bank-related commercial paper.

Beginning in 1961, the Kennedy administration attempted to coordinate fiscal and monetary policy by proposing large tax cuts to encourage investment and economic expansion. A new problem was that the United States was experiencing large gold outflows as the world continued to recover from the world war. To cope with this new approach and problem, the FOMC was encouraged to abandon its bills-only policy and to attempt to twist the yield curve by buying long-term bonds and selling bills. As short-term rates rose the Board repeatedly raised the ceiling on interest rates that banks could pay on time and savings deposits. It was argued that lower long-term interest rates would encourage capital formation and that higher short rates would discourage foreign interests from converting dollars into gold, as they were entitled to under the Bretton Woods agreements. These efforts were not successful in discouraging gold outflows, but investment and the economy expanded strongly. In 1965 the Board introduced a Voluntary Foreign Credit Restraint programme, which discouraged banks from overseas lending that was not financing US exports. Nevertheless, gold continued to flow out and the requirement that Federal Reserve notes and reserves be backed by gold was cancelled in 1968. Large open-market purchases had been needed to offset gold losses.

Policy coordination between the Board and the new Johnson administration effectively ended in December 1965, when the Board approved an increase in the discount rate because of inflation arising from mobilizing for the Vietnamese War. Net free reserves had turned negative in 1965 and were increasingly so until late 1966. Short-term interest rates rose until October. Higher rates increased the cost of the mobilization and had devastating effects on residential construction and the savings and loan associations and mutual savings banks (hereafter thrifts) that financed it, because in September Congress passed legislation limiting interest rates that thrifts could pay on time and savings accounts. These limits meant thrifts would experience withdrawals of funds or ‘disintermediation’ because depositors switched funds to government securities, which had no limits. This policy transmission channel would soon disappear because Congress and the administration could not withstand the resulting political pressures. In 1968 the Federal National Mortgage Association was privatized and in 1970 the Federal Home Loan Mortgage Corporation was created. Both bypassed depository institutions by securitizing mortgage
loans. Banks also responded to Board policies and restrictions on innovations by opening overseas offices that were not subject to them. A ten per cent income tax surcharge in 1967 was insufficient to stop inflation, and short-term interest rates rose to new highs in January 1970, when Chairman Martin’s term ended. Net free reserves averaged about a negative $1 billion between May 1969 and July 1970. A decrease in short-term interest rates followed the then largest-ever US bankruptcy of the Penn Central Transportation Company in June 1970, but led to large new capital outflows in 1971 that pressured the dollar. The FOMC responded by forcing short-term rates and net borrowed reserves up again.

Towards flexible exchange rates

The amplitude of changes in interest rates increased between 1965 and 1971, and the United States experienced a recession in 1970. As in the 1950s the Federal Reserve was unable simultaneously to achieve satisfactory unemployment, inflation, and exchange rate outcomes. Many of the Board's policy instruments, such as the discount rate, reserve requirement changes, and many regulations had effectively been disabled by innovations, so that only open-market operations were available to achieve multiple targets. For example, an increase in reserve requirements induced banks to resign from the system or to conduct more of their business overseas. One exception to this loss of powers was the 1970 amendments to the Bank Holding Company Act, which finally gave the Board regulatory authority over one-bank holding companies. In August 1971 the Nixon administration, with new Board Chairman Arthur F. Burns as an advisor, announced a 90-day freeze on prices and wages, suspension of gold sales, and several other major changes in the United States. The suspension of gold sales led to a floating exchange rate system, devaluation of the dollar, and sharp rises in dollar-denominated prices in international markets. The shift from a fixed to a floating exchange rate system is likely to have increased the potency of monetary policy, as was predicted by Mundell (1961). The FOMC responded to consequent high inflation by driving nominal short-term interest rates to very high levels in 1973 and 1974, which helped to induce a severe recession beginning in August 1973, but were inadequate because on average the real federal funds interest rate (calculated with the GDP deflator) was negative between the end of 1973 and 1978. Real estate and other durable goods prices rose relative to the GDP deflator, and the international value of the dollar fell. After the resignation of President Nixon in 1974, Congress required the Chairman to explain policy in semi-annual public hearings and report the FOMC's targets for two money stock measures: M1, a measure of transactions balances, and M2, a measure of liquid assets. Friedman and Schwartz (1963) had recommended using money as an indicator of monetary policy instead of interest rates or net free reserves.

Part of the explanation for the policy failure was continuing financial market innovation. Foreign banks operating in the United States grew rapidly and were unregulated until the 1978 International Banking Act, which placed them under Board supervision. The introductions of money market mutual funds (MMMFs) and negotiable order of withdrawal (NOW) accounts in 1972, the Chicago Board Options Exchange in 1973, and financial futures markets in 1975 again began changing the relation between financial and real markets. A more important change was the rapid expansion of repurchase agreements after 1970. In a repurchase agreement, a client's deposits are borrowed to finance a bank's or dealer's inventory of government securities, often only overnight. Large bank holdings of government securities often represented transactions balances of large corporations and state governments that could not easily be controlled.
The real federal funds rate turned distinctly positive in the third quarter of 1979 when Paul A. Volcker became chairman. In early October he announced that the FOMC would no longer limit fluctuations in short-term interest rates and would use open-market operations to control bank reserves. This was a major policy change from practices dating from the 1951 accord. Further, he imposed eight per cent marginal reserve requirements on non-deposit liabilities, that is, Eurodollar borrowing, federal funds purchased from non-member banks, and funds acquired through repurchase agreements. These vigorous actions together with large income tax cuts by the Reagan administration between 1981 and 1983 drove real short-term interest rates to levels not seen since the early 1930s and caused MMMFs to grow rapidly. In only two quarters between 1979 and 1986 was the average real federal funds less than five per cent. These high rates caused the trade-weighted value of the US dollar to appreciate by 87 per cent between July 1980 and February 1985, which savaged US exports and attracted imports with adverse consequences for US manufacturing.

Financial deregulation

The landmark Depository Institutions Deregulation and Monetary Control Act was signed by President Carter at the end of March 1980. It radically changed the Federal Reserve System by eliminating the significance of membership in the system. After an eight-year phase-in period, all depository institutions would be subject to uniform reserve requirements on demand and time deposits, although the requirement on the first $25 million of transactions deposits was less than that on other transactions deposits. The Board could vary reserve requirements. All depository institutions had access to reserve bank discount windows. This strengthened the system because banks could no longer threaten to leave it in order to get the lower requirements that many states imposed. Further, Federal Reserve banks were required to charge banks for the cost of services they provided. Before this act they had been giving away services as an inducement for banks to stay in the system. This pricing requirement in turn forced depository institutions to begin to charge their clients for services, which changed the way banking services were used. The act mandated that interest rate ceilings on time and savings accounts be eliminated after six years, increased deposit insurance, and had other important provisions that are beyond the scope of this discussion.

In late 1980 the Board announced that transfers from overseas branches to the United States could be treated as collected funds on the day they were transferred. Before then, transfers in a day were not ‘good funds’ until the following day. The expansionary effects of this change, rapidly growing repurchase agreements, and other innovations are evident in demand deposit turnover statistics that the Board reported from 1919 until August 1996. Turnover is the annualized value of all withdrawals from deposit accounts divided by aggregate deposit balances.

High interest rates were savaging thrift institutions, which had negative gaps (more fixed-rate assets than fixed-rate liabilities on most future dates), and allowed MMMFs to expand rapidly. Congress intervened in September 1982 by passing the Garn–St Germain Act, which provided temporary emergency assistance and among other changes introduced money market deposit accounts and super NOW accounts, which paid market interest rates. MMMF growth was slowed by this act, but the weakening condition of banks and thrift institutions would result in large numbers of failures as the decade wore on. Large banks also experienced large losses because the appreciating dollar had resulted in failures of sovereign states, especially in Latin America, to meet their loan obligations. Chairman Volcker was
heavily involved in negotiating solutions for these defaults. The restrictive monetary policy resulted in the deepest recession since the Depression; the unemployment rate was 10.8 per cent at the end of 1982. At the end of Volcker's term in August 1987 the unemployment rate had fallen to six per cent and the consumer inflation rate was less than two per cent. Real interest rates had fallen from 10.5 per cent in mid-1981 to four per cent, and the trade-weighted value of the dollar fell correspondingly. Volcker's February 1987 statement of monetary policy objectives to the Congress reported that M1 was not a reliable indicator of monetary policy and would be de-emphasized.

While his successor, Alan Greenspan, inherited a much improved economy, many problems remained from a rising wave of bank failures and the collapse of thrift institutions. Real estate markets were especially disorderly when the thrift crisis was resolved beginning in 1989 and were further distorted by provisions in the Tax Reform Act of 1986, which disallowed many interest tax deductions. After 1990 interest on home loans was effectively the only deductible interest on individual income tax returns. In addition, a collapse of stock prices in October 1987, strong foreign demand for US currency associated with the collapse of the Soviet Union, and a recession at the end of 1990 presented further challenges. The FOMC responded to these challenges by varying the real federal funds rate, defined using the contemporaneous GDP price deflator inflation rate. This rate fell sharply for two quarters after the stock market crash, rose before falling for two quarters after a second stock market dip in October 1989, and then began to fall in the fourth quarter of 1990. In July 1993 testimony before Congress, Greenspan disclosed that the FOMC was downgrading M2 as an indicator of monetary policy and, as could have been surmised from its actions, that an important guidepost was now real interest rates. The real federal funds rate averaged less than one per cent in 1993. In early 1995 it had risen to four per cent and held that value as an average until the collapse of a large hedge fund in September 1998. After the fallout from the hedge fund collapse had been resolved, the real federal funds rate was restored to an average of about four per cent in 2000. When a new recession appeared in 2001 together with a sustained large collapse in stock market prices, the real federal funds rate was lowered to near zero in the fourth quarter; the rate had averaged zero for 13 consecutive quarters as of March 2005.

Between December 1990 and April 1992 reserve requirements on time and demand deposits were reduced, which helped banks to increase net income. In January 1994 ‘retail sweep programmes’ were introduced. In these programmes, a bank shifts funds from a depositor's transactions account to a synthetic time deposit account in the depositor's name in order avoid reserve requirements, usually without the depositor's knowledge. The Board does not measure the amount of funds swept, except at the time the programme was established. The Board estimated that as of August 1997 required reserves fell by one-third because of these programmes.

In November 1999 President Clinton signed the Financial Services Modernization (Gramm–Leach–Bliley) Act, which reversed the 1933 Glass–Steagall Act's ban on combining commercial and investment banking. The ban had been eroding since 1987, when some large bank holding companies were authorized by the Board to establish subsidiaries that could underwrite state and local government revenue bonds. The new act authorized the establishment of financial holding companies, which were to be regulated by the Board and could engage in an approved list of activities that included commercial banking, insurance, securities underwriting, merchant banking, and complementary financial undertakings. In 2003 there were more than 600 financial holding companies, which resemble the universal banks that exist in other countries.
In December 2002 the Federal Reserve discarded the discount rate as a policy instrument by replacing it with an interest rate on primary credit extended by the discount window that is one per cent above the FOMC target federal funds rate. Primary credits are collateralized loans to banks in sound financial condition.

As the foregoing dramatic institutional changes suggest, the Federal Reserve System is a work in progress. Its set of policy instruments and its dimensions have radically changed. Because of offshore banking facilities and retail sweep accounts, reserve requirement changes are no longer an effective policy instrument. As noted in the preceding paragraph, the discount rate has been discarded as an instrument; it is simply a penalty rate that is related to a bank rate, as is often the practice in other countries. Regulations on the interest rates banks pay on time and savings deposits have been discarded. Open-market operations are almost the sole policy instrument that can be used to achieve the Board's target nominal and real federal funds interest rates. While the FOMC has been able to control the overnight federal funds rate, the linkage between it and real economic activity is changing. First, the combined holdings of US government securities by foreign central banks have recently exceeded those of Federal Reserve banks. Foreign central bank holdings are partly a result of their efforts to manipulate exchange rates; their holdings are likely to change when FOMC policies change. Second, repurchase agreements and offshore transactions vary considerably over time and their volumes appear to be sensitive to US economic activity. Third, the outstanding stock of securitized mortgage and other debt has been growing rapidly; such debt is a close substitute for US government debt and its amount has real economic effects. Fourth, because of decreasing required reserves and growing offshore holdings of US currency, 89 per cent of Federal Reserve liabilities were in the form of Federal Reserve notes in December 2003; the corresponding share was 34 per cent in 1941, 57 per cent in 1970, and 79 per cent in 1989. In part, the Federal Reserve recently has become an institution for collecting seigniorage from the rest of the world. Finally, over the decade ending in 2003, the share of all credit market assets held by depository institutions in the Federal Reserve’s flow of funds accounts fell. In the context of the most recent 13 quarters of a zero real federal funds interest rate, more changes could be expected.

Fel'dman, Grigorii Alexandrovich (1884–1958)

Abstract

Fel'dman was one of the founders of the theory of economic growth, the economics of planning and development economics. His contributions were made in the USSR in the late 1920s. He developed a two-sector growth model and showed how different growth rates implied different economic structures. He derived two theorems. He is regarded as the father of the ‘heavy industry first’ strategy of economic development. A brilliant pioneer, Fel’dman’s work was cut short by the Stalinists. Later analysis and international experience revealed a number of limitations of a narrowly Fel’dmanite approach to economic policy.

Article

Fel’dman was one of the founders of the theory of economic growth under socialism, the economics of planning and development economics. An electrical engineer by profession, he worked in Gosplan from February 1923 to January 1931. It was in this period that his contribution to economics was made. At first he was in the department analysing and forecasting developments in the world economy (he concentrated on Germany and the USA). His first work on the theory of growth was a comparative study of the structure and dynamics of the US economy in 1850–1925 with projections of the Soviet economy between 1926/27 and 1940/41. His most important work (‘On the theory of the rates of growth of the national income’) was a report to Gosplan’s committee for compiling a long-term plan for the development of the national economy of the USSR. It was published in two parts in Gosplan’s journal in 1928. A year later Fel’dman published a paper (1929c) which provides a more popular presentation of how to utilize his ideas to calculate long-term plans. The ideas of Fel’dman formed the methodological basis for the preliminary draft of a long-term plan worked out by the committee, then headed by N.A. Kovalevskii. This draft was discussed at meetings of Gosplan's economic research institute in February and March 1930. Apart from this serious discussion, during 1930 Fel’dman came under public attack for his ideas. His reliance on mathematics and his lack of fanaticism did not fit in well with the political fervour of 1930. The concrete numerical work of Fel’dman and Kovalevskii in 1928–30 was much too optimistic. It treated as feasible entirely unrealizable goals. The attempt to realize them had disastrous effects on the economy. Unfortunately, the political situation in the USSR prevented Fel’dman from publishing anything on economics after 1930. Even when, in 1933, he reverted from the sensitive subject of socialist industrialization to the problems of capitalist growth, his book was not published.

As far as growth theory is concerned, Fel’dman's work was much in advance of contemporary Western work. He developed a two-sector growth model and showed how different growth rates implied different economic structures. He derived two important results, one about the ratios of the capital stocks in the two sectors, the other about the allocation of investment between the two sectors. The first result is that a high rate of growth requires that a high proportion of the capital stock be in the producer-goods sector. This is illustrated in Figure 1. Fel’dman's second theorem is that, along a steady growth path, investment should be allocated between the sectors in the same proportion as the capital stock. For example, suppose that a 20 per cent rate of growth requires a $K_c/K_p$ of 3.7. Then, to maintain growth at 20 per cent p.a. requires that 3.7/4.7 of annual investment goes to the consumer-goods industries and 1.0/4.7 of annual investment goes to the producer goods industries.

Figure 1
Fel’dman’s first theorem. **Notes:** $K_c$ is the capital stock in the consumer goods industry, $K_p$ is the capital stock in the producer goods industry.
The interrelationship between the two theorems is shown in Table 1, in which Fel’dman explained how any desired growth rate, given the capital–output ratio, determined both the necessary sectoral composition of the capital stock and the sectoral allocation of investment.

Fel’dman’s two theorems

\[
\frac{K_p}{K_c} \quad \frac{\Delta Y}{\Delta t} \quad \text{(in % p.a.)(when } K/Y = 2.1) \quad \frac{\Delta K_p}{\Delta K_c + \Delta K_p}
\]

Given the capital–output ratio, the higher the \(K_p/K_c\) ratio, that is, the greater the proportion of the capital stock in the producer-goods sector, and correspondingly the higher the \(\Delta K_p/\Delta K_c + \Delta K_p\) ratio, that is, the greater the proportion of new investment in the producer-goods sector, the higher the rate of growth. With a capital–output ratio of 2.1, to raise the growth rate from 16.2 to 24.3 per cent requires raising the proportion of the capital stock in the producer-goods sector from a third to a half, and the share of investment in the producer-goods sector from a third to a half.

The conclusion Fel’dman drew from his model was that the main tasks of the planners were to regulate the capital–output ratios in the two sectors and the ratio of the capital stock in the producer-goods sector to that in the consumer-goods sector. For the former task, Fel’dman recommended rationalization and multi-shift working; for the latter, investment in the producer-goods sector.

As far as the economics of planning is concerned, the main lesson to be learned from the Fel’dman model is that the capacity of the capital-goods industry is one of the constraints limiting the rate of growth of an economy. There may well be other constraints, such as foreign exchange, urban real wages or the marketed output of agriculture. (Indeed, it is possible that one or more of these are binding constraints and that the limited capacity of the producer-goods sector is a non-binding constraint.) Economic planning is largely concerned with the removal of constraints to rapid economic growth. Accordingly, a planned process of rapid growth may require that the planners stimulate the rapid development of the producer-goods sector.

As far as development economics is concerned, Fel’dman is important because of the argument in his 1928 paper that ‘an increase in the rate of growth of income demands industrialization, heavy industry, machine building, electrification …’. When first formulated, this conclusion struck many economists as counter-intuitive and paradoxical. Fel’dman’s work, as is natural for a pioneer, suffers from serious limitations. As far as the theory of economic growth under socialism is concerned, he was an important early contributor, but his work has to be complemented by Kalecki’s (1969) emphasis on the limits of growth and Kornai’s (1992, ch. 9) emphasis on the behavioural regularities actually generating the growth process. As for the economics of planning, his arguments have to be complemented by a proper understanding of the role of agriculture, foreign trade and personal consumption and of the danger of an over-accumulation crisis. In development economics, experience in the USSR in the 1930s, India in the 1950s and China in the Maoist period has shown the limitations of a narrowly Fel’dmanite approach.

A brilliant pioneer, Fel’dman’s work was ended after only a few years by the Stalinists. In January 1931 Fel’dman was forced out of Gosplan. He seems to have been arrested in 1937 and only released – probably from the Gulag – in 1943, but even then was forbidden to return to Moscow. He was only allowed to return to Moscow in 1953, by which time he was seriously ill.

Feminist economics is a field that includes both studies of gender roles in the economy from a liberatory perspective and critical work directed at biases in the economics discipline. It challenges economic analyses that treat women as invisible, or that serve to reinforce situations oppressive to women, and develops innovative research designed to overcome these failings. Feminist economics points out how subjective biases concerning acceptable topics and methods have compromised the reliability of economics research. Topics addressed include the economics of households, labour markets, care, development, the macroeconomy, national budgets, and the history, philosophy, methodology, and teaching of economics.

Feminist economics is a field that includes both studies of gender roles in the economy from a liberatory perspective and critical work directed at biases in the content and methodology of the economics discipline. It challenges economic analyses that treat women as invisible or that serve to reinforce situations oppressive to women, and develops innovative research designed to overcome these failings.
Feminist economics points out how subjective biases concerning acceptable topics and methods have compromised the reliability and objectivity of economics research, and explores more adequate alternatives.

The origins of feminist economics

Feminist economics in its contemporary form began in the 1970s in response to the prevailing pattern of labour market and household studies. Up until the 1960s, women and women's traditional activities had been subsumed into the ‘black box’ of the household within neoclassical economics. Neoclassical theory had been defined as the study of choices made in markets by rational, autonomous actors. A household was generally understood to be represented by its male ‘head’, whose preferences, it was assumed, determined household labour supply and consumption decisions. The household was assumed to enjoy a single utility level, and activities within the household were classified as ‘leisure’. Studies of paid labour generally focused on men only, and household production was (and is still) excluded from national accounts. Women, women's traditional activities, and the well-being of women and children were invisible.

During the 1960s, issues of labour market discrimination by race and sex began to be debated. The idea that household activities might include unpaid work as well as leisure also gained ground. The New Home Economics school sought to extend rational choice theory to intra-household decisions. Often, however, work by economists on these issues simply defended traditional sex roles in the family, women's segregation into a narrow range of paid occupations, and women's lesser earnings in the paid labour market. In general, neoclassical economists of the time argued that the prevailing patterns resulted from rational choices, with variations between men and women due only to presumably innate differences between men and women in tastes and abilities, often expressed in different choices about human capital formation. As well, circular reasoning was used: women's lesser market earnings were used to explain their specialization in household work, and women's household responsibilities were used to justify their lesser market earnings. While these works recognized women's existence, they were not feminist in that they served to rationalize rather than explore and question women's assignment to second-class status and financial dependency.

A key distinction feminist economists make is between sex, understood as the biological difference between males and females, and gender, the social beliefs that society constructs on the basis of sex. While traditional economists saw household and labour market outcomes as reflecting only sex differences, feminist economists raised the question of how much these outcomes might, instead, reflect misleading stereotypes and rigid social constraints. Some works called into question, for example, the ideas that specialization in household work would be an optimizing choice for a woman (given rising divorce rates) or that it would necessarily yield greater household well-being than other, more egalitarian, arrangements (Ferber and Birnbaum, 1977; all references given in this article are examples from larger literatures). Others emphasized the role of discrimination in limiting women's labour market opportunities (Bergmann, 1974) or the interplay of household and workplace power relations (Hartmann, 1976).

In actuality, as the equal rights movements of the 1960s and 1970s loosened many of the legal restrictions and social norms that had artificially narrowed women's educational and job choices in a
number of countries, women moved increasingly into the labour market and into formerly all-male occupations. Surveys of women's economic history, economic status, and progress towards gaining economic equality have since been undertaken for many countries and regions, along with surveys of policies related to gender equity. Recognition of the importance of social beliefs and power structures in creating gendered economic outcomes has remained a hallmark of feminist economics.

The critique of mainstream economics

While feminist were originally dissatisfied with mainstream economic scholarship because it neglected and distorted women's experiences, by the late 1980s feminists were also advancing a more thoroughgoing critique. Many feminist economists were finding that traditional formal choice-theoretic modelling and a narrow focus on mathematical and econometric methods were a Procrustean bed when it came to analysing phenomena characterized by connection to others, tradition, and relations of domination. Feminists began to raise questions about the mainstream definition of economics, its central image of 'economic man' and the exclusive use of a particular set of methodological tools. Essays on this theme were brought together in a 1993 volume, Beyond Economic Man: Feminist Theory and Economics (Ferber and Nelson, 1993). In this volume it was suggested that economics be defined by a concern with the provisioning of life in all spheres where this occurs rather than only in markets. Investigations were undertaken into how a particular set of professional values, emphasizing culturally masculine-associated factors such as autonomy, separation, and abstraction, had come to take precedence over culturally feminine-associated factors such as interdependence, connection, and concreteness. The contributors argued that, rather than taking the former as a sign of 'rigour' in the discipline, the truncation of methods created by masculinist bias had weakened the discipline's ability to explain real-world phenomena. Questions were raised about mainstream economics not because it was too objective but because it was not objective enough.

A conference held in Amsterdam in 1993 further developed this theme, and contributed innovative discussions on economic methodology (Kuiper and Sap, 1995). While many feminist economists continue to make use of traditional mainstream tools, on the whole the field has come to be characterized by the inclusion of a broader range of concepts and methods. Theories of human behaviour that include a balance between individuality and relationship, autonomy and dependence, and reason and emotion are being developed (Ferber and Nelson, 1993; 2003). The use of historical studies, case studies, interviews and other qualitative data, as well as greater attention to issues such as data quality and replication in quantitative work, are being explored (Bergmann, 1989; Nelson, 1995). Feminist economists tend to find that such serious efforts to create and promote more adequate forms of economic practice lead to new insights across the board, whether or not the topic being studied is explicitly gender-related.

The formation of a field

With the publication of a number of books and articles, and gatherings at early conferences, feminist economics coalesced into an organized field in the early 1990s. The International Association for Feminist Economics was formed in 1992, and its journal, Feminist Economics, commenced publication.
a few years later (Strassmann, 1995). The field was first described in a journal of the American Economic Association in 1995 (Nelson, 1995), an encyclopedia of feminist economics was published in 1999 (Peterson and Lewis, 1999), and a review of developments during the first ten years of feminist economics was published in 2003 (Ferber and Nelson, 2003).

International and wide-ranging in scope, feminist economics now includes work on a number of subjects, including topics in microeconomics, macroeconomics, history, and philosophy.

Labour, households and care

True to its roots, feminist economics continues to develop analyses of gender roles in labour markets and households. Many studies of women's paid labour supply, labour market discrimination, and the origins of occupational segregation have been undertaken. Some feminists make use of mainstream theories or econometric models to examine the wage gap between men and women and its possible explanations. Other feminist economists raise questions about the ability of such tools, used alone, to shed light on the underlying causes of inequality, and encourage increased investigation into the social, political and institutional structures of gender and labour markets (Bergmann, 1989; Rubery, 1998; Figart, Mutari and Power, 2002).

Studies of unpaid work within households have sought to obtain quantitative measures of this labour and to increase the attention paid to unpaid work in the design of policies (Waring, 1988; Ironmonger, 1996). The issue of valuing this work remains controversial among feminists. Some feminists endorse the use of replacement cost or opportunity cost methods of assigning dollar values to unpaid household labour. Others argue that these methods lead to understatement because the wages used in such imputations have been kept artificially low by discrimination. Still others believe that this issue serves to draw attention away from women's lack of access to real money and power.

Issues of intra-household distribution and decision-making have been investigated by many feminist economists. The dramatic effect of skewed intra-household distribution by sex in countries such as China, India and Pakistan has been brought to public attention (Sen, 1990). Bargaining models (McElroy and Horney, 1981) have been developed as one way of bringing women's agency within households to the fore. Issues concerning marriage, divorce, fertility and the well-being of children have been investigated from feminist perspectives. A number of feminist economists go beyond choice-theory-based bargaining models to examine legal, social, and psychological issues related to intra-household decision-making and well-being (Sen, 1984, ch. 16; Agarwal, 1997; Wheelock, Oughton and Baines, 2003).

Much of women's traditional work in sex-segregated occupations (such as nursing and childcare) and within households can be described as ‘caring work’. Caring work presents a challenge to mainstream economics since the traditional image of ‘economic man’ is of an autonomous, self-interested individual who neither requires care nor has any inclination to provide it. The conceptual and empirical study of work with dependency, emotional or other-regarding components has recently become a field of active investigation for many feminist economists (Folbre, 1994; Himmelweit, 1999; Folbre and Nelson, 2000; Bettio and Plantenga, 2004).

Feminist economists have developed critiques of theories and policies that assume that economic agents
Feminist economics: The New Palgrave Dictionary of Economics

are unencumbered prime-age workers, and that delve into the economic problems of elderly women, parents of young children, and lone mothers who are faced with simultaneous responsibilities for income generation and family care (MacDonald, 1998; Albelda, Himmelweit, and Humphries, 2004).

Development, macroeconomics and national budgets

Feminist economists have also made innovations in the analysis of national and global economies. Studies of the effects of including unpaid production in GDP (Wagman and Folbre, 1996) and the analysis of government budgets according to their effects on gender equity (Budlender et al., 2002) have become well-developed fields.

Feminist economists have challenged the definition of economic development in terms of industrialization and GDP growth, drawing attention instead to issues of growth in human well-being and capabilities (Elson, 1991; Benería, 2003; Agarwal, Humphries, and Robeyns, 2003). Many have studied the changes in women's status that have come about during transitions from socialism and during other forms of macroeconomic restructuring (Aslanbeigui, Pressman and Summerfield, 1994). The effects of macroeconomic policies of structural adjustment and the liberalization of global trade and finance have been looked at from a feminist point of view (Çagatay, Elson and Grown, 1995; Grown, Elson and Çagatay, 2000). For example, programmes that prescribe macroeconomic belt-tightening through cutbacks in health care often have their most immediate impact on women, as women are expected to take on, unpaid, the work of providing services no longer provided by governments. Men and women may also be affected differently, depending on the degree to which they work in subsistence or traded sectors. Women's employment in subcontracting firms has also received considerable attention (Kabeer, 2000; Balakrishnan, 2002).

History, philosophy and teaching

As well as investigating the history of women's economic activities (Humphries, 1990) and the history of economic thought in relation to women (Folbre, 1991; Pujol, 1992), feminist economists have looked at the history of women and feminists within the economics discipline itself (Dimand, Dimand and Forget, 1995). The most recent national studies indicate that women are still under-represented in the top ranks of academic economics (Booth, Burton and Mumford, 2000), receiving tenure less frequently than men even when factors such as publications and family are controlled for (Ginther and Kahn, 2004). Sexual harassment, sex discrimination, and inhospitable environments are among the barriers yet to be overcome in some departments and universities (Ginther and Kahn, 2004).

Feminist economists have also engaged in philosophical discussion concerning the epistemological and methodological foundations of economics in dialogue with postmodernist, post-colonialist, critical realist and other perspectives (Barker and Kuiper, 2003). Feminists have also explored comparisons of aims and methods with various heterodox schools of economics including institutionalist economics (Waller and Jennings, 1990), social economics (Emami, 1993), radical economics (Matthaei, 1996) and Post Keynesian economics (Danby, 2004).
Regarding the teaching of economics, feminist economists have investigated how the content of economics courses can be made less biased concerning women (Feiner, 2004), how courses can be enriched by feminist re-evaluation of theories and methods, and how pedagogy can be adapted to better reach students with diverse backgrounds and learning styles (Shackelford, 1992; Aerni and McGoldrick, 1999).

Feminism and other concerns

Feminist economists have also analysed how such factors as race and caste (Brewer, Conrad and King, 2002) and sexual preference (Badgett, 2001), in interaction with gender, affect economic outcomes. Feminist economists’ scepticism about the adequacy of the image of ‘economic man’ has also stimulated new thinking in areas other than gender relations. The analysis of relations of power and of care, first generated by study of women's work and family relations, has been extended to the subject of interpersonal relations among people economy-wide (Nelson, 2005). Feminist explorations into ecological economics examine how natural processes, like women, have been treated as invisible and freely exploitable in traditional economic thought (Perkins, 1997).

fertility in developed countries

Alicia Adsera
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

After completing the first demographic transition, developed countries experienced a fertility boom in the post-Second World War period. However, after the 1960s fertility rates fell dramatically and now, in 2007, stand below the replacement level of 2.1 births per woman in most of these countries. The entry of women into the workforce, economic development and changes in values and secularization are the causes of this demographic transformation.

Decrease in fertility rates

Fertility rates in the developed world started to decline sharply at the end of the 19th century. In Europe fertility declined by about 40 per cent between 1870 and 1930, and the majority of Western countries experienced this transition before the Second World War (Lee, 2003). The Second World War was followed by a period of increases in fertility. After peaking during the ‘baby boom’ years of the late 1950s, the average total fertility rate in developed countries fell from an average of 2.8 births per woman in 1960 to 2.0 in 1975 and then to 1.6 in the late 1990s (and below 1.3 in southern Europe). The total fertility rate (TFR) estimates the number of children a woman would bear if she went through her childbearing years exposed to the current age-specific birth rates for women between the ages of 15–44 years. Table 1 presents the evolution of the total fertility rate since 1965 to 2004 in the most developed economies. In 1965, fertility rates were almost three children in many of these countries and even higher in Canada, Portugal, Iceland and Ireland. During the next decade, rates fell sharply in the richest countries, but they remained above replacement level in southern Europe, Ireland and Iceland. The transition to lower fertility has only occurred in southern Europe since the early 1980s but its speed and extent went beyond what previous countries had experienced. By the mid-1990s fertility rates in these countries were under 1.3, a threshold level used by some demographers to define ‘lowest-low fertility’ (Kohler, Billari and Ortega, 2002). With the exception of the United States, Iceland and Ireland, all advanced countries now have fertility rates well below the replacement rate of 2.1 (the fertility rate needed to sustain a steady level of population) though cross-national differences have remained significant.

Synthetic indices such as total fertility rates may not provide a precise picture of fertility changes in periods when the younger cohorts of women shift the timing of their fertility to older ages. Both the age at first marriage and the age at first birth have been rising since the early 1980s across the developed world. Delayed maternity may artificially deflate total fertility rate since a larger proportion of births is bound to occur among older mothers over time, but this is not still reflected in the behaviour of women currently in their thirties. Adjustments for these ‘tempo effects’ suggest that, even though important for some countries, such as France or the Netherlands in the mid-1980s, they account for only part of the reduction in TFR (Bongaarts, 2001). Completed fertility by cohort provides an alternative and more accurate way to measure fertility changes. It computes the mean number of children born to women of a given generation at the end of their childbearing years. Recent data in completed fertility show for most countries a downward trend similar to that in TFR though with more moderate inter-country differences. Among women born in 1965, for example, whereas the Irish are projected to bear around 2.2 children, Spaniards, German and Italians are expected to bear only 1.5 children.

In any case, delayed childbearing itself is likely to imply lower completed fertility. Women who become mothers at a later age are expected to bear fewer children by the end of their fertile life because of both time and fecundity constraints (Kohler, Billari and Ortega, 2002). Still, the negative relationship between postponement and completed fertility seems to have weakened somewhat, possibly due to the improvement in reproductive techniques. Even if lifetime childlessness has risen steadily among women born between the 1940s and 1970s, particularly in German-speaking countries, demographers project it will stabilize around 15 to 20 per cent in these countries.

### Quantity and quality of children

The basic microeconomic model of fertility (Willis, 1973; Becker, 1991) identifies a broad set of factors that influence fertility: household preferences over the number and quality of children, their labour supply decisions and their access to family planning. Each one of these factors has been relevant to the dramatic reduction in fertility rates across developed countries as income kept rising during the 20th century. In addition, with modernization, infant mortality decreased sharply. For parents interested in a certain number of surviving children, the increase in the likelihood of survival of any child born constituted an independent cause of the reduction in fertility.

The quantity–quality model developed by Becker and Lewis (1973) and Willis (1973) provided the first explanation of the observation that the number of children per family did not increase with income. In this model, each family maximizes a utility function depending on the quantity of children, the quality of children (expenditures on a child's well-being such as health or education) and consumption goods. Parents provide the same quality for all their children. The quality and quantity of children enter multiplicatively in the budget constraint of the household through the total expenditures on children. Overall expenditures on children tend to increase with income, which indicates that children are normal goods. An increase in the quantity of children raises the shadow price of the quality of children and vice versa. For example, an increase in the number of children raises the cost of providing more quality for each child because there are more children. This explains why the quantity and quality of children interact more closely than any other random pair of goods, even without assuming that both are close substitutes (Becker and Lewis, 1973). If the income elasticity of demand for quality of children is higher than that of quantity, rising income increases the optimal ratio of quality to quantity of children. This implies a rise in the relative cost of an additional child relative to quality and can lead both to higher quality per child and fewer children. The income effect on fertility may be offset by the substitution effect induced by the increase in the shadow price of an additional child. If a high average education in a society generates positive externalities that boost the returns to each individual's human capital, the quality–quantity trade-offs are strengthened as families invest more heavily in each of the children (Becker, Murphy and Tamura, 1990).

**Labour market participation and fertility**

Household production models in which both consumption and production decisions are jointly analysed provide a second major explanation for the decrease in the number of children per woman. These models spell out how labour supply decisions are related to choices in both the timing and the level of fertility. As a result of economic development since the Industrial Revolution, capital intensity in production increased and, further, the emphasis in activities that require physical strength diminished with the gradual shift from manufacturing towards services. This technological transformation pushed upwards the demand for activities where women have a comparative advantage and increased the relative wage of women (Galor and Weil, 1996). Developed countries therefore experienced a massive entry of women into the labour market, with average female labour force participation rates climbing from 41 per cent in 1960 to 64 per cent by the late 1990s. Childbearing is time-intensive relative to other activities and its associated opportunity cost can be measured by the potential wages of the mother. While increases in men's work mainly entail an income effect that increases the demand for children, increases in women's wages give rise to a combination of income and substitution effects as they result in an increase in the cost of a child relative to other goods (Mincer, 1963). Accordingly, women with high potential wages may restrict their fertility and trade off children for less time-demanding alternatives if the substitution effects are important (Becker, 1991). An alternative to this is the purchase of childcare services in the market. This may lessen the substitution effect and the net impact of higher wages may even turn positive (Ermisch, 1989). In Scandinavian countries, for example, where publicly provided childcare is abundant, work–family trade-offs are diminished. As women's wages have increased across the developed world, however, the cost of childcare outside the home has also risen because its provision is intensive in woman's work. The original fertility models are static since all life-cycle choices are made at the beginning of the parent's lifetime without assuming any uncertainty. Later models emphasize the sequential nature of these decisions and incorporate stochastic shocks to the household— for example, contraceptive failure (Heckman and Willis, 1976). Moffit (1984) explores how, in addition to current wage losses, lower experience and skill depreciation from career interruption may result in permanent wage gaps between women with different childbearing patterns. (His model supports the prediction that women with strong preferences for children may self-select into occupations with low wage-growth prospects: Mincer and Polachek, 1974.) Hotz, Klerman and Willis (1997) offer a good review of dynamic models of fertility.

**Family planning**

The decrease in the cost of contraception is a third important factor that facilitates the family choices discussed in the previous models. Widespread access to the birth control pill since the late 1960s had two important effects on women's careers and fertility behaviour in developed nations (Goldin and Katz, 2002). First, it promoted women's career investment by reducing pregnancy risk while allowing women to remain sexually active. Second, it had an indirect impact through a social multiplier effect: the overall delay of marriage produced a thicker marriage market for career women and increased their likelihood of finding a suitable spouse later in life. Accordingly, in the United States from around 1970, more women entered professional schools and delayed marriage.

**Differences across countries**

As expected from the household production models, during the 1960s and the 1970s fertility was lower in the countries where women had entered the labour market more rapidly. Surprisingly, as female labour participation kept growing the cross-country negative relationship between fertility and labour force participation reversed by the mid-1980s. As shown...
in Figure 1 for the mid-1990s, those countries with the lowest levels of female labour force participation – such as Spain, Italy and Greece – also portrayed the lowest fertility rates. Further, even if fertility differed substantially across countries at that time (Table 1), surveys indicated that the ideal family size was above replacement level and relatively homogenous. Hence, this positive correlation was probably related to the differential support to women from government policies as well as the flexibility and performance of their labour markets.

The rapid increase in persistent unemployment since the mid-1980s was contemporaneous with the sharpest fall of fertility rates and postponement of childbearing in many countries. European unemployment went up from less than three per cent before 1975 to about ten per cent in the 1990s. By 1990, around 50 per cent of those unemployed in the European Union had been out of work for more than 12 months. Within the standard microeconomic model of fertility the associated fall in current opportunity costs (in terms of forgone wages) makes unemployment spells good times for childbearing (Butz and Ward, 1979). Still, job loss impairs human capital accumulation and, with it, the future prospects of employment, particularly of young workers with low labour market experience. Among the employed, (temporary) withdrawals from the labour market associated with maternity

Have a similar effect. High and long-lasting unemployment intensifies the relevance of the latter and negative income effects can reduce fertility, as happened during the Great Depression (Becker, 1991). Individuals may want to secure an adequate level of human capital (experience or education) before starting a family, and so the attractiveness of an early childbearing strategy declines. Since the 1980s, fertility postponement was more important in countries where joblessness was more prevalent and persistent – particularly among women – such as those in southern Europe (Adsera, 2005).

The extent of the negative impact of unemployment, however, is related to the labour regulation and types of contractual arrangements available in each labour market. The rapid feminization of the labour force in southern Europe, where traditionally there was low female participation, collided with rigid labour market institutions that favoured traditional full-time male employment and limited the availability of part-time positions for women (Adsera, 2005). In addition, the expansion of temporary contracts among young workers after partial labour reforms were passed in the late 1980s exacerbated those problems. By contrast, fertility rates are among the highest in countries with high female participation and either a flexible regulation and access to part-time employment (and low unemployment), such as the United States, the United Kingdom, or the Netherlands, or abundant public sector employment (mostly tenured jobs with features that make childbearing and participation compatible), as in the Nordic countries and France.

Changes in values and the ‘second demographic transition’

Changes in values as well as secularization have long been considered independent causes of recent demographic adjustments. The fall in period fertility has been coupled with a set of changes to childbearing behaviour and family formation in most Western countries that demographers characterize as a ‘second demographic transition’ (Van de Kaa, 1987). The most relevant features of the second demographic transition are a reduction in fertility, extensive use of modern contraceptive methods, increases in mean age at marriage and age at first birth, together with rises in extra-marital childbearing, cohabitation and divorce. In 2003, around one-third of births in developed countries occurred out of wedlock, but cross-country differences remained substantial. The share of births outside marriage ranged from just under five per cent in Greece to 63 per cent in Iceland and 56 per cent in Sweden. At the core of these changes are an accentuation of individual autonomy, the abandonment of traditional religious beliefs, and a decline in sentiments of religiosity among individuals (Lesthaeghe and Surkyn, 1988). This transformation, which was already under way in most of Western Europe during the 1970s, became increasingly widespread in southern Europe from the middle of the 1980s.

Future implications

These demographic transformations have progressively moved to the centre of public debate both because of their social implications and the challenge they pose to the sustainability of welfare states in Western economies. As women continue to enter the labour force, labour market institutions need to adapt to minimize the trade-offs connected with childbearing to encourage fertility. In the absence of massive migration flows, smaller future cohorts facing improved economic conditions thanks to lower pressure in labour and housing markets may increase their fertility, as predicted by Easterlin’s model (1975). However, since this would take place only in the long run, fertility rates are not likely to rebound to the replacement level in the near future (Bongaarts, 2001). In the meantime, recent data from the Eurobarometer shows that the ideal number of children has been decreasing for women aged between 20 and 34 since the late 1980s across the European Union. The average is just above 2.1, but for the first time, some countries such as Germany and Austria already portray below-replacement desired fertility (Goldstein, Lutz and Testa, 2003).

fertility in developing countries

T. Paul Schultz
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The associations between fertility and outcomes in the family and society have been treated as causal, but this is inaccurate if fertility is a choice coordinated by families with other life-cycle decisions, including labour supply of mothers and children, child human capital, and savings. Estimating how exogenous changes in fertility that are uncorrelated with preferences or constraints affect others depends on our specifying a valid instrumental variable for fertility. Twins have served as such an instrument and confirm that the cross-effects of fertility estimated on the basis of this instrument are smaller in absolute value than their associations.

Fertility is a choice by parents involving a life-cycle claim on their resources, from which they may receive satisfaction as consumers and benefit as producers from children's labour and care-giving support. In addition, fertility may be the source of externalities that affect members of society other than the decision-making parents, in which case society may view fertility as a legitimate issue for social policy. To forecast fertility and the conditions under which public policies might be justified to modify fertility, economists require a basic understanding of its determinants as well as social consequences. In approaching this topic from the perspective of low-income countries today, the ideas of Malthus remain influential. He argued that population growth caused by high fertility erodes the welfare and productivity

of workers, and thus social policy which fostered greater fertility, such as the English Poor Law, contributed to ‘overpopulation’. Before considering how these spillover effects of fertility might be identified, an overview of historical thinking about the demographic–economic system may help to indicate the context in which Malthus's thinking was relevant to pre-industrial Europe, and how modern economics has extended his thinking to fertility as a lifetime choice of parents related to their time allocation and accumulation of human and physical capital.

Malthus's framework for the pre-industrial demographic–economic equilibrium

The determinants of fertility have engaged the interest of economists for some time. Adam Smith (1776) noted families were larger in settings where labour was scarce and child labour was especially valuable to parents, as in North America with its abundant land. Smith recognized that child mortality was higher among the poor, especially among those who were dependent on charity (for example, the Poor Laws). However, Malthus (1798) viewed fertility not as an individual choice but as an outcome of social institutions, because he did not think birth control was effective. He thought fertility was governed by the economic requirements society placed on a couple before allowing them to marry. Once married, the ‘constant passion of the sexes’ would lead in unregulated fashion to fertility. Society therefore restricted entry into marriage to those with favourable prospects for a livelihood or the income and assets to support the children that were expected to follow from the union. Over his lifetime, Malthus accumulated corroborating evidence on fertility, population growth and economic growth. Historians have since added to Malthus's evidence, confirming that Europe exhibited a late median age at marriage for a woman in her mid-twenties. This delay in childbearing led European women to have four or five births over their lifetime, rather than the six or seven if they had married five years earlier. Given the short life expectancy in pre-industrial Europe of about 35–40 years, this restrained level of fertility diminished substantially the resulting rate of population growth, except at frontiers of settlement where labour was scarce, land abundant, and marriage consequently early.

Heckscher (1963) thought Malthus's framework was relevant to Sweden. With the Swedish church's good records of marriages, births and deaths, and the Swedish king's need to estimate crop yields (for the purposes of taxation), annual time series for Sweden after 1720 appear accurate and show a positive covariation in marriage and fertility with good crop years, and shortfalls in marriage and subsequently fertility following poor crop years. Temperature and rainfall data available for Sweden after 1750 allow later analysts to incorporate this exogenous variation in weather and employ vector autoregression to estimate weather-driven Malthusian cycles in wages, fertility, as well as mortality (Eckstein, Schultz and Wolpin, 1984).

Working with French and Swiss parish registries of marriage, births, and deaths, Louis Henry (1972), the demographer, found evidence that couples exhibited a ‘natural’ rate of childbearing after marriage, until they eventually began to increase the intervals between their births after later parities, if economic conditions became less favourable. The emergence of this form of parity-specific application of birth control over the life-cycle of marriages was interpreted by Coale (1973) as an indicator of the onset of the ‘demographic transition’, when cultural restraints on fertility evolved from ‘natural’ proximate determinants to controlled ‘modern’ reproductive behaviour relying primarily on birth control. Parish registries were then sampled from England from 1541 to 1871 by Wrigley and Schofield (1981).
to further investigate the Malthusian framework. Lee (1981) found that increases in marriage and birth rates were related to good weather and resulting declines in the price of wheat, as Malthus would have expected. But only about half of the covariation in weather/prices and annual birth rates is due to the fluctuations in first births that follow in the wake of variations in marriage. The other half is explained by variation in the length of inter-birth intervals. The latter finding casts doubt on Malthus's view that in this pre-industrial period couples did not exercise fertility choices within marriage. This spacing of births in response to economic wage cycles implied that the adoption of parity-specific birth control may not have been a cultural innovation, as assumed by Coale, but a customary form of individual behaviour adopted when additional births were unwanted. Some couples in pre-industrial societies appear able and willing to practice effective birth control when motivated economically. Fertility is thus to some degree a voluntary choice variable within marriage even in pre-industrial societies.

As the Industrial Revolution progressed in Europe and real wages increased, fertility nonetheless began to decline widely by the end of the 19th century. The Malthusian framework needed to be amended further to fit this experience in Europe and be applicable to low-income countries after 1960 as new methods of family planning were disseminated in the world and fertility fell despite modern economic growth. How was the secular decline in fertility to be explained in the face of rising personal incomes? The decline in child mortality, which gathered speed after 1870, reduced the need for parents to have extra births to replace the one out of five who might have at earlier times died from childhood diseases and infections. Parents might also scale back their demand for ‘insurance’ births motivated to reduce the likelihood that a couple would sustain above average child losses (Schultz, 1981). Becker (1960) proposed that the relative price of rearing children increased over time, causing the decline in parents’ demand for children. Mincer (1963) hypothesized that an increase in women’s wages increased a couple’s opportunity cost of having children, raising the shadow price of children. He argued that the rise in female labour-force participation and the decline in fertility were both caused by conditions increasing women’s wages relative to other consumer prices and men’s wages. These empirical patterns in the United States were soon replicated in other high-income countries.

Changing the relative prices of outputs of the economy is one possible source of variation in women’s wages relative to men’s that could explain changes in fertility. Men’s labour in European agriculture was critical for plowing and producing food grains, whereas women specialized in home production as domestic servants and wives and to some degree in animal husbandry and the production of dairy commodities. Consequently, changing scarcity of grains relative to livestock and dairy product contributed to swings in the relative wages of men and women in Europe. The secular decline in international grain prices relative to dairy and livestock prices in the latter half of the 19th century was unprecedented due to the opening of new lands at the frontiers of European settlement in the United States and Russia, and contributed along with changes in production technologies to the rise in women’s agricultural wages relative to men’s in northern Europe and to the decline in fertility. Swedish historical data by region document after 1860 the fall in world grain prices, the associated increase in the wages of women relative to men, and the secular fall in fertility, when other developments are controlled for (Schultz, 1985).

Another factor credited with reducing fertility is the improvement in birth control technology, which reduced the monetary and psychic cost of limiting births, and provided techniques controlled by women, which were independent of sex. The major advances in technology occurred in the 1960s with the introduction of oral steroids (the pill) and the intra-uterine device (IUD), followed by further refinements.
in their delivery systems. Traditional mechanisms for population control such as abortion, infanticide, coitus interruptus, and condoms have nonetheless allowed individuals to adjust their family size and affect population growth in various periods and parts of the world, well before the advent of these modern means of birth control. Although they may have facilitated the later demographic transition, these birth control technologies do not appear to have been necessary.

Microeconomic models of fertility behaviour

Willis (1973) adapted a comparative advantage trade model to the household lifetime fertility choice problem, wherein women's education was assumed to enhance women's productivity only in the market, and thereby increase the relative price of home production and decrease their demand for fertility. In his economic treatise on the family, Becker (1981) assigns a central role to market/non-market specialization of spouses in the household, with childbearing and rearing being the dominant non-market production activity traditionally performed by women.

To place more structure on fertility choices, Becker (1960; 1981) and Willis (1973) hypothesize that parents viewed the human capital of their children (child quality) as a substitute for their number of children (child quantity). If this were the case, then by definition income-compensated cross-price effects should be positive between child quantity and quality. In other words, increasing the price of children, for example by reducing the cost of birth control, would directly decrease fertility and indirectly increase the demand for child quality (with income held constant). Conversely, increasing the wage returns to schooling in the labour market would directly increase the demand for schooling and indirectly decrease the demand for births. Becker and Lewis (1974) postulate further that the income elasticity of demand for child quality exceeded the positive income elasticity for child quantity, which could account for the paradoxical decline in fertility with growth in income, without having to assume that children (quantity) are an ‘inferior’ good for which income effects are negative, or to show increases in women's value of their time in the modern economy caused the decline in their fertility.

The decline in fertility by half in high-income countries during the 20th century brought population growth to a halt in many of these countries. The decline in fertility by more than half in low-income countries in 40 years (1965–2005) is not yet comprehensively accounted for, although demographers are agreed that these trends in fertility are irreversible and the size of the world's population will stabilize later in the 21st century. How much does each of these conceptually distinct factors economists have described explain of this remarkable decline in fertility? I do not yet find a consensus on how to weight these factors in explaining cohort fertility. What fraction is due to an exogenous decline in mortality, the decline in the relative value of child labour, the increase in the value of women's time used in child care and the related increase in their empowerment, the increase in returns to schooling children, the greater income elasticities of demand for child quality than for quantity, and finally the improvements in birth control technology?

Identifying the effect of fertility on the welfare of families and society

The policy-relevant externalities of fertility could arise at the aggregate level or in terms of substitution effects within families. Malthus assumed that fertility added to subsequent generations of workers,
which reduced their wages and also changed the age composition of the population. But empirical evidence for these aggregate effects of fertility has not led to a consensus on their importance for today's low-income countries (National Research Council, 1986). At the microeconomic level of the family, fertility is found to be closely associated with other life-cycle choices by parents, including the share of time women allocate to the market economy, the investments parents make in the human capital of each of their children, and perhaps the savings out of income they accumulate in physical capital, possibly for old age support or precautionary insurance. But to assess the magnitude of these cross-effects of fertility, researchers must first specify an exogenous factor (not a choice variable within the orbit of the family) that affects fertility but leaves other constraints on the family life-cycle choices and outcomes unaffected and is unrelated to parent preferences (Schultz, 2007). In other words, an exclusion restriction or a valid instrumental variable is needed to account for some part of the variation in fertility that is independent of parent preferences and family life-cycle economic constraints. Otherwise, these cross-effects observed at the family level may not be causal and cannot be expected to occur when population policies reduce (or increase) fertility.

Twins are proposed by Rosenzweig and Wolpin (1980; 2000) as a ‘shock’ to the quantity of children that is uncorrelated with parent preferences or unobserved determinants of other family and child outcomes. Adjustment of investment in the schooling of other children in the family due to the occurrence of twins can then test the quantity–quality substitution hypothesis. They found support for the trade-off of quantity–quality on non-twin siblings in rural Indian households observed in 1970. A larger sample of twins collected in China provides the basis for estimating the impact of a twin on the quality of earlier- or later-born siblings, providing bounds to the magnitude of the cross effects, adjusted for substitution effects between siblings (Rosenzweig and Zhang, 2006). However, when twins are an instrument for fertility, the estimated quantity–quality trade-off tends to be smaller in absolute value than when estimated by direct association, that is, ordinary least squares (OLS). This could be due to the twin instrument being weak either because it occurs for only a small fraction of births (for example, one per cent) or because the underlying causal relationship is in fact weak and appears important only in biased single-equation associations (that is, OLS). The heterogeneity in parent preferences or other unobserved determinants of behavior could inversely affect child quantity and quality (Schultz, 2007).

Other studies have exploited twins as an instrument for fertility to assess how exogenous fertility affects the mother's market labour supply. These studies in high- and low-income countries generally confirm that the twin instrumental variable estimate of the effect of a birth on the mother's market labour supply tends to be absolutely smaller (negative) than the OLS estimate. The Durbin–Wu–Hausman specification test rejects the exogeneity of fertility in the determination of the mother's allocation of time to market work (Schultz, 2007), implying that the consistent instrumental variable estimate is preferred over the OLS estimate.

This twin-based cross effect of fertility on mothers’ labour supply may help to explain how policies which reduce fertility can facilitate modern economic growth, by adding to the per capita supply of labour and increasing the human capital of future generations. Finally, if parents when they have fewer children increase life-cycle savings for their support in old age, policies that facilitate a decline in fertility could raise savings and further augment growth rates. But estimates of these three potential cross effects of fertility-reducing population policies remain currently speculative.

The other instrument commonly used to identify the consequences of fertility on the welfare of families
fertility in developing countries: The New Palgrave Dictionary of Economics

relies on the sex composition of births, and has serious drawbacks. This variable may significantly affect parents’ decisions on whether to have further children, and it may be assumed to be approximately independent of parent preferences or family constraints if there is no sex-selective abortion or infanticide. But this variable may not satisfy the criteria for a valid instrument, because the social and economic consequences of a child's sex involve many culturally distinct costs and benefits for his or her parents, such as the provision of dowries for daughters in some parts of the world. Thus, the sex composition of early births is likely to involve lifetime wealth effects for parents, in addition to affecting fertility, giving rise to many changes in family time allocation, expenditure patterns, and life-cycle savings (Rose, 2000). Therefore, the sex composition of children is not an instrumental variable for estimating how parents respond to a change in their fertility due to a population policy, if income and other family constraints are held constant. Finally, it should be noted that population policies may on the one hand subsidize learning and use of birth control, or at the other extreme fix a birth quota, as in China. There is no reason to expect expanding voluntary choices in the first case will have the same effect as rationing choices in the other policy regime.

Conclusions and research challenges

Parents may altruistically internalize in their fertility decisions the effects of their fertility on their welfare and that of their children, including investments in child quality and lifetime savings in financial assets (Becker, 1981). These parents are typically assumed to have secure property rights to their savings and access to financial institutions that minimize credit constraints. Population policies that reduce the cost of avoiding unwanted births may also be expected to affect gender empowerment, which does not enter decisively in the unitary model of the family proposed by Becker, but emerges in various recent bargaining and collective models of the family. Women may differentially gain from improved control of reproduction, because they physically bear the health costs of having births and invest disproportionately their time in child rearing. To derive predictions on how family bargaining affects fertility or vice versa requires more context-specific assumptions. Do mothers or fathers value children more highly? Does improved birth control technology empower women to bargain for a larger share of the gains from marriage? These remain open questions for more study. Women may value children as much as men do, and use their own increases in wealth to have more. Increased unearned income owned by the wife is associated, if the husband's income is held constant, with higher fertility in Thailand but not in Brazil (Schultz, 1990). Microcredit targeted to groups of women in Bangladesh increases women's earnings and increases their later fertility (Pitt et al., 1999).

In an experimentally designed family planning and health programme started in 1977 for women in rural villages of Matlab, Bangladesh, the women in villages benefiting from the programme had one fewer child by 1996 than did comparable women in comparison villages (Joshi and Schultz, 2006). The programme is also associated with increased woman's health, as measured by their body mass index (weight divided by height squared), reduced child mortality before age five, and increased years of schooling of boys aged 9–14 and 15–29. More studies of these long-run consequences of population policies on fertility and other family outcomes will be needed to assess the within-family consequences of fertility and population policies. Recognition that fertility is endogenous to other family life-cycle choices challenges economists to measure these potentially important life-cycle causal connections, and
thereby provide a sounder basis for evaluating how population policies affect the social allocation of resources.

Fetter was born on 3 March 1863 in the town of Peru, Indiana, and died on 21 March 1949 in Princeton, New Jersey. He was educated at Indiana and Cornell Universities and received his doctorate in economics at the University of Halle in Germany in 1894; he spent most of his life teaching at Cornell (1901–11) and Princeton universities (1911–34).

In journal articles on capital, interest and rent written largely between 1900 and 1914 (Fetter, 1977), and particularly in two treatises on economic principles (Fetter, 1904 and 1915), Fetter built upon Böhm-Bawerk and the Austrian School to develop a lucid and remarkable integrated structure of economic theory. He was able to accomplish this feat by purging economics of all traces of Ricardian or other British objectivist theories of value and distribution, in particular any differential theories of rent or productivity theories of interest.

Much of Fetter's achievement rested on his insight into the ordinary language meaning of ‘rent’ as simply the price of any durable good per unit time. He was then able to show that the prices of consumer goods are determined by their marginal utilities, and that these values are imputed back to determining the rental prices of factors of production by their marginal value productivity in serving consumers. The capital value, or price of the whole good (whether land, capital goods, or, Fetter might have added, the labourer under slavery) is then determined by the sum of its expected future returns, or rents, discounted by the social rate of time preference, or rate of interest. Thus, Fetter went beyond Böhm-Bawerk by arriving at a pure time preference theory of interest. Productivity and time preference are both highly important, but they have very different functions: the former in determining rents, and the latter determining the rate of interest. Thus, future rents are discounted by the rate of time preference and summed up, or ‘capitalized’, into their present capital value. Indeed, Fetter often called his contribution the ‘capitalization theory of interest’.
Fetter presented the fullest portrayal yet attained of the time market, the market for present as against future goods, as it permeates the economic system. The time market is not only the loan market, but also exists when entrepreneurs purchase or hire discounted factors of production (future goods) in return for money (a present good) and then reap a time or interest return when the product is later sold as a present good. Entrepreneurs earn profits, or suffer losses, as they lead the economy in the direction of a general equilibrium determined by marginal utility, marginal value productivity, and time preference.

While Fetter was led by his capitalization theory to arrive independently at the Mises–Hayek theory of the business cycle in 1927 (Fetter, 1977, pp. 260–316), he virtually abandoned value and distribution theory in the last two decades of his life to concentrate on the alleged monopolistic evils of basing-point pricing. He assumed that competition requires uniform pricing of products at the mill, while uniform pricing at centres of consumption is somehow monopolistic and deserves to be outlawed (Fetter, 1931). Fetter's shift of concern, coupled with a general loss of interest in economic theory in the United States between the two world wars and the continuing dominance of neo-Ricardian Marshallian theory in Britain, gravely hindered the incorporation of Fetter's notable contributions into modern economics.

Modern discussions of feudalism have been bedevilled by disagreement over the definition of that term. There are three main competing conceptualizations. (1) Feudalism refers strictly to those social institutions which create and regulate a quite specific form of legal relationship between men. It constitutes a relationship in which a freeman (vassal) assumes an obligation to obey and to provide, primarily military, services to an overlord who, in turn, assumes a reciprocal obligation to provide protection and maintenance, typically in the form of a fief, a landed estate to be held by the vassal on condition of fulfilment of obligations (Bloch, 1939–40). (2) Feudalism refers, more broadly, to a form of government or political domination. It is a form of rule in which political power is profoundly fragmented geographically; in which, even within the smallest political units, no single ruler has a monopoly of political authority; and in which political power is privately held, and can thus be inherited, divided among heirs, given as a marriage portion, mortgaged, and bought and sold. Finally, the armed forces involve, as a key element, a heavy armed cavalry which is secured through private contracts, whereby military service is exchanged for benefits of some kind (Strayer, 1965; Ganshof, 1947). (3) Feudalism refers to a type of socio-economic organization of society as a whole, a mode of production and of the reproduction of social classes. It is defined in terms of the social relationships by which its two fundamental social classes constitute and maintain themselves. Specifically, the peasants, who constitute the overwhelming majority of the producing population, maintain themselves by virtue of their possession of their full means of subsistence, land and tools, so require no productive contribution by the lords to survive. This possession is secured by means of the peasants’ collective political organization into self-governing communities, which stand as the ultimate guardian of the individual peasants’ land. As a result of the peasants’ possession and their consequent economic independence,
meme ownership of property cannot be assumed to yield an economic rent; in consequence, the lords are obliged to maintain themselves by appropriating a feudal levy by the exercise of extra-economic coercion. The lords are able to extract a rent by extra-economic coercion only in consequence of their political self-organization into lordly groups or communities, by means of which they exert a degree of domination over the peasants, varying in degree from enserfment to mere tribute taking (Marx, 1894; Dobb, 1946).

Though often thought to be in conflict, these conceptions are not only complementary but in fact integrally related to one another. While the lords’ very existence as lords was based, as Marxists correctly insist, upon their appropriating a rent from the peasantry by extra-economic coercion, their capacity actually to exert such force in the rent relationship depended upon from their ability to construct and maintain the classically political ties of interdependence which joined overlord to knightly follower and thereby constituted the feudal groups which were the ultimate source of the lords’ power. Conversely, while feudal bonds of interdependence were constructed, as the Weberians emphasize, to build highly localized governments capable at once of waging warfare, dispensing justice and keeping the peace, the *raison d’être* of the mini-states thus created was to constitute the dominant class of feudal society by establishing the instruments for extracting, redistributing and consuming the wealth upon which this class depended for their maintenance and reproduction. State and ruling class were thus two sides of the same coin. The distinctive ties which bound man to man in feudal society (not only the relations of vassalage strictly speaking, but also the more loosely defined associations structured by patronage, clientage, and family) constituted the building blocks, at one and the same time, for the peculiarly fragmented, locally based and politically competitive character of the feudal ruling class and for the peculiarly particularized nature of the feudal state. It was the lords’ feudal levies which provided the material base for the feudal polity. It was the parcellized character of the feudal state, itself the obverse side of the decentralized structure of lordship through which rent was appropriated from the peasantry, which thus created the basic opportunities, set the ultimate limits and posed the fundamental problems for the lords’ reproduction as a ruling class.

**The origins of feudalism**

The rise of feudalism was conditioned by an extended process of political fragmentation within the old Carolingian Empire. This is understandable, in part, in terms of a tendency to decentralization inherent in patrimonial rule. The patrimonial lord, to maintain his following, had, paradoxically, to provide his followers with the means to establish their independence from him. He could counteract their tendency to assert their autonomy through successful warfare and conquest, in which the followers found it worth their while to continue to submit to his authority. But in the absence of such profitable aggression, the followers had every incentive to assert their independence. It was in this way that the devolution and dissolution of more centralized forms of authority took place within the Carolingian Empire during the 9th and 10th centuries, as the Franks and their followers ceased to be conquerors, following a long period in which the empire had expanded. Fragmentation was hastened by the contemporaneous invasions of the Northmen, Saracens and Magyars. Effective authority fell, successively, from the king to his princes, to the counts and, ultimately, to local castleholders and even manorial lords, as the newly emerging, highly localized rulers turned their pillaging from foreign enemies to the local population.
Feudalism originally took shape in the early part of the 11th century in many parts of western Europe, including much of France, northern Italy and western Germany. Feudal rule was first constituted through the formation of lordly political groups, initially organized around a castle and led by the castellan. The castellan's power was derived from his knightly followers. The knights possessed military training, fought on horseback wearing (increasingly elaborate) coats of armour, often lived in the castle, and, from around the second third of the 11th century, tended to be bound to the castellan through ties of vassalage. The castellan's hegemony was manifested in his capacity to exert the right of the ban over his district – whose outer limits were usually no more than half a day's ride from the central fortress. The right of the ban, traditionally in the hands of the early medieval kings and the direct expression of their authority, allowed the castellan, above all, to extract dues from the peasant households within his jurisdiction, as well as to dispense justice and keep the peace. Although the surrounding lesser lords were usually tied to a castellan, in some cases they retained their full independence, not only collecting feudal rents derived from their authority over their tenants, but imposing taxes and exerting justice within their manorial mini-jurisdictions. In any case, all these lords confirmed their membership in the dominant class by claiming exemption from fiscal exactions: freedom under feudalism thus took the form of privilege. The peasants' unfreedom in some cases originated from their ancestors' having formally commended themselves to their lord; that is, their having subjected themselves to his domination in exchange for his assuring their safety. But, with the crystallization of feudal domination, it simply expressed the lords' having appropriated the right to extort protection money from them. The peasants' unfreedom was thus defined and constituted precisely by their subjection to arbitrary levies (Duby, 1973; 1978).

The feudal economy was thus structured, on the one hand, by a form of pre-capitalist property relations in which the individual peasant families, as members of a village community, individually possessed their means of reproduction. This contrasted with other pre-capitalist property forms in which the village community itself was the possessor (or more of one). On the other hand, under feudalism, the individual lords reproduced themselves by individually appropriating part of the peasants’ product, backed up by localized communities of lords connected by various sorts of political bond, classically vassalage. This contrasted with other pre-capitalist property systems, in which the community, or communities, of lords appropriated the peasants’ product collectively (as a tax) and shared out the proceeds among the community's, or communities’, members.

Feudal property relations and the forms of individual economic rationality

The fundamental feudal property relationships of peasant possession and of lordly surplus extraction by extra-economic compulsion shaped the long-term evolution of the feudal economy. This was because these relationships were systematically maintained by the conscious actions of communities of peasants and of lords and thus constituted relatively inalterable constraints under which individual peasants and lords were obliged to choose the patterns of economic activity most sensible for them to adopt in order to maintain and improve their condition. The potential for economic development under feudalism was thus sharply restricted because both lords and peasants found it in their rational self-interest to pursue individual economic strategies which were largely incompatible with, if not positively antithetical to, specialization, productive investment and innovation in agriculture.
First, and perhaps most fundamental, because both lords and peasants were in full possession of what they needed to maintain themselves as lords and peasants, they were free from the necessity to buy on the market what they needed to reproduce, thus freed from dependence on the market and the necessity to produce for exchange, and thus exempt from the requirement to sell their output competitively on the market. In consequence, both lords and peasants were free from the necessity to produce at the socially necessary rate so as to maximize their rate of return and, in consequence, relieved of the requirement to cut costs so as to maintain themselves, and so of the necessity constantly to improve production through specialization and/or accumulation and/or innovation. Feudal property relations, in themselves, thus failed to impose on the direct producers that relentless drive to improve efficiency so as to survive, which is the differentia specifica of modern economic growth and required of the economic actors under capitalist property relations in consequence of their subjection to production for exchange and economic competition.

Absent the necessity to produce so as to maximize exchange values and in view of the underdeveloped state of the economy as a whole, the peasants tended to find it most sensible actually to deploy their resources so as to ensure their maintenance by producing directly the full range of their necessities; that is, to produce for subsistence. Given the low level of agricultural productivity which perforce prevailed, harvests and therefore food supplies were highly uncertain. Since food constituted so large a part of total consumption, the uncertainty of the food market brought with it highly uncertain markets for other commercial crops. It was therefore rational for peasants to avoid the risks attached to dependence upon the market, and to do so they had to diversify rather than specialize, marketing only physical surpluses. In fact, beyond their concern to minimize the risk of losing their livelihood, the peasants appear to have found it desirable to carry out diversified production simply because they wished to maintain their established mode of life – and, specifically, to avoid the subjection to the market which production for exchange entails, and the total transformation of their existence which that would have meant.

To make possible ongoing production for subsistence, the peasants naturally aimed to maintain their plots as the basis for their existence. To ensure the continuance of their families into the future, they also sought to ensure their children’s inheritance of their holdings. Meanwhile, they tended to find it rational to have as many children as possible, so as to ensure themselves adequate support in their old age. The upshot was relatively large families and the subdivision of plots on inheritance.

Like the peasants, the lords occupied a ‘patriarchal’ position, possessing all that they needed to survive and thus freed of any necessity to increase their productive capacities. Moreover, even to the extent they wished, for whatever reason, to increase the output of their estates, the lords faced nearly insuperable difficulties in accomplishing this by means of increasing the productive powers of their labour and their land. Thus, if the lords wished to organize production themselves, they had no choice but to depend for labour on their peasants, who possessed their means of subsistence. But precisely because the peasants were possessors, the lords could get them to work only by directly coercing them (by taking their feudal rent in the form of labour) and could not credibly threaten to ‘fire’ them. The lords were thereby deprived of perhaps the most effective means yet discovered to impose labour discipline in class-divided societies. Because the peasant labourers had no economic incentive to work diligently or efficiently for the lords, the lords found it extremely difficult to get them to use advanced means of production in an effective manner. They could force them to do so only by making costly unproductive investments in supervision.

In view of both the lords’ and the peasants’ restricted ability effectively to allocate investment funds to
improved means of production to increase agricultural efficiency, both lords and peasants found that the only really effective way to raise their income via productive investment was by opening up new lands. Colonization, which resulted in the multiplication of units of production on already existing lines, was thus the preferred form of productive investment for both lords and peasants under feudalism. Beyond colonization and the purchase of land, feudal economic actors, above all feudal lords, found that the best way to improve their income was by forcefully redistributing wealth away from the peasants or from other lords. This meant that they had to deploy their resources (surpluses) towards building up their means of coercion by means of investment in military men and equipment, in particular to improve their ability to fight wars. A drive to political accumulation, or state building, was the feudal analogue to the capitalist drive to accumulate capital.

The long-term patterns of feudal economic development

Feudal property relations, once established, thus obliged lords and peasants to adopt quite specific patterns of individual economic behaviour. Peasants sought to produce for subsistence, to hold on to their plots, to produce large families and to provide for their families’ future generations by bequeathing their plots. Both lords and peasants sought to use available surpluses funds to open new lands. Lords directed their resources to the amassing of greater and better means of coercion. Generalized on a society-wide basis, these patterns of individual economic action determined the following developmental patterns, or laws of motion, for the feudal economy as a whole:

(i) Declining productivity in agriculture (Bois, 1976; Hilton, 1966; Postan, 1966)

The generalized tendency to adopt production for subsistence on the part of the peasantry naturally constituted a powerful obstacle to commercial specialization in agriculture and to the emergence of those competitive pressures which drive a modern economy forward. In so doing, it also posed a major barrier to agricultural improvement by the peasantry, since a significant degree of specialization was required to adopt almost all those technical improvements which would come to constitute ‘the new husbandry’ or the agricultural revolution (fodder crops, up-and-down farming, and so on). In addition, production aimed at subsistence and the maintenance of the plot as the basis for the family’s existence posed a major barrier to those rural accumulators, richer peasants and lords who wished to amass land or to hire wage labour, since the peasants would not readily part with their plots, which were the immediate bases for their existence, unless compelled to do so; nor could they be expected to work for a wage unless they actually needed to.

Further counteracting any drive to the accumulation of land and labour was the tendency on the part of the possessing peasants to produce large families and subdivide their holdings among their children. The peasants’ parcellization of plots under population growth tended to overwhelm any tendency towards the build-up of large holdings in the agricultural economy as a whole, further reducing the potential for agriculture improvement.

Finally, individual peasant plots were, most often, integrated within a village agriculture which was, in critical ways, controlled by the community of cultivators. The peasant village regulated the use of the pasture and waste on which animals were raised, and the rotation of crops in the common fields. Individual peasants thus tended to face significant limitations on their ability to decide how to farm their
plots and thus, very often, on their capacity to specialize, build up larger consolidated holdings, and so forth.

To the extent that the lords succeeded in increasing their wealth by means of improving their ability coercively to redistribute income away from the peasantry, they further limited the agricultural economy's capacity to improve. Increased rents in whatever form reduced the peasants’ ability to make investments in the means of production. Meanwhile, the lords’ allocation of their income to military followers and equipment and to luxury consumption ensured that the social surplus was used unproductively, indeed wasted. To the extent – more or less – that the lords increased their income, the agricultural economy was undermined.

(ii) Population growth (Postan, 1966)

The long-term tendency to the decline of agricultural productivity thus conditioned by the feudal structure of property was realized in practice as a consequence of rising population. The peasants’ possession of land allowed children to accede to plots and, on that basis, to form families at a relatively early age. Married couples, as noted, had an incentive to have many children, both to provide insurance for their old age and to assure that the line would be continued. The result was that all across the European feudal economy we witness a powerful tendency to population growth from around the beginning of the 12th century, which led, almost everywhere, to a doubling of population over the following of two centuries.

(iii) Colonization (Postan, 1966; Duby, 1968)

The only significant method by which the feudal economy achieved real growth and counteracted the tendency to declining agricultural productivity was by way of opening up new land for cultivation. Indeed, economic development in feudal Europe may be understood, at one level, in terms of the familiar race between the growth of the area of settlement and the growth of population. During the 12th and 13th centuries, feudal Europe was the scene of great movements of colonization, as settlers pushed eastward across the Elbe and southward into Spain, while reclaiming portions of the North Sea in what became the Netherlands. The opening of new land did, for a time, counteract and delay the decline of agricultural productivity. Nevertheless, in the long run – as expansion continued, as less fertile land was brought into cultivation, and as the man/land ratio rose – rents rose, food prices increased, and the terms of trade increasingly favoured agricultural as opposed to industrial goods. At various points during the 13th and early 14th centuries, all across Europe, population and production appear to have reached their upper limits, and there began to ensue a process of demographic adjustment along Malthusian lines.

(iv) Political accumulation or state building (Dobb, 1946; Anderson, 1974; Brenner, 1982)

Given the limited potential for developing the agricultural productive forces and the limited supply of cultivable land, the lordly class, as noted, tended to find the build-up of the means of force for the purpose of redistributing income to be the best route for amassing wealth. Indeed, the lords found themselves more or less obliged to try to increase their income in order to finance the build-up of their...
capacity to exert politico-military power. This was, first of all, because they could not easily escape the
politico-military conflict or competition that was the inevitable consequence of the individual lords’
direct possession of the means of force (the indispensable requirement for their maintenance as members
of the ruling class over and against the peasants) and thus of the wide dispersal of the means of coercion
throughout the society. It was, secondly, because they had to confront increasingly well-organized
peasant communities and, as feudal society expanded geographically, to counteract the effects of
increasing peasant mobility.

In the first instance, of course, military-politico efficacy required the collecting and organizing of
followers. But to gain and retain the loyalty of their followers the overlords had to feed and equip them
and, in the long run, competitively reward them. Minimally, the overlord's household had to become a
focus of lavish display, conspicuous consumption and gift-giving, on par with that of other overlords.
But beyond this, it was generally necessary to provide followers with the means to maintain their status
as members of the dominant class – that is, a permanent source of income, requiring a grant of land with
associated lordly prerogatives (classically the fief). But naturally such grants tended to increase the
followers’ independence from the overlords, leading to renewed potential for disorganization,
fragmentation and anarchy. This was the perennial problem of all forms of patrimonial rule and at the
centre of feudal concerns from the beginning. The tendency to fragmentation was, moreover,
exacerbated as a result of the pressure to divide lordships and lands among children. To an important
degree, then, feudal evolution may be understood as a product of lordly efforts to counteract political
fragmentation and to construct firmer intra-lordly bonds with the purpose of withstanding intra-lordly
politico-military competition and indeed of carrying on the successful warfare that provided the best
means to amass the wealth ultimately required to maintain feudal solidarity. This meant not only the
development of better weapons and improved military organization, but also the creation of larger and
more sophisticated political institutions, and naturally entailed increased military and luxury
consumption.

Actually to achieve more effective political organization of lordly groups required political innovation.
Speaking broadly, the constitution of military bands around a leading warlord for external warfare,
especially conquest, most often provided the initial basis of intra-lordly cohesion. This served as the
foundation for developing more effective collaboration within the group of lords for the protection of
one another's property and for controlling the peasantry. As a further step in this direction, the overlord
would establish his pre-eminence in settling disputes among his vassals (as in Norman England). Next,
the leading lord might extend feudal centralization by establishing immediate relations with the
undertenants of his vassals. One way this took place was through constructing direct ties of dependence
with these rear vassals (as in 11th-century England). More generally, it was accomplished by the
extension of central justice to ever broader layers of the lordly class, indeed the free population as a
whole. Sometimes the growth of central justice was achieved through the more or less conscious
collaboration of the aristocracy as a whole (as in 12th-century England). On other occasions it had to be
accomplished through more conflicted processes whereby the leading lord (monarch, prince) would
accept appeals over the heads of his vassals from their courts (as in medieval France). Ultimately, the
feudal state could be further strengthened only by the levying of taxes, and this almost always required
the constitution of representative assemblies of the lordly class.

This is not to say that a high level of lordly organization was always required. Nor is it to argue that state
building took place as an automatic or universal process. At the frontiers of European feudal society, to
the south and east, colonization long remained an easy option, and there was relatively little (internally generated) pressure upon the lordly class to improve its self-organization. At the same time, just because stronger feudal states might become necessary did not always determine that they could be successfully constructed. Witness the failure of the German kings to strengthen their feudal state in the 12th century, and the long-term strengthening of the German principalities which ensued. The point is that, to the degree that disorganization and competition prevailed within and between groups of feudal lords, they would tend to be that much more vulnerable not only to depredations from the outside, but to the erosion of their very dominance over the peasants. The French feudal aristocracy thus paid a heavy price for their early, highly decentralized feudal organization, suffering not only significant losses of territory to the Anglo-Normans, but a serious reduction in their control over peasant communities and a consequent decline in dues. The French aristocracy's later recovery and successes may be attributed, at least in large part, to their evolution of a new, more centralized, more tightly knit form of political organization – the tax/office state, where property in office (rather than lordship/land) gave the aristocracy rights to a share in centralized taxation (rather than feudal rent) from the peasants. In sum, the economic success of individual lords, or groups of them, does seem to have depended upon successful feudal state building, and the long-term trend throughout Europe, from the 11th through to the 17th century, appears to have been towards ever more powerful and sophisticated feudal states.

**Trade, towns and feudal crisis**

The growing requirements of the lordly class for the weaponry and luxury goods (especially fine textiles) needed to carry on intra-feudal politico-military competition were at the source of the expansion of commerce in feudal Europe. The growth of trade made possible the rise of a circuit of interdependent productions in which the artisan-produced manufactures of the towns were exchanged for peasant-produced necessities (food) and raw materials, appropriated by the lords and sold to merchant middlemen. Great towns thus emerged in Flanders and north Italy in the 11th and 12th centuries on the basis of their industries’ ability to capture a preponderance of the demand for textiles and armaments of the European lordly class as a whole.

In the first instance, the growth of this social division of labour within feudal society benefited the lords, for it reduced costs through increasing specialization, thus making luxury goods relatively cheaper. Nevertheless, in the long run it meant a growing disproportion between productive and unproductive labour in the economy as a whole, for little of the output of the growing urban centres went back into production to augment the means of production or the means of subsistence of the direct peasant producers; it went instead to military destruction and conspicuous waste. Over time, increasingly sophisticated political structures and technically more advanced weaponry meant growing costs and thus increased unproductive expenditures. At the very time, then, that the agricultural economy was reaching its limits, the weight of urban society upon it grew significantly, inviting serious disruption. Because the growth of lordly consumption proceeded in response to the requirements of intra-feudal competition in an era of increasingly well-constructed feudal states, the lords could not take into account its effect on the underlying agricultural productive structure. All else being equal, the growth of population beyond the resources to feed it could have been expected to call forth a Malthusian adjustment, and most of Europe did witness the onset of famine and the beginning of demographic downturn in the early 14th century. Nevertheless, while the decline of population meant fewer mouths to
feudalism: The New Palgrave Dictionary of Economics

feed with the available resources, it also meant fewer rent-paying tenants and so, in general, lower returns to the lords. The decline in seigneurial incomes induced the lords to seek to increase their demands on the peasantry, as well as to initiate military attacks upon one another. The peasants were thus subjected to increasing rents and the ravages of warfare at the very moment that their capacity to respond was at its weakest, and their ability to produce and to feed themselves was further undermined. Further population decline brought further reductions in revenue leading to further lordly demands – resulting in a downward spiral which was not reversed in many places for more than a century. The lordly revenue crisis and the ensuing seigneurial reaction thus prevented the normal Malthusian return to equilibrium. A general socio-economic crisis, the product of the overall feudal class/political system, rather than a mere Malthusian downturn, gripped the European agrarian economy until the middle of the 15th century (Dobb, 1946; Hilton, 1969; Bois, 1976; Brenner, 1982).

In the long run, feudal crisis brought its own solution. With the decline of population, peasant cultivation drew back onto the better land, making for the potential of increased output per capita and growing peasant surpluses. Meanwhile, civil and external warfare seem to have abated, a reflection perhaps of the exhaustion of the lordly class, and the weight of ruling class exactions on the peasantry declined correspondingly, especially as the peasants were now in a far better position to pay. The upshot was a new period of population increase and expansion of the area under cultivation, of the growth of European commerce, industry and towns, and, ultimately, of the familiar outrunning of production by population. Meanwhile, lordly political organization continued to improve, feudal states continued to grow, intra-feudal competition continued to intensify, and, over the long run, lordly demands on the peasants continued to increase even as the capacity of the peasantry began, once again, to decline. By the end of the 16th century one witnesses, through most of Europe, a descent into the ‘general crisis of the 17th century’ which took a form very similar to that of the ‘general crisis of the 14th and 15th centuries’. Clearly, through most of Europe, the old feudal property relations persisted, undergirding the repetition of established patterns of feudal economic non-development.

Approaches to transition

It is an implication of the foregoing analysis that so long as feudal property relations persisted, the repetition of the same long-term economic patterns could be expected. So long as feudal property relations obtained, lords and peasants could be expected to find it rational to adopt the same patterns of individual economic behaviour; in consequence, one could expect the same long-term cyclical tendencies to declining agricultural productivity, population growth, and the opening of new land, issuing in a tendency to Malthusian adjustment but overlaid by a continuation of the secular tendency to lordly state building and growing unproductive expenditures. Generally speaking, so long as feudal property relations obtained, no inauguration of a long-term pattern of modern economic growth could be expected. From these premises, it is logical to conclude that the onset of economic development depended on the transformation of feudal property relations into capitalist property relations, and that indeed is the point of departure of a long line of theorists and historians (Marx, 1894; Dobb, 1946; Hilton, 1969; Bois, 1976).

Nevertheless, beginning with Adam Smith himself, a whole school of historically sensitive theorists have found it quite possible to ignore, or sharply to downplay, the problem of the transformation of property relations and of social relationships more generally in seeking to explain economic
development. These theorists naturally refuse to go along with the Adam Smith of Wealth of Nations Book I in contending that the mere application of individual economic rationality will, directly and automatically, bring economic development. They nevertheless follow the Adam Smith of Wealth of Nations Book III in arguing that, given the appearance of certain specific, quite-reasonable-to-expect exogenous economic stimuli, rational self-interested individuals can indeed be expected to take economic actions which will detonate a pattern of modern economic growth. Specifically, it is their hypothesis that the growth of commerce, an enormously widespread if not universal phenomenon of human societies, systematically has led pre-capitalist economic actors to assume capitalist motivations or goals, to adopt capitalist norms of economic behaviour, and, eventually, to bring about the transformation of pre-capitalist to capitalist property relations. It is undoubtedly because Adam Smith and his followers have believed that the growth of exchange will in itself sooner or later create the necessary conditions for modern economic growth that they have not greatly concerned themselves with these conditions or viewed their emergence as a problem which needs addressing.

Thus, Smith and a long line of followers, prominently including the economic historian of medieval Europe Henri Pirenne and the Marxist economist Paul Sweezy, have all produced analyses which follow essentially the same progression. First, merchants, emanating from outside feudal society, offer previously unobtainable products to lords and peasants who hitherto had produced only for subsistence. This is understood as a more or less epoch-making historical event, an original rise of trade. Next, the very opportunity to purchase these new commodities induces the individual economic actors to adopt businesslike attitudes and capitalist motivations, specifically to relinquish their norm of production for subsistence and to adopt the economic strategy of capitalists-in-embryo – viz., production for exchange so as to maximize returns by way of cost cutting. Third, since pre-capitalist property relations, marked by the producers' possession of the means of subsistence and by the lord's extraction of a surplus by means of extra-economic coercion, prevent the individual economic actors from most effectively deploying their resources to maximize exchange values, both lords and peasants move, on a unit-by-unit basis, to transform these property relations in the direction of capitalist property relations. In particular, the lords dispense with their (unproductive) military followers and military luxury expenditures; they free their hitherto dominated peasant producers; they expropriate these peasants from the land; then, finally, they enter into contractual relations with these free, expropriated peasants. This gives rise, within each unit to the installation of free, necessarily commercialized (market dependent) tenants on economic leases, who, ultimately, hire wage labourers. The end result is the establishment of capitalist property relations and capitalist economic norms in the society as a whole and the onset of economic development (Smith, 1776; Pirenne, 1937; Sweezy, 1950).

The foregoing argument of what might be called the Smithian school is designed, implicitly or explicitly, to show how the rise of exchange in a feudal setting, in itself creates the conditions under which rational economic actors will pursue self-interested action which leads, on an economy-wide basis, to modern economic growth. Nevertheless, the validity of each step in the Smithian argument can be, and has been, challenged by those who take as their point of departure the historically established property relations. It is the essence of their position that the Smithians can sustain their argument only by failing sufficiently to understand what patterns of economic activity individual lords and peasants will find it rational to adopt in response to the rise of trade, given the prevalence of feudal property relations (Marx, 1894; Dobb, 1946; Bois, 1976).

In the first place, although long-distance merchants may bring to feudal lords and peasants commodities
they could not previously obtain, the merchants’ mere offer of these commodities cannot ensure that the lords and peasants will, in turn, put their own products on the market in order to buy them. Given the existence of feudal property relations, both lords and peasants may be assumed to have everything they need to maintain themselves. The opportunity to buy new goods may very well make it possible for the pre-capitalist economic actors to increase or enrich their consumption, but this does not mean that they will take advantage of this opportunity. The increased potential for exchange simply cannot determine that exchange will increase (Luxemburg, 1913).

Secondly, even where the appearance of new goods brought by merchants does induce the lords to try to increase their consumption by raising their output and increasing the degree to which they orient their production towards exchange, this will hardly lead them to find it in their rational self-interest to dismantle, in piecemeal fashion, the existing feudal property relations by freeing and expropriating their peasants. Given the reproduction of feudal property relations by communities of feudal lords and peasants, the individual lords can hardly find it in their rational self-interests to free their peasants, for they would lose thereby their very ability to exploit them, and thus their ability to make an income. The point is that, once freed from the lord's extra-economic domination, his possessing peasants would have no need to pay any levy to him, let alone increase the quality and quantity of their work for him. Moreover, even if the lord could, at one and the same time, free and expropriate his peasants, he would still lose by the resulting transformation of his unfree peasant possessors into free landless tenants and wage labourers, for the newly landless tenants or wage labourers would have no reason to stay and work for their former lord or to take up a lease from him.

To the degree, then, that lords sought to increase their output in response to trade, they appear to have found it in their rational self-interest not to transform but to intensify the pre-capitalist property relations. Because they found it, on the one hand, difficult to get their possessing peasants effectively to use more productive techniques on their estates, and, on the other hand, irrational to install capitalist property relations within their units, they seem to have had little choice but to try so within the constraints imposed by feudal property relations – by increasing their levies on the direct producers in money, kind or labour. To make this possible, they had no choice but to try to strengthen their institutionalized relationship of domination over their peasants, by investing in improved means of coercion and by improving the politico-military organization of their lordly groups. It needs to be emphasized that the lords could not be sure they could succeed in this, for the peasants would likely resist, and perhaps successfully. But in so far as the lords could dictate terms, this was the route they found most promising. Witness the growth of demesne farming in response the growth of the London market in 13th-century England or, more spectacularly, the rise of a neo-serfdom throughout later medieval and early modern eastern Europe in response to the growth of trade with the west (Dobb, 1946).

Finally, it needs to be noted that the sorts of products on the market which were most likely to stimulate the exploiters to try to increase their income for the purpose of trade were goods which ‘fit’ their specific reproductive needs. These were not producer goods but, on the contrary, means of consumption – specifically, materials useful for building up the exploiters’ political and military strength. They were certainly not luxury goods in the ordinary sense of superfluities, for they were, in fact, necessities for the exploiters. But they were luxuries in that their production involved a subtraction from the means available to the economy to expand its fundamental productive base. Paradoxically, then, to the extent that the rise of trading opportunities, in itself, can be expected to affect
Feudalism: The New Palgrave Dictionary of Economics

Precapitalist economies, it is likely to bring about not the loosening but the tightening of pre-capitalist property forms, the growth of unproductive expenditure, and the quickening not of economic growth but of stagnation and decline.

From feudalism to capitalism

The onset of modern economic growth thus appears to have required the break-up of pre-capitalist property relations characterized by the peasants’ possession of their means of subsistence and the lords’ surplus extraction by extra-economic compulsion. Nevertheless, neither the regular recurrence of system-wide socio-economic crisis nor the widespread growth of exchange could, in themselves, accomplish this. The problem which thus emerges is how feudal property relations could ever have been transformed.

To begin to confront this question, one can advance two basic hypotheses which follow more or less directly from the central themes of this article:

1. In so far as lords and peasants, acting either individually or as organized into communities, were able to realize their conscious goals, they succeeded, in one way or another, in maintaining pre-capitalist property forms. This is to say, once again, that the patterns of economic activity that individual lords and peasants found it reasonable to pursue could not aim at transforming the feudal property structure. It is also to emphasize that, because peasants and lords organized themselves into communities for the very purpose of maintaining and strengthening, respectively, peasant possession and the institutionalized relationships required for taking a feudal rent by extra-economic coercion, lords and peasants acting as communities were unlikely to aim at undermining feudal property forms. Peasants might, through collective action, conceivably have reduced to zero the lords’ levies and eliminated the lords’ domination; but, even in this extreme case, they would have ended up constituting a community of peasants fully in possession of their means of subsistence, with all of the barriers to economic development entailed by that set of property relations. Were the lords, on the other hand, to have succeeded to the greatest extent conceivable in overcoming peasant resistance, they would only to that degree have strengthened their controls over the peasants and increased their rate of rent, thus tightening feudal property relations.

2. Where breakthroughs took place to modern economic growth in later medieval and early modern Europe, these must be understood as unintended consequences of the actions by individual lords and peasants and by lordly communities and peasant communities in seeking to maintain themselves as lords and peasants in feudal ways. In other words, the initial transitions from feudal to capitalist property relations resulted from the attempts by feudal economic actors, as individuals and collectivities, to follow feudal economic norms or to reproduce feudal property relations under conditions where, doing so, actually had the effect – for various reasons – of undermining those relations.

To give substance to these hypotheses would require a lengthy historical discussion. It is here possible only to note a broad contrast in the historical evolutions of the different European regions during the late medieval and early modern periods. Through most of pre-industrial Europe, east and west, varying processes of class formation brought, in one form or another, the reproduction of feudal property relations and, in turn, the repetition of long-term developmental patterns familiar from the medieval period. However, in a few European regions, feudal property relations dissolved themselves, giving rise, for the first time, to essentially modern processes of economic development.
Thus, through much of later medieval and early modern western Europe (France and parts of western Germany), although peasants succeeded in very much strengthening peasant possession, winning their freedom and destroying all forms of surplus extraction by extra-economic coercion by individual lords, the lords succeeded, in response, in maintaining themselves by means of constituting a new, more potent form of now-collective surplus extraction by extra-economic compulsion, the tax/office state. At the same time, throughout late medieval and early modern eastern Europe, despite the peasants’ initially very powerful rights in the land and the lords’ initially very weak feudal controls, the lords ended up erecting an extremely tight form of individual lordly domination and surplus extraction by extra-economic compulsion – serf-operated demesne production. The consequence of these reconsolidations of essentially feudal property relations throughout most of Europe, east and west, was the reappearance throughout most of Europe during the early modern period of the same trends towards demographically powered expansion, towards the continued build-up of larger and more sophisticated states and, ultimately, towards socio-economic crisis as had characterized the medieval period.

The evolution of property relations in late medieval and early modern England was in some contrast to that of both eastern and (most of) western Europe, with epochal consequences for the long-term pattern of economic development. During this period, English lords, unlike those in eastern Europe, failed, as did those throughout almost all of western Europe, in their attempts to maintain, let alone intensify, their extra-economic controls over their peasantry. On the other hand, the English lords, unlike those throughout much of western Europe, did ultimately succeed in maintaining their positions by means of preventing their customary tenants from achieving full property in their plots. They were able, in consequence, to consign these tenants to leasehold status, and thus to assert their own full property in the land.

The unintended consequence of the actions of English peasants and lords aiming to maintain themselves as peasants and lords in feudal ways was thus to introduce a new system of now-capitalist property relations in which the direct producers were free from the lords’ extra-economic domination but also separated from their full means of reproduction (subsistence). In the upshot, tenants without direct access to their means of reproduction had no choice but to produce competitively for exchange and thus, so far as possible, to specialize, accumulate and innovate. At the same time, the landlords found themselves obliged to create larger, consolidated and well-equipped farms if they wished to attract the most productive tenants. The long-run results were epoch making. Under the pressures of competition, processes of differentiation led to the emergence of an entrepreneurial class of capitalist tenant farmers who were ultimately able to employ wage labourers. Meanwhile, the drive to cut costs in agricultural production ultimately brought about an agricultural revolution, as market-dependent farmers were obliged to adopt techniques which long had been available, but long eschewed by possessing peasants who would not intentionally take the risks of specialization, let alone make the necessary capital investments. The secular decline in food costs and the secular rise in living standards which resulted underpinned the movement of population off the land and into industry and made possible the rise of the home market. Industry and agriculture, for the first time, proved mutually supporting, rather than mutually competitive, and population increase served to stimulate economic growth rather than to undermine it. England experienced unbroken industrial and demographic growth right through the 17th and 18th centuries, which ultimately issued in the Industrial Revolution.

Fiat money is an intrinsically useless object that serves as a medium of exchange. One challenge is to construct models that depict the ancient notion that a medium of exchange is beneficial. Another is to construct models in which the medium of exchange has a low rate of return. Article
An object is often said to qualify as *money* if it plays one or more of the following roles: a unit of account, a medium of exchange, a store of value. The first and third seem insufficient. The Arrow–Debreu model with prices expressed in terms of either an abstract numeraire or one of the goods is not a model of a monetary economy. Neither is every model that contains an asset or durable good. That leaves the medium-of-exchange function: an object is a medium of exchange if it appears in many transactions – in the sense of a Clower (1967) transaction matrix.
As regards kinds of money, one distinction is between outside money, such as gold coins, and inside (private sector) money, such as demand deposits. (The quantity of outside money is unaffected by consolidation over the balance sheets of everyone in the economy, while the quantity of inside money disappears when that consolidation is performed – an inside money being someone's asset and someone else's liability.) Among outside monies, a distinction is usually made between commodity and fiat money. A commodity money is an object that has intrinsic value as a consumption good or as an input, while a fiat money does not.

One challenge is to construct models that depict the ancient notion that a medium of exchange is beneficial. (This notion goes back at least to the Roman jurist Paulus who said: ‘Since occasions where two persons can just satisfy each other's desires are rarely met, a material was chosen to serve as a general medium of exchange’ –Monroe, 1966.) Another is to construct models in which media of exchange are relatively poor stores of value, have low rates of return. And accompanying those challenges is a wide range of related policy questions. How, if at all, should inside money be regulated? How should a government monopoly on outside money be managed? Should there be country-specific outside monies?

Progress in meeting those challenges and in addressing policy questions has come about by taking seriously some old ideas: money is helpful when there are absence-of-double-coincidence difficulties that cannot be easily overcome with credit; and a good money has some desirable physical properties – recognizability, portability, and divisibility. In order to better appreciate the challenges and the progress, it is helpful to review the history of monetary theory.

The classical dichotomy

At the beginning of the 20th century, the dominant economic theory was a two-part model: a rudimentary Arrow–Debreu theory of relative prices and allocations; and a quantity-theory equation that was often interpreted as a supply-equals-demand for money equation. As was widely recognized, this model suffers from a blatant inconsistency. Everybody in the model is completely described in the theory of relative prices and allocations. Who, then, holds money, which is not one of goods in the relative price-allocation part of model? Patinkin (1951) called attention to this inconsistency by pointing out that the model fails to satisfy Walras's Law.

The model has other defects. Because the model does not describe transactions, it is silent about whether money is a medium of exchange. Whether it is or not, money is not helpful in the model because allocations are determined exactly as they would be in its absence. And, as was widely recognized, the real return on money in the model – determined entirely by the time path of the stock of money and its effect on the time path of the price level – could be less than, equal to, or greater than the real interest rate determined in the relative price part of the model. The third possibility was viewed as problematic because people would then, presumably, hold only money.

Notice, by the way, that money in the above model is implicitly fiat money and that holdings of it are minimized subject to being able to carry out transactions. Neither was an obvious feature of the economies to which the theory was applied for centuries. For most of that time, money was in fact a commodity and one that may not have been a poor store of value – if only because few alternatives were available. The distinction between commodity and fiat money may not be important because for some specifications of the intrinsic value of commodity money, the value of commodity money is determined
in the same way as the value of fiat money (see, for example, Samuelson, 1968; Sargent and Wallace, 1983). The implicit assumption that money is a poor store of value is more significant because it means that money cannot be treated as an ordinary asset.

**Real balances in utility or production functions**

The first models to overcome the blatant inconsistency of the classical dichotomy and to, in some way, integrate value and monetary theory were models of fiat money in which its quantity and its price were arguments of utility or production functions (see Samuelson, 1961). Such models are consistent with individual endowments of money and have equilibria in which it has value.

The models were intended to overcome the inconsistency of the classical dichotomy, while preserving as much of the relative price part of the model as possible. However, not everything was preserved. After explaining why real balances, not nominal balances, are introduced as an additional argument of utility functions, Samuelson (1961, p. 119) says, ‘This is not the only case in which economists have found it necessary to introduce prices into the indifference loci; there is also the example of goods which have snob appeal, or scarcity appeal…’ Samuelson (1968) describes the welfare consequences of his formulation: the failure of the first welfare theorem. That failure should not be surprising; putting prices into utility or production functions is a back-door way of introducing externalities. The failure gave rise to the vast literature on the so-called Friedman rule: tax to support the payment of interest on money either explicitly or through deflation.

A desirable feature of these models is that money cannot have a higher pecuniary real return than other assets. The models treat real balances like clothing or refrigerators. Such assets throw off services and, therefore, in equilibrium have lower pecuniary rates of return than assets like bonds that do not throw off services.

**Cash in advance and trading posts**

Utility or production functions with real balances as arguments were always regarded as *indirect* functions. If so, then there ought to be a direct or underlying model. One suggestion for the underlying model is a model in which the Arrow–Debreu budget set is replaced by separate sets which insure that money will appear in many trades (see Clower, 1967). Some goods can be purchased only with money and the sellers of those goods who receive money can use that money only in subsequent trades. Such models, dubbed cash-in-advance models, are special cases of models of *incomplete markets* (see, for example, Magill and Quinzii, 2006).

Viewed that way, cash-in-advance models depart from the Arrow–Debreu model by amending its equilibrium concept. Shubik (1973) adopts that way of modelling money, but insists that trade be modelled as an explicit game. In particular, he suggests that it be modelled using what are called Shapley–Shubik trading posts, with each post defined by the pair of objects traded at the post. In static versions of that model in which the game is modelled as the simultaneous choice of quantities (a version of a Cournot quantity game), inactivity at any subset of posts (including all posts) is a Nash equilibrium. Such inactivity has been used as a rationale for selecting a subset of posts that produces the kind of transaction matrix we observe – for example, some goods cannot be traded for anything other than
money and, in a multi-country context, some goods can be traded only for home money. However, Krishna (2005) questions the robustness of shutting down posts in which goods trade for assets that dominate money in rate of return.

Starr and Stinchcombe (1999) use a version of this model with fixed costs of operating a post to suggest that scale economies can imply that the efficient arrangement of posts when there are \( n + 1 \) objects, \( n \) goods and money is a monetary structure: at each of \( n \) active posts, money trades for one of the goods. Howitt (2005) uses an infinite-horizon version of that model with utility-maximizing agents who operate the posts to argue that there can be equilibria with that monetary structure of posts.

**Imperfect monitoring and money**

A different approach to modelling money is to depart from the environment of the Arrow–Debreu model – in particular, from its assumptions about commitment and information. Implicit in the absence-of-double-coincidence rationale for money is that the two persons cannot commit to future actions and are strangers. After all, a student in a class is more likely to say to a neighbouring student ‘lend me a pencil’ than ‘sell me a pencil’. More generally, in order that absence of double coincidence be a basis for a beneficial role for money, it must be augmented by no-commitment and by informational assumptions that inhibit the use of credit in its most general sense – informational assumptions that in game theory are called imperfect monitoring.

One of the first discussions of the informational assumptions is in Ostroy (1973). Townsend (1989) uses imperfect monitoring in an explicit intertemporal model and Kocherlakota (1998) further formalizes it. This work treats fiat money as a mechanism whose only role is to provide evidence of previous actions that would otherwise not be known. Fiat money, a physical object, can play that role because, counterfeiting aside, others can say ‘show me’ if one tries to overstate ones holdings of it.

The potentially crucial role of imperfect monitoring can be illustrated by considering the well-known risk-sharing model in Green (1987) and the variant of it studied by Levine (1990). There is a non-atomic measure of people who have identical preferences and maximize expected discounted utility. The model is one of pure exchange with a single good at each date. At each date, each person receives an endowment realization from a two-point set (high or low), where realizations are i.i.d. among people at a date and over time and are private information. Green studies a version of this model with perfect monitoring: at each date, each person makes a report about the person's endowment realization, a report which in the future is associated with that person.

Levine (1990) studies a variant of this model, but assumes no monitoring at all. In his version, no announcement or action made by a person at a date is associated with that person in the future. Moreover, if endowments are treated as owned by individuals, then under Levine's assumption, there is a role for money even if endowment realizations are public information. If there is no way to remember in the future that a person with a high endowment surrendered some of it, then the person will not surrender it – except for something that the person can carry into the future. In a pure-exchange setting, that thing can only be fiat money.
Absence of double coincidence is almost always described in terms of meetings between two people. That, of course, is very different from having everyone together or at least connected as in the Arrow–Debreu model. But, if the role of such pairwise meetings is only to prevent quid pro quo trade in commodities, then it is unnecessary. Such trade cannot happen in Green (1987), even in deterministic versions of it. So why bother with models of pairwise meetings?

One reason is that Paulus and others were reporting what they were seeing: namely, exchanges between two people. Another reason to study such models is to investigate their implications for transactions. Kiyotaki and Wright (1989) are the first to succeed in formulating and analysing such a model. In a world with many objects, they study the relationship between the intrinsic storage properties of objects – in particular, the (utility) cost of storing them – and their role in exchange. In order to make headway on that question, they adopt simplifying assumptions: objects are indivisible, each person can hold at most one unit of some object, and the intrinsic storage quality of an object is modelled as a utility cost which once realized does not become part of the state of the economy. Even with those simplifying assumptions, their model is not simple because the state of the economy is a distribution of holdings of the different objects. Nevertheless, they could show that there can be steady states in which objects other than the least costly-to-store object can play a medium-of-exchange role. (For the welfare properties of different equilibria in their model, see Renero, 1999.)

Still another reason for studying models with pairwise meetings is that such meetings can provide a rationale for imperfect monitoring. In a large economy, if people meet in pairs and, therefore, know only what they have experienced or what they have been told by people they meet, then imperfect monitoring emerges as an implication. This point of view is explored in non-monetary models in Kandori (1992) and in monetary models in Kocherlakota (1998) and Araujo (2004). Finally, models of pairwise meetings are attractive settings for exploring the consequences of imperfect recognizability and imperfect divisibility of money and other assets.

Models of pairwise meetings, however, also come with complications. One is the wide range of equilibrium concepts used to answer the old question: what do a pair who meet to trade do? One approach taken in the literature is descriptive – for example, the buyer and the seller make alternating offers, buyers make take-it-or-leave-it offers, or sellers commit to posted prices. Another approach explores all implementable outcomes subject either to individual defection or to such defection and cooperative defection by the pair in the meeting.

Another complication is the endogeneity of the distribution of assets. Such endogeneity also arises in models in which fiat money is the only durable object, in which people can hold more than one unit of money, and in which the meeting process gives rise to a distribution of outcomes – a person can end up buying, selling, or not trading. Obviously, in such models we do not expect to obtain simple closed-form solutions for equilibria or even steady states.

One response is to accept the endogeneity and to derive results for the model despite not having closed-form solutions (see Green and Zhou, 1998; Molico, 2006; Zhu, 2003; 2005). Another is to avoid it: by using the so-called large-family model (see Shi, 1997); by using a setting in which pairwise meetings alternate in some fashion with centralized meetings in which preferences are quasi-linear (see Lagos and Wright, 2005); or by using some other meeting process that lends itself to a simple or degenerate distribution of money.
Applications

New theoretical work should provide insights previously unavailable – insights about seemingly paradoxical observations or policies or both.

Outside money, credit and cashless economies

If we maintain the innocuous assumption that people cannot commit to future actions, then a model economy with perfect monitoring has no role for money, while one with no monitoring has no role for credit. Therefore, in order to find roles for both money and credit, we should study models with some, but not perfect, monitoring.

Several alternative formulations of such imperfect monitoring have been studied. Kocherlakota and Wallace (1998) use the pairwise setting in Trejos and Wright (1995) and Shi (1995), and assume that there is a lag in updating the public record of individual actions. They show that the set of implementable allocations is larger the shorter the lag – an obvious result, but one that represents the sense in which technological improvements that allow better monitoring improve trade outcomes. Cavalcanti and Wallace (1999) use the same background model, but assume that some people are perfectly monitored and others not at all. They permit each person to issue perfectly recognizable durable objects that are specific to the person, objects that are best interpreted as transferable trade-credit instruments. They show that the set of implementable outcomes in which such instruments are not valued (or are prohibited) is a strict subset of those in which such instruments issued by monitored people are valued. (Kocherlakota, 2002, shows that there is a way to support efficient allocations in such models using only spot trade with money. However, his punishment scheme would not survive allowing either the defector or the non-defector to move first in a meeting.) Aiyagari and Williamson (2000) use an environment that is close to that of Green (1987), but assume that a report to the planner can be made with some probability less than 1. Their focus is on how competitive trade in money influences what the planner can achieve.

Obviously, limiting cases of the above formulations of imperfect monitoring give rise to what can be interpreted as cashless economies. Although there are many conceptions of cashless economies, one of which is the Arrow–Debreu model, the above formulations have the desirable property that the cashless limit is a limit of a cash economy in which a medium of exchange plays a beneficial role. Moreover, because the cashless economy is achieved by taking a limit with respect to monitoring while maintaining the no-commitment assumption, the cashless limit is not an Arrow-Debreu model.

In Cavalcanti and Wallace (1999) and Cavalcanti, Erosa and Temzelides (1999), the money issued by monitored people is used by and passed around among nonmonitored people. Wallace and Zhu (2007) use that idea to offer a new interpretation of the paradox concerning banknote issue pointed out by Friedman and Schwartz (1963). Toward the end of 19th century, many countries permitted banks to issue payable-to-the-bearer notes subject to redemption on demand and to collateral restrictions. In the United States and, presumably, in other countries, those systems seemed to give rise to a failure of an arbitrage condition: the yields on eligible collateral often seemed too high to be reconciled with their use as collateral for note issue. Put differently, those systems seemed not to produce currencies that were elastic with respect to the yield on eligible collateral. The explanation offered by Wallace and Zhu has
two components. First, the profitability of note issue depends on the implied float. Second, note issuers face a menu of opportunities for issuing notes – a menu that displays an inverse association between the magnitude of possible note placements and the implied float. The paradox results from treating the observed float as if it applied to all possible uses of notes, rather than taking into account the fact that high-placement low-float opportunities – for example, in organized financial markets – are not chosen. In Wallace and Zhu, the low-placement, high-float opportunities are in pairwise meetings.

Physical properties of assets

Discussions of money have often described desirable physical properties of media of exchange: recognizability, portability and divisibility. Implicit in any such discussion is the idea that those properties are scarce, are not shared equally by all objects. However, only recently have the consequences of such scarcity been explored.

Recognizability

Freeman (1985) and Williamson and Wright (1994) use imperfect recognizability of alternatives to fiat money to produce models in which fiat money is helpful. In Freeman, the alternative to fiat money is a claim to long-lived capital. Under the assumption that such claims can be costlessly counterfeited, he argues that genuine claims cannot be traded competitively. Williamson and Wright use a model of pairwise matching without an absence-of-double-coincidence problem to show that imperfect recognizability of the (durable) goods is enough to make trade involving fiat money helpful. In both of those models and many others, the holder of an asset knows more about it than at least some potential holders. (An exception is Huggett and Krasa, 1996.) Models of pairwise meetings are attractive for studying the role of such imperfect recognizability because it is in such meetings, rather than in ‘large markets’, that asymmetric information about quality ought to be important. Moreover, if, as in Freeman or Williamson and Wright, the low-quality asset is worthless, then it gets traded when subject to asymmetric information only if it masquerades as being genuine – that is, only in a pooling equilibrium. However, pooling equilibria do not always exist – at least if refinements on beliefs about off-equilibrium actions are imposed. It remains to be determined whether such refinements could be used to strengthen the Freeman result. In particular, could a small difference in counterfeiting costs between two assets – between fiat money and claims to capital, or home money and foreign money, or outside money and inside money – be enough to generate trade in one of the assets and no trade in the other even if the less-costly-to-counterfeit asset, as in Freeman, has a large rate-of-return advantage?

Portability

Townsend (1989) and Smith (2002) build models based on portability of fiat money and the lack of portability of capital. However, as they emphasize, the mere lack of portability of real capital needs to be supplemented by imperfect monitoring. And when supplemented by sufficiently imperfect monitoring, such models give rise to a role for fiat money that is very similar to its role in other absence-of-double-
coincidence settings. To see the similarity, consider a version of those models in which people meet in pairs and in which there is one good per date. When two people meet, suppose that they have available to them some amount of the good that can either be consumed or used as an input (investment) that will give output at the next date, but only at the same location. Moreover, suppose that one and only one of the two people will be at the same location at the next date. If there is no monitoring, then fiat money, despite having a lower real return than investment, can have a beneficial role—the same role it has in other absence-of-double-coincidence settings with no monitoring. That is, the stayer retains all the capital, while the leaver takes some fiat money. The absence of monitoring prevents the leaver from retaining a claim to any of the capital.

Divisibility

Historians of monetary systems and others have often noted that money was generally not available in conveniently small denominations (see, for example, Redish, 2000; Sargent and Velde, 2002). However, until recently no models described how such absence would inhibit trade. Models of pairwise meetings are an obvious candidate: if neither the buyer nor the seller has small change, then trade (even if lotteries are permitted) is inhibited. If the model is to have implications for optimal divisibility, then it should also contain something to limit divisibility. Lee, Wallace and Zhu (2005) assume that there is a direct cost of carrying monetary items that is independent of denomination (that is, carrying thousands of pennies is very costly), while Lee and Wallace (2006) assume costs of producing and maintaining the stock of money that increase with divisibility.

Concluding remarks

Why is it better to make assumptions about meeting patterns, information, and the physical characteristics of potential assets than about which markets are open or the pattern of transaction costs over objects? First, the former lends itself to standard notions of incentive feasibility, which is what we ought to mean by integrating monetary economics with the rest of economics. Second, such an approach meets the proof-of-the-pudding criterion. Compare, for example, the results about inside money that can be obtained by working with the imperfect-monitoring point of view with what can be done with a cash-in-advance model.

But is such foundational work needed to deal with the nuts and bolts of monetary policy? It is generally agreed that open-market operations matter because the medium of exchange is a low-return asset and because the central bank has a monopoly on its supply. Can it be that beneficial management of that monopoly does not depend on how we explain the low return of the medium of exchange? Finally, can we look forward to a monetary theory that in generality rivals the Arrow–Debreu model? Probably not. A need for a medium of exchange does not arise in every conceivable economy—think of Robinson Crusoe, even after he meets Friday, or of the Arrow–Debreu model. Such a need arises when there is some absence-of-double-coincidence difficulty that cannot be overcome with credit because people cannot commit to future actions and because there is imperfect monitoring. Those features may not lend themselves to a general formulation.

Fiducial inference introduced the pivotal inversion that is central to modern confidence theory. Initially this provided confidence bounds but later was generalized to give confidence distributions on the parameter space. For this it came in direct conflict with the then prominent Bayesian approach called inverse probability. Confidence distributions are now however widespread in modern likelihood theory. Recent results from this theory indicate that the developed fiducial confidence approach is giving a consistent statement of where the parameter is with respect to the data, and indeed is consistent with recent Bayesian approaches that allow data dependent priors.

Article

In a seminal paper, R.A. Fisher (1930) introduced the notion of fiducial inference as an alternative to what was then called inverse probability. The key step in fiducial inference is pivotal inversion, which is now standard in all of confidence theory. Fisher's example involved four pairs of observations with a concern for the correlation coefficient $\rho$ between observations in a pair. He had available the distribution function $F(r; \rho)$ for the sample correlation coefficient $r$, which depends only on the population correlation $\rho$; and he had an observed correlation value $r^0 = .99$. He did numerical calculations with the distribution function $F(r; \rho)$, which he had himself previously derived. And he then reported (.765, 1) as a 95 per cent interval for $\rho$. This is fully in accord with current confidence interval theory. In present notation we would write...
where the solution of \( F(r, \rho) = .95 \) for \( \rho \) to obtain the parameter lower bound \( \hat{\rho}_L = \hat{\rho}_L(r) \) is standard confidence or pivotal inversion applied to the pivot \( u = F(r, \rho) \), which of course has a Uniform (0,1) distribution.

But Fisher (for example, 1930; 1933; 1935; 1956) went further and presented a distribution, called a fiducial distribution, for the parameter \( \rho \), which as a density can be used for calculations such as

\[
\int_{.765}^{1} f_{\text{fid}}(\rho; r_0) \, d\rho = .95,
\]

and where for the example the density has the form

\[
f_{\text{fid}}(\rho; r) = - (\partial / \partial \rho) F(r, \rho);
\]

this density agrees with what in recent likelihood theory would be called a confidence distribution.

But Fisher went still further and spoke of fiducial probability rather than just statements for an interval such as confidence level that we would commonly use. This attribution of probability that a parameter lies in the interval (.765, 1) attracted attack from both the inverse probability community at the time and from the more conventional community that would now be called the frequentist, and includes those having philosophical persuasions. As a consequence, many have viewed fiducial probability as wrong, and strong stigmata have been attached to it. This is rather extraordinary, given that the papers by Fisher are seminal for all of confidence theory and differ only in small deviations of presentation and development.

The key aspects of fiducial that evoked criticism are (a) that different pivots can lead to different distributions and thus different intervals, (b) that marginalization of a parameter distribution to a component parameter can give a distribution that depends on data in a way different from the obvious that would come from that data, and (c) that constraints on the parameter can give a distribution without total probability being equal to 1.

The alternative culture when Fisher (1930) introduced fiducial inference was inverse probability (Bayes, 1763). For this, the probability at a data point \( y^0 \), given as \( f(y^0; \theta) \) and now called likelihood (Fisher, 1922) and written \( L(\theta; y^0) \), is adjusted by a weight function \( w(\theta) \) to give the composite

\[
P(r < .99; \rho) = .95 = P(\hat{\rho}_L < \rho; \rho) = \{\rho \text{ in } (\hat{\rho}_L, 1); \rho\},
\]
which is then treated as an unnormed density for the parameter. The weight function \( w(\theta) \) is chosen based on properties of the model and called by various names, with default prior being the most unassuming. The present rather large community using this approach is a subgroup of the Bayesian community and the approach has come to be called default Bayesian inference rather than inverse probability analysis; it can also be viewed as a routine frequentist use of the frequentist likelihood function coupled with an ad hoc weight function.

This commonly called default Bayesian approach offers great freedom for the development of statistical techniques: take an observed likelihood \( L(\theta; y^0) \) based on Fisher's (1922) proposal; attach a convenient weight function \( w(\theta) \) to it; and use the composite for inference for \( \theta \). With available high-powered computers and Markov Chain Monte Carlo this leads to a wealth of possible analyses, in contrast to rather limited results from earlier frequentist approaches.

But this leads to perhaps the most influential criticism of the fiducial method (Lindley, 1958): (d) that a fiducial distribution is typically not an inverse probability or default Bayesian posterior. Curiously, one finds that the default Bayesian approach is subject to precisely the same criticisms (a), (b), (c) that have been attached to the fiducial approach (for example, concerning (b), see Dawid, Stone and Zidek, 1973; see also Fraser, 1961; 1995). So the fact (d) that a fiducial analysis is not in general a default Bayesian analysis seems a rather hollow criticism by Lindley (1958). And of course default Bayes typically does not lead to intervals that have the confidence property. Moreover, a recently dominant interest within the current Bayesian community (Fraser and Reid, 2002) is to have methods that do reproduce in repeated sampling as do confidence intervals. Perhaps the default Bayesian community is rushing in where the frequentist community neglected its own likelihood function. But perhaps Fisher and his fiducial approach should be given credit for the fundamental contribution of the pivotal inversion, and of giving rise to the universal confidence procedures. The change of name from fiducial to confidence and then the derogation of fiducial seem a rather heavy historical penalty to Fisher and his profound and seminal developments in statistics. Perhaps ‘fiducial’ did move too quickly, certainly for the times, and did neglect to develop some fine details. But the results are profound; and the default Bayesian community is finding that it cannot ignore in substance the fiducial criticisms (a), (b), (c); and can’t avoid the repeated sampling reproducibility that is the foundation of confidence theory (d).

But then, how does fiducial inference work in more general contexts, particularly in the light of recent likelihood theory? For each independent coordinate, say, \( y_i \), a pivot \( z_i = h_i(y_i; \theta) \) is needed that describes with full deference to continuity how the coordinate \( y_i \) measures or provides information on the parameter \( \theta \); this pivot needs to be of the same dimension as the variable \( y_i \) and of course as implied by its name has a fixed distribution free of \( \theta \). If a coordinate is scalar, the pivot is necessarily equivalent to the distribution function \( F_i(y_i; \theta) \) for that coordinate; if it is vector then the choice of pivot represents an explicit statement of how that coordinate variable affects the parameter and is taken as a given for the inference process. Likelihood theory then shows that the full pivot can be re-expressed to third-order accuracy in the moderate deviations region by an equivalent pivot in which the parameter \( \theta \) of, say, dimension \( p \).
fiducial inference: The New Palgrave Dictionary of Economics

appears in only \( p \) coordinates of the new pivot. The conditional distribution of these \( p \) coordinates given the remaining pivot coordinates (which are of course directly observable) gives effectively a new pivot with of course the same dimension as the parameter. This allows for the standard confidence pivotal inversion to produce confidence regions.

If inference focuses on a particular parameter component \( \psi (\theta) \) of interest with dimension \( d \), then the recent likelihood theory shows that the interest parameter can be isolated to third order in a \( d \) dimensional component of an equivalent pivot, and the marginal model for that pivot is otherwise free of the full parameter and provides third-order confidence regions for the interest parameter. For some background see Fraser and Reid (2001), Fraser, Reid and Wu (1999), and Fraser (2004).

field experiments

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Field experiments have grown significantly in prominence since the 1990s. In this article, we provide a summary of the major types of field experiments, explore their uses, and describe a few examples. We show how field experiments can be used for both positive and normative purposes within economics. We also discuss more generally why data collection is useful in science, and more narrowly discuss the question of generalizability. In this regard, we envision field experiments playing a classic role in helping investigators learn about the behavioural principles that are shared across different domains.

Field experiments occupy an important middle ground between laboratory experiments and naturally occurring field data. The underlying idea behind most field experiments is to make use of randomization in an environment that captures important characteristics of the real world. Distinct from traditional empirical economics, field experiments provide an advantage by permitting the researcher to create exogenous variation in the variables of interest, allowing us to establish causality rather than mere correlation. In relation to a laboratory experiment, a field experiment potentially gives up some of the control that a laboratory experimenter may have over her environment in exchange for increased realism. The distinction between the laboratory and the field is much more important in the social sciences and the life sciences than it is in the physical sciences. In physics, for example, it appears that every hydrogen atom behaves exactly alike. Thus, when astronomers find hydrogen’s signature wavelengths of light coming from the Andromeda Galaxy, they use this information to infer the quantity of hydrogen present there. By contrast, living creatures are much more complex than atoms and molecules, and they correspondingly behave much more heterogeneously. Despite the use of ‘representative consumer’

models, we know that not all consumers purchase the same bundle of goods when they face the same prices. With complex, heterogeneous behaviour, it is important to sample populations drawn from many different domains – both in the laboratory and in the field. This permits stronger inference, and one can also provide an important test of generalizability, testing whether laboratory results continue to hold in the chosen field environment.

We find an apt analogy in the study of pharmaceuticals, where randomized experiments scientifically evaluate new drugs to treat human diseases. Laboratory experiments evaluate whether drugs have desirable biochemical effects on tissues and proteins in vitro. If a drug appears promising, it is next tested in vivo on several species of animals, to see whether it is absorbed by the relevant tissues, whether it produces the desired effects on the body, and whether it produces undesirable side effects. If it remains with significant promise after those tests, it is then tested in human clinical trials to explore efficacy and measure any side effects.

Even after being tested thoroughly in human clinical trials and approved by regulators, a drug may sometimes reveal new information in large-scale use. For example, effectiveness may be different from the efficacy measured in clinical trials: if a drug must be taken frequently, for example, patients may not remember to take it as often as they are supposed to or as often as they did in closely supervised clinical trials. Furthermore, rare side effects may show up when the drug is finally exposed to a large population. Much like this stylized example, in economics there are a number of reasons why insights gained in one environment might not perfectly map to another. Field experiments can lend insights into this question (see also Bohm, 1972; Harrison and List, 2004; Levitt and List, 2007; List, 2007). First, different types of subjects might behave differently; university students in the laboratory might not exhibit the same behaviour as financial traders or shopkeepers. In particular, the people who undertake a given economic activity have selected into that activity and market forces might have changed the composition of players as well; you might expect regular bidders to have more skill and interest in auctions than a randomly selected laboratory subject, for example.

A second reason why a field experiment might differ from a laboratory experiment is that the laboratory environment might not be fully representative of the field environment. For example, a typical donor asked to give money to charity might behave quite differently if asked to participate by choosing how much money to contribute to the public fund in a public-goods game (List, 2007). The charitable-giving context could provide familiar cognitive cues that make the task easier than an unfamiliar laboratory task. Even the mere fact of knowing that one's behaviour is being monitored, recorded, and subsequently scrutinized might alter choices (Orne, 1962).

Perhaps most important is the fact that any theory is an approximation of reality. In the laboratory, experimenters usually impose all the structural modelling assumptions of a theory (induced preferences, trading institutions, order of moves in a game) and examine whether subjects behave as predicted by the model. In a field experiment, one accepts the actual preferences and institutions used in the real world, jointly testing both the structural assumptions (such as the nature of values for a good) and the behavioural assumptions (such as Nash equilibrium).

For example, Vickrey (1961) assumes that in an auction there is a fixed, known number of bidders who have valuations for the good drawn independently from the same (known) probability distribution. He uses these assumptions, along with the assumption of a risk-neutral Nash equilibrium, to derive the ‘revenue equivalence’ result: that Dutch, English, first-price, and second-price auctions all yield the same expected revenue. However, in the real world the number of bidders might actually vary with the
good or the auction rules, and the bidders might not know the probability distribution of values. These exceptions do not mean that the model should be abandoned as ‘wrong’; it might well still have predictive power if it is a reasonable approximation to the truth. In a field experiment (such as Lucking-Reiley, 1999, for this example), we approach the real world; we do not take the structural assumptions of a theory for granted.

Such an example raises the natural question related to the actual difference between laboratory and field experiments. Harrison and List (2004) propose six factors that can be used to determine the field context of an experiment: the nature of the subject pool, the nature of the information that the subjects bring to the task, the nature of the commodity, the nature of the task or trading rules applied, the nature of the stakes, and the environment in which the subjects operate. Using these factors, they discuss a broad classification scheme that helps to organize one's thoughts about the factors that might be important when moving from the laboratory to the field.

A first useful departure from laboratory experiments using student subjects is simply to use ‘non-standard’ subjects, or experimental participants from the market of interest. Harrison and List (2004) adopt the term ‘artefactual’ field experiment to denote such studies. While one might argue that such studies are not ‘field’ in any way, for consistency of discussion we denote such experiments as artefactual field experiments for the remainder of this article, since they do depart in a potentially important manner from typical laboratory studies. This type of controlled experiment represents a useful type of exploration beyond traditional laboratory studies.

Moving closer to how naturally occurring data are generated, Harrison and List (2004) denote a ‘framed field experiment’ as the same as an artefactual field experiment but with field context in the commodity, task, stakes, or information set of the subjects. This type of experiment is important in the sense that a myriad of factors might influence behaviour, and by progressing slowly towards the environment of ultimate interest one can learn about whether, and to what extent, such factors influence behaviour in a case-by-case basis.

Finally, a ‘natural field experiment’ is the same as a framed field experiment but where the environment is one where the subjects naturally undertake these tasks and where the subjects do not know that they are participants in an experiment. Such an exercise represents an approach that combines the most attractive elements of the laboratory and naturally occurring data – randomization and realism. In this sense, comparing behaviour across natural and framed field experiments permits crisp insights into whether the experimental proclamation, in and of itself, influences behaviour.

Several examples of each of these types of field experiments are included in List (2006). Importantly for our purposes, each of these field experimental types represents a distinct manner in which to generate data. As List (2006) illustrates, these field experiment types fill an important hole between laboratory experiments and empirical exercises that make use of naturally occurring data. Yet an infrequently discussed question is: why do we bother to collect data in economics, or in any science?

First, we use data to collect enough facts to help construct a theory. Several prominent broader examples illustrate this point. After observing the anatomical and behavioural similarities of reptiles, one may theorize that reptiles are more closely related to each other than they are to mammals on the evolutionary tree. Watson and Crick used data from Rosalind Franklin's X-ray diffraction experiment to construct a theory of the chemical structure of DNA. Careful observations of the motions of the planets in the sky led Kepler to theorize that planets (including Earth) all travel in elliptical orbits around the Sun, and
Newton to theorize the inverse-square law of gravitation. After observing with a powerful telescope that the fuzzy patches called ‘spiral nebulae’ are really made up of many stars, one may theorize that our solar system is itself part of its own galaxy, and the spiral nebulae are external to our Milky Way galaxy. Robert Boyle experimented with different pressures using his vacuum pump in order to infer the inverse relationship between the pressure and the volume of a gas. Rutherford's experiments of shooting charged particles at a piece of gold foil led him to theorize that atoms have massive, positively charged nuclei.

Second, we use data to test theories’ predictions. Galileo experimented with balls rolling down inclined planes in order to test his theory that all objects have the same rate of acceleration due to gravity. Pasteur rejected the theory of spontaneous generation with an experiment that showed that microorganisms grow in boiled nutrient broth when exposed to the air, but not when exposed to carefully filtered air. Arthur Eddington measured the bending of starlight by the sun during an eclipse in order to test Einstein's theory of general relativity.

Third, we use data to make measurements of key parameters. On the assumption that the electron is the smallest unit of electric charge, Robert Millikan experimented with tiny, falling droplets of oil to measure the charge of the electron. On the assumption that radioactive carbon-14 decays at a constant rate, archaeologists have been able to provide dates for various ancient artifacts. Similarly, scientists have assumed theory to be true and designed careful measurements of many other parameters, such as the speed of light, the gravitational constant, and various atomic masses.

Field experiments can be a useful tool for each of these purposes. For example, Anderson and Simester (2003) collect facts useful for constructing a theory about consumer reactions to nine-dollar endings on prices. They explore the effects of different price endings by conducting a natural field experiment with a retail catalogue merchant. Randomly selected customers receive one of three catalogue versions that show different prices for the same product. Systematically changing a product's price varies the presence or absence of a nine-dollar price ending. For example, a cotton dress may be offered to all consumers, but at prices of 34, 39, and 44 dollars, respectively, in each catalogue version. They find a positive effect of a nine-dollar price on quantity demanded, large enough that a price of 39 dollars actually produced higher quantities than a price of 34 dollars. Their results reject the theory that consumers turn a price of 34 dollars into 30 dollars by either truncation or rounding. This finding provides empirical evidence on an interesting topic and demonstrates the need for a better theory of how consumers process price endings.

List and Lucking-Reiley (2000) present an example of a framed field experiment designed to test a theory. The theory of multi-unit auctions predicts that a uniform-price sealed-bid auction will produce bids that are less than fully demand-revealing, because such bids might lower the price paid by the same bidder on another unit. By contrast, the generalized Vickrey auction predicts that bidders will submit bids equal to their values. In the experiment, List and Lucking-Reiley conduct two-person, two-unit auctions for collectible sportscards at a card trading show. The uniform-price auction awards both items to the winning bidder(s) at an amount equal to the third-highest bid (out of four total bids), while the Vickrey auction awards the items to the winning bidder(s) for amounts equal to the bids that they displaced from winning. List and Lucking-Reiley find that, as predicted by the theory of demand reduction, the second-unit bids submitted by each bidder were lower in the uniform-price treatment than in the Vickrey treatment. The first-unit bids were predicted to be equal across treatments, but in the experiment they find that the first-unit bids were anomalously higher in the uniform-price treatment. Subsequent laboratory experiments (see, for example, Engelmann and Grimm, 2003; Porter and Vragov,
Finally, Karlan and List (2007) is an example of a natural field experiment designed to measure key parameters of a theory. In their study, they explore the effects of ‘price’ changes on charitable giving by soliciting contributions from more than 50,000 supporters of a liberal organization. They randomize subjects into several different groups to explore whether solicitees respond to upfront monies used as matching funds. They find that simply announcing that a match is available considerably increases the revenue per solicitation – by 19 per cent. In addition, the match offer significantly increases the probability that an individual donates – by 22 per cent. Yet, while the match treatments relative to a control group increase the probability of donating, larger match ratios – 3:1 dollars (that is, 3 dollars match for every 1 dollar donated) and 2:1 dollar – relative to smaller match ratios (1:1 dollar) have no additional impact.

In closing, we believe that field experiments will continue to grow in popularity as scholars continue to take advantage of the settings where economic phenomena present themselves. This growth will lead to fruitful avenues, both theoretical and empirical, but it is clear that regardless of the increase in popularity, the various empirical approaches should be thought of as strong complements, and combining insights from each of the methodologies will permit economists to develop a deeper understanding of our science.

Abstract

This survey of some of the developments in finance since the mid-1980s begins with advances in the application of arbitrage pricing, and then expands into areas of general asset pricing under the title ‘risk and return’. Limitations in our current understanding of risk as well as more data explorations have led to the ‘discovery’ of anomalies, which challenge classic notions of market efficiency. We examine recent attempts to expand the neoclassical framework to incorporate market imperfections in asset pricing, which, in their more general forms, take centre stage in advances in corporate finance.

Article

This article attempts to survey some of the developments in finance since the mid-1980s. By then, what
we know as neoclassical finance had taken its broad shape and become a foundation for our understanding of the central issues in finance as well as the starting point for further developments. As true for any science, the advances in finance since then are characterized by an interactive process of more rigorous testing and revision of the existing theories, more extensive exploration of the data, old and new, and further expansion of theory beyond the known territories.

Finance is concerned with how the financial market facilitates the allocation of capital or assets. In a well-functioning market, it is prices that guide the allocation. Thus, how to value financial assets or financial securities is a primary focus of finance. Since the value of an asset comes from its future payoff, which extends over time and is uncertain in nature, risk is the key element in asset valuation. Relying on a few basic principles, neoclassical finance has developed a rich set of models and tools for asset pricing, risk analysis and corporate finance.

However, much of the neoclassical finance abstracts away from market imperfections, most notably information asymmetry and market frictions. Such an abstraction draws the boundaries of the neoclassical theory. In particular, the theory's applicability softens when these imperfections are important. Moreover, the theory itself does not provide much guidance in gauging the relevance of imperfections. The omission of imperfections also leaves the neoclassic theory mostly free of institutions. Such an simplification is perhaps most stark in corporate finance, as the very existence and consequently the behaviour of firms are presumably institutional arrangements in response to imperfections, but it is similarly striking in the context of financial market, which consists of a complex and collection of institutions and intermediaries. Naturally, this limits what the neoclassical theory says about the behaviour of institutions as major participants in the market and its implications on market behaviour and capital allocation. It should be emphasized that significance of imperfections in a given context is as much, if not more, of an empirical issue as a theoretical matter. To a large extent, developments beyond the neoclassical theory involve very much the interplay between the research in these two dimensions.

Our discussion of these developments will begin with the advances in the application of arbitrage pricing, arguably the most successful area of modern finance. It then expands into areas of general asset pricing under the title ‘risk and return’. Limitations in our current understanding of risk as well as more data explorations have led to the ‘discovery’ of anomalies, which amounted to new challenges to classic notions of market efficiency. After reviewing some of this empirical evidence, we examine some of the recent attempts to expand the neoclassical framework to incorporate market imperfections. We then turn to advances in corporate finance, in which imperfections, in their more general forms, take centre stage.

This article is intended to provide an update to finance, which remains a timeless piece in capturing the spirit and the essence of neoclassical finance. We will rely on it for a more detailed review of the earlier work as well as their historical context. In order to make the two articles more integrated, we adopt a similar framework, but adjusted to reflect the current landscape. Needless to say, any survey of a broad and fast-growing field such as finance will be partial and incomplete.

Arbitrage pricing

The first principle of asset pricing is the absence of arbitrage. Here, an arbitrage refers to a set of transactions in the market based on public information that always yields net gains. The intuition for no arbitrage is straightforward: any such an opportunity would be exploited by market participants until it
disappears. When transactions of financial securities face little frictions, no arbitrage yields sharp results on the prices of securities which are close substitutes. In particular, securities with same payoffs must have the same price. Classical applications of this principle include arbitrage relations between the prices of default-free bonds with different coupons, spot and forward prices of commodities, and spot and forward exchange rates between currencies and their corresponding interest rates. The path-breaking work of Black and Scholes (1973) and Merton (1973) on option pricing greatly expanded the applications of arbitrage pricing. Vasicek (1977) and Cox, Ingersoll and Ross (1985b) demonstrated how the arbitrage method can be applied to the pricing of default-free bonds. Merton (1974) and Black and Cox (1976) applied the option pricing technique to value bonds with default risks.

Arbitrage pricing as a general methodology enjoyed unprecedented success in finance and in all of economics. Not only did earlier empirical tests find strong support from the data (see, for example, Black and Scholes, 1973), but data converged to theory as deviations disappeared quickly with the theory's dissemination. The explosive applications of the methodology by the financial industry, ranging from new products and markets, new pricing and trading technologies, to new investment and risk management practices, gave the core substance for what is now branded as financial engineering. For a set of traded securities, let $P_t$ denote their current prices and $X_{t+1}$ their next period payoffs (in vector forms). In its general formulation by Ross (1976) and Harrison and Kreps (1979), the absence of arbitrage is equivalent to the existence of a set of positive state prices $\phi$ such that

$$P_t = \sum_{\omega} \varphi_t(\omega) X_{t+1}(\omega) = E_t^* [e^{-r_{0,t+1}} X_{t+1}]$$

(1)

where $\omega$ denotes a future state of the economy, $\varphi_t(\omega)$ the state price at $t$ for state $\omega$ at $t+1$, $r_{0,t+1}$ denotes the risk-free interest rate from $t$ to $t+1$, and $E_t^* [\cdot]$ denotes the conditional expectation using normalized stated prices as probabilities, which is also referred to as the risk-neutral measure. For a set of securities with payoffs determined by the same set of future states $\omega$, they become substitutes. Their prices will then be related by arbitrage through the corresponding state prices. If we can identify a sufficient number of such securities, then their prices will reveal the corresponding state prices, which then allow us to value other substitutes. Certain securities are natural substitutes, such as an underlying asset and its derivatives, the whole collection of fixed income securities, and a firm's bonds and its equity. Arbitrage pricing has been widely used in the valuation of these securities.

**Equity options**

The basic framework for option valuation was established by the pioneer work of Black and Scholes (1973) and Merton (1973) and the contributions of Cox and Ross (1976a; 1976b) and Cox, Ross and Rubinstein (1979). The huge body of work that followed has enriched this framework substantially. One
focus is to allow for more general price behaviour for the underlying asset. This is in part motivated by deviations in the observed prices from the Black–Scholes formula, which assumes a geometric Brownian diffusion for the price of the underlying asset. For example, from the observed option prices, the volatility implied from the Black–Scholes formula changes over time and differs for different strike prices, a phenomenon referred to as volatility smiles or smirks. Two natural extensions are to allow stochastic volatility and jumps. Hull and White (1987), Heston (1993) and Stein and Stein (1991) proposed models with time-varying volatility. Extending Merton (1976), Amin (1993), Scott (1997) and Bates (2000) have incorporated jumps into stochastic volatility models. Empirical analysis of the data on both options and underlying equities suggests that both stochastic volatility and jumps are helpful in explain their behaviour (see, for example, Melino and Turnbull, 1990; Bates, 1996; Bakshi, Cao and Chen, 1997; Pan, 2002). In a discrete-time setting, the distinction between stochastic volatility and jumps becomes moot. Rubinstein (1994) has suggested modifications to binomial model of Cox, Ross and Rubinstein (1979) to accommodate the effects of time-varying price dynamics. Although most of the recent work on equity options stays within the neoclassical arbitrage pricing framework, it significantly enriches the pricing models to better fit the data. But the fit is never perfect. Is the gap eventually going to be closed with more sophisticated models or revealing something more? We are not totally sure. The arbitrage approaches works when options are truly substitutes of the underlying asset. If so, why do they appear in the first place? Market imperfections may be part of the reason, but the exact nature of this link is far from being well understood.

Default-free bonds

Bonds of no default risk are closely related to each other as their prices are all driven by interest rates. From (1), the price of a pure discount bond, which has a unit payoff at date T, is given by

\[
B_t(T) = \mathbb{E}_t^* \left[ e^{-\int_t^T r_{0,s} ds} \right].
\]

The specification of the interest rate process under the risk-neutral measure will then allow us to price bonds by computing the above conditional expectation. It is well known that bond returns share a small number of common factors (for example, Litterman and Scheinkman, 1991). A natural approach is to specify the interest rate as a function of a few state variables. Earlier work chooses the short-term interest rate as the single state variable and assumes tractable dynamics. For example, Vasicek (1977) assumes a Gaussian Markov process for the short rate and Cox, Ingersoll and Ross (1985b) assume a square-root process (the CIR model). Other candidate models include Brennan and Schwartz (1979), Cox, Ingersoll and Ross (1980), Courtadon (1982), and more recently Longstaff (1989), Chan et al.
(1992), Constantinides (1992) and Ahn, Dittmar and Gallant (2002). These models aim at tractable solutions to bond prices to capture their basic behaviour. The empirical evaluation of these models requires the further specification of $r_t$ under the statistical measure, that is, the true data-generating process. The transformation from the risk-neutral measure to the statistical measure effectively reflects the risk premium. Thus, the test of an arbitrage-based pricing model is really a joint test of the proposed interest rate process and the associated risk premium process. Analysis by Brown and Dybvig (1986), Chan et al. (1992) and Gibbons and Ramaswamy (1993) readily demonstrates that the parsimony of single factor models also limits their ability to fit the data. Nonparametric tests, such as Ait-Sahalia (1996) and Stanton (1997), further suggest that single-factor diffusion models are unable to capture several important features of interest rate dynamics. Following Langetieg (1980), Cox, Ingersoll and Ross (1985b) and Schaefer and Schwartz (1984), multifactor extensions became the next pursuit, notably Chen and Scott (1992), Longstaff and Schwartz (1992) and Hull and White (1994).

Despite their added flexibility, multifactor models face two challenges. On the one hand, they quickly become less tractable as more state variables are added. On the other hand, even though a small number of factors, typically three, capture a large percentage of commonality in bond returns, it is far from clear if they are enough in describing bond prices.

The first challenge has largely limited the focus to tractable models. One notable example is the so-called affine models, in which the short-term interest rate is assumed to be an affine function of a set of state variables. In addition, the vector of state variables follows a diffusion process with its drift and covariance both being its own affine functions. Closed-form solutions can be obtained for bond prices and yields under this specification. Brown and Schaeffer (1994), for example, explored an extension of the CIR model under the affine structure. Duffie and Kan (1996) expanded the scope of the affine models and Dai and Singleton (2000) provided an extensive empirical analysis of their pros and cons. They can capture many aspects of the bond price behaviour, but always leaving a few others. This situation is not unique to the affine models as it is shared by other multifactor models outside the affine class (for example, Ahn, Dittmar and Gallant, 2002). Other enrichments have also been considered, such as jumps in interest rates (for example, Johannes, 2004; Piazzesi, 2005) and regime shifts in interest rate dynamics (for example, Hamilton, 1988; Gray, 1996), to enhance the descriptive power of the arbitrage-based models.

It might be unrealistic to attempt to describe the rich behaviour of a large cross-section of bond prices by a small number of risk factors following relatively simple dynamics. One possibility is to relax the limit on the dimension of risk factors. Kennedy (1994), Goldstein (2000) and Santa-Clara and Sornette (2001) have explored models with an infinite-dimensional state vector. However, to make these models empirically implementable, restrictive structures need to be imposed.

Aside from specific modelling issues, what we confront is a more general situation. To the extent that default-free bonds are substitutes, we can rely on arbitrage methods in their valuation. While being very close, they are rarely exact substitutes. From this perspective, arbitrage results provide only an approximation. We can take comfort in the empirical success of existing models so far – the bottle is not full, but close to it. But to fill the rest is proven hard. It suggests that old tricks may be inefficient and something new is at play.
Defaultable bonds

As Black and Scholes (1973) and Merton (1973) observed, a firm's securities, its bonds and equity, all share the same risk, the risk of its asset value. Given the firm's value and its dynamics, we can then value its bonds in the same way as we value equity options. Merton (1974) and Black and Cox (1976) are among the first set of so-called structural models, which rely on the specific risk structure of corporate bonds with respect to its underlying asset to value them using arbitrage methods. More comprehensive models were further developed to incorporate richer risk structures embedded in corporate bonds. For example, Longstaff and Schwartz (1995) and Saa-Requejo and Santa-Clara (1999) allow interest rate risks, which can affect when a bond defaults and its value then. Richer debt structure, the cost of default and shareholders optimal financing and default choices are also considered by Leland (1994), Anderson and Sundaresan (1996), and Leland and Toft (1996), among others.

Structural models, coupled with specific description of the firm value dynamics, also impose certain behaviour on the event of default. The desire to have more flexibility in modelling the default event has led to the development of so-call reduced form models, for example, Jarrow and Turnbull (1995), Lando (1998) and Duffie and Singleton (1999). These models start by modelling the default process and recovery rate under the risk-neutral measure. From (1), the price of a defaultable bond with zero coupon and unit par value is given by

\[
P_t(T) = E_t^* \left[ e^{-\int_t^T r_0, sds} 1_{\{\tau > T\}} \right] + E_t^* \left[ e^{-\int_t^T r_0, sds} Z_\tau 1_{\{\tau \leq T\}} \right]
\]

(3)

where \( \tau \) denotes the default time, \( Z_\tau \) the recovery rate in the case of default and \( 1_{\{\cdot\}} \) is an indicator function. The implementation and evaluation of the reduced form models requires additional information on default events under both the risk-neutral and the statistical measures. Such information is scarce as default is relatively infrequent. However, these models become more applicable for credit derivatives when more securities related to the same default events became available.

Other derivatives

The application of arbitrage pricing finds its most fertile ground in valuing derivatives, which, together with the underlying asset, are close substitutes. Its success has fuelled the big bang of derivatives since the 1970s, which provided new areas for more applications of the theory. Commodity and financial futures, interest rate derivatives such as swaps, caps and swaptions, credit derivatives such as credit default swaps (CDS) and collateralized debt obligations (CDO) are major examples.

While no arbitrage as a theoretical principle is quite general, its usefulness in asset valuation remains a
practical matter. It applies to financial securities which are close substitutes, when market frictions are negligible. Its success in asset pricing as opposed to in pricing physical goods very much reflects the fact that financial securities are easy to trade and replicate and they are close in nature in the sense that their value all arises from their financial payoffs. Nonetheless, market frictions do exist. Moreover, except in certain instances, securities of interest are often not exact substitutes. The theory is much less definitive about how it extends to these situations.

Its limitations are evident even in areas where it was successful, such as equity options, bonds and other derivatives. Nagging deviations from arbitrage-based models, though arguably small, persist. The need to address these deviations tends to push for more complex models with more risk factors. However, a blind pursuit in this process might be losing not only the empirical ground, as data becomes less sufficient in supporting the models, but also the theoretical ground. The deviations may well reflect the influence of market frictions or other factors, which are beyond the ‘limits’ of arbitrage arguments. Another limitation of the arbitrage approach, perhaps a more fundamental one, is that it takes the risks and their risk premia, that is, the relevant states and the corresponding state prices, as given in establishing price relations among substitutable securities. From a broader perspective, it is important to understand the economic underpinnings of different risks and their pricing implications. Such an understanding may provide the basis to further improve arbitrage pricing models. More importantly, it will allow us to value assets more broadly.

Risk and return

The broader principle in asset pricing is market equilibrium, which requires that security prices must equate supply and demand. This approach is general since it focuses on how security prices are determined by economic fundamentals, which drive supply and demand. Its application, however, faces several challenges. We need to first specify what constitute the fundamentals. We also need to determine how these fundamentals influence the supply and demand for securities and ultimately their prices. Additional structure on the fundamentals is also needed before we can arrive at useful results. A key fundamental is the risk characteristics of asset payoffs. We start with the pricing equation (1). Suppose that given the state of the economy at \( t \), the conditional probability for state \( \omega \) at \( t+1 \) is \( p_t(\omega) \).

We can then rewrite (1) as

\[
P_t = \sum_{\omega} p_t(\omega) \frac{\varphi_t(\omega)}{p_t(\omega)} X_{t+1} = E_t[m_{t+1}X_{t+1}],
\]

where \( E_t \) is the expectation under the actual probability measure given the state at \( t \) and \( m_{t+1} \equiv \varphi_t(\omega)/p_t(\omega) \) is referred to as state price density or the stochastic discount factor (SDF). Realizing that \( X_{t+1}/P_t \equiv 1 + r_{t+1} \) where \( R_{t+1} \) is the security's return from \( t \) to \( t+1 \), we can also re-express (4) as
A slight variation of (5) gives a commonly used expression for the pricing equation (4):

\[ E_t[r_{t+1}] - r_{0,t+1} = -\text{Cov}_t[m_{t+1} / E_t[m_{t+1}], r_{t+1} - r_{0,t+1}], \tag{6} \]

where \( \text{Cov}_t \) denotes the conditional covariance. Equation (6) suggests that we can decompose an asset's risk into two components:

\[ r_{t+1} - r_{0,t+1} - (E_t[r_{t+1}] - r_{0,t+1}) = \alpha_t (1 - m_{t+1}) / E_t[m_{t+1}] + \nu_{t+1}. \tag{7} \]

The first component, which is correlated with the SDF, will influence the asset's expected return or its price. The second component, which is uncorrelated, does not. Such a decomposition clearly reveals that risks come in two types, 'priced' and 'not priced'. The amount of an asset's priced risk is measured by \( \alpha_t \), its covariance with the SDF, which determines its risk premium:

\[ E_t[r_{t+1}] - r_{0,t+1} = \alpha_t \sigma^2_{m,t}, \tag{8} \]

where \( \sigma^2_{m,t} \) is the conditional variance of the SDF. Knowing the SDF will allow us to specify the priced risk and its premium. Thus, the goal for a general asset pricing theory is then to determine the SDF. Two differently approaches have been followed in developing models for the SDF. The first approach is to start from the primitives of the economy such as asset payoffs and investors’ preferences, derive the asset demand (and supply) and finally arrive at the equilibrium SDF. The second approach is to start from the equilibrium, rely on certain properties of the equilibrium to arrive at the SDF. The first approach has more micro-texture to it and often leads to sharper specifications of the SDF, while the second approach allows more flexibility but with less microeconomic basis.
Factor models of the SDF

The well-known capital asset pricing model (CAPM) follows the first approach. Under the mean-variance framework of Markowitz (1952) and Tobin (1958), all investors will hold mean-variance efficient portfolios. Such a commonality in investors’ asset demand implies that, in equilibrium, the market portfolio, which represents the total supply of assets, must be a mean-variance efficient portfolio. This insight has led Sharpe (1964) and Lintner (1965) to identify the return on the market portfolio $r_{M,t+1}$ to be a proxy for the SDF:

$$1 - m_{t+1} / E_t[m_{t+1}] = b_{M,t}(r_{M,t+1} - E_t[r_{M,t+1}]),$$

which immediately leads to the CAPM:

$$E_t[r_{i,t+1}] - r_{0,t+1} = \beta_{iM,t}(E_t[r_{M,t+1}] - r_{0,t+1}),$$

(9)

where $\beta_{iM,t}$ is the market beta for asset $i$. Ross (1976a; 1976b) started directly from the risk structure of asset payoffs. By proposing a linear factor model for asset returns and requiring the absence of limiting arbitrages as an equilibrium condition, he obtained a factor representation for the SDF:

$$1 - m_{t+1} / E_t[m_{t+1}] = \sum_{k=1}^{K} b_{k,t}f_kt + 1,$$

(10)

which leads to the arbitrage pricing theory (APT):

$$E_t[r_{i,t+1}] - r_{0,t+1} = \sum_{k=1}^{K} \beta_{ik,t}\lambda_k,t$$

(11)
where $\beta_{ik,t} = \frac{\sigma_{ik,t}}{\sigma^2_k}$ is the ‘beta’ of asset $i$ on risk factor $k$ (that is, the regression coefficient of its return on $f_{k,t+1}$), $\sigma^2_k$ the conditional variance of factor $k$, $\sigma_{ik,t}$ is its conditional covariance with the return of asset $i$, and $\lambda_k = b_k \sigma^2_k$ its risk premium. Thus, both the CAPM and the APT can be viewed as the case when the SDF has a linear factor structure. The key distinction is that the CAPM identifies the market return as the SDF while the APT allows the SDF to be spanned by multiple factors.

Earlier empirical tests found some supporting evidence for the CAPM (see, for example, Black, Jensen and Scholes, 1972; Fama and MacBeth, 1973). Due to the noise in estimating expected returns and the difficulty to actually identify the market portfolio, questions regarding the strength of the support as well as the nature of these tests have left a strong need for more tests (see, for example, Roll, 1977). Further empirical exploration also reveals evidence that is at odds with the CAPM, at least on the face of it. Banz (1981) discovered the size effect that small stocks (measured by market capitalization) yield higher average returns than large stocks, after controlling for what the CAPM predicts. Basu (1983) reported the value effect that stocks with book values higher than their market values – the book-to-market ratio – yield higher average returns than stocks with lower ratios. In a comprehensive empirical analysis, Fama and French (1992) synthesized this evidence, demonstrating the weak explanatory power of the CAPM for the cross-section of stock returns as well as certain patterns they display.

The APT allows a richer structure than the CAPM. However, the fact that the theory itself does not identify the factors poses challenges to its empirical testing (see, for example, Shanken, 1982; Dybvig and Ross, 1985). Other means need to be used, theoretical or statistical, to identify the factors. Earlier empirical tests along this route find some supportive evidence (for example, Chen, Roll and Ross, 1986) but leaves more to be desired. Relying on statistical analysis, Connor and Korajczyk (1988) use principal components and Lehmman and Modest (1988) use factor analysis to empirically identify the factors. The evidence in support of the APT is, however, mixed. Exposures to the empirically identified factor risks explain only part of the cross-sectional variation in average returns. Based on the observed average returns, Fama and French (1993) propose to use firm characteristics such as size and book-to-market ratio to form portfolios, whose returns are then used to identify risk factors in addition to the market. They show that the size factor (the difference in returns from small and large stocks), the value factor (the difference in returns from high and low book-to-market stocks), plus a broad market index can explain most of the cross-sectional variation in returns from portfolios sorted on by their loadings.

What to take away from the empirical results remains a matter of active discussion. The appeal of the CAPM has led to continuous efforts to reconcile it with the empirical evidence. All empirical implementations of the CAPM use a market index as a proxy for the market portfolio, which leaves the possibility of misidentifications. The lack of significant gains from improving market proxies based on traded assets, as Stambaugh (1982) and Shanken (1987) have shown, has led to the inclusion of non-traded assets. Using labour income growth to measure the return on human capital, Jagannathan and Wang (1996) showed that including human capital in the market proxy may help to increase the explanatory power of the CAPM.

In general the CAPM gives a conditional relation between risk, as measured by an asset's conditional beta, and its conditional risk premium, as (9) clearly indicates. However, earlier tests are mostly
unconditional, looking at the relation between assets’ unconditional beta and their unconditional premia. By allowing time-varying betas and the market premium, more tests are directed at the conditional version of the CAPM, notably Harvey (1989), Shanken (1990), Jagannathan and Wang (1996), and, more recently, Wang (2003) and Petkova and Zhang (2005). How far the added flexibility from the conditional variables and their impact can lead us remains to be seen, as Lewellen and Nagel (2006) demonstrate. More fundamental questions exist about the test of conditional CAPM. For example, what are the appropriate conditioning variables implied by the model? Without knowing this, how do we distinguish the impact of conditioning variables from additional risk factors?

The added flexibility in the empirical multi-factor models like that of Fama and French (1992; 1993) also leave plenty of room for alternative interpretations. It is open to potential dangers of data snooping, as Lo and MacKinlay (1990) and Kothari, Shanken and Sloan (1995) point out. It can also be a result of misidentification of the true risk factor even when the conditional CAPM holds (see, for example, Berk, Green and Naik, 1999; Gomes, Kogan and Zhang, 2003).

The intertemporal CAPM

Merton (1973) developed an intertemporal version of the CAPM (ICAPM), which shows that time-varying market conditions give rise to dynamic risk factors in addition to the risk of the market portfolio. In particular, if we let the first factor in (10) be the return on the market portfolio, the other factors will represent the state variables driving the market conditions. The ICAPM contains the conditional CAPM as the special case when the dynamic risks carry no premium. In this sense, any test of the conditional CAPM can be viewed as a test of the ICAPM with additional restrictions on risk premia. However, in the ICAPM, the dynamic risk factors are taken as given, not derived from the theory. The pricing relation, in the form of (11), comes as an equilibrium condition under a given form of price dynamics rather than an equilibrium outcome in terms of economic primitives. In this regard, the ICAPM has more in common with APT than with the classical CAPM.

The ICAPM provides a useful framework for analysing risk and return in an intertemporal setting. Its empirical implementation has been limited until recently. Tests of the APT, which also allows multiple risk factors, were often interpreted as tests of the ICAPM, since both models allow plenty of flexibility in identifying these factors. However, such a view leaves out the additional implications from the ICAPM on the intertemporal properties of the dynamic risks. Lo and Wang (2006) have developed a version of the ICAPM in which the time-varying market risk premium captures the dynamic risk. Using the cross-sectional data on trading volume, they empirically identify the dynamic risk factor and test its power in explaining the time series and the cross section of asset returns. Ang et al. (2006) and Adrian and Rosenberg (2006) also test a version of the ICAPM in which the market volatility is a dynamic risk factor.

By identifying risk factors other than the market proxy as dynamics risks, the ICAPM gives more guidance on the properties of these additional risk factors, in particular, their correlation structure with the underlying state variables. These properties may help the empirical construction of these factors and their tests. More work along this direction is called for.
Consumption-based CAPM

The APT and the ICAPM focus on the statistical properties of risks, in particular, their correlation structure, both in cross-section and time series. But from a pricing perspective, their economic properties are particularly important. Clearly, investors’ attitude towards different risks also matter. For an investor, an asset is riskier if its return co-varies more strongly with his future marginal utility. Using the same setting as Merton's ICAPM, Breeden (1979) showed that for pricing purposes, all risks can be collapsed into one, measured by assets' covariance with aggregate consumption (see also Rubinstein, 1976). As a result, the beta of an asset with respect to aggregate consumption, the consumption-beta, determines its risk premium. This is the so-called consumption-based CAPM (CCAPM).

Let us start with the principle of market equilibrium, namely, asset prices must equate demand and supply. Since demand and supply for assets are determined by the fundamentals through market participants’ optimizing behaviour, so will be their equilibrium prices. Consider a representative investor in the market who has a time-separable, expected utility function $u(c_t)+\rho u(c_{t+1})$. The optimality of his asset holdings requires that $u'(c_t)P_t=E_t[\rho u'(c_{t+1})X_{t+1}]$ or

$$1 = E_t \left[ \frac{\rho u'(c_{t+1})}{u'(c_t)} (1 + r_{t+1}) \right].$$

Comparing (12) with (5), it is apparent that market equilibrium imposes additional restrictions on asset prices. In particular, it relates the stochastic discount factor to the marginal utilities of the representative investor: $m_{t+1}=\rho u'(c_{t+1})/u'(c_t)$.

The simple structure of the CCAPM and its economic appeal has generated a lot of interest in its empirical implementation, lead by Breeden (1980), Grossman and Shiller (1981) and Hansen and Singleton (1983). The focus has been on two fronts, the behaviour of aggregate prices and the cross section of asset returns. The procedure typically involves an estimation of the consumption process and certain specification of the marginal utility function for the representative investor. Combining the two gives an estimate for the SDF, which can then be used to test its pricing implications.

From (7) and (8), Hansen and Jagannathan (1991) established the following condition on the SDF:

$$\sigma_t(m_{t+1}) / E_t[m_{t+1}] \geq \frac{E_t[r_{i,t+1}] - r_0,t+1}{\sigma_t(r_{i,t+1} - r_0,t+1)},$$

(13)
where $i$ denotes any traded asset. The right-hand side is asset $i$'s Sharpe ratio. Thus, the maximum Sharpe ratio of traded assets gives a lower bound for the volatility of the SDF. In the CCAPM, the volatility of the SDF comes from the volatility of aggregate consumption. However, the aggregate consumption data seems very ‘dull’, exhibiting close to i.i.d. growth with very low volatility. This poses certain challenges to the simple forms of the CCAPM. In order for the SDF to have the desired properties, the marginal utility function has to do all the work. Using a time-separable utility function with constant relative risk aversion, Mehra and Prescott (1985) show that the implied risk aversion has to be very high to yield a volatility of the SDF that exceeds the bounds posted by the Sharpe ratio of the market index. Such a high implied risk aversion seems inconsistent with other evidence on individual risk preferences, leaving us with what is referred as the ‘equity premium puzzle’. Applying the model in such a manner quickly led to many more ‘puzzles’. Real interest rates have been low, at least in developed markets, which is inconsistent with the observed consumption growth and a high risk aversion (for example, Weil, 1989). Also, the low variability in the SDF and the low observed variability in aggregate dividend growth are at odds with the high observed volatility in aggregate asset prices or asset returns (for example, LeRoy and Porter, 1981; Shiller, 1981; Campbell and Shiller, 1988).

Many efforts have been made to reconcile the volatility on the SDF implied by asset returns and the consumption data, mostly along three directions. The first is to improve on the measure of consumption risk. For example, Rietz (1988) suggests that the small probability events like severe drops in consumption may be important risks not fully captured by the data. Bansal and Yaron (2004) propose to use the variability in long-horizon consumption growth as a measure of risk. These explorations are useful, but also stretches the boundaries of the data (for example, a finite sample period will limit the length of the horizon).

The second direction is to allow for more general preferences. The simple form of utility function assumed for the representative investor in early studies is probably too restrictive. For example, even if the preferences of individual investors are restricted to simple forms – such as those exhibiting constant relative risk aversion – a certain degree of heterogeneity will lead to a more complex preference at the aggregate level, which depends on the relative importance of each investor (see, for example, Dumas, 1989; Wang, 1996; Chan and Kogan, 2002). As more flexibility is needed in fitting the data, different forms of state-dependent preferences were considered, notably Sundaresan (1989), Abel (1990), Constantinides (1990), Epstein and Zin (1991), and Campbell and Cochrane (1999), allowing factors like habit, aggregate consumption, and the timing of risk resolution to influence behaviour. The flexibility this approach enjoys also comes at certain costs. On the theory side, the aggregation properties of simple preferences are lost, which leads to questions about the link between what is assumed for the representative agent and the micro justifications used to motivate the preference structure. On the empirical side, there is a lack of discipline in identifying the true preference structure.

The third direction is to allow for certain forms of market imperfections. This approach opens up many possibilities but goes beyond the neoclassical setting. We will return to market imperfections in the next section.

The CCAPM has also been applied to explain the cross section of asset returns, as the other pricing models. From $m_{t+1} = \rho \ u'(c_{t+1})/u'(c_t)$, $m_{t+1}$ can be approximated by
\[ 1 - m_{t+1} / E_t[m_{t+1}] \approx b_t(\Delta c_{t+1} - E_t[\Delta c_{t+1}]), \]

(14)

where \( \Delta c_{t+1} \) denotes the aggregate consumption growth. The cross section of asset returns are then given by a formula similar to (9) with the exception that the beta is now replaced by the consumption beta, the beta of assets’ payoff with respect to aggregate consumption growth. Lettau and Ludvigson (2001) have implemented the CCAPM in this form and find that it can explain the cross-sectional pattern in portfolio returns as presented by Fama and French (1992; 1993). Bansal, Dittmar and Lundblad (2005) also find encouraging signs in using assets’ betas of their long-run dividends with respect to the long-horizon consumption growth to explain the cross section of their returns.

The appeal of the consumption-based CAPM mainly comes from its simple economic structure. However, its validity relies on strong assumptions about the behaviour of market participants and the structure of the market. It is unclear how much the behaviour of major market participants, such as institutional investors and delegated money managers, is related to consumption. It is also unclear whether the existing market structure allows the kind of efficiency in risk allocation and the proper aggregation needed for the CCAPM. Market imperfections will cause deviations from these assumptions, which may well contribute to the challenges in fitting the model to data. On the empirical side, it is worth pointing out that estimates on risk premium and consumption risk are fairly rough.

Market efficiency and anomalies

The neoclassical theory of asset pricing relies on two simplifications, namely, frictions are negligible in financial markets and information is reasonably homogenous among market participants. While the second simplification is less relevant for arbitrage pricing, both are needed for equilibrium-based pricing models. The idea that market participants have similar information regarding future asset payoffs is closely related to the notion of financial markets being informationally efficient, a hallmark of neoclassical finance. The efficient market hypothesis (EMH) postulates that market prices fully reflect all the relevant information available in the market (see, for example, Fama, 1970). The intuition behind the hypothesis is simple, very much in the spirit of no arbitrage. Any available information that is not properly reflected in prices will be taken advantage of by profit-seeking market participants, sometimes referred to as arbitrageurs, until prices fully adjust for it.

The exact formulation of the hypothesis, however, involves important subtleties, including the precise definition of relevant information and its reflection in prices. Perhaps the simplest formulation of EMH is to assume the presence of arbitrageurs with unlimited risk tolerance and access to capital (see, for example, Samuelson, 1965). This then implies that current prices are unbiased forecasts of future prices (adjusted for time value). Event studies found broad support for prices reacting quickly and quite accurately on average to public news. Extensive tests of predictability found the evidence to be largely consistent. Nonetheless, deviations exist. A natural way to account for the deviations is to relax the condition of risk-neutrality and properly account for risks. After all, (imperfect) predictability does not
imply arbitrage, as apparent in Lucas (1978). But such an approach immediately leads us to the choice of a particular method of risk adjustment or an asset pricing model. Tests of EMH then becomes tests of the asset pricing model used, which complicates the matter substantially.

Perhaps as a reaction to the incredible success of the EMH, the initial empirical support was followed by the recording of an increasing number of exceptions, which are also referred to as anomalies. The earlier set of results is about the predictability on equity returns. DeBondt and Thaler (1985) studied long-horizon returns over three to five years. They examined two portfolios, a winner portfolio and a loser portfolio, which consist of stocks with higher or lower than market adjusted returns, respectively, and found that the winner portfolio yields lower returns in the following years and the loser portfolio yields higher returns. Fama and French (1988) and Poterba and Summers (1988) also found negative serial correlation in long-horizon market index returns. While it is harder to make inferences from long-horizon returns as the sample size becomes relatively small, Lo and MacKinlay (1988) and others have documented positive serial correlation in market index returns over weekly and monthly horizons. This evidence suggests that stock prices need not follow random walks as the weak form of the EMH claims. It was also documented that returns of large stocks can predict returns of small stocks on weekly and monthly basis, the so-called lead–lag phenomenon (see, for example, Lo and MacKinlay, 1990). Bernard and Thomas (1989), extending the earlier work by Ball and Brown (1968) and Jones and Litzenberger (1970), have presented convincing evidence of the under-reaction of stock prices to earnings announcements, which is later called the ‘post earnings announcement drift’. Many studies, such as Campbell and Shiller (1988) and Fama and French (1988), have also suggested that financial ratios such as dividend yield can predict aggregate market returns. These results are certainly at odds with the semi-strong form of the EMH, which requires no predictability of asset returns using public information. Jegadeesh and Titman (1993) take the winner–loser comparison to individual stocks over shorter horizons. By sorting stocks on returns over past one or two quarters, they show that winner portfolio continues to yield higher returns while loser portfolio yields lower returns, a phenomenon called ‘momentum’. If we take long positions in winners and offsetting short positions in losers, the average return can be substantial. This is particularly intriguing as we expect diversification and cancellation to greatly limit the net risk exposure of this strategy.

The search for predictability in stock returns has also gained momentum of its own. Different variables were found to have predictive power for equity returns such as trading volume (for example, Gervais, Kaniel and Mingelgrin, 2001), short interest (for example, Jones and Lamont, 2002), share repurchases (for example, Ikenberry, Lakonishok and Vermaelen, 1995), dispersion in analysts forecasts (for example, Diether, Malloy and Scherbina, 2002), and transactions of institutional investors (for example, Chan and Lakonishok, 1995). The list goes on and may continue to grow. However, several caveats always accompany these findings. First, their significance, both statistical and economical, is quite moderate. Second, their persistence over time needs further testing. Third, more work is desired to distinguish them from potential spurious findings due to data mining.

A corollary of the EMH is that news on future payoffs or the SDF move prices. Roll (1988) showed that \textit{ex post} public news can only explain a fraction of price movements of individual stocks over daily to monthly horizons (see also Roll, 1984a). This result parallels what is observed at the aggregate level by LeRoy and Porter (1981) and Shiller (1981), that is, aggregate market indices exhibit a volatility much
higher than the volatility in aggregate dividends in the data. But it is more striking as risk considerations seem to be less important over short horizons. The inability to explain price movements even \textit{ex post} has been viewed as a serious challenge to neoclassical theory, in particular the EMH. One possible explanation is that much of the price movement is driven by private news which is not captured by the information set used in the empirical studies. Another is the influence of time-varying risk which may contribute to movements in the discount factor.

To avoid the complication of risk, some studies have focused on more direct tests on the foundation of the EMH, the principle of no arbitrage. A longtime puzzle along this line is the significant discount on closed-end funds from their net asset values (see, for example, Malkiel, 1977; Lee, Shleifer and Thaler, 1991). In violation of the law of one price, anomalies of this nature document price differences between two seemingly identical assets. Other well-known examples include the price differences between the on-the-run and the off-the-run Treasury bonds with close to identical payoffs and shares of the same company with the same dividend streams but traded on different exchanges. A pair trade, to buy the security with lower price and sell the price with the higher price, which requires no private information and substantial capital but yields sure profits, seems to present an arbitrage opportunity. Obviously, the persistent existence of these price anomalies suggests that there is more to what meets the eye. For example, Ross (2002) has shown that management fees contribute significantly to the close-end discounts.

How to interpret the empirical anomalies, assuming their presence, requires further assessment. In the whole, as the name suggests, anomalies do not overweight the vast positive evidence in support of the EMH. Additional factors also need to be included in the consideration. First, predictable patterns in returns or deviations from the law of one price documented in the data are not equivalent to actual profitable opportunities in the market. Frictions in the market need to be taken into account (see, for example, Tuckman and Vila, 1992). Second, strategies attempted at taking advantage of these anomalies always involve certain risks in the presence of frictions. The dynamic nature of these risks make them harder to assess (see, for example, Merton, 1981; Dybvig and Ross, 1985).

Nonetheless, these anomalies, together with deviations in asset returns from neoclassical asset pricing models, do pose a challenge to our understanding of how the market works and how asset prices are determined. It is clear that the notion of market efficiency need to be examined in an equilibrium asset pricing framework, which allows for information asymmetry (and possibly market frictions). Grossman (1976) and Grossman and Stiglitz (1980) demonstrated that such a framework is much richer than the simple form of market efficiency implies, for both the behaviour of asset prices and the importance of information asymmetry in determining it. However, many of the implications of this framework needed to be fleshed out, which became a fertile ground for recent work.

\textbf{Market imperfections}

Limitations of the neoclassic theory have led to efforts to incorporate imperfections into our analysis, in particular, frictions and asymmetric information. Imperfections influence how the market operates at two levels. At a superficial level, imperfections directly affect why and how investors trade in the market, which ultimately determine asset prices. At a more fundamental level, imperfections also determine the institutional structure of the market itself as well as the economic characteristics of major
Market frictions

Despite the relative ease of transactions in the financial market, frictions exist. They range from simple trading costs such as commissions and bid–ask spreads to price impact, costs and restrictions on short sales, constraints on borrowing to simple inability to trade-certain claims or contracts. They also include the costs of setting up trading operations, gathering and processing information, maintaining market presence and the costs of introducing a new security, creating and maintaining a market and providing liquidity for it. Since frictions hinder the efficient allocation of capital in the market, their impact is closely related to the notion of liquidity or illiquidity.

Factoring in market frictions sheds new light on the empirical anomalies. Many of them do not provide profitable trading opportunities when trading costs are included. For example, Krishnamurthy (2002) finds that costs in financing the arbitrage between the on-the-run and off-the-run bonds are substantial and outweigh the potential gains. Lesmond, Schill and Zhou (2004), among others, show that momentum in individual stocks is not profitable after adjusting for trading costs. These results are comforting for the EMH and in many ways not surprising. But they do not settle all the questions. In particular, why are these patterns there in the first place, and how do they fit into the overall asset pricing framework?

The general impact of market frictions on asset prices is hard to analyse as they make the behaviour of market participants, the interaction among them and the equilibrium outcome very complex. Recent studies have mainly focused on how specific frictions such as transactions costs, short-sale constraints and borrowing constraints may influence three aspects of asset prices, the overall level, the cross section and dynamics.

Relying on partial equilibrium arguments, earlier work has examined how transactions costs may influence the level of asset prices. For example, Constantinides (1986) considered the equivalent price adjustment to offset the welfare loss from proportional transactions costs and found that its magnitude is of higher order of the cost and quantitatively insignificant. Amihud and Mendelson (1986) calibrated the present value of implied transactions costs using observed stock trading volume and showed it to be substantial. What is not fully incorporated in the partial equilibrium analysis is how costs affect the actual equilibrium. Vayanos (1998) considered a general equilibrium model in which investors trade for life-cycle reasons and reached the same conclusion as Constantinides. This is not surprising since life-cycle considerations generate little trading and consequently transactions costs have a limited effect.

When high levels of trading are needed, as observed in the market, the situation can be different. Unable to trade frequently, investors have to bear additional risks they could otherwise unload in the market, which can significantly alter their behaviour. Allowing high frequency trading needs compatible with observed volume, Lo, Mamaysky and Wang (2004) show that moderate fixed transactions costs can have a significant impact on investors’ asset demand and the resulting equilibrium prices.

In the context of consumption-based CAPM, incorporating market frictions can potentially help to reconcile a high-risk premium with a smooth consumption path (see, for example, He and Modest, 1995;
Luttmer, 1999). The mechanism is quite straightforward. In the presence of frictions, the equality in (12) is in general replaced by inequalities. For example, with proportional transaction costs $\kappa$ and no short sales and borrowing, (12) becomes

$$\mathbb{E}_{t} \left[ \rho \frac{u'_{t+1}(c_{t+1})}{u'_{t}(c_{t})} (1 + r_{t} + 1) \right] \leq \frac{1 + \kappa}{1 - \kappa},$$

(15)

which loosens the link between prices and marginal utilities. However, using an equilibrium model calibrated to the trading needs of households' heterogeneous labour income risks, Heaton and Lucas (1996) found that transactions costs have a limited effect on the equilibrium risk premium because trading is very moderate in consumption-based models, but trading restrictions such as short-sale and borrowing constraints can potentially have larger effects (see also Constantinides and Duffie, 1996; Constantinides, Donaldson and Mehra, 2002; Brav, Constantinides and Geczy, 2002).

How market frictions affect the cross section of asset returns is a challenging issue. Merton (1987) considered an extension of the CAPM in which investors invest only in a subset of assets due to the information cost of learning about them. He showed that the segmentation of the market leads to modifications to the CAPM which exhibit a complex structure, depending on investor preferences, endowments and the nature of the segmentation. Here, more empirical guidance can be helpful. Using various measures of liquidity for individual stocks, Brennan and Subrahmanyam (1996) have documented an empirical link between liquidity and average returns. Liquidity of individual assets seems to exhibit commonalities (see Chordia, Roll and Subrahmanyam, 2000). This suggests the possibility that liquidity may contain factor risks. Assuming the CAPM to hold net of costs, Acharya and Pedersen (2005) allowed the effective costs in asset trading to be correlated with market returns to help explain the deviations in observed, pre-cost returns from the CAPM. Pastor and Stambaugh (2003) directly include the market average of a liquidity measure proposed by Campbell, Grossman and Wang (1993) as an additional risk factor in the SDF and find that it can enhance the explanatory power of multifactor models. Much is needed for the theoretical basis of the connections between frictions and the cross section of asset returns.

From a theoretical point of view, market frictions can contribute to the dynamic properties of asset prices. When flow of capital is costly, for example, the risk tolerance of marginal investors may increase and become dependent on market conditions, which can lead to predictable asset returns and more volatile prices. For example, Grossman and Vila (1992) showed that borrowing constraints can force risk-neutral investors to behave in a risk-averse manner. Grossman and Miller (1988) emphasize the imperfect mobility of capital by imposing costs on maintaining market presence and demonstrate that these costs lead to limited risk tolerance in the market and mean reversion in returns when trades are not perfectly synchronized. Using return and volume to infer order imbalances in the market, Campbell,
Grossman and Wang (1993) find that they indeed generate return reversals. Pagano (1989) and Allen and Gale (1994) also argue that costly participation in the market can exacerbate price volatility driven by demand shifts over long horizons. Huang and Wang (2006a; 2006b) further point out that low capital mobility in the form of costly participation in the market can lead to endogenous order imbalances. Moreover, the endogenous order imbalances tend to be asymmetric and large when they occur, leading to market crashes, fat-tails in asset returns and return reversals. There is now growing empirical evidence suggesting the low mobility of capital (for example, Coval and Stafford, 2006; Mitchell, Pedersen and Pulvino, 2007).

Constraints can also influence asset price dynamics. E. Miller (1977) and Harrison and Kreps (1979) have shown that short-sale constraints can inflate asset prices as they prevent short positions and thus can increase asset demand. Scheinkman and Xiong (2003) further demonstrated that short-sale constraints can lead to bubbles and high volatility in prices. Basak (1995) and Grossman and Zhou (1996) show that wealth constraints on market participants can lead to positive correlation between their risk tolerance and price movements. Such a correlation can contribute to higher and more persistent price volatility and mean reversion in returns.

Frictions have also been considered in explaining many other pricing anomalies. For example, Duffie (1996) and Vayanos and Weill (2006) examine how costs in trading from searching in the market can help to explain the price premium and the specialness (that is, high borrowing cost) of on-the-run Treasury bonds. Chen, Hong and Stein (2002) attempt to associate individual stock return momentum with short-sale constraints. Short-sale constraints can also help to explain empirical findings relating short interests, volume, and dispersion of analysts’ forecasts to future returns. Kyle and Xiong (2001) suggest that capital constraints can be the cause of market contagion, which refers to negative co-movements across markets in the absence of negative news affecting both markets.

Although most of the literature has focused on how frictions in the market affect asset demand and consequently prices, some work has also examined the asset supply side, in particular how frictions in firms’ real investments may affect the payoffs of corporate securities and their equilibrium prices. For example, Kogan (2001) shows that irreversibility in firms’ real investments can lead to time-varying stock risks, which can help to explain their returns. Zhang (2006) examines potential links between the time-varying risks from the real side and several empirical anomalies.

The empirical and theoretical work so far suggest that market frictions can be an important factor in determining asset prices. However, they are mainly indicative. The models and the phenomena they address tend to be quite specialized. A more general framework capable of providing both a qualitative characterization and a quantitative assessment of the importance of frictions on the market behaviour is still lacking. This in part reflects the complexity of the problem. In the presence of frictions, the behaviour of market participants and the interactions among them become much more involved, and the simple aggregation properties assumed in the neoclassical framework no longer hold. Whether a general theory will eventually emerge or we have to settle for a collection of specialized models to deal with each individual phenomenon remains unclear at this point.

Information asymmetry
Information is a critical force driving financial markets. As is evident from (4), it is the expectation of market participants of discounted future cash flows that determines asset prices. In general, information is asymmetric among different market participants. Under the extreme situation when the market is competitive and sufficiently complete, the price system will be efficient in aggregating and revealing the information of all participants in the market, which gives a strong form of the EMH (see, for example, Grossman, 1976; Milgrom and Stokey, 1982). However, in the presence of frictions, in particular certain forms of market incompleteness, prices fail to be a sufficient static for the information in the market (see, for example, Grossman and Stiglitz, 1980; Hellwig, 1980; Diamond and Verrecchia, 1981). While information asymmetry also contributes to the existence of frictions, most of the analysis takes certain form of frictions as given and examines the effect of information asymmetry.

Information asymmetry substantially enriches the possible behaviour of asset prices. In general, current prices do not reveal all the information in the market. This immediately implies that past prices or other public information can provide additional information over current prices (see, for example, Brown and Jennings, 1989; Grundy and McNichols, 1989). More importantly, under asymmetric information, the behaviour of market participants will depend not only on their own information but also on their perception of the information others may have. In an intertemporal equilibrium setting, Wang (1993) demonstrates that information asymmetry can have a broad impact on asset prices, ranging from increasing the risk premium and price volatility to generating rich patterns in return dynamics. Allen, Morris and Shin (2006) further show that speculation on what others think may lead to price bubbles. While information asymmetry increases the flexibility of the theory, its impact is harder to identify empirically as private information, by its nature, is mostly unobservable. By comparing price volatility on days when the stock market is open for trading with days when it is closed, French and Roll (1986) demonstrated convincingly the important role private information plays. Wang (1994) proposed using the joint behaviour of price and volume to examine the effect of information asymmetry (see also He and Wang, 1995). Empirical work along this line, notably, Llorente et al. (2002), have found supporting evidence for this approach. Recently, more detailed data on individual investors’ trading records has become available (for example, Odean, 1998; Grinblatt and Keloharju, 2000), which will allow more direct tests on the importance of information asymmetry. For example, following a segment of the market, Evans and Lyons (2002) find that order flow in the currency market contains significant amount of information.

Another challenge to the neoclassical theory is market crashes, that is, large price drops without significant macro news. If the prices before and after a crash both reflect the market's expectation of discounted future cash flows, either the discount rate or the expectation (or both) must have changed during crash. As discussed earlier, liquidity effect can cause the discount rate to vary abruptly, as shown by Huang and Wang (2006b). Alternatively, the market expectation can change, reflecting changes in the information it contains. In the absence of big exogenous news, this information must come from the private information investors already possess. Various models have been proposed to explain market crashes, including Grossman (1988), Gennette and Leland (1990), Bikhchandani, Hirshleifer and Welch (1992) and Romer (1993). These models typically allow both information asymmetry and market frictions, such as restrictions on what and how to trade, which prevent private information from being fully reflected in market prices. An unsettling issue for some of these models is the symmetry in large
price movements they produce, that is, equal likelihood of market crashes and surges. Asymmetry in favour of crashes can arise when frictions of asymmetric nature are present, such as borrowing constraints (for example, Yuan, 2005) and short-sale constraints (for example, Bai, Chang and Wang, 2006).

With regard to the impact of information asymmetry on return cross section, we face a similar situation as with frictions. The theory loses its tractability very quickly. Using a simple setting similar to that of the CAPM, Admati (1985) demonstrated that, under information asymmetry, the behaviour of equilibrium prices becomes very complex and sensitive to the information structure. We have not moved much beyond this point.

How information influences prices is a central issue in asset pricing. Existing work points to important channels for these influences, but the analysis is far from complete. On the one hand, the models so far are quite simplistic, especially in capturing the nature of information asymmetry in the market, and richer models are needed. On the other hand, even models with simple forms of information asymmetry are easily lost in their complexity. Both empirical and methodological breakthroughs are needed here.

**Market microstructure**

Many frictions are endogenous. A lot of effort has been devoted to studying how certain frictions, in particular liquidity, are determined in the market through the actual trading process, which is also referred to as the market microstructure (Garman, 1976). Despite its sophistication, the trading processes in the financial market are far more complex than what is assumed in most of the theoretical models, that is, through a Walrasian auction. The trading process also differs across different markets, ranging from over-the-counter markets and centralized exchanges with specialists to electronic limit order books, and constantly evolves over time. Several questions arise. How does a particular trading process influence the ease of trading or liquidity, investors’ trading behaviour, and the properties of prices? How does it influence the efficiency of the market and overall asset valuation? What determines the form of the trading process in a given market and how it evolves?

A large body of work focuses on how market-makers, who provide liquidity by absorbing transitory order imbalances, influence effective trading costs and high-frequency price dynamics. Market-makers’ behaviour depends on the costs they face, which have two components: the cost of holding an inventory and the cost of adverse selection when trading against better informed investors. Earlier analysis emphasized the former. Attributing the inventory cost to the risk in the value of inventory, Stoll (1979) showed that the effective trading cost, as measured by the bid-ask spread, increases with competitive market makers’ risk aversion and the volatility of asset value (see also Amihud and Mendelson, 1980). Roll (1984b) developed an empirical measure of the effective bid-ask spread and found it to be nontrivial for most individual stocks. Later attention has turned to the effect of adverse selection. Glosten and Milgrom (1985) showed how the existence of informed trades contributes to the bid-ask spread. Kyle (1985) demonstrated how an insider’s strategic behaviour hinders the informational efficiency of the market and reduces its liquidity. Similar analysis have been carried out for markets organized as a limit order book, such as in Copeland and Galai (1983), Rock (1990) and Glosten (1994). High frequency data on quotes and trades made it possible for extensive studies of the behaviour of trading and prices in different markets, following the intuition developed in theory, including Glosten...
and Harris (1988), Hasbrouck (1991), Madhavan and Smidt (1993), Biais, Hillion and Spatt (1995), and Lyons (1995). Imperfect competition among market makers also leads to additional complexity in the supply of liquidity (see, for example, Christie and Schultz, 1994; Barclay et al., 1999; Wahal, 1997; Ellis, Michaely and O’Hara, 2002). Additional theoretical work has been directed at how market-makers behave strategically in their liquidity provision under different trading processes, notably Glosten (1989), Foucault (1999), Vayanos (1999), and Goettler, Parlour and Rajan (2005).

Although most of the theoretical analysis on microstructure has focused on centralized markets, some considers the over-the-counter (OTC) markets, which by some measures are more common. Duffie, Garleanu and Pedersen (2005) develop a search-based model for the OTC market. It was then applied to several markets such as securities borrowing (Duffie, Garleanu and Pedersen, 2002) and Treasury bonds (Vayanos and Weill, 2006).

Market microstructure effects provide new insights on market behaviour at high frequency. For example, Admati and Pfleiderer (1988) and Foster and Viswanathan (1990) considered how traders’ strategic behaviour in response to the liquidity in the market can help to explain intraday variations in trading volume and price volatility (see also Hong and Wang, 2000, for alternative explanations). To the extent that market microstructure affects transactions costs in the market, it also influences asset prices in general, as we discussed earlier (see also O’Hara, 2003).

Many studies have also compared the different ways trading is organized, in particular how different market organizations may affect their liquidity provision and informational efficiency. For example, Copeland and Galai (1983) illustrated certain benefits of call auctions. Grossman (1992) examined the efficiency of upstairs market for block trades. Glosten (1994) discussed the advantage of an electronic limit order book. Seppi (1997) considered the impact of competition between a limit order book and a specialist when they coexist. Direct empirical comparisons of different trading mechanisms are difficult as they are usually adopted for different markets. But the general evidence is clear: market behaviour does vary with the actual trading process (for example, Amihud and Mendelson, 1991; Ready, 1999; Goldstein and Kavajecz, 2000; Bessembinder, 2003; Boehmer, Saar and Yu, 2005).

Although a lot has been learned about market microstructure, more remains to be learned. Many factors are at play and only a few are considered at a time, both theoretically and empirically. Their relative importance is hard to gauge empirically to allow for possible simplification. It remains a question why a given market is organized in a certain fashion. A better understanding of the precise nature and the magnitude of its impact on asset valuation and market efficiency is also needed.

From a broader perspective, there is also the question on the overall market structure (such as what securities are traded and why), which we may refer as market macrostructure. Most of the neoclassical theory takes it as given. But the dramatic evolution of the market, driven by a flood of innovations in finance and advances in technology and changes in the global economy, has forced researchers to think hard about this question. Some preliminary work has emerged in addressing this question. Allen and Gale (1988) consider the choice of firms in issuing securities when taking into account its impact on market structure and the resulting prices. Duffie and Rahi (1995) examine how exchanges decide on the derivative contracts to offer. Huang and Wang (1997) analyse how the introduction of new securities may influence the overall informational efficiency of the market. Of course, a significant number of
financial transactions are carried out through financial intermediaries rather than in the form of financial securities. Allen and Gale (2004) further explore the interplay between the two. Despite the importance of this question, the work so far is extremely primitive and in many ways merely serves to keep the question in play.

**Behavioural finance**

In the search for alternative explanations of asset pricing anomalies, attention has also turned to some of the basic assumptions of the neoclassical theory. The absence of arbitrage and the notion of efficient markets rely on the assumption that marginal investors in the market are not hindered by market frictions. The work on frictions has attempted to relax this assumption. Equilibrium models of asset pricing further adopt the assumption that average investors behave ‘rationally’. However, the notion of rationality is an ambiguous one. Earlier models describe rationality in the form of expected utility, where the expectation is taken under the actual probability measure, for example, in the form of von Neumann and Morgenstern (1944). This implies that an investor's belief about market behaviour is consistent with its true behaviour. In addition, the utility function is assumed to depend only on the level of consumption. In a simple form, an investor's behaviour is described by the following expected utility

\[
u_t(c_t) + \mathbb{E}_t[u_{t+1}(c_{t+1})] = u_t(c_t) + \sum_\omega p(\omega) u_{t+1}(c_{t+1}),
\]

where \(p(\omega)\) is the actual probability for a future state \(\omega\) and \(c_{t+1}\) is the level of future consumption. For simplicity, here we assume time-separable utility function and symmetric information. (In the case of asymmetric information, \(p(\omega)\) becomes the probability conditional on the investor's information.) Since its justification is more normative than positive, this form of rationality has attracted many criticisms from very earlier on, notably, Allais (1953), Ellsberg (1961), Kahneman and Tversky (1974). Deviations from this simple form of rationality have gained prominence in various attempts to explain market anomalies. Since these explanations are mostly based on various assumptions on investor behaviour, this area of research has gained the name of behaviour finance.

Most of the evidence against the simple form of rationality is from laboratory experiments on human subjects with hypothetical prospects or small-stake choices. It was documented that subjects often fail to form objective and consistent probabilistic assessments, exhibiting patterns like overconfidence (for example, Fischhoff, Slovic and Lichtenstein, 1977; Weinstein, 1980), belief perseverance, and anchoring (Kahneman and Tversky, 1974). When facing gambles with stated probabilities, subjects’ choices are incompatible with the expected utility, as documented by Kahneman and Tversky (1974). In addition, when confronted with outcomes with unknown probabilities, subjects’ choices cannot be reconciled with a consistent probabilistic assessment of the possible outcomes (for example, Ellsberg, 1961). Knight (1936) referred to this situation as uncertainty as opposed to risk, for which probabilities are known.
The richness in these behavioural variations, when used to describe investor behaviour, gives tremendous flexibility in providing possible explanations of asset price behaviour. For example, DeBondt and Thaler (1985) attribute the reversals in long-horizon market returns to investor overreaction. Using a version of prospect theory, in which investors exhibit loss aversion (that is, over weighting potential losses from a benchmark point over gains), Barberis, Huang and Santos (2001) demonstrate that it can help to reconcile the high equity premium and price volatility with smooth consumption. Daniel, Hirshleifer and Subrahmanyam (2001) interpret the cross-sectional deviations in average equity returns from the CAPM, in particular the value and size premia, as a result of overconfidence in investors’ interpretation of their private information. Models based on belief perseverance and representativeness (for example, Barberis, Shleifer and Vishny, 1998), overconfidence (Daniel, Hirshleifer and Subrahmanyam, 1998), and under-reaction to information (Hong and Stein, 1999) have been used to explain anomalies like short-horizon return momentum, long-horizon return reversal, and post-earnings announcement drift. Liu, Pan and Wang (2005) assume uncertainty aversion to reconcile the high premium of options paying off in rare events with their low probabilities seen in the data.

The experimental basis of behavioural assumptions raises the question of their relevance for actual individual behaviour in real economic decisions. As data on individual investments becomes available, more direct examination of their behaviour is possible. Investors are found to invest more in stocks they are familiar with (for example, French and Poterba, 1991; Grinblatt and Keloharju, 2001), to diversify naively (for example, Benartzi and Thaler, 2001), to trade excessively (for example, Barber and Odean, 2000), and to sell winners quickly while holding on to losers (for example, Odean, 1998). These investment patterns are interpreted as being consistent with some of the behavioural assumptions. However, the presence of many other factors, ranging from taxes, information to portfolio considerations, leaves plenty of space for alternative interpretations.

Although the behavioural patterns explored in the literature are not fully described by the expected utility theory and are thus referred to as irrational, most of them can be captured by a more general form of rationality formulated by Savage (1954), which allows for subjective beliefs and state-dependent utility functions:

$$u_t(c_t) + \sum_{\omega} p^i(\omega) u_{t+1}(c_{t+1}, \omega),$$

(17)

where $p^i(\omega)$ denotes the subjective probability of an investor $i$. The subjective expected utility theory in (17) still exhibits a general form of consistency on behaviour but can accommodate rich variations in individual beliefs and preferences. In addition, within this more general notion of rationality, the distinction between beliefs and preferences become more of a formality. For example, a subjective expected utility function after the following transformation

where \( \bar{u}_{t+1}(c_{t+1}, \omega) = \frac{p^i(\omega)}{p(\omega)} u_{t+1}(c_{t+1}, \omega) \), becomes an expected utility function (under the true probability measure \( p \)) describing the same behaviour. From this point of view, we have three observations. First, many behavioural patterns can be obtained from state-dependent expected utility, a form of rationality slightly more general than that defined by state-independent expected utility. Second, with state dependent utility, many behaviour models are formally indistinguishable from those considered within the neoclassic framework. Third, without additional restrictions, the distinction between belief and preference is largely arbitrary.

As for the consumption-based CAPM with habits, behavioural models, as they stand now, also face major limitations. First, without additional discipline, the theory is simply too flexible. As the distance between assumption and result decreases, the multiplicity of potential explanations actually increases. Second, even taking the behavioural patterns at the individual level as given, it is less clear how they aggregate. Idiosyncratic biases at the individual level may well average out at the market level. Another critical and perhaps more important issue is to what extent deviations in individual behaviour from rationality, even if they persist at the market level, influence asset prices. Take momentum as an example. If the predictability arises from the under-reaction of some investors to new information, investors who have information and capital, also referred to as arbitrageurs, should jump in to take advantage of the predictability until it disappears. As discussed in the section on market efficiency, two factors can hold back this market force, namely, risk and frictions. De Long et al. (1990) argued that irrationality can generate sufficient risk in the market to deter the arbitrageurs. But Sandroni (2000) demonstrated that, in a perfect market, investors acting on irrational beliefs do not survive in the long run (although their price impact may persist longer, as shown in Kogan et al., 2006). For risk to matter and the impact of irrational behaviour to persist, frictions or ‘limits of arbitrage’ are essential, a point emphasized by Shleifer and Vishny (1997). However, as discussed earlier in this section, in the presence of frictions various so-called anomalies can be accounted for without relying on additional behavioural assumptions. Faced with many competing and piece-wise ‘theories’, the challenge we face is to further pin down the actual causes of observed pricing patterns within a unified, and hopefully simple theory.

Corporate finance

Guided by prices, the actual allocation of capital is achieved by transactions among market participants, mainly firms and households. Firms’ financial behaviour is of particular importance as their main function is to create value from the existing capital, while households are the ultimate owner and beneficiaries. The pricing principles from the neoclassical finance have lent powerful tools for corporate and individual financial decision making. A better understanding of the financial behaviour of firms and individuals, which drives the demand and supply of assets, is also essential to our understanding of asset prices.
Corporate finance in the neoclassical theory began with the seminal work of Modigliani and Miller (1958; 1963). Using the principle of no arbitrage, they showed that in the absence of imperfections a firm's value depends only on its investment decisions. Financing and payout decisions merely determine how payoffs from investments are split between different claims associated with each financing vehicle – for example, equity and debt. The irrelevancy results of Modigliani and Miller (MM) clearly points to the areas where corporate finance matters. Much of the work since has focused on these areas where assumptions of MM are relaxed, in particular when frictions and information problems are important. The information problems have been mostly framed in the interaction between a firm's insider who manages it and its outside investor who finances it. The insider can be an entrepreneur seeking outside capital or a manager running a mature public company. Two types of information problems were identified early on, namely, adverse selection and moral hazard. Leland and Pyle (1977) and Ross (1977) examined how the adverse-selection problem influences the firm's financial decisions when firm insiders/managers know more about firm assets. In this case, firms’ actions also serve as signals to outside investors, which will influence their perception of firm value. Viewing outside investors (for example, equity and debt holders) as the principal and managers as agents, Wilson (1968) and Ross (1973) considered the moral hazard problem when managers have more information on firm assets and their own actions. Based on this type of agency theory, Jensen and Meckling (1976) and Myers (1977) examined how firm value can be influenced by the conflicts between different stakeholders, that is, investors versus managers and shareholders versus bondholders.

Recent developments in corporate finance have followed this theme. Corporate behaviour was often viewed as a manifestation of these conflicts. In order to turn this general perspective into testable theories, more structure is needed with regard to the nature and the magnitude of these imperfections. In this regard, more guidance from the data becomes critical. Our discussion starts with how a firm chooses its financing or capital structure, the focus of neoclassical theory. We then turn to how inefficiencies in financing caused by frictions and information problems influence a firm's investments. Finally, we consider the issues concerning corporate control, which looks at the problems in corporate finance from a more fundamental perspective.

Financing

Financially, a firm is about how to raise capital and how to use it. The two questions are obviously intertwined. Under MM, the two become independent. A firm's overall cost of capital, that is, the valuation of its assets, is not affected by how it is financed. An important friction omitted in this irrelevancy result is taxes. With different tax treatments on debt and equity financing, different choices of capital structure will affect the firm's tax liability and naturally its value. For example, when interest payments on corporate debt are excluded from corporate taxes, the firm can pass on higher returns to its investors by substituting debt for equity. This tax arbitrage, however, has its barbs. First, it does not account for investors’ personal taxes. Miller (1977) showed that, as investors of different tax clienteles settle for different mixes of debt and equity, an equilibrium is reached when marginal investors are indifferent between the two, which determines the total amount of debt and equity but not for individual firms as their securities are substitutes. Second, it does not take into account the potential cost of using debt, which can lead to bankruptcy. When the effects of personal and corporate taxes are different (for
example, when securities of different firms are not perfect substitutes) and bankruptcy is costly, we have the so-called ‘trade-off’ theory of capital structure. Each firm is trading off the tax benefits of debt and the bankruptcy costs. How significant these benefits and costs are remains an empirical question. Data seems to suggest that they are important. For example, Graham (2000) estimates that the effective tax rate paid by marginal investors on debt is significantly higher than that on equity, suggesting a large benefit of debt finance. The cost of bankruptcy has several sources, the direct cost of bankruptcy process (for example, Weiss and Wruck, 1998) and the indirect cost of financial distress such as conflicts between different stakeholders (for example, Asquith and Wizman, 1990), loss of business and financial counter parties (for example, Maksimovic and Titman, 1991), pressure from competitors (for example, Chevalier, 1995). A more recent study by Andrade and Kaplan (1998) estimates costs of financial distress to be in the range of 10–20 per cent of the firm value prior to distress. Ex post the cost of this size may seem modest since on an ex ante basis one has to factor in its probability. However, the fact that these costs tend to have large negative beta (negatively correlated with the market) may imply that their present value is non-trivial (for example, Almeida and Philippon, 2006).

The trade-off theory has several implications. First, each firm should have an optimal capital structure, which depends on its tax status and cost of financial distress. Although the theory does not fully specify what determines these two factors, different proxies were used empirically. For example, firms with higher business risk and more intangible assets were associated with higher distress costs and thus a low debt–asset ratio. Many empirical studies have found positive evidence on the link between these proxies and the capital structure, such as Auerbach (1985), Titman and Wessels (1988) and Rajan and Zingales (1995). But the evidence is not uniformly supportive. Wald (1999) finds that profitability has a strong negative relation with debt–asset ratios, while the trade-off theory would imply that more profitable firms should use more debt to shield their income. Second, if adjustment is costly, a firm's capital structure will be away from its optimum most of the time but always evolves towards it. As a result, the firm is more likely to issue debt when below the target and equity when above. Earlier tests found this prediction to be consistent with the data (for example, Taggart, 1977; Auerbach, 1985), but more recent tests have found mixed evidence (for example, Hovakimian, Opler and Titman, 2001). The trade-off theory is intuitive and enjoys partial empirical success, but still leaves some gaps. In particular, the significant costs of financial distress need both theoretical and empirical justification.

Based on patterns in firms’ financing choices, Myers and Majluf (1984) propose the pecking-order theory of capital structure. It starts with the premise that outsider investors have less information about a firm's use of capital. Thus, they face an adverse selection problem and will on average undervalue new shares. Equity becomes more costly as a financing vehicle than debt. This simple theory yields several predictions: (a) firms prefer internal to external finance and debt to equity finance; (b) the market reacts negatively to new share issues; (c) dividends are persistent; (d) a firm's debt–asset ratio changes with its cumulative needs for external financing. Heuristic empirical observations are surprisingly compatible with the pecking-order theory. But more extensive tests reveal some inconsistencies. For example, Jung, Kim and Stulz (1996) and Fama and French (2002) have found that small-growth firms rely heavily on equity financing. Although the pecking-order theory is very much in the spirit of Ross (1977), it relies on simplifying assumptions. In particular, no optimal contracting is considered by allowing for more
complex forms of financing and incentives to resolve the information problem. The agency theory of capital structure focuses on the conflict of interest between managers and shareholders. This is different from the trade-off and pecking-order theories, in which managers act on behalf of current shareholders. When their information and actions are not fully observable to outsiders, which may include current shareholders, managers can benefit themselves at the cost of shareholders. When incentives through contracting fail to fully mitigate this conflict, capital structure will be influenced by investors’ efforts to contain managers. Following Jensen (1986), different variations of the agency theory have been proposed, notably Harris and Raviv (1993), Stulz (1990), and Zwiebel (1996). For example, Jensen (1986) argued that debt helps to get cash out of managers’ hands and is thus preferred to outside equity before bankruptcy becomes important. Although empirically leverage does curb investments (for example, Lang, Ofek and Stulz, 1996), new debt issues do not seem to increase firm value (Eckbo, 1986).

Factors like taxes, cost of financial distress, information and agency problems do matter for firms’ financing decisions, as the empirical evidence suggests. But each of the theories captures only part of the picture. They are also mostly partial equilibrium by nature, taking certain aspects of the problem as given such as the contracting environment and firms’ investment opportunities. A more integrated and empirically refutable theory would be desirable. On the empirical side, it remains a challenge to reconcile the financing patterns found under certain circumstances with the lack of a link between taxes, financing and market value documented in Fama and French (1998) over a large sample of firms.

Investments

Clearly, the forces driving a firm's financing choices also influence its investments, that is, the use of capital. We have identified at least two channels. The first channel is simply through the cost of capital. In the case of trade-off theory, for example, a firm's cost of capital varies with its capital structure and so will its investments. The second channel is through the behaviour of managers, who make investment decision in response to the incentives they face, which are also related to the firm's financing choices. The direct effect of cost of capital has found supportive evidence. For example, using a structural model to calibrate firms’ investment opportunities, Hennessy (2004) finds that a high debt level curbs investments. In the state of distress, firms also cut down their investments, as documented in many studies, including Chevalier (1995b), Phillips (1995) and Zingales (1998).

The agency effect has attracted more interest. A variety of private benefits of managers were suggested, ranging from empire building (Williamson, 1964; Jensen, 1986) and career considerations (Narayanan, 1985; Holmstrom, 1999) to inertia (for example, Bertrand and Mullainathan, 2003). Misalignment between managers’ and shareholders’ interests will lead to suboptimal investment decisions. A simple prediction of this argument is that firms with more free cash in hand will make more and less desirable investments. Broad empirical evidence was found to be consistent with this prediction, such as Fazzari, Hubbard and Petersen (1988), Hoshi, Kashyap and Scharfstein (1991), and Gilchrist and Himmelberg (1995). One challenge in establishing the empirical link is the problem of endogeneity. For example, a firm's free cash is endogenous and may vary with its investments opportunities. Several studies have used ‘natural experiments’ to avoid the endogeneity issue. For example, Blanchard, Lopez-de-Silanes
and Shleifer (1994) find that firms’ acquisition activities increase after receiving cash windfalls from legal settlements unrelated to their business.

A positive correlation between cash and investments does not prove the agency theory. It can also be consistent with the pecking-order theory. More cash relaxes the capital constraint imposed by high cost of external financing. The question is whether free cash flow leads to negative net present value (NPV) investments. Evidence such as the negative price reaction to new equity issues (for example, Asquith and Mullins, 1986) may suggest so. However, more direct evidence indicates otherwise. For example, McConnell and Muscarella (1985) documented positive market reactions to firms’ capital expenditure announcements.

Firms’ investment decisions are of central importance to finance. Frictions and information problems imply inefficient use of capital. Extensive evidence is suggestive of such inefficiencies, but it is far from definitive. A comprehensive empirical evaluation of the extent and the magnitude of these efficiencies and the potential forces driving them is not available yet.

**Corporate control and governance**

Most of the new theories in corporate finance take as given the means different parties use to resolve conflicts. For example, in the pecking-order theory or the agency theory of financing, the mixture of debt and equity is the tool available to balance the interests of managers and outside investors. But a whole set of devices can be utilized to resolve their conflicts, including incentive contracts for managers and a rich set of corporate securities beyond equity and bonds. It makes sense to think at a deeper level about the economic structure of a firm and its resulting behaviour.

Built on the ideas of Coase (1937), Grossman and Hart (1986) proposed the idea that a firm is defined by the allocation of control rights over its assets, the rights to utilize these assets. In such a setting, conflicts among different stakeholders are resolved by optimal allocation of control rights rather than extensive contracting, which is assumed to be infeasible with hard-to-specify future contingencies. Such an allocation will then determine how the firm behaves, including its investment decisions and financing arrangements. It will also determine how it is governed – for example, who takes control and when. A collection of theories on corporate behaviour was developed under this setting.

Aghion and Bolton (1992) considered the financing problem of an entrepreneur who also enjoys private benefits from running his firm (see also Hart and Moore, 1998). The optimal structure of the firm would be for him to retain the control rights of the firm (so he can enjoy the private benefits) while selling cash flow claims to outside investors. This looks very much like a mixture of equity and debt financing, except that now it is the outcome of optimal corporate control. If embedded in an intertemporal environment with uncertainty, the model also lead to implications on the dynamics of the firm's financing and investments. By looking at venture capital investments in start-up companies, Gompers (1995) and Kaplan and Stromberg (2001) have found patterns compatible with the model's predictions. This model, however, captures mostly inside equity and is less descriptive of large public firms, which involves mostly equity held by outsiders. Fluck (1998) and Myers (2000) have considered models for outside equity financing. Within a similar framework, Grossman and Hart (1980, 1988) analyse the market for corporate control in the form of takeovers (see also Harris and Raviv, 1988) when
shareholdings are diverse. Aghion and Tirole (1997) examined issues concerning corporate governance, such as the role of corporate boards, which act as shareholders’ representative in exercising their control rights.

Models of incomplete contracting capture some salient features of firms and attempt to examine corporate finance issues from a more basic and integrated perspective. But they are highly simplified. Their predications are mostly qualitative and dependent on deeper parameters, such as what can or cannot be contracted. The fact that these parameters are hard to observe make it hard to empirically test the models.

Another approach is to consider the firm as a full contract among its stakeholders, including managers and outside investors, very much in the spirit of Leland and Pyle (1977) and Ross (1977) (see also Townsend, 1978; Gale and Hellwig, 1985). For example, Gertler (1992), Clementi and Hopenhayn (2006), and DeMarzo and Fishman (2007) examine optimal contracts between investors and a manager to induce optimal investments. Atkeson and Cole (2005) consider the optimal financing contract in the presence of agency problems and manager risk aversion. In contrast to the assumptions in the models based on incomplete contracts, this approach explores what optimal contracting can achieve. As shown in Dybvig and Zender (1991), under certain circumstances optimal contracting can largely resolve the information problems between managers and shareholders.

The full contracting approach avoids some of the arbitrariness in the theory of incomplete contracts. But it has its own challenges. It is quite limited in describing large public companies, which involves a large number of stakeholders, including a hierarchy of managers and a diverse set of investors. Its predictions depend on the assumptions about other frictions such as verification and enforcement costs. Realistic assumptions about these frictions are also hard to pin down. This also leads to the question of the robustness of contractual arrangements from the models.

**Conclusion**

Developments in finance since the mid-1980s have expanded the success of neoclassical theory, especially in the area of arbitrage pricing, as well as its boundaries. Extensive and more rigorous empirical analysis has exposed the limitations of the simple asset pricing models and the simplistic notion of market efficiency. The fact that we still don't have a satisfactory notion of risk and can't explain movements in asset prices after the fact clearly suggests the need to enrich our theory. Imperfections such as frictions and information asymmetry are part of the market reality and should be incorporated. They can very much enhance our understanding of market participants’ behaviour and its impact on the market itself. A rich set of models, accompanied by empirical work, has been explored to explain the observed patterns in the financial market and in corporate finance. Liquidity and agency problems have been identified as manifestations of imperfections in the market and corporate contexts and useful lenses through which to examine their behaviour.

An unavoidable challenge in modelling imperfections is that they come in all shapes and sizes, and their impact is in general complex. Empirical evaluation of the significance of various imperfections is very much needed to arrive at a unified framework, synthesizing the important intuition from the collection of specialized models we have. After carefully collecting and studying the pieces and parts, we may be able to hope for a more general theory of finance.

Abstract

The neoclassical theory of finance is based on the study of (a) efficient markets, meaning markets that use all available information in setting prices, (b) the trade-off between return and risk, (c) option pricing and the principle of no arbitrage, and (d) corporate finance, that is, the structure of financial claims issued by companies. This article surveys these theories and their empirical support and it also identifies certain empirical regularities unexplained by the neoclassical theory that are being addressed by theories of asymmetric information.

Article

Finance is a subfield of economics distinguished by both its focus and its methodology. The primary focus of finance is the workings of the capital markets and the supply and the pricing of capital assets. The methodology of finance is the use of close substitutes to price financial contracts and instruments. This methodology is applied to value instruments whose characteristics extend across time and whose payoffs depend upon the resolution of uncertainty.

Finance is not terribly concerned with the problems that arise in a barter economy or, for that matter, in a static and certain world. But, once the element of time is introduced, transactions develop a dual side to them. When a loan is made, the amount and the terms are recorded to assure that repayment can be enforced. The piece of paper or the computer entry that describes and legally binds the borrower to repay the loan can now trade on its own as a ‘bearer’ instrument. It is at the point when debts were first traded that capital markets and the subject of finance began.

The study of finance is enriched by having a large body of evolving data and market lore and some powerful and, at times, competing intuitions. These intuitions are used to structure our understanding of the data and the markets which generate it. The modern tradition in finance began with the development of well-articulated models and theories to explore these intuitions and render them susceptible to empirical testing.

While the subject of finance is anything but complete, it is now possible to recognize the broad outlines of what might be called the neoclassical theory. In the discussion which follows we will group the subjects under four main headings corresponding with four basic intuitions. The first topic is efficient markets, which was also the first area of finance that matured into a science. Next come the twinned subjects of return and risk. This leads naturally into option pricing theory and the central intuition of pricing close substitutes by the absence of arbitrage. The principle of no arbitrage is used to tie together the major subfields of finance. The fourth section looks at corporate finance from its well-developed form as a consequence of no arbitrage to its current probings. A short conclusion ends the entry.
The word efficient is too useful to be monopolized by a single meaning in economics. As a consequence, it has a variety of related but distinct meanings. In neoclassical equilibrium theory efficiency refers to Pareto efficiency. A system is Pareto efficient if there is no way to improve the well being of any one individual without making someone worse off. Productive efficiency is an implication of Pareto efficiency. An economy is productively efficient if it is not possible to produce more of any one good or service without lowering the output of some other.

In finance the word efficiency has taken on quite a different meaning. A capital market is said to be (informationally) efficient if it utilizes all of the available information in setting the prices of assets. This definition is purposely vague and it is designed more to capture an intuition than to state a formal mathematical result. The basic intuition of efficient markets is that individual traders process the information that is available to them and take positions in assets in response to their information as well as to their personal situations. The market price aggregates this diverse information and in that sense it ‘reflects’ the available information.

The relation between the definitions of efficiency is not obvious, but it is not unreasonable to think of the efficient markets definition of finance as being a requirement for a competitive economy to be Pareto efficient. Presumably, if prices did not depend on the information available to the economy, then it would only be by accident that they could be set in such a way as to guarantee a Pareto efficient allocation (at least with respect to the commonly held information).

If the capital market is competitive and efficient, then neoclassical reasoning implies that the return that an investor expects to get on an investment in an asset will be equal to the opportunity cost of using the funds. The exact specification of the opportunity cost is the subject of the section on risk and return, but for the moment we can observe that investing in risky assets should carry with it some additional measure of return beyond that on riskless assets to induce risk averse investors to part with their funds. For now we will defer the measurement of this risk premium, and simply represent the opportunity cost by the letter ‘$r$’.

In much of the early empirical work on efficient markets no attempt was made to measure risk premia, and the opportunity cost of investing was set equal to the riskless rate of interest. This can be justified either by assuming that there are risk neutral investors who are indifferent to risk (or, as we shall see, by assuming that the asset's risk is diversified away in large portfolios). Whatever the rationale, to focus on the topic of efficient markets rather than on the pricing of risk, we will let $r$ be the riskless interest rate.

If $R_t$ denotes the total return on the asset – capital gains as well as payouts – over a holding period from $t$ to $t + 1$, then the efficient markets hypothesis (EMH) asserts that

$$E(R_t | I_t) = (1 + r_t),$$

(1)

where $E$ is the expectation taken with respect to a given information set $I_t$, that is available at time $t$ (and that includes $r_t$). An alternative formulation of the basic EMH equation is in terms of prices. For an asset with no payouts, since

$$R_t = \frac{p_{t+1}}{p_t},$$

we can rewrite (1) as

$$E(p_{t+1} | I_t) = (1 + r_t)p_t,$$

(2)

or, equivalently, discounted prices must follow the martingale,
The EMH is given empirical content by specifying the information set that is used to determine prices. Harry Roberts (1967) first coined the terms which have come to describe the categories of information sets and, concomitantly, of efficient market theories that are employed in empirical work. Fama (1970) subsequently articulated them in the form which we now use. These categories describe a hierarchy of nested information sets. As we go up the hierarchy from the smallest to the biggest set (i.e. from coarser to finer partitions) we are requiring efficiency with respect to increasing amounts of information. At the far end of the spectrum is strong-form efficiency. Strong-form efficiency asserts that the information set, \( I_t \), used by the market to set prices at each date \( t \) contains all of the available information that could possibly be relevant to pricing the asset. Not only is all publicly available information embodied in the price, but all privately held information as well.

A substantial notch down from strong-form efficiency is semistrong-form efficiency. A market is efficient in the semistrong sense if it uses all of the publicly available information. The important distinction is that the information set, \( I_t \), is not assumed to include privately held information, i.e. information that has not been made public. Making this distinction precise is possible in formal models but categorizing information as publicly available or not can be subjective. Presumably, accounting information such as the income statements and the balance sheets of the firm is publicly available, as is any other information that the government mandates should be released such as the stock holdings of the top executives in the firm. Presumably, too, the true but unrevealed intention of a major stockholder would fall into the category of private information. In between these extremes is a large grey area.

The tendency in the empirical literature has been to take a purist's view of semistrong efficiency, and to adopt the position that if the information was in the public domain then it was available to the public and should be reflected in prices. This ignores the cost of acquiring the information, but the intuitive justification for this position is that the costs of acquiring such public information are small compared to the potential rewards. Thus, while the government mandated and publicly reported trades of the top executives require a bit more effort to obtain in a timely fashion than some average of their past holdings, such trades, when reported, would fall squarely within the realm of publicly available information under the semistrong version of the EMH.

If the asset is traded on an organized exchange, then of all the information that is clearly available to the public, none is as accessible and cheap as its past price history. At the bottom of the ladder in the efficiency hierarchy, weak-form efficiency requires only that the current and past price history be incorporated in the information set. If there is empirical validity to the EMH then, at the very least, the market for an asset should be weak-form efficient, that is, efficient with respect to its own past price history.

**Empirical testing**

The empirical implications of efficiency with respect to a particular information set are that the current price of the asset embodies all of the information in that set. Since the categories of information sets are nested, rejection of any one type, say, weak-form efficiency, implies the rejection of all stronger forms. For example, according to weak-form efficiency, the current price of an asset embodies all of the information contained in the past price history. This implies that,

\[
E(R_t R_{t-1}, R_{t-2}, \ldots) = (1 + r_2),
\]

or, in price terms,

\[
E(p_{t+1} | p_t, p_{t-1}, \ldots) = (1 + r_t) p_t.
\]

The most dramatic consequence of the EMH and certainly the one that receives the most attention from the public, is that it denies the possibility of successful trading schemes. If, for example, the market is weak-form efficient, then an investor who makes use of the ‘technical’ information of past prices can only expect to receive a return of the opportunity cost \((1 + r_t)\). No amount of clever manipulation of the past information can improve this result.
As a test of weak-form efficiency, then, we could test (although not as a simple regression) the null hypothesis that

$$H_0: E(p_{t+1} | p_t, p_{t-1}) = \beta_0 + \beta_1 p_t + \beta_2 p_{t-1},$$

(4)

where

$$\beta_0 = 0 \beta_1 = (1 + r_t).$$

and

$$\beta_2 = 0.$$

The important feature of this hypothesis is that it tells what information does not play a role (given $r_t$), namely the lagged price, $p_{t-1}$. If the coefficient $\beta_2$ should prove to be statistically significant, then this would constitute a rejection of the weak-form EMH.

The other empirical implication of the EMH that is often cited as a defining characteristic is that an efficient price series should ‘move randomly’. The precise meaning of this in our context is that price changes should be serially uncorrelated.

Consider the serial covariance between two adjacent rates of return,

$$\text{cov}(R_{t+1}, R_t) \equiv E([R_{t+1} - E(R_{t+1})] [R_t - E(R_t)]) = E(R_{t+1}[R_t - E(R_t)]) = E[E(R_{t+1}| R_t)] [R_t - E(R_t)]$$

(5)

In equation (5), since we have not specified the information set with respect to which the expectations are to be taken, they are unconditional expectations. Under weak-form efficiency, the information set will contain the past rates of return. Suppose that the (expected) opportunity cost, e.g. the interest rate $r$, independent of past returns on the asset or that changes are of a second order of magnitude. This would occur, for example, if we held $r_t$ constant at $r$. In such a case, since weak-form efficiency implies that $I_{t+1}$ contains $R_t$, we have

$$E(R_{t+1}| R_t) = E[E(R_{t+1}| R_t) | R_t] = E[(1 + r_{t+1}) | R_t] = E(1 + r_{t+1}),$$

(6)

the unconditional expectation of next period’s opportunity cost. Putting (5) and (6) together yields,
which is to say that rates of return are serially uncorrelated.

Tests of the EMH are legion and by and large they have been supportive. The early tests were essentially tests of the inability of trading schemes or of the random walk nature of prices, which implies that actual rates of return are serially uncorrelated. While the EMH does not imply that prices follow a random walk, such a price process is consistent with market efficiency. Alternatively, unable to specify closely the opportunity cost, some of the early tests took refuge in the view that it must be positive, which leads to a submartingale model for prices,

\[ E(p_{t+1}|t) \geq p_t. \]

The lack of a specification of the opportunity cost characterizes the early tests (see Cowles (1933), Granger and Morgenstern (1962) and Cootner (1964) and see Roll's (1984) study of the orange juice futures market for a modern example of such a test). Following Fama (1970), the literature shifted to a concern for specifying the opportunity cost and, in this sense, empirical tests became joint tests of the EMH and of the correct specification of the opportunity cost and its attendant theory.

In terms of the information hierarchy, the general message that emerged from the testing is that the market does appear to be consistent with weak-form efficiency. Tests of stronger forms of efficiency, though, have produced mixed results. Fama, Fisher, Jensen, and Roll (1969) introduced a new methodology to test semistrong efficiency and applied it to stock splits. They observed that the residuals from a simple regression of a stock's returns on a market index would measure the portion of the return that was not attributable to market movements. By adding the residuals over a period of time, the resulting cumulative residual measures the total return over that period that is attributable to nonmarket movements. If a stock splits, say, 2 for 1, then under semistrong efficiency its price should split in proportion, i.e., halve for a 2 for 1 split. Using this ‘event study’ approach, Fama et al. verified that stock split data was consistent with semistrong efficiency. The event study methodology they introduced and the use of cumulative residuals (averaged over firms) has become the standard method for examining the impact of information on stock returns.

By contrast with their supportive findings, Jaffé (1974), for example, found that a rule based on the publicly released information about insider trades produced abnormal returns. These results and others like them (see the section on Risk and Return below) have been much debated and no final verdict on the matter is likely.

Recently a more interesting empirical challenge to the EMH has come from a different tack. Shiller (1981), has argued that the traditional statistical tests that have been employed are too weak to examine the EMH properly and, moreover, that they are misfocused. Shiller adopts the intuitive perspective that if stock prices are discounted expected dividends, then they ought not to vary over time as much as actual dividends. He argues that since the price is an expectation of the dividends and future price, what actually occurs will be this expectation plus the error in the forecast and should be more variable than the price. This leads him to formulate statistical tests of the EMH based on the volatility of stock prices which are claimed to be more powerful than the traditional (regression based) tests.

An alternative view has been taken by critics of this perspective, notably Kleidon (1986), Flavin (1983), and Marsh and Merton (1986). These critics have taken issue with Shiller's specification of the statistical tests of volatility and, more importantly, with his basic intuition. In particular, they contend that the single realization of dividends and prices that is observed is only one drawing from all of the random possibilities and that the price is based on the expectation taken over all of these possibilities. A little bit of information, then, can have an important influence on the current price. Furthermore, they argue that when the smoothing of dividends and the finite time horizon of the data samples are taken into account, volatility tests do not reject the EMH. The testing of the EMH is taking a new direction because of this work, but, at present, the results are still mixed.

Less cosmic in scope, but perhaps more worrisome is the discovery by French and Roll (1985) that the variance per unit time of market returns over periods when the market is closed (for example, from Tuesday's close to Thursday's close when the market was closed on Wednesday because of a backlog of paperwork) is many times smaller than when it is open. It is difficult to reconcile this result with the requirement that prices reflect information about the cash flows of the assets, unless the generation of fundamental information slows dramatically when the market closes – no matter why it is closed.

Theoretical formulations
The attempts to formalize the EMH as a consistent, analytical economic theory have met with less success than the empirical tests of the hypothesis. The theory can be broken into two parts. The first part is neoclassical and is largely formulated in terms of models in which investors share a common information set. Such models focus on the intertemporal aspects of the theory and the changing shape of the information set. It has long been recognized that a competitive economy with a single risk neutral investor would lead to the traditional efficient market theories with respect to the information set employed by that investor. More interestingly, Cox, Ingersoll and Ross (1985a), and Lucas (1978) have developed intertemporal rational expectations models each of which is consistent with certain versions of the efficient market theories.

Risk and return

The theory of efficient markets leads inexorably to the second central intuition in finance, the trade-off between risk and return. It has long been recognized that risk-averse investors require additional return to bear additional risk. Indeed, this insight goes back to the earliest writings on gambling and it is as much a definition of risk aversion as it is a description of risk-averse behaviour. The contribution made by finance has been to translate this observation into a body of intuition, theory, and empirics on the workings of the capital markets.
The intuition that in a competitive market higher return is accompanied by higher risk owes at least as much to Calvin as it does to Adam Smith, but, in large part the development of capital market theory has been an attempt to explain risk premia, the difference between expected returns and the riskless interest rate. The foundations for the models that would first explain risk premia and that would become the workhorses of financial asset pricing theories were laid by Hicks (1946), Markowitz (1959), and Tobin (1958). These authors developed a rigorous micro-model of individual behaviour in a ‘mean variance’ world where investment portfolios were evaluated in terms of their mean returns and the total variance of their returns. They justified focusing on these two distributional characteristics by assuming either that investors had quadratic von Neumann-Morgenstern utility functions or that asset returns were normally distributed. In such a world, investors would choose mean variance efficient portfolios, i.e., portfolios with the highest mean return for a given level of variance. This observation reduced the study of portfolio choice to the analysis of the properties of the mean variance efficient set. Building on their work, Sharpe (1964), Lintner (1965), and Mossin (1966), all came to the fundamental insight that this micromodel could be aggregated into a simple model of equilibrium in the capital markets, the capital asset pricing model or CAPM.

The mean variance capital asset pricing model (CAPM)

In neoclassical equilibrium models, an investor evaluates an asset in terms of its marginal contribution to his or her portfolio. The decision to alter the proportion of the portfolio invested in an asset will depend on whether the cost of doing so in terms of risk is greater or less than the benefit in expected return. An individual in a personal equilibrium will find the cost at the margin equal to the benefit.

We will assume that a unit addition of an asset to the portfolio can be financed at an interest rate of $r$. In a mean variance model the net benefit of adding an asset to a portfolio is the additional expected return it brings, $E_i$, less the cost of financing it. Such a change, $\Delta x$, will augment the expected return on the portfolio, $E_p$, by the risk premium of the asset, i.e. by the difference between the expected return on the asset, $E_i$, and the cost of the financing, $r$.

$$\Delta E_p = (E_i - r) \Delta x. \quad (9)$$

The marginal cost, in terms of risk, of an increase in the holding of an asset is the addition to the total variance of the portfolio occasioned by an increase in the holding of the asset. To compute this increase, let $\nu$ denote the variance of returns on the current portfolio, let $\text{var}(i)$ stand for the variance of asset $i$'s returns, let $\text{cov}(i, p)$ denote the covariance between the return of asset $i$ and that of the portfolio, $p$, and let $\Delta x$ be the addition in the holding of asset $i$.

The variance of the portfolio after adding $\Delta x$ of asset $i$ will be,

$$\nu + \nu = \nu + 2 \Delta x \text{cov}(i, p) + (\Delta x)^2 \text{var}(i),$$

which means the change in the variance is given by

$$\Delta \nu = 2 (\Delta x) \text{cov}(i, p) + (\Delta x)^2 \text{var}(i),$$

and for a small marginal change, $\Delta x$ this approximates,

$$\Delta \nu \approx 2 (\Delta x) \text{cov}(i, p).$$
The marginal rate of transformation between return and risk, then, is given by

\[
\text{MRT} = \frac{\Delta E_p}{\Delta \nu} = \frac{(E_i - r)\Delta x}{2(\Delta x) \text{cov}(i, p)} = \frac{(E_i - r)}{2 \text{cov}(i, p)}.
\]

An investor will be in a personal equilibrium when this trade-off is equal to his or her personal marginal rate of substitution between return and risk. But, if the portfolio \( p \) is an optimal one for the investor then it must also have a trade-off between return and risk that is equal to the investor’s marginal rate of substitution, and this permits us to use it as a benchmark. Consider, then, the alternative possibility of changing the portfolio position not by changing the amount of asset \( i \) being held, but rather by changing the amount of the entire portfolio \( p \) being held, again financing the change by an alteration in the holding of the riskless asset. This is equivalent to leveraging the portfolio of risky assets and altering the amount of the riskless asset so as to continue to satisfy the budget constraint. Such a change will produce a trade-off between return and risk exactly analogous to the one examined above.

\[
\text{MRS} = \frac{E_p - r}{2 \text{var}(p)},
\]

where we have written this as the marginal rate of substitution, MRS. Since in equilibrium all of the marginal rates of transformation must equal the common marginal rate of substitution, putting these two equations together we have,

\[
E_i - r = (E_p - r)\beta_{ip},
\]

where

\[
\beta_{ip} = \frac{\text{cov}(i, p)}{\text{var}(p)},
\]

the regression coefficient of the returns of asset \( i \) on the returns of portfolio, \( p \). Equation (12) is the famous security market line equation, the SML. It describes the necessary and sufficient condition for a portfolio \( p \) to be mean variance efficient. It also provides a clear statement of the risk premium, asserting that it is proportional to the asset’s beta, \( \beta_{ip} \).

The insight of Sharpe, Lintner and Mossin was the observation that the SML and the mean variance analysis could be aggregated almost without change to a full equilibrium in the
capital market. If we assume that all individuals have the same information and, therefore, see the same mean variance picture, then each individual’s efficient portfolio will satisfy equation (12). Since the SML equation is linear in the portfolio holding, \( p \), we can simply weight each individual’s equation by the proportion of wealth that individual holds in equilibrium, and add up the individual SML’s. The result will be an SML equation for the aggregate portfolio, \( m \), that is the weighted average of the individual portfolios. In equilibrium, the weighted average of all of the individual portfolios, \( m \), is the market portfolio, i.e., the portfolio of all assets held in proportion to their market valuation. In other words, each asset \( i \), must lie on the SML with respect to the market,

\[
E_i - r = (E_m - r) \beta_{iM},
\]

which means that the market portfolio, \( m \), is a mean variance efficient portfolio.

The geometry of the mean variance analysis is illustrated in Figure 1. The set of mean variance efficient portfolios maps out a mean variance efficient frontier in the mean standard deviation space of Figure 1. Each investor will pick some point on this frontier and that point will be associated with a mean variance efficient portfolio that is suitable for the investor’s particular degree of risk aversion. All such portfolios will themselves be portfolios of just two assets: the riskless asset, \( r \), and a common portfolio, \( p \), of risky assets. This fortunate simplification of the individual portfolio optimization problem is referred to as two fund separation. It implies that the only role for individual preferences lies in choosing the appropriate combination of the risky portfolio, \( p \), and the riskless asset, \( r \). As a consequence, when we aggregate, the market risk premium, \((E_m - r) / \text{var}(m)\), will be an average of individual measures of risk aversion.

Figure 1
Black (1972) showed that two fund separation would still hold in the mean variance model even if there were no riskless asset. In such a case he found that an efficient portfolio orthogonal—the ‘zero beta portfolio’—to the market portfolio could be found, and that all investors would be able to find their optimal portfolios as combinations of $m$ and this zero beta portfolio. In the above development of the CAPM we can simply let $r$ be the expected return on a zero beta portfolio.

The necessary and sufficient conditions on return distributions for them to have this two fund separation property—for any concave utility function—were established by Ross (1978a). Ross characterized the class of distribution whose efficient frontier, i.e. the set of portfolios that some investor would choose, was spanned by $k$ funds, and showed that it extended beyond the normal distributions in the case of $k=2$ fund separation. This work was extended by Chamberlain (1983), who found the class of distributions for which expected utility was a function of just mean and variance for any portfolio as well as for the efficient ones. Cass and Stiglitz (1970) found the conditions on investor utility functions for a similar property to hold regardless of assumptions on return distributions.

It follows immediately from two fund separation that the tangency portfolio, $p$, in Figure 1 must be the market portfolio of risky assets since all investors hold all risky assets in the same proportions. If there is no net supply of the riskless asset then $p$ must be the market portfolio, $m$, itself.

The central feature of the CAPM is the mean variance efficiency of the market portfolio and the emergence of the beta coefficient on the market portfolio as the determinant of the risk premium of an asset. Those features of an asset that contribute to its variance but do not affect its covariance with the market will not influence its pricing. Only beta matters for
pricing; the idiosyncratic or unsystematic risk, i.e. that portion which is the residual in the regression of the asset's returns on the market's returns and is therefore orthogonal to the market, playing no role in pricing.

This produces some results that were at first viewed as counter-intuitive. The older view that the risk premium depended on the asset's variance was no longer appropriate, since if one asset had a higher covariance with the market than another, it would have a higher risk premium even if the total variance of its returns were lower. Even more surprising was the implication that a risky asset that was uncorrelated with the market would have no risk premium and would be expected to have the same rate of return as the riskless asset, and that assets that were inversely correlated with the market would actually have expected returns of less than the riskless rate in equilibrium.

These results for the CAPM were supposedly explicated by the twin intuitions of diversification and systematic risk. There could be no premium for bearing unsystematic risk since a large and well diversified portfolio (i.e. one whose asset proportions are not concentrated in a small subset) would eliminate it - presumably by the law of large numbers. This would leave only systematic risk in any optimal portfolio and since this risk cannot be eliminated by diversification, it has to have a risk premium to entice risk averse investors to hold risky assets. From this perspective it becomes clear why an asset that is uncorrelated with the market bears no risk premium. One that is inversely correlated with the market actually offers some insurance against the all pervasive systematic risk and, therefore, there must be a payment for the insurance in the form of a negative risk premium.

There is nothing wrong with this intuition, but it does not fit the CAPM very well. The residuals from the regression of asset returns on the market portfolios are orthogonal to the market, but they could be highly correlated with each other. In fact, they are linearly dependent since when they are weighted by the market proportions they sum to zero. This means the law of large numbers cannot be used to insure that large portfolios of residuals other than the market portfolio will be negligible. But, if that is the case, then the residuals could capture systematic risks not reflected in the market portfolio.

The CAPM was the genesis for countless empirical tests (see, e.g., Black, Jensen, and Scholes, 1972; and Fama and MacBeth, 1973). The latter paper developed the most widely used technique. The general structure of these tests was the combination of the efficient market hypothesis with time series and cross section econometrics. Typically some index of the market, such as the value weighted combination of all stocks would be chosen and a sample of firms would be tested to see if their excess returns, $E - r$, were ‘explained’ in cross-section by their betas on the index, i.e., whether the SML was rejected.

Roll (1977b, 1978) put a stop to this indiscriminate testing by calling into question precisely what was being tested. Roll's critique had two parts. First, he argued that the tests were of very low power and probably could not detect departures from mean variance efficiency. His central point, though, began by noting that tests of the CAPM were tests of the implications of the statement that the entire market portfolio was mean variance efficient, and were not simply tests of the efficiency of some limited index such as could be formed from the stock market. The essential role played by the market portfolio in the CAPM had been stressed by others; Ross (1977b) had shown the equivalence between the CAPM and the mean variance efficiency of the market portfolio. (Ross (1976a) had also shown that in the absence of arbitrage there was always some efficient portfolio.) Roll went beyond this simple observation, though, by stressing the essential point that the market portfolio is unmeasurable. This called into question the entire cottage industry of testing the CAPM and all of the uses to which the theory had been put, such as performance measurement.

**Inter-temporal models**

In the aftermath of Roll's critique, attention was turned to alternative models of asset pricing and the intertemporal nature of the theory became more important. Two separate strands of development can be traced. One essentially followed the lines of the CAPM and developed the intertemporal versions of it, the ICAPM. Merton (1973a) pioneered in this. Using continuous time diffusion analysis, Merton showed that the CAPM could be generalized to an intertemporal setting. Most interestingly, though, he demonstrated that, if the economic structure is one of the most important subfields of finance, and the bond markets were one of the first areas where the EMH was applied. In an efficient market, ignoring risk aversion, expectations general equilibrium in continuous time was developed in Cox, Ingersoll and Ross (1985a).

Cox, Ingersoll and Ross (1985b) applied their model to analyse and resolve some long-standing questions in the theory of the term structure of interest rates. The theory of the term structure is one of the most important subfields of finance, and the bond markets were one of the first areas where the EMH was applied. In an efficient market, ignoring risk aversion, forward rates should be (unbiased) predictors of future spot rates and many early theories and tests of the EMH were formulated to examine this proposition (see e.g. Malkiel, 1966).

Roll (1970) integrated the EMH with the CAPM and used the resulting framework to examine empirically liquidity premia in the bond markets; the work of Cox, Ingersoll and Ross (1985b) can be considered as the logical extension of his analysis to a rational inter-temporal setting.

Merton's model was simplified markedly by Breeden (1979), who showed that, if investors had intertemporally additive utility functions, then Merton's ICAPM and its version of the SML could be collapsed back into a single beta model, the consumption beta model, with all assets being priced, that is, having their risk premiums determined, by their covariance.
with aggregate consumption (see also Rubinstein (1976)). If we think of returns as relative prices between wealth today and in future states of nature, then optimizing individuals will set their marginal rates of substitution between consumption today and in future states equal to the rates of return. With continuous asset prices and additive utility functions, indirect utility functions are locally quadratic in consumption and this implies that consumption plays the role of wealth in the static CAPM. This work led to a variety of attempts to measure the ability of betas on aggregate consumption to explain risk premia (see e.g. Hansen and Singleton, 1983).

Arbitrage pricing theory (APT)

A separable but related strand of theory is the arbitrage pricing theory (APT) (see e.g. Ross, 1976a, 1976b). The CAPM and the consumption beta model share the common feature that they explain pricing in terms of endogenous market aggregates, the market portfolio, and aggregate consumption, respectively. The APT takes a different tack. The intuition of the CAPM (or of the Consumption Beta model) is that idiosyncratic risk can be diversified away, leaving only the systematic risk to be priced. Idiosyncratic risk, though, is defined with reference to the market portfolio as the residual from a regression of returns on the market portfolio’s returns. Since no further assumptions are made about the residuals, contrary to intuition a large diversified portfolio that differs from the market portfolio will not in general have insignificant residual risk. The exception is the market portfolio, but then the intuition that diversification leads to pricing by the market portfolio is circular at best.

The APT addresses this issue by assuming directly a return structure in which the systematic and idiosyncratic components of returns are defined a priori. Asset returns are assumed to satisfy a linear factor model,

$$ R_i = E_i + \sum_j \beta_{ij} f_j + \epsilon_i, \quad i = 1, \ldots, n, $$  

(15)

where $E_i$ is the expected return, $f_j$ is a demeaned exogenous factor influencing each asset $i$ through its beta on the factor, $\beta_{ij}$, and $\epsilon_i$ is an idiosyncratic mean zero term assumed to be sufficiently uncorrelated across assets that it is negligible in large portfolios. An implication of the factor structure is that the $\epsilon_i$ terms become negligible in large well diversified portfolios and, therefore, such portfolios approximately follow an exact factor structure,

$$ R_i \approx E_i + \sum_j \beta_{ij} f_j, $$  

(16)

where $i$ now denotes the $i$th well diversified portfolio. In an Arrow–Debreu state space framework, equation (16) can be interpreted as a restriction on the rank of the state-space tableaux.

An exact factor structure implies that there will be arbitrage unless the expected return on each portfolio is equal to a linear combination of the beta coefficients,

$$ E_i - r = \sum_j \lambda_j \beta_{ij}, $$  

(17)

where $\lambda_j$ is the risk premium associated with the $j$th factor, $f_j$. This equation is the APT version of the SML in the CAPM.
The APT is consistent with a wide variety of equilibrium models (including the CAPM if there is a factor structure) and it has been the object of much theoretical and empirical attention. In a sense, the APT can be thought of as a snapshot of any intertemporal model in which the factors represent innovations in the underlying state variables. This means that a rejection of the APT would imply a fairly wide ranging rejection of attempts to model asset markets with a finite set of state variables.

The original theoretical development of the APT (Ross, 1976a, 1976b) showed formally that, if preferences are continuous in the quadratic mean, then the returns on a sequence of portfolios which require no wealth cannot converge to a positive return with a zero variance. This, in turn, implies that the sum of squared deviations from exact APT pricing is bounded above. These results were simplified by Huberman (1982) and extended by Ingersoll (1984) and Chamberlain and Rothschild (1983), all of whom side-stepped the issue of preferences by simply assuming that there could be no sequences converging to an arbitrage situation of a positive return with no variance. By contrast, Dybvig (1983) makes assumptions on preferences and aggregate supply to obtain a tight bound on pricing. His simple order of magnitude calculation is evidence that the pricing error is too small to be of practical significance.

By modelling the capital market explicitly as responding to innovations in exogenous variables, the APT is immediately inter-temporally rational. By contrast with the CAPM and the Consumption Beta models which price assets in terms of their relation with a potentially observable and endogenous market aggregate (wealth for the CAPM and consumption for the Consumption Beta models), the APT factors are exogenous, but unspecified. Much empirical work is now under way to determine a suitable set of factors for representing systematic risk in a factor structure and to examine if they price assets successfully. (For example, see Roll and Ross, 1980; Brown and Weinstein, 1983; and Chen, Roll and Ross, 1986.)

The lack of an a priori specification for the factors has been the focus of criticism of the testability of the APT by Shanken (1982). Shanken argues that, since the factors are not pre-specified, the intuitive derivation of the APT given above can be used to verify APT pricing falsely even when it does not hold, and that to prevent this some equilibrium model, such as that proposed by Connor (1984), must be used. Shanken emphasizes that his critique applies not to the theory of the APT but rather to the way in which it has been tested. Dybvig and Ross (1985) dispute his arguments, stressing that Shanken wants to test the theory including its assumptions and approximations rather than take the positive approach of testing the model’s conclusions.

**Empirical testing of asset pricing models**

Since Roll’s critique, the methodology for testing asset pricing models has changed. There has been a retreat from testing a model per se to an explicit view that what is being tested is not the CAPM, for example, but rather whether the particular index being used for pricing is mean variance efficient. This change of focus has led to a more formal approach to the statistics of testing. Ross (1980) developed the maximum likelihood test statistic for the efficiency of a given portfolio and pointed out the analogy between this and the mean variance geometry, and Gibbons (1982) showed that the test of efficiency could be conducted by the use of seemingly unrelated regressions. These results have been extended by others. For example, Kandel (1984) and Jobson and Korkie (1982) and Gibbons, Ross and Shanken (1986) have developed and exploited an exact small sample test of the efficiency of a given index in the presence of a riskless asset. Similar tests of the APT have not yet been developed, and to date much of the testing of the APT has focused on comparisons between the APT and pricing using the value weighted index (see e.g. Chen, Roll, and Ross, 1986).

The most important empirical finding in asset pricing, though, has been the discovery of a wide array of phenomena that appear to be inconsistent with nearly any neoclassical model. Consider, first, the secular effects. Asset returns fall, on average, over the weekend and rise during the week (see French, 1980). Similarly, it has been found that asset returns behave differently in the first half of the month than they do in the second. The most attention, though, has been lavished on the ‘small firm effect’. It appears that the average returns on small firms exceed those on large firms no matter what theory of asset pricing is used to correct for differences in the risk premium between these two categories of assets. Furthermore, the bulk of the return difference is concentrated in the first few days of January. Indeed, on average, returns in January appear to be abnormally large for all stocks (see, for example, Keim, 1983, or Roll, 1981; 1983). Potentially these sorts of anomalies can be explained by secular changes in risk premia – perhaps due to secular patterns in the release of information – but their persistence and magnitude make them serious challenges to all the asset pricing models. When evidence of this sort appears difficult to explain by any pricing model it calls into question the efficient market hypothesis itself. Tests of an asset pricing model are usually joint tests of both market efficiency and the pricing model; rejecting a wide enough range of such models is tantamount to rejecting efficiency itself.

**Substitution and arbitrage: option pricing**

The APT is the child of one of the central intuitions of finance, namely, that close substitutes have the same price. This intuition reached fruition in the path breaking paper by Black and Scholes (1973) on option pricing. Since then the theory has found myriad applications and has been significantly extended; see, for example, Merton (1973b), Cox and Ross (1976a; 1976b; 1976c), Rubinstein (1976), Ingersoll (1977), Cox, Ross and Rubinstein (1979), and Cox, Ingersoll and Ross (1985a). The Black-Scholes model employed stochastic calculus, but a simpler framework for option pricing was presented by Cox, Ross and Rubinstein (1979) that retained its essential features and was more flexible for computational
purposes. We will briefly outline this binomial approach and show its connections to the major theoretical features of option pricing.

The binomial model

The binomial model begins with the assumption that the price of a stock, $S$, follows a proportional geometric process:

$$ S(t + 1) = \begin{cases} aS(t) & \text{with probability } \pi \\ bS(t) & \text{with probability } 1 - \pi \end{cases} $$

(18)

In addition to the stock there is also a riskless bond with a return of $1 + r$. The basic problem of option pricing theory is to determine the value of a derivative security, i.e., a security whose payoff depends only upon the value of an underlying primitive security, the stock in this case. Let $C(s, t)$ denote the value of the derivative security as a function of the price of the stock and the time, $t$. Since its value depends only upon the movement of the stock – a result that is sometimes derived as a function of other attributes such as its value at the end of some period – it will also follow a binomial process:

$$ C(S, t + 1) = \begin{cases} C(aS, t) & \text{with probability } \pi \\ C(bS, t) & \text{with probability } 1 - \pi \end{cases} $$

(19)

The time $t+1$ values are illustrated in Figure 2. At any moment of time the information structure branches into relevant states, state $a$ and state $b$, defined by whether the stock goes up by $a$ or $b$. As the figure is drawn, $a>1+r>b$, and clearly $1+r$ must lie between $a$ and $b$ to prevent the stock or the bond dominating. At this point there are two separate approaches to the analysis. The first is in the spirit of the original Black-Scholes model.

Figure 2
Suppose that at time $t$ we form a portfolio of the riskless bond and the stock with $\alpha$ dollars invested in the stock and $1 - \alpha$ dollars invested in the bond. We will choose the investment proportion so that the return on the portfolio coincides with the return on the derivative security in state $b$. This means choosing $\alpha$ so that
which implies that

\[ \alpha = \frac{(1 + r) - \frac{C(\delta S, t + 1)}{C(S, t)}}{(1 + r) - b}. \]  

(21)

But, since the portfolio's return matches that of the derivative security in state \( b \), it must also match it in state \( a \). If it did not, then either the portfolio or the derivative security would dominate the other, which would be an arbitrage opportunity. In other words, we must have,

\[ \frac{C(\delta S, t + 1)}{C(S, t)} = \alpha a + (1 - \alpha)(1 + r). \]  

(22)

Putting these two equations together produces a difference equation which is satisfied by the value of the derivative security,

\[ \pi^* C(\delta S, t + 1) + (1 - \pi^*)C(\delta S, t + 1) - (1 + r)C(S, t) = 0, \]  

(23)

where

\[ \pi^* = \frac{(1 + r) - b}{a - b}. \]  

(24)

Perhaps the most remarkable feature of this equation is that it does not involve the original probabilities for the process, \( \pi \), but rather is a function of what are called the martingale probabilities, \( \pi^* \).

To solve this difference equation for the value, \( C \), of a particular derivative security we would need only to append the contractual boundary conditions that define it. For example, a European call option is specified to have the value \( \max(S - E, 0) \), at a specified future date, \( T \), where \( E \) is its exercise price. Such an option gives the holder the right – but not the...
obligation – to buy the stock for $E$ at time $T$. The dual security is a European put option which gives the holder the right, but again not the obligation, to sell the stock for $E$, at time $T$. The problem is more difficult if the derivative security is of the American variety which means that the holder may exercise it any time up to and including the maturity date $T$ and need not wait until $T$.

Soon after the Black–Scholes paper, Merton (1973b) examined a variety of option contracts and showed how extensive was the range of the technique. Notably, Merton was able to derive a number of qualitative results on option pricing that were relatively independent of the particular process being modelled. For example, he showed that an American call option on a stock that pays no dividends will never be exercised before its maturity date and, therefore, will have the same value as a similar European call. He also demonstrated that put/call parity, i.e. the equivalence between the positions of holding the stock and a put option and holding a bond and a call option, was not generally valid for American options. Ross (1976c) showed that the literature's emphasis on puts and calls was not misplaced since any derivative security could be composed of puts and calls.

A second approach to the valuation problem in our simple example illuminates why the original probabilities played no role in the analysis. Figure 2 displays what is essentially a two-state Arrow-Debreu model. In such a model if there are two pure contingent claims contracts paying one dollar in each state, then all securities can be valued as a function of their values, $q_a$ and $q_b$. It follows, then, that any two securities which are not linearly dependent will span the space just as two pure contingent claims would and they can be used to value all securities in the space.

In our example, the value of the bond is 1 and it must satisfy,

$$1 = q_a(1 + r) + q_b(1 + r),$$

(25)

and the value of the stock must satisfy,

$$S = q_a(aS) + q_b(bS),$$

or

$$1 = q_a a + q_b b.$$

(26)

Solving these two equations we can find the implicit values of the state contingent claims,

$$q_a = \frac{(1 + r) - b}{(1 + r)(a - b)},$$

and
\[ q_b = \frac{a - (1 + r)}{(1 + r)(a - b)} \] (27)

Notice that these prices do not depend on the original probability, \( \pi \), since they are derived from the values of the stock and the bond. Whatever influence the probability, \( \pi \), has on values is already reflected in the returns on the stock and the bond, and the derivative security value will just be a function of the implicit state prices. Using these prices, it is readily verified that the difference equation for the value of the derivative security, equation (23), is the same as,

\[ q_a C(aS, t + 1) + q_b C(bS, t + 1) = C(S, t). \] (28)

Geometrically, this means that the point,

\[ \{ (C(bS, t + 1) / C(S, t)) \}, \{ (C(aS, t + 1) / C(S, t)) \}, \]

we plot on the same line as the return points for the bond and the stock, \((1+r, 1+r)\) and \((b, a)\). For a call option the point will be as drawn in Figure 2 indicating that the call is more volatile than the stock.

Notice from (24) and (27) that

\[ \pi^* = (1 + r) q_a, \]

which means that the state space price can be interpreted as the discounted martingale probability. It is this interpretation that ties together the Cox and Ross (1976a) risk-neutral approach to solving option pricing problems and the general theory of the absence of arbitrage.

Cox and Ross (1976a) argued that since the difference equation that emerged for solving option pricing problems made no explicit use of any preference information, the resulting solution must also be independent of preferences. For example, then, the resulting solution must be the same as that which would obtain in a risk neutral world. In such a world, the state probabilities must be such that the expected returns on all assets are the same,

\[ \pi^* a + (1 - \pi^*) b = 1 + r, \]

where the solution for the probability, \( \pi^* \), is the same martingale probability defined above. For a European call option, then, the solution will be
where $E^*$ is the expectation with respect to the martingale probabilities, $\pi^*$ and $(1 - \pi^*)$. It is easily verified that (29) is the solution to the difference equation (23) subject to the boundary condition,

$$C(S, T) = \max(S - E, 0).$$

Contrast this formula with the original Black-Scholes formula for the value of a call option in a continuous time diffusion model,

$$C(S, t) = SN(d_1) - e^{-r(T-t)}N(d_2),$$

(30)

where $N(\cdot)$ is the standard cumulative normal distribution function and,

$$d_1 = \frac{\ln(S/E) + r(T-t) + \frac{1}{2}\sigma^2(T-t)}{\sigma\sqrt{T-t}},$$

and

$$d_2 = d_1 - \sigma\sqrt{T-t}.$$

Equation (30) is the solution to the Black–Scholes option pricing differential equation,

$$\frac{1}{2} \sigma^2 S^2 \frac{\partial C}{\partial S} + rSC_S - rC = - \frac{\partial C}{\partial t},$$

(31)

subject to the boundary condition,
\[ C(S, T) = \max(S - E, 0). \]

The Black–Scholes differential equation (31) is derived from an analogous hedging argument to that for the binomial model, applied to the continuous log-normal stock process,

\[ \frac{dS}{S} = \mu dt + \sigma dz \]

where \( z \) is a standard Brownian motion. In fact, as the time interval between jumps converges to zero and the jump sizes shrink appropriately, the binomial converges to the lognormal diffusion and its option pricing solution will converge to that for the lognormal diffusion. Notice, too, that in analogy with the binomial whose solution does not depend upon the state probabilities, the Black-Scholes option price (30) is independent of the expected return on the stock, \( \mu \).

The most interesting comparative statics result from these models is the observation that call or put option values increase with increasing variance, \( \sigma^2 \). This is a consequence of these options being convex functions of the terminal stock value, \( S_T \) (Cox and Ross, 1976b).

The general theory of arbitrage

All of the above analysis can be tied together by the general theory of arbitrage. Under quite general conditions, it can be shown that the absence of arbitrage implies the existence of a linear pricing rule that values all of the assets (see e.g., Ross, 1976a, 1978b; Harrison and Kreps, 1979). In a static model with \( m \) states of nature, this means the existence of implicit state prices, \( q_j \), such that \( q_j > 0 \), and such that any asset with payoffs of \( x_j \) in the states of nature will have the value,

\[ p = \sum_i q_j x_j. \]

The intertemporal extension of this result is most neatly displayed in terms of the martingale expectation used above. The absence of arbitrage now implies the existence of a martingale measure such that, with obvious notation,

\[ p = \mathbb{E}^* \left\{ \exp \left[ - \int_0^T r(s) ds \right] x_T \right\}. \]

This theory permits us to tie together not only the basic results of option pricing, but also our previous analysis of asset pricing models. For example, applying it to the exact factor model,
yields the APT,

\[ R_i = E_i + \sum_j \beta_{ij} f_j, \]

Similarly, in a mean variance framework the martingale analysis can be used to prove that there is always a portfolio whose covariances are proportional to the excess returns on each asset. In other words, the absence of arbitrage implies the existence of a mean variance efficient portfolio (see Ross, 1976a; Chamberlain and Rothschild, 1983).

Empirical testing

Perhaps because the option pricing theory works so well, it has generated a surprisingly small empirical literature. Some early tests, for example, Black and Scholes (1973) and Galai (1977), focused on whether the models could be used to generate successful trading rules and found that any success was easily lost to transactions costs. Most interestingly, MacBeth and Merville (1979) found that the option formulas tended to underprice ‘in the money’ options and overprice ‘out of the money’ options, but Geske and Roll (1984) have argued that this effect disappears with a reformulation of the statistics.

Given a theory that works so well, the best empirical work will be to use it as a tool rather than to test it. Chiras and Manaster (1978), for example, show that implicit volatilities, i.e. variances computed by inverting the option formulas to obtain variance as a function of the quoted option price, have strong predictive power for explaining future realized stock variances. Patell and Wolfson (1979) use the implicit variances to examine whether stock prices are more volatile around earnings announcements.

These efforts should increase; options and option pricing theory give us an opportunity to measure directly the degree of anticipated uncertainty in the markets. Financial press terms such as ‘investor confidence’ take on new meaning when they can actually be measured.

This does not mean, however, that there are no important gaps in the theory. Perhaps of most importance, beyond numerical results (see, for example, Parkinson, 1977; or Brennan and Schwartz, 1977), very little is known about most American options which expire in finite time. The American call option on a stock paying a dividend or the American put option are both easily solved in the infinite maturity case since the optimal exercise boundary is a fixed stock value independent of time (Merton, 1973b; Cox and Ross, 1976a, 1976b). If
dividends occur at discrete points, then if the call is exercised prematurely it will only be optimal to do so just prior to a dividend payment. This permits a recursive approach to the solution of this finite maturity option (see Roll, 1977a; Geske, 1979). But, with continuous payouts, surprisingly little is known about the exercise properties of either of these options in the American case.

Despite such gaps, when judged by its ability to explain the empirical data, option pricing theory is the most successful theory not only in finance, but in all of economics. It is now widely employed by the financial industry and its impact on economics has been far ranging. At a theoretical level, we now understand that option pricing theory is a manifestation of the force of arbitrage and that this is the same force that underlies much of neoclassical finance.

**The whole is the sum of the parts— corporate finance**

The use of arbitrage as a serious tool of analysis coincided with the beginning of the modern theory of corporate finance. In two seminal papers on the cost of capital, Modigliani and Miller (1958, 1963) argued that the overall cost of capital and, therefore, the value of the firm would be unaffected by its financing decision. Specifically, using arbitrage arguments, Modigliani and Miller showed that the debt/equity split would not alter a firm's value and they then argued that with the investment decision held constant, the dividend payout rate of the firm would also not affect that value. These two irrelevance propositions defined the study of corporate finance in much the same way that Arrow's Impossibility Theorem defined social choice theory. At one and the same time they propounded an irreverent theory whose central feature was the irrelevance of the topic under study. This challenge, to weaken in a useful way the assumptions of their analysis, has guided research in this area ever since.

**The Modigliani– Miller analysis**

Since the Modigliani-Miller (henceforth MM) irrelevance propositions are developed from the absence of arbitrage, they are quite robust to alternative specifications of the economic model. To derive the Modigliani-Miller propositions we will employ the no arbitrage theory above. Consider a firm which will liquidate all of its assets at the end of the current period, and let \( x \) denote the random liquidation value of the assets. Assume that the firm has debt outstanding with a face value of \( F \) and that the remainder of the value of the firm is owned by the stockholders who have the residual claim after the bondholders.

At the end of the period, if \( x \) is large enough the stockholders will receive \( x - F \) and if \( x \) falls short of \( F \) they will receive nothing. Formally, then, the terminal payment to the stockholders is

\[
\max(x - F, 0),
\]

which will be recognized as the terminal payment on a call option. In other words – in a tribute to the ubiquitous nature of option pricing theory – the stockholders have a call option on the terminal value of the firm, \( x \), with an exercise price equal to the face value of the debt, \( F \). The bondholders can claim the entire assets if \( x \) is not sufficient to cover the promised payment of \( F \), which means that they will receive,

\[
\min(x, F)
\]

The current value of the firm, \( V \), is defined to be the value of all of the outstanding claims against its assets which in this case is the value of the stocks, \( S \), and the bonds, \( B \). Using the no arbitrage analysis, we find that (ignoring discounting),

\[
V = S + B = E^S(\max(x - F, 0)) + E^B(\min(x, F)) = E^S(\max(x - F, 0) + \min(x, F)) = E^S(x),
\]
which is independent of the face value, \( F \), of the debt and, therefore, independent of the relative amounts of debt and equity. This verifies the first of the MM irrelevance propositions. To verify the irrelevance of value to the dividend payout, consider a firm about to pay a dividend, \( D \). The current, pre-dividend, value of the stock is \( p^-(D) \) and by the no arbitrage martingale analysis this is given by,

\[
p^-(D) = E^* [D + p^+(D)] = D + E^* [p^+(D)],
\]

where \( p^+(D) \) is the ex-dividend price. If the investment policy of the firm has been fixed, then the only impact that the current dividend payout can have on the stockholders is through its alteration of the cash in the firm. This means that changing the dividend to, say \( D + \Delta D \), would necessitate a change in current assets of \(-\Delta D\). From the first MM proposition the mode of financing this change in the dividend will be irrelevant to the determination of the firm's value and to simplify the analysis we will assume that it is financed by riskless debt. At an interest rate of \( r \) this would entail, say, a perpetual outflow from the firm of \( r\Delta D \). Again applying the analysis and letting \( x_{t+s} \) be the cash flow at time \( t+s \) given that a dividend of \( D \) is paid now, we have,

\[
p^+(D + \Delta D) = E^* \left[ \int_0^\infty e^{-rs} [x_{t+s} - r\Delta D] ds \right] = E^* \left[ \int_0^\infty e^{-rs} x_{t+s} ds \right] - E^* \left[ \int_0^\infty e^{-rs} r\Delta D ds \right] = p^+(D) - \Delta D.
\]

Thus, we have the irrelevance proposition,

\[
p^-(D + \Delta D) = E^* [(D + \Delta D) + p^+(D + \Delta D)] = D + \Delta D + E^* [p^+(D + \Delta D)] = D + \Delta D + E^* [p^+(D)] - \Delta D = D + E^* [p^+(D)] = p^-(D).
\]

The MM results were startling to those who had worked in corporate finance and had taken it for granted that the way in which a firm was financed affected its value. To understand the importance of the MM results for the most practical of problems; recall that the original impetus for the study of corporate finance was the determination of the firm's opportunity cost for investments, \( \rho \). For a marginal investment, financed by the issuance of debt and equity, the cost of capital, \( \rho \), also known as the weighted average cost of capital, WACC, would be the weighted average cost of the debt, \( r \), and the cost of equity, \( k \),

\[
\rho = (S/V)k + (B/V)r,
\]

(33)

(where we have ignored tax effects).

If debt is riskless, then \( r \) is the interest rate on such debt and \( k \), the cost of equity, will be the return required by investors for the risk inherent in the stock. Presumably \( k \) could be found by appeal to one of the asset pricing models discussed above.

Now it is tempting to think, for example, that if \( k > r \), then an increase in debt relative to equity will lower \( \rho \). If this goes too far, debt will become risky and as \( r \) rises there will be a unique optimal debt/equity ratio, \( (B/S)\), that minimizes the cost of capital, \( \rho \). This would be the discount rate to use for present value calculations and it would maximize the value of the firm. This was the traditional analysis of the leverage decision before MM.

By the MM theorem, though, value, \( V \), is unaffected by leverage. This means that \( \rho \) is unaltered, since the total (expected) return to the stockholders and the bondholders, \( S + B \), is
unaltered [see Equation (33)]. In terms of the WAAC, then, as the leverage \((B/S)\) is increased by the substitution of debt for equity, the cost of equity changes.

\[
k = \rho + \left( \frac{B}{S} \right) (\rho - r),
\]

but not the WAAC.

**Spanning arguments**

The efforts to elude these results and to develop a meaningful theory of corporate finance have taken many forms. First, it has been argued that the analysis itself contains a hidden and critical assumption, namely that the pricing operator is independent of the corporate financial structure. The alternative is that the change in the debt/equity decision, for example, will also change the span of the marketed assets in the economy and, consequently, the operator used for pricing will change. The simplest such example would be a single firm in a two-state world. If the firm is an all equity firm and if there are no other traded assets, then individuals cannot adjust their consumption across the states of nature and must split it according to the equity payoff. If this firm now issues debt the two securities will span the two states of nature and complete the market. This, in turn, will generally alter pricing in the economy.

While this argument has generated a large literature, the problem of the determination of the corporate financial structure and the value of the firm is primarily a microeconomic question and it is difficult to believe that it will be resolved or even illuminated by assuming that firms have some monopoly power that enables them to alter pricing in the capital markets. At the microlevel the MM propositions are unlikely to be seriously affected by such general equilibrium arguments.

At the microlevel, too, the intuition behind the MM propositions and its conclusions is so robust as to be daunting. Consider the following argument. According to MM there can be no optimal, i.e. value maximizing, financial structure since value is independent of structure. Suppose that there was an optimal, say, debt/equity ratio, \((B/S)^{0}\). Any departure from this target \((B/S)^{0}\), however, could not lower the firm's value since it would immediately afford an arbitrage opportunity to buy the total firm at its lowered value and refinance it in the optimal target propositions, \((B/S)^{0}\). (This somewhat facetious argument gets the point across, but it really means that we have not fully specified the rules of the game, e.g., who moves first, what happens when no one moves, etc.)

**Signalling models**

A more promising route which formally exploits incomplete spanning, but does not argue that the pricing operator itself is altered by any one firm changing its financial structure, makes use of the theory of asymmetric information and signalling (see Ross, 1977a; Leland and Pyle, 1977; and Bhattacharya, 1979). If the managers of the firm possess information that is not held by the market then the market will make inferences from the actions of the firm and in particular, from financial decisions. Changes in its financial structure or its dividend policy will alter investors’ perceptions of its risk class and, therefore, its value. While the operator, \(E^{*}(\cdot)\), does not change, the perception of the distribution of the firm's cash flows does. In an effort to maximize their value, firms will take actions, such as taking on high debt to equity ratios, which can be imitated by lesser firms only at a prohibitive cost. This will distinguish them from lesser firms that the uninformed market erroneously puts into the same classes with them. In this fashion, a hierarchy of firm risk classes will emerge, and, in equilibrium, firms will signal their true situations and investors will draw correct inferences from their signals.

All of this has a nice ring to it, but the nagging question that remains is why firms use their financial decisions to accomplish all of this information transfer. Financial changes are cheap, but even cheaper might be guarantees or, for that matter, a system of legislation. These issues remain unresolved, but it is difficult to think that much will be explained by theories that argue that firms take on more debt just to show the world that ‘they can do it’. There is a limit to macho-finance.

**Taxes**

Another line of attack has been to introduce more ‘imperfections’, especially taxes, into the models. Modigliani and Miller originally had noted that the presence of a corporate tax meant that firms would have an incentive to issue additional debt. Since interest payments on debt are excluded from corporate taxes, substituting debt for equity permits firms to pass returns to investors with a lowered tax cut to the government. At the limit, firms would be all debt if the tax authorities still recognized such debt payments as excludable from taxable corporate income. Presumably, the only brake to this expansion would be the real costs of dealing with the inevitable bankruptcies of high debt firms. This is logically possible, but at the expense of reducing corporate finance to the study of the tradeoff between the tax advantages of debt and the costs of bankruptcy.
A boom in merger and acquisition activity in the late 1970s and through to the present time has brought some striking and unexplained empirical regularities. On average, shareholders in firms that are the targets of tender offers gain significantly from such offers while the rewards to bidders are still ambiguous (Jensen and Ruback, 1983). For unsuccessful tenders the target firms appear to average an eventual loss and the bidders may, too. These results and the discrepancy between targets and bidders have been the object of close scrutiny.

Miller (1977) found a more profound brake to this tendency to increase debt. He argued that while the firm could lower its taxes by increasing its debt, the ability of investors to defer or offset capital gains implies that they pay higher taxes on interest income than on the returns from equities. With a rising tax schedule, an equilibrium is possible in which the marginal investor has a tax differential between ordinary income and equity returns that exactly offsets the firm's corporate tax advantage to debt. In such an equilibrium, investors in a higher tax bracket than the marginal investor would purchase only equity (or non-taxed bonds such as municipals for US investors) and those in lower tax brackets would purchase corporate bonds. There would be an equilibrium amount of debt for the corporate sector as a whole, but not for any individual firm (assuming the absence of inframarginal firm tax schedules).

Miller's analysis led to a large literature on the impact of taxes on pricing. Black and Scholes (1974) had made a related argument for the absence of a tax effect on dividends, arguing that stocks with relatively higher yields should not have higher gross returns to compensate investors for the additional tax burden since companies would then just cut their dividends to increase the stock price. Black and Scholes verified their results empirically, but, using a different methodology, Litzenberger and Ramaswamy (1982) found that gross returns were higher for stocks with higher dividends. Whether the supply side or the demand side dominates remains undecided.

Whatever the resolution of this and similar debates, the equilibrium tax argument initiated by Miller has changed much of the analysis of these issues. Miller and Scholes (1978), for example, argue that by employing a number of ‘laundering’ devices individuals can dramatically cut their taxes. Their conclusion that, in theory, taxes should be much lower than they appear to be in practice, focuses attention on the role played by informational asymmetries and the related costliness of using techniques such as investing through tax exempt intermediaries.

Agency models

The emphasis on informational asymmetries has been the cornerstone of an alternative approach to corporate finance, agency theory. Wilson (1968) and Ross (1973) developed agency models in which one party, the agent (e.g. a corporate manager) acts on behalf of another the principal (e.g. stockholders). Jensen and Meckling (1976), building on the agency theory and on Williamson's (1975) transaction cost approach, argue that corporate finance can be understood in terms of the monitoring and bonding costs imposed on stockholders and managers by such relations. The manager qua employee has an incentive to divert firm resources to his own benefit. Jensen and Meckling refer to the loss in value in restraining this incentive as the (equilibrium) agency cost of the relation.

To some extent this conflict can be resolved ex ante by the indenture agreements and covenants in financial contracts, but the cost of doing so rises with the monitoring requirements. Myers (1977), for example, has studied the implications for investment policy of the conflict between the stockholders and the bondholders. Stockholders own a call option on the assets of the firm and the value of a call increases with the variance of the asset value. Conversely, such increases will come at the expense of the bondholders. Ex ante indenture agreements can limit the ability of management and stockholders to take on additional risk, but the more precise the limits the costlier it is to write, observe and enforce them.

These trade-offs are the intuition and subject matter of the agency approach to corporate finance, but to date it is more a collection of intuitions than a well-articulated theory. The agency approach has pointed in some intriguing directions, but it fares poorly if judged by asking what it is that would be a counter observation or count as evidence against it. To the contrary, no phenomenon seems beyond the reach of ‘agency costs’ and at times the phrase takes on more of the trappings of an incantation than an analytical tool. The role of asymmetric information in corporate finance and in explaining the managerial and financial forces at work in the firm is self evident, but it remains fertile ground for theory.

Empirical evidence

The early empirical work examined the relation between the corporate financial structure and other characteristics of the firm. Hamada (1972), for example, studied whether the beta of a firm's equity was related to the beta of the firm's assets as would be predicted by the cost of capital, equation (33). There continues to be empirical work on these issues, but the attention of empiricists has shifted to the arena of corporate control.

A boom in merger and acquisition activity in the late 1970s and through to the present time has brought some striking and unexplained empirical regularities. On average, shareholders in firms that are the targets of tender offers gain significantly from such offers while the rewards to bidders are still ambiguous (Jensen and Ruback, 1983). For unsuccessful tenders the target firms appear to average an eventual loss and the bidders may, too. These results and the discrepancy between targets and bidders have been the object of close scrutiny.

If firms realize such abnormal gains as targets, and if it reflects the release of information about the value of their underlying assets, then that raises the question of why they were not priced correctly to begin with. On the other hand, if the returns for successful targets reflect synergies rather than simply a revaluation of their assets, why does the bidder get so little? Several game theoretic and bidding models have been built in an attempt to explain these results (see, e.g., Grossman and Hart, 1980), but a consensus has yet to emerge. Furthermore, some of the important empirical issues, such as whether bidders actually gain or lose on average remain unresolved.
Conclusion

For corporate finance, like the other major areas of finance, the neoclassical theory is now well established, but, like the other areas, the inadequacy of the neoclassical analysis is pushing researchers to begin the challenging but promising exploration of theories of asymmetric information. This work holds out the hope of explaining some of the deeper mysteries of finance that have eluded the neoclassical theory, from the embarrassing plethora of anomalies in capital markets to the basic questions of financial structure. Perhaps the feature that truly distinguishes finance from much of the rest of economics is this constant interplay between theory and empirical analysis. The test of these new approaches will be decided less by reference to their aesthetics and more by their usefulness in explaining financial data. At the height of the subject, these two criteria become one.

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article deals with the process of financial intermediation; that is, savings and investment flows that are intermediated through organizations such as banks and insurance companies. There are five major topics: stylized facts about financial intermediary organizations and markets; the history of thought about financial intermediation; the theory of financial intermediaries, with an aside on equilibrium credit rationing; the regulation of financial intermediation; and trends in recent research and open research questions.

Article

1 Preliminaries and introduction

Writing an article such as this requires making some tough decisions about what to include and what not. Many deserving topics in financial intermediation have not been mentioned at all and I cannot begin to cite all the good papers that deserve reference. Primarily, I rely on two excellent survey articles, one that focuses on theory (Gorton and Winton, 2003), and another that focuses on empirics (Levine, 2005). I received helpful comments from Doug Diamond, Jack Kareken, Ross Levine and Ed Prescott; however, they are totally absolved from any errors that remain. It is the convention to distinguish between ‘financial markets’ and ‘financial intermediaries’. A financial
market is a market in which investors acquire direct claims against ultimate borrowers, usually in the form of debt or equity. A financial intermediary (FI) is a firm that substitutes its own liability for that of some ultimate borrower. That is, an investor lends to the FI and, in turn, the FI lends to an ultimate borrower. I adopt this standard convention even though the distinction is often imprecise. (For example, debt and equity claims are rarely traded directly between the ultimate claimants. Even these are 'intermediated'.) Next, let us turn to some facts about FIs.

The assets of FIs are almost exclusively financial claims. FIs do not have many physical assets, except buildings and computers, and they produce no physical products; thus they are service firms. Important and easily recognizable examples of FIs would include commercial banks, savings and loan associations, credit unions, life insurance firms, property and casualty insurers, consumer finance companies, and mortgage bankers.

Banks largest

Commercial banks (hereafter banks) are the most important class of FIs, and this has been true for centuries. In developing economies, banks often play a dominant role and may be, essentially, 'the only game in town'. Even in the United States, with its highly developed financial markets, banks accounted for about 14.2 per cent of financial intermediary assets, which is the largest private share, followed by mutual funds at 12.4 per cent (Board of Governors of the Federal Reserve System, 2005). This size factor helps explain why banks have been the most-studied class of FI by a wide margin. Banks are also especially important and heavily studied because they create money and thus are the conduit for monetary policy. This article follows the norm and devotes a disproportionate amount of its attention to banks.

Heavily regulated

FIs are heavily regulated relative to non-financial firms. Most of this regulation is advertised to promote 'safety and soundness', meaning that its stated intent is to reduce the frequency of failures and other problems in the industry. There are four basic forms of regulation: minimum capital requirements, examination by regulatory authorities, portfolio restrictions on asset holdings, and restrictions on who can own or manage an FI. In many countries, there has been a trend towards less intensive regulation of FIs since the mid-1990s, but in these four forms regulation remains obtrusive relative to most industries.

A large industry

The FI industry is relatively large. Especially in developed economies, the FI sector is a significant part of the economy, with a substantial share of measured output. In the United States, for example, the total value-added of financial intermediaries (essentially profits, wages and salaries) amounts to about 8.1 per cent of GDP. This makes the US FI sector much larger than (say) the agricultural sector, whose share of total value-added is about one per cent (Bureau of Economic Analysis, 2006). Across countries, there is a strong correlation between size and quality of the FI sector and the level of economic development. This relationship is an important topic in development economics but such issues are not considered
Organizational form

In most countries the dominant form of organization for FIs is the corporation; however, there are important exceptions. In particular, many FIs are organized as ‘mutuals’ or ‘cooperatives’. With this alternative form of organization, there is no separate class of shareholders or equity owners, as would be the case in a corporation. For example, in mutual life insurance companies the policy holders are also the owners. In mutual savings and loan associations, the depositors are the owners. These alternative organizational forms are common in the United States, Europe and many other parts of the world.

Recent trends

Since the mid-1990s, the FI sector has experienced substantial change. The main trends worldwide are towards consolidation (a smaller number of larger firms), diversification (a larger set of financial activities or ‘products’ offered at the same FI), and internationalization (operating across borders). Almost every part of the world has participated in these developments, excepting sub-Saharan Africa (De Nicolò et al., 2004).

2 History of thought on financial intermediation

In the 1960s and 1970s, the economic analysis of FIs was largely focused on banks, and these were viewed essentially as ‘black box’ organizations that turned high-powered money (bank reserves) into money. At that time, most intellectual interest in banks derived from their role in creating money, and their being the conduits for monetary policy. In some sense, the study of banking was in those decades incidental to the study of monetary policy and macroeconomics. There had been an earlier literature on FIs that showed great depth of understanding, but in a non-mathematical, descriptive context. Scholars such as Bagehot, Goldsmith and Schumpeter wrote about, and clearly understood, information asymmetries, liquidity, and so forth. When ambitious scholars, such as Tobin (1969) or McKinnon (1973), tried to incorporate FIs into Keynesian models before the profession had invented the mathematical tools to formally model information and liquidity, the crucial intuitive insights about the role of FIs were absent from the models. Thus, finance became money, and money was simply a stock associated with real capital.

In the mid-1980s a new body of thought emerged and was largely attributable to the seminal work of Diamond (1984) and Diamond and Dybvig (1986). Other significant papers at about that same time included Williamson (1986) and Boyd and Prescott (1986). This new approach to studying financial intermediation stressed that FIs are firms that produce valuable economic services of a variety of kinds, and explicitly modelled the nature of those services. This literature was careful to model the profit, share price, or utility-maximizing behaviour of FIs subject to appropriate constraints, and much of this work was done in general equilibrium. More importantly, almost all this work and the large literature that followed featured environments with private information – private in the sense that different agents were endowed with different knowledge. This was a major deviation from the previously studied world of...
Arrow–Debreu, in which markets are frictionless and perfectly competitive, and all relevant information is common knowledge. It was a critical innovation because in the environment of Arrow–Debreu FIs are irrelevant (cannot increase welfare). In that world FIs are just not very interesting to study in a serious way, and they weren’t.

Sequence was also very important in the development of the modern FI literature. Since the post-1983 FI literature almost exclusively employed models with private information, this meant that development of the literature depended on, and naturally followed, advances in information economics thanks to the pioneering work of Akerlof, Hurwitz, Stigler and others. Most likely, this is why earlier efforts to force FIs into Keynesian macro models were a failure; the required tools simply had not yet been invented. In the next section, I briefly review some of the modern FI models developed in the 1980s and subsequently. Later, in Section 5, I discuss some areas in financial intermediation where, in my judgment, there remain important gaps in our knowledge.

3 The theory of financial intermediation

Banks and other FIs are firms that take in funds (FI liabilities) through a hypothetical front door, and put out funds (FI assets) through a hypothetical back door. They produce no physical products. To survive, they must earn a profit, meaning that the average rate of return on their assets must exceed the average cost of their liabilities. This spread between asset returns and liability costs must be large enough to cover operating costs (primarily wages and salaries), and to earn a rate of return to equity investors. That FIs earn such positive profits has always troubled critics of the industry (of which there have always been many), who may conclude that FIs are somehow exploiting consumers or businesses. In fact, FIs are permitted to earn these positive interest rate spreads because they provide valuable economic services to the economy, and it is costly to provide these valuable economic services. Let us next consider these services.

One important function, offered by banks but not other FIs, is payment services. This is the ‘creators of money’ banking function that the old literature stressed, virtually to the exclusion of other FI functions. When we need to execute transactions, we use cash and coin, paper checks, credit cards, and wire transfers. All of these transaction tools are generally provided by banks and for obvious reasons they are economically important.

Another important function of FIs is that they are ‘brokers’ in the sense that they bring together large numbers of ultimate borrowers and lenders. When they bring these groups together, FIs substitute their own liabilities for those of ultimate borrowers, and this is what ultimately distinguishes FIs from financial markets. This process has been given many names in the literature (‘asset transformation’ is common) and understanding it is key to understanding what FIs actually do. Hypothetically, consider one single bank depositor, a wealthy individual, and one single bank borrower, a small business. The bank depositor might have lent directly to the small business through the stock or bond market. Instead, by assumption, he or she lends to the bank in the form of a deposit. In turn, by assumption, the small business borrows from the bank in the form of a commercial loan. The bank places itself in the middle of the exchange and becomes the counter-party to the others.

Why is this valuable? The answer is that bank liabilities typically have different attributes from ultimate borrower liability attributes, ones that are crafted to be desirable to the bank liability holders. If they are made better off, they are willing to lend at a lower rate than they would have required to lend directly.
Thus, this process of asset transformation can, and usually does, make both borrowers and lenders better off.

For banks, the general direction of such asset transformation is well understood: bank liabilities will typically have shorter maturity than bank assets, and will be more liquid and less risky. As will become apparent, a key ingredient to this process is that the banks borrow from a large number of creditors, and lends to a large number of borrowers.

**Shorter maturity**

Bank liabilities often have shorter average maturity (or duration) than bank assets, and *ceteris paribus* this may make bank liabilities relatively more attractive to savers. Such maturity mismatching exposes banks to an interest rate lottery and the risk that interest rates will increase, in which case they will suffer capital losses. Bank creditors are partially protected against interest rate risk by the bank’s equity, at least until that is exhausted. The degree of interest rate risk exposure naturally depends on the magnitude of the asset–liability maturity mismatch, and on how volatile are interest rates. In the 1970s, the US savings and loan (S&L) industry experienced massive losses due to interest rate risk, losses so large as to bankrupt much of the industry as well as its government insurer, the Federal Savings and Loan Insurance Corp (FSLIC). The S&Ls’ maturity mismatch was substantial, and interest rates had become extremely volatile by historical standards. However, the savings and loan industry should not be blamed for this sad experience. Government regulations essentially forced this industry to borrow short and lend long. Since the mid-1990 banks and other FIs have become clever in finding ways to hedge interest rate risk in the forward, futures and swap markets. (Of course, someone still has to bear the aggregate risk.) Also, there is some evidence that, in the United States at least, FIs have in recent years become less willing to expose themselves to interest rate risk. As a practical matter, however, it is difficult to accurately measure the maturity mismatch of banks, and standard duration methods may not work very well for this industry. That’s because a substantial proportion of bank liabilities are in the form of demand (checking) deposits. For these liabilities, the technical maturity is instantaneous but the true maturity is much longer, depends on economic conditions, and must be empirically estimated.

**More liquid**

Bank liabilities, especially deposits, are more liquid than bank assets. This is another desirable form of asset transformation since, *ceteris paribus*, lenders like to hold liquid assets. The liquidity provision function has been heavily studied by scholars, and the seminal reference on the topic is Diamond and Dybvig (1986). Now, liquidity is hard to define, let alone understand, and it may help to consider a simple theoretical environment, similar in some ways to the more complicated environment studied by Diamond and Dybvig (1986). Imagine a world in which there are only two assets: gold coins and land. By assumption, gold coins are perfectly liquid and can be spent at any time but earn no rate of return. Land, on the other hand, is highly productive but illiquid. It is hard to sell land in an emergency, and possibly it can’t be sold at all. All agents in this economy have a known, say one per cent, chance of an ‘emergency’, the occurrence of which is independent across agents. In an emergency, agents desperately want to have all their wealth immediately so they can consume it. Now, consider the problem facing
individual agents. If they put all their wealth in coins (land) they will do well 1 (99) per cent of the time; however, they will do very badly 99 (1) percent of the time. Common sense suggests that the best strategy will be to split up their holdings, and if you guessed that you would be right at least for most preferences. Even then, however, agents are not doing as well as they potentially could in either state of the world.

Next, assume a bank is organized, which offers each individual a deposit account that can be redeemed in gold coins on demand. Further, assume the bank puts 1 per cent of its assets in gold coins and 99 per cent in land. Now, if the bank deals with a sufficiently large number of depositors, it will have enough coins to just cover withdrawals and all the remaining can be invested in highly productive land. Everyone is better off than they could have done on their own account.

This kind of an arrangement is usually referred to as ‘fractional reserve banking’. The key to its smashing success is diversification across a large number of depositors, and the fact that depositor withdrawal demands are independent. Now, as Diamond and Dybvig are quick to point out, this idealized solution may not always work out in practice. Suppose, for example, that emergency withdrawals become correlated, perhaps because there is a war. Then the bank can easily run out of coins, fail on its obligations, and land must be inefficiently liquidated. Even worse, just a false rumour of war could send too many depositors to the bank and cause it to fail. This sort of occurrence is called a ‘bank run’ and these have been quite common both historically and in recent times. In an imperfect world where withdrawals may be correlated and bank runs are possible, every bank faces a fundamental and unpleasant trade-off: if it holds a high fraction of gold coins (reserves) risk of insolvency will be low, but the average rate of return on its assets will be low. If it holds a high fraction of land (earning assets) its average rate of return on assets will be high, but its risk of insolvency will be high. There is a large literature on this topic, much of which is referenced in Gorton and Winton (2003).

Less risky

Bank liabilities are on average less risky than bank assets, and obviously this tends to make bank liabilities ceteris paribus more attractive. Now, bank liabilities can be less risky than the representative bank loan for a variety of reasons. One is that banks often place some fraction of their assets in default-risk-free government securities. A second reason is that banks raise part of their funds in the form of equity, and the bank's shareholders must suffer a total loss before liability holders lose. A third reason is that banks hold portfolios of different kinds of loans that are diversified by industry and geography, so that their loan portfolio is less risky than its individual components. A fourth reason is that in most countries bank deposits are fully or partially insured by government.

In addition, banks are very good at determining to whom to lend, and in setting loan terms for those who are funded. This topic has been heavily studied in the FI literature and the reader can find many studies under the headings ‘adverse selection’, ‘sorting’ and ‘screening’ in Gorton and Winton (2003). In most of these models, some loan applicants are better credit risks than others, applicants know their own types, and are willing to misrepresent (say they’re good when they’re bad). FIs do not know the applicants’ types, although it is conventional to assume that everyone knows the underlying distribution of applicant types. The FI’s objective is to accept (reject) good (bad) applicants where possible. In some but not in all cases, it is possible to adroitly choose terms of lending such that good applicants voluntarily sign up, and bad applicants withdraw. In other cases, the best strategy is simply to accept
Another important aspect of lending, and an aspect at which FIs excel, is monitoring borrowers after they have received the money. This ‘ex post monitoring’ has also been heavily studied in the FI literature. Once they have the money, borrowers may take actions that reduce their probability of repaying, or events beyond their control may have the same effect. To protect their interests lenders normally pre-specify loan covenants that state what happens in such cases, and they monitor borrowers to enforce these covenants. An example that homeowners will understand is a residential mortgage: to protect its interests, the lender must be sure that property taxes are being paid, and that the house is fully insured. Now, it is often the case that loans are large relative to the wealth of individual agents in the economy. This naturally occurs because many production technologies exhibit economies of scale. For example, an automobile plant must be of a particular size to be efficient, and few if any agents can fund such an investment with their own wealth. Therefore, to fund a loan often requires obtaining financing from several agents simultaneously. Unless FIs are present there is a coordination problem among the several lenders, and it is a problem first studied by Diamond (1984) and Williamson (1986).

Monitoring of borrowers is costly, and no one wants to do it if they don't have to. Now, for simplicity, assume that there are just two lenders for a given loan, lender A and lender B. Now, A (B) may assume that B (A) will monitor, in which case neither lender actually does. This is obviously undesirable because their interests are not being protected. Alternatively, lender A and lender B might both be conservative, assume the other is unreliable, and monitor themselves. In that case there would be redundant monitoring which is unnecessary and wasteful. Clearly, what is needed is an arrangement in which all lenders agree to have ex post monitoring done by a single, efficient ‘delegated monitor’. What is critical, if such an arrangement is to work, is that the delegated monitor finds it in its own interests (incentive compatible) to actually do the work as promised. Otherwise, it might be necessary to monitor the monitor, which obviously would be inefficient, too. Diamond (1984) and Williamson (1986) showed that efficient ex post monitoring can be achieve by a bank that pools funds from many depositors and uses the proceeds to make many loans.

Summary

In a world in which different agents have different information sets FIs earn a positive interest spread between their average asset returns and average liability costs, in return for providing valuable services. They are brokers between ultimate borrowers and ultimate lenders, and they provide payments services. They transform ultimate financial claims in the sense that their liabilities have different attributes from their assets. Typically, their liabilities are shorter in maturity, more liquid and less risky; thus, such liabilities are more desirable to savers. This process of ‘asset transformation’ is not without risk. FIs are exposed to interest rate risk and particularly vulnerable to unexpected interest rate increases. We discussed the case of the US savings and loan industry and its devastating exposure to interest rate increases. Due to their liquidity provision, banks are exposed to the risk of bank runs. Bank runs have been common historically, and still have occurred with some frequency in the modern wave of banking crises. Finally, all FIs are exposed to default risk when their loans or other investments do not pay off in a timely manner.

4 An aside on equilibrium credit rationing
When economists began studying intermediation environments with private information, in which agents could withhold the facts, intentionally deceive one another, and so on, all manner of new and interesting results were obtained. One seminal model of financial intermediation featured an outcome called ‘equilibrium credit rationing’ (Stiglitz and Weiss, 1981). In such cases, at the equilibrium rate of interest there is excess demand in the sense that some would-be borrowers are denied access to credit. This is quite at odds with a classical market equilibrium, and immediately raises the question, ‘why don’t lenders just increase the rate of interest to a level at which demand equals supply?’ A variety of answers to this question can be found in the literature, reflecting the different environments that have been shown to produce equilibrium credit rationing. For one example, assume that credit applicants are of two types, good and bad, and that lenders take account of borrower heterogeneity in their rate setting. Then, it can be the case that for sufficiently low interest rates both good and bad will borrow, but above some threshold rate $r^*$ good types become unwilling to borrow. In such cases lenders may find it optimal to set the rate at $r^*$ even though there is excess demand at that rate. A second example is an environment with moral hazard in the form of a bad action that borrowers may take ex post (such as increasing the risk of their investment project). For some parameterizations, when rates are below a threshold $r^+$, borrowers will not take the bad action, but above $r^+$ they will. As in the case above, it may be optimal for lenders to set the rate at $r^+$, thus avoiding the bad action, and resorting to credit rationing.

These first two environments are with private information: however, a third one can result in equilibrium credit rationing even when all information is public. Imagine that default by borrowers results in a deadweight loss – for example, an out-of-pocket bankruptcy cost. Then, the probability of costly default directly depends on the rate of interest, and the higher that rate is the higher the default probability is. Increasing the rate of interest increases the expected rate of return to lenders in good (non-default) states, but also increases the probability of default which is costly to both parties. Depending on the distribution of possible returns facing borrowers, it may be that raising the rate beyond some threshold $r^-$ is futile in the sense that the marginal cost exceeds the marginal benefit. In these cases, rates above $r^-$ are harmful to both parties and will never be observed in equilibrium. Yet it may also be true that $r$-plus is too low to clear the market, and equilibrium credit rationing will again be observed (Williamson, 1986).

Arguably, equilibrium credit rationing is a topic where theory leads measurement. There has not been a lot of good empirical work on credit rationing per se, primarily because it is so hard to do right. Credit rationing equilibria are off the usual demand and supply curves that econometricians like to estimate, and they may exhibit nasty jumps, discontinuities, and so on. If the theorists are right, however, and credit rationing is popping up all over, more empirical work would be useful, especially in the area of finance and development.

5 Regulation

Banks and other FIs are, almost without exception, rather heavily regulated. This is true in virtually all countries and has been true for centuries. There are at least three reasons for this special and obtrusive regulatory treatment. First, banks are the conduit for monetary policy, and problems in banking are likely to interfere with monetary policy conduct. Second, it is widely believed that bank failures may result in negative externalities (social costs). And third, governments may find it irresistible to control a
critical industry that creates money and allocates a large fraction of investment capital. Some recent work has emphasized the importance of political economy issues for regulation, in particular arguing that it is unlikely that bank regulation can contribute positively to social welfare in economies with weak and/or corrupt governments (Barth, Caprio and Levine, 2006).

The Great Depression was a difficult time for banks in the United States and many other countries, and during the late 1920s and early 1930s there were literally thousands of bank failures worldwide. Many of these were associated with bank runs and panics. In response, many nations substantially beefed up their regulation of FIs and put in mechanisms such as deposit insurance to reduce or eliminate the prevalence of bank runs. For example, the Federal Deposit Insurance Corporation was created by US federal legislation in 1933. Beginning in the mid-1930s, the industry stabilized (at least in developed nations), and went through a period of relative calm that lasted for about three decades. Many observers believed that these policy interventions had solved the problem of instability in banking; but that was not to be. Beginning in roughly the mid-1960s, a new wave of banking crises affected well over 100 nations. Banking crises – some of them severe – have been recently experienced in developing and developed economies alike.

No one knows for sure what has caused this interesting historical sequence of events in banking, but many scholars have emphasized that policy interventions intended to stabilize the industry may have actually had opposite effect. In most countries, banks have access to emergency borrowing from the government (a Discount Window), and have some form of government insurance to protect depositors. Additionally, there is a common practice known as ‘too big to fail’ whereby governments will prop up their very largest FIs if they get into trouble. This package of interventions is widely referred to as ‘the safety net’, and it has been very heavily studied. Most of the literature on this topic concludes that, whatever the benefits of a safety net, it also distorts bank incentives in a perverse way. Depositors and other bank creditors don't care how much risk the bank takes (they are protected by government), and normal market risk-constraining mechanisms become ineffective.

In the presence of a safety net, banks may have an incentive to take on more risk ceteris paribus than otherwise; indeed, they may even become risk lovers who intentionally seek out investments with low expected returns and high variance. It's not hard to see why this is so. If an FI has very risky investments and these payoff, all the profits go to FI shareholders. If they don't payoff the FI goes broke, but the resulting losses are mostly absorbed by government. In essence, this is a ‘heads I win tails you lose’ gamble. Perhaps the most dramatic evidence of this distortion turned up during the U.S. S&L crisis. At that time, many S&Ls were obviously bankrupt but could not be closed down since their federal deposit insurer, the FSLIC, had run out of money. Many such institutions gambled for redemption by taking extreme risks. If they were lucky enough they might survive, and if not … well, they were already broke. As of 2007, solving the problems associated with the safety net is arguably the most vexing policy issue facing FI regulators and scholars of that industry. Many regulatory interventions, such as restrictions on asset holdings, attempt to control FIs’ behaviour but do not deal with the fundamental distortion of risk incentives. Other regulatory interventions such as capital regulation are intended to reduce FIs’ distortion of risk incentives, but may not be effective (Hellmann, Murdoch and Stiglitz, 2000). FIs have a natural tendency to try to get around all these regulations, pursuing strategies that render the regulations ineffective. On the other hand, getting rid of the safety net would have its own risks, and it is far from obvious how governments could ever credibly commit to a policy of no FI bailouts. This issue is probably best described as important but unfinished business.
6 Trends in recent research, and open research questions

1. As discussed earlier, the modelling of financial intermediaries has come a long way since the mid-1980s, and most modern macroeconomic models reflect that reality. Even so, there is still recent work that reflects old ways of thinking about FIs. To make this point I provide just one example: the ongoing discussions of the so-called ‘Friedman Rule’. This rule, in simplest form, calls for a monetary policy that produces a rate of deflation such that the real rate of return on bank reserves equals the rate of interest on real investment. Then, it is argued, banks will voluntarily hold all their assets in the form of reserves, and bank runs, crises, and so on will never happen. Bruce Smith (whose death in 2003 was a great loss to economics) makes it beautifully clear that this once-beguiling idea should be relegated to the history of economic thought (Smith, 2002). Application of the Friedman rule may indeed result in risk-free banks. However, except for the provision of payments services, it precludes banks from making any of their valuable economic contributions detailed by Diamond (1984), Diamond and Dybvig (1986) and others, and as discussed earlier.

2. Boyd and Prescott (1986) have a theorem that financial intermediary coalitions composed of large numbers of agents can support allocations that cannot be supported with decentralized markets, and are efficient subject to resource and incentive constraints. As lamented by Green and Zhou (2001), virtually all subsequent theoretical research on FIs has studied decentralized (market) environments. Now, this could be just a matter of preferences amongst theorists as to the most interesting and tractable environment in which to study FIs. It's not, in my opinion, and this topic is of more than theoretical interest. Boyd–Prescott financial intermediary coalitions look (at some high level of abstraction) like mutual or cooperative FIs. It is fact that over several continents and many centuries mutual FIs seem to endogenously spring up with great regularity. When a class of arrangements is ‘revealed preferred’ so often, there is probably a good reason for it. There has been some theoretical research on this topic, but arguably not enough.

3. Virtually all of our general equilibrium models with FIs force agents into discrete silos: for example, an agent must choose to become a producer (borrower), a consumer (lender), or an FI. In reality we often observe organizations that are both producers and financial intermediaries at the same time (for example, General Electric or Cargill). Moreover, we sometimes see firms radically change their blend of activities. For example, in a few years Enron evolved from a production firm to a financial intermediary. I am aware of only one study (Bhanot and Mello, 2006) that allows, in a serious way, for endogenous choice of FI and non-FI activities in the same organization. More work along these lines could be useful.

4. As discussed, banks, even very simple ones, perform a number of economic functions simultaneously: brokerage, payments service provision, maturity transformation, liquidity provision, and default risk reduction. This is what we observe in reality and there is undoubtedly a reason. Yet our theoretical models tend to isolate these economic functions and look at them one at a time. Only a few studies have seriously looked at the jointness in providing even two services simultaneously (Kasyap, Rajan and Stein, 2002). This separation of functions is done for tractability, and even then our models can become complex. Putting all of these features in a
model simultaneously becomes technically daunting, but it needs to be done. There are undoubtedly interesting interactions or synergisms among these activities, and we cannot learn about those by studying them individually.

financial liberalization

Abstract

Financial liberalization has led to financial deepening and higher growth in several countries. However, it has also led to a greater incidence of financial crises. Here, we review the empirical evidence on these dual effects of financial liberalization across different groups of countries. We then present a conceptual framework that explains why there is a trade-off between growth and incidence of crisis, and helps account for the cross-country difference in the effects of financial liberalization.

Article

Financial liberalization (FL) refers to the deregulation of domestic financial markets and the liberalization of the capital account. The effects of FL have been a matter of some debate. In one view, it strengthens financial development and contributes to higher long-run growth. In another view, it induces excessive risk-taking, increases macroeconomic volatility and leads to more frequent crises. This article brings together these two opposing views.

The data reveals that FL leads to more rapid economic growth in middle-income countries (MICs), but does not have the same effect in low-income countries (LICs). In MICs this process is not smooth, however: It takes place through booms and busts. Indeed, MICs that have experienced occasional financial crises have grown faster, on average, than non-liberalized countries with stable credit conditions. In LICs liberalization does not lead to higher growth because their financial systems are not sufficiently developed so as to permit significant increases in leverage and financial flows.

The contrasting experiences of Thailand and India illustrate these dual effects. Thailand, a liberalized economy, has experienced lending booms and crises, while India, a non-liberalized economy, has followed a slow but safe growth path (see Figure 1). In India GDP per capita grew by only 99 per cent between 1980 and 2002, whereas Thailand's GDP per capita grew by 148 per cent, despite a major crisis. As will be shown below in a set of data analyses, this trade-off exists more generally across MICs.

Figure 1

Asymmetric financial opportunities across sectors are key to understanding the effects of FL. In particular, in MICs contract enforceability problems affect the tradable (T) and non-tradable (N) sectors differently. Many T-sector firms are able to overcome these problems and gain access to international capital markets, whereas most N-sector firms are financially constrained and depend on domestic banks for their financing. Trade liberalization promotes faster productivity growth in the T-sector, but is of little direct help to the N-sector. By allowing banks to borrow on international capital markets, FL leads to an increase in investment by financially constrained firms, most of which are in the N-sector. However, while FL increases investment, it also increases borrowers’ incentives to take on insolvency risk because there are implicit and explicit bail-out guarantees that cover lenders against systemic defaults. This is why greater leverage and growth is associated with aggregate financial fragility and occasional crises.

In the rest of this article we describe the ways in which FL has been measured and the empirical estimates of its effects on growth and crises. We then present a conceptual framework and a review of the policy issues. In a nutshell, any evaluation of FL must weigh its benefits against its costs. Focusing exclusively on the growth effects of liberalization during good times would miss the link between FL and crises. Focusing only on volatility and crises could lead to an excessive cautiousness about the risks of FL. The case for FL requires that its growth and welfare benefits outweigh the costs associated with more frequent financial crises.

Measuring financial liberalization

There are three classes of FL indices. First, there are de jure indices based on official dates of policy reforms. An example is the index based on the IMF Annual Report on Exchange Arrangements and Exchange Restrictions (Grilli and Milesi-Ferretti, 1995). This class of indices permits a comparison of the periods before and after liberalization. A drawback, however, is that legislated changes take time to translate into liberalization on the ground. Liberalization may even fail to materialize altogether when well-functioning domestic financial markets are absent. Bekaert, Harvey and Lundblad (BHL, 2005) overcome this problem by constructing a de jure indicator of equity market liberalization that records the date after which foreign investors are able to invest in domestic securities. A second class of indices uses de facto measures of financial openness, like the capital flows–GDP ratio used by Edison et al. (2004). The drawback is that these measures are contaminated by cyclical fluctuations and thus are imprecise indicators for dating FL. Lastly, de facto indices identify structural breaks in the trend of capital inflows (Tornell, Westermann and Martinez TWM, 2003). These indices combine the advantages of the two previous classes as they provide more precise FL dates based on actual, rather than merely legislated, policy reforms.

Financial liberalization and growth
BHL (2005) find that equity market liberalization leads to an increase of one percentage point in average real per-capita GDP growth. Rancière, Tornehill and Westermann (RTW, 2005) find that capital account liberalization leads to a similar gain in growth. To illustrate the link between FL and growth we add liberalization dummies to a standard growth regression:

$$\Delta y_{it} = \lambda y_{i,ini} + \gamma X_{it} + \varphi_1 T_{Lit} + \varphi_2 F_{Lit} + \varepsilon_{it}$$

(1)

where $\Delta y_{it}$ is the average growth rate of GDP per capita; $y_{i,ini}$ is the initial level of GDP per capita; $X_{it}$ is a vector of control variables that includes initial human capital, the average population growth rate, and life expectancy; and $T_{Li}$ and $F_{Li}$ are the trade and financial liberalization dummies of TWM (2003), respectively. For each country and each variable, we construct ten-year averages starting with the period 1980–9 and rolling forward to the period 1990–9. Thus each country has up to ten data points in the time-series dimension. The liberalization dummies take values in the interval [0,1], depending on the proportion of liberalized years in a given window. We estimate the panel regressions using generalized least squares.

The FL dummy enters significantly at the five percent level in all regressions. Regression 1-1 of Table 1 shows that following FL growth in real GDP per-capita increases by 1.5 percentage points per year, after controlling for the standard variables. Trade liberalization increases growth by 0.8 percent per year (column 1-2). When both liberalization dummies are included (column 1–3), both enter significantly. This suggests that trade and financial liberalization have independent effects and jointly contribute to higher long-run growth.

Notes: aThe estimated equations are eqs. (1) and (2) in the text; the dependent variable is the average annual growth rate of real GDP per capita. Control variables include initial per capita income, secondary schooling, population growth, and life expectancy. Standard errors are reported in parentheses and are adjusted for heteroskedasticity according to Newey and West (1987).

bThis regression includes the group of middle-income countries only.

cSignificance at the 5% level. The equation is estimated in an overlapping panel regression by GLS with data as ten-year averages starting with 1980–9 and rolling forward to 1990–9.

Figure 2 illustrates the link between FL and growth for individual MICs. For each country, we plot growth residuals before and after FL. Growth residuals are obtained by regressing real per capita growth on initial income per capita and population growth. Figure 2 shows clearly that for almost all countries growth has been higher in the financially liberalized period.

**Figure 2**

Liberalization and annual percent growth. *Note:* The country episodes are constructed using windows of different length for each country. Country episodes that are shorter than five years are excluded. Averaging over these periods, we estimate a simple growth regression by OLS in which real per capita growth is the dependent variable and which only includes the respective initial income and population growth. The figure plots the residuals from this regression, from 1980 to 1999. *Sources:* Population growth for Portugal: International Financial Statistics (IMF). Several studies find mixed evidence on the link between financial openness and growth. This can be attributed either to the indicators of openness used or to the sample considered. First, some studies include low-income countries that do not have functioning financial markets. In these countries we do not expect the financial deepening mechanism to work. One might also expect the growth effect of FL to be smaller in high-income than in middle-income countries as the latter face more severe borrowing constraints. Hence, sample heterogeneity can create a bias against finding a linear growth effect of FL. Klein (2005) finds that FL contributes to growth among MICs but not among poor or rich countries.

Second, some studies test the effect of changes in the capital flows–GDP ratio on growth. However, because this index does not identify a specific liberalization date, it is not appropriate for comparing the behaviour of macroeconomic variables before and after liberalization. Furthermore, these measures tend to exhibit year-to-year fluctuations that do not reflect actual changes in the degree financial openness.

Financial liberalization and crises

FL is typically followed by boom–bust cycles. During the boom, bank credit expands very rapidly and excessive credit risk is undertaken. As a result, the economy becomes financially fragile and prone to crisis. Although the likelihood that a lending boom will crash in a given year is low, many booms do eventually end in a crisis. During such a crisis, new credit falls abruptly and recuperates only gradually.

The incidence of crises can be measured by analysing countries’ financial histories and by codifying the occurrence of banking crises, currency crises, and sudden stops in capital inflows. Kaminsky and Reinhart (1999) use such a crisis index in a probit model to test whether banking and currency crises are crises are more likely to occur after FL. RTW (2005) use a more parsimonious indicator of financial fragility: the negative skewness of credit growth. Negative skewness is a de facto indicator that captures the existence of infrequent, sharp and abrupt falls in credit growth. Since credit growth is relatively smooth during boom periods, and crises happen only occasionally, in financially fragile countries the distribution of credit growth rates is characterized by negative outliers in a long enough sample. These outliers correspond to the abrupt falls in credit growth that occur during the crisis or ‘bust’ stage of the boom–bust cycle. The advantages of this skewness measure, relative to other more complex indicators of crises, are that it is objective and comparable across countries.

In the literature variance is the typical measure of volatility. Variance, however, is not a good instrument to identify growth-enhancing credit risk because high variance reflects not only the presence of boom–bust cycles but also the presence of high-frequency shocks.

Table 2 partitions country-years into two groups: liberalized and non-liberalized. The table shows that, across MICs, the financial deepening induced by FL has not been a smooth process but has been characterized by booms and occasional busts. We can see that FL leads to an increase in the mean of credit growth of four percentage points (from 3.8 percent to 7.8 percent) and a fall in the skewness of credit growth from near zero to –1.09, and has only a negligible effect on the variance of credit growth. Notice that, across high-income countries, credit growth exhibits near-zero skewness, and both the mean and the variance are smaller than across MICs. This difference reflects the absence of severe credit market imperfections in high-income countries.

To close the circle we show that countries with a greater incidence of crises have grown faster than those with smooth credit paths. We do so by adding three moments of real credit growth to growth regression (1)

\[
\Delta y_{it} = \lambda y_{i,ini} + \gamma X_{it} + \beta_1 \Delta \delta_{it} + \beta_2 \sigma_{\delta_{it}} + \beta_3 S_{\delta_{it}} + \psi_1 T L_{it} + \psi_2 F L_{it} + \epsilon_{it},
\]

where \(\Delta y_{it}, y_{i,ini}, X_{it}, TL_{it}, \) and \(FL_{it}\) are defined as in eq. (1), and \(\mu_{\Delta \delta_{it}}, \sigma_{\Delta \delta_{it}}, \text{ and } S_{\Delta \delta_{it}}\) are the mean, standard deviation, and skewness of the real credit growth rate, respectively. We estimate eq. (2) using the same type of overlapping panel data regression as for eq. (1). Columns 1–4 through 1–7 of Table 1 report the estimation results. Consistent with the literature, we find that, after controlling for the standard variables, the mean growth rate of credit has a positive effect on long-run GDP growth, and the variance of credit growth has a negative effect. Both variables enter significantly at the five percent level in all regressions.

The first key point is that the financial deepening that accompanies rapid GDP growth is not smooth but, rather, takes place via booms and busts. Columns 1–4 and 1–5 show that negative skewness – a bumpier growth path – is on average associated with faster GDP growth across countries with functioning financial markets. This estimate is significant at the five percent level.

To interpret the estimate of 0.27 for skewness, consider India, which has near-zero skewness, and Thailand, which has a skewness of about minus 2. A point estimate of 0.27 implies that an increase in the bumpiness index of 2 (from zero to minus 2) increases the average long-run GDP growth rate by 0.54 of a percentage point a year. Is this estimate economically meaningful? To address this question, note that, after controlling for the standard variables, Thailand grows about two percentage points faster per year than India. Thus, about a quarter of this growth differential can be attributed to credit risk taking, as measured by the skewness of credit growth.

The second key point is that the association between skewness and growth does not imply that crises are good for growth. Crises are costly. They are the price that has to be paid in order to attain faster growth in the presence of credit market imperfections. To see this, consider column 1–6. When the FL dummy is included, bumpiness enters with a negative sign (and is significant at the five percent level). In the MIC set, given that there is FL, the lower the incidence of crises the better. We can see the same pattern when we include high-income countries in column 1–7.

Clearly, liberalization without fragility is best, but the data suggest that this combination is not available to MICs. Instead, the existence of contract enforceability problems implies that liberalization leads to higher growth because it eases financial constraints but, as a by-product, also induces financial fragility. However, because crises occur relatively rarely, FL has a positive net effect on long-run growth.

### A unified approach

An alternative approach to understand the contrasting effects of FL is to combine the linear growth regression with a crisis probit model. In this way one can decompose the net effect of FL into a direct pro-growth effect and an indirect anti-growth effect, via a higher propensity to crises. Using this approach, RTW (2006) find that the direct effect of FL on growth is 1.2 percentage points and the indirect effect is minus 0.25 percentage points. In order to understand this result, one should keep in mind that even in financially liberalized countries crises are rare events. Therefore, even if crises have large output consequences, their estimated growth effect remains modest. In contrast, since FL is likely to improve access to external finance, it has a first-order impact on growth.

### Conceptual framework

To analyze FL and the subsequent boom–bust cycles, consider an economy with two sectors: non-tradables (N) and tradables (T). Alternatively, one can think of ‘new-economy’ and ‘traditional’ sectors, respectively. The key is that each sector uses as input the other sector’s output. This economy is subject to severe contract enforceability problems that generate financing constraints. While T-firms can overcome such constraints and finance themselves in bond and equity markets, most N-firms are financially constrained and bank-dependent. Since N-goods serve as intermediate inputs for both sectors, the N-sector constrains the long-run growth of the T-sector and that of GDP: there is a bottleneck.

In such an economy, FL increases GDP growth by increasing the investment of financially constrained firms. However, the easing of financial constraints is associated with the undertaking of insolvency risk because FL not only lifts restrictions that preclude risk taking but also is associated with explicit and implicit systemic bail-out guarantees that cover...
financial liberalization: The New Palgrave Dictionary of Economics

creditors against systemic crises. It is a stylized fact that, if a critical mass of borrowers is on the brink of bankruptcy, authorities will implement policies to ensure that creditors get repaid (at least in part) and thus avoid an economic meltdown. These bail-out policies may come in the form of an easing of monetary policy in response to a financial crash, the defence of an exchange rate peg in the presence of liabilities denominated in foreign currency, or the recapitalization of the financial sector. Because domestic banks have been the prime beneficiaries of these guarantees, investors use domestic banks to channel resources to firms that cannot pledge international collateral. Thus liberalization results in biased capital inflows. T-firms and large N-firms are the recipients of foreign direct investment (FDI) and portfolio flows, whereas most of the inflows to the N-sector are intermediated through domestic banks, which enjoy bail-out guarantees. Insolvency risk often takes the form of maturity mismatch or risky debt denomination (currency mismatch).

Taking on insolvency risk reduces expected debt repayments because authorities will cover part of the debt obligation in the event of a systemic crisis. Thus the guarantee allows financially constrained firms to borrow more than they could otherwise. This increase in borrowing and investment is accompanied by an increase in insolvency risk. When many firms take on insolvency risk, aggregate financial fragility arises together with increased N-sector investment and growth. Faster N-sector growth then helps the T-sector grow faster because N-sector goods are used in T-sector production. Therefore, the T-sector will enjoy more abundant and cheaper inputs than otherwise. As a result, as long as a crisis does not occur, growth in a liberalized economy is faster than in a non-liberalized one.

Of course, financial fragility implies that a self-fulfilling crisis may occur. And during crises GDP growth falls. Crises must be rare, however, in order to occur in equilibrium – otherwise agents would not find it profitable to take on credit risk in the first place. Thus, average long-run growth is greater along a risky path than along a safe one even if there are large crisis costs. This is why FL leads both to higher long-run growth and to a greater incidence of crises. Schneider and Tornell (2004) and RTW (2003) formalize the intuitive argument we described using a general equilibrium model with rational agents.

This discussion of the mechanism through which FL affects the growth of MICs also explains why FL does little to improve the growth of LICs. LICs often do not have functioning financial markets and thus lack the infrastructure that allows the financial system to direct international funds to profitable firms. MICs, by contrast, have enough financial infrastructure to allocate funds reasonably well, even though contract enforceability problems prevent them from doing so as efficiently as high-income countries (HICs). Because of the imperfections in their financial systems, the price of fast growth in MICs is financial fragility. The contrasting experiences of Thailand and India during the period 1980–2002 illustrate this trade-off clearly. As we discussed earlier, Thailand experienced booms and busts while India did not. While Thailand experienced spectacular growth, India's growth was dismally. Recently, India has opened its economy to both trade and finance. Not surprisingly, India is currently experiencing a lending boom. It will be interesting to analyse the evolution of the Indian economy around 2015.

Economic policy

Several observers have suggested that partial liberalization is the optimal policy to reap the growth benefits of openness without having to suffer from volatility and crises. They suggest the implementation of trade liberalization but not of FL, or the restriction of capital flows to FDI, the least volatile form of capital flows. These recommendations seem impractical. First, an open trade regime is usually sustained by an open financial regime because exporters and importers need access to international financial markets. Since capital is fungible, it is difficult to insulate the financial flows associated with trade transactions. The data indicates that trade liberalization has typically been followed by FL. As Figure 3 shows, by 1999 72 percent of countries that had liberalized trade had also liberalized financial flows, bringing the share of MICs that were financially liberalized to 69 percent, from 25 percent in 1980.

Figure 3

Share of MICs that liberalized trade and financial flows, 1980–99. Note: The figure shows the share of countries that have liberalized relative to the total number of MICs in our sample. Source: Tornell, Westermann and Martinez (2003).
Second, FDI does not obviate the need for risky international bank flows. FDI goes mostly to financial institutions and large firms, which are mostly T-firms. Thus, bank flows are practically the only source of external finance for most N-firms (Tornell and Westermann, 2005). Curtailing such risky flows would reduce N-sector investment and generate bottlenecks that would limit long-run growth. Bank flows are hardly to be recommended, but for most firms it might be that or nothing. Clearly, allowing risky capital flows does not mean that anything goes. Appropriate prudential regulation must also be in place.

In an environment with asymmetric financial opportunities authorities may be tempted to make direct investment subsidies to constrained sectors. The historical evidence indicates that such centrally planned policies typically fail. We now know that either authorities do not possess the appropriate information or crony capitalism and rampant corruption take over. A second-best policy is to liberalize financial markets and allow banks to be the means through which resources are channelled to financially constrained firms. Here, it is important to make a distinction between ‘systemic’ and ‘unconditional’ bail-out guarantees. The former are granted only if a critical mass of agents default. The latter are granted on an idiosyncratic basis whenever there is an individual default. We have argued that, if authorities can commit to grant only systemic guarantees, and if prudential regulation works efficiently, then FL will induce higher long-run growth in a credit-constrained economy. In contrast, if guarantees are granted on an unconditional basis or there is a lax regulatory framework, the monitoring and disciplinary role of banks in the lending process will be negated. In this case, FL will simply lead to overinvestment and corruption.

One should not conclude that in order to enjoy the growth and welfare benefits of FL countries have to be exposed for ever to the risk of crises. The amelioration of contract enforceability problems, through a better legal system and other institutional reforms, is a fundamental source of higher growth and lower volatility in the long-run. However, it often takes time for these reforms to be achieved. In the meantime, countries with functioning financial markets can be made better off by liberalizing and experiencing a rapid but risky

Financial market anomalies are cross-sectional and time series patterns in security returns that are not predicted by a central paradigm or theory. The focus here is on equity market anomalies including the size effect, value effect, serial correlation in returns and calendar-related patterns in returns related to month of the year and day of the week. Many of these patterns have persisted for decades, suggesting they are not evidence of market inefficiencies. Although transactions costs might preclude trading that would eliminate such patterns, it is possible that our benchmark models might be less than complete descriptions of equilibrium price formation.

Article

Financial market anomalies are cross-sectional and time series patterns in security returns that are not predicted by a central paradigm or theory. This sense of the term ‘anomaly’ can be traced to Kuhn (1970). Documentation of anomalies often presages a transitional phase towards a new paradigm.

Discoveries of financial market anomalies typically arise from empirical tests that rely on a joint null hypothesis – to wit, security markets are informationally efficient and returns behave according to a pre-specified equilibrium model (for example, the capital asset pricing model, CAPM). If the joint hypothesis is rejected, we cannot attribute the rejection to either branch of the hypothesis. Thus, even though anomalies are often interpreted as evidence of market inefficiency, such a conclusion is inappropriate because the rejection may be due to an incorrect equilibrium model. Some have argued that, once identified by researchers, the magnitude of financial anomalies will tend to dissipate as investors seek to profitably exploit the return patterns or because their discovery was simply a sample-specific artifact. Although this has happened for some of the findings discussed below (such as the weekend effect), most of the anomalies discussed continue to persist. The fact that so many of these patterns have persisted for decades suggests that they are not evidence of market inefficiencies. Rather, our benchmark models might be less than complete descriptions of equilibrium price formation.

The number of documented anomalies is large and continues to grow. The focus here is on equity market anomalies, and on the subset whose existence has proven most robust with respect to both time and the number of stock markets in which they have been observed. We broadly classify the findings as being cross-sectional or time series in nature.

Cross-sectional return patterns

Given certain simplifying assumptions, the CAPM states that the return on a security is linearly related to the security’s non-diversifiable risk (or beta) measured relative to the market portfolio of all marketable securities. If the model is correct and security markets are efficient, security returns will on average conform to this linear relation.

Empirical tests of the CAPM first became possible with the creation of computerized databases of stock prices in the United States in the 1960s. To implement the tests, researchers
often estimate cross-sectional regressions of the form

\[ R_i = \alpha_0 + \alpha_1 \beta_i + \sum \alpha_j c_{ij} + \epsilon_i \]  

(1)

where \( \beta_i \) is the security's beta which measures its covariance with the return on the market and \( c_{ij} \) represents security-specific characteristic \( j \) (size, earnings yield, and so on) for security \( i \). The CAPM predicts that the \( \alpha_j \), for \( j \geq 1 \), are zero. Early tests supported the CAPM (for example, significant positive values for \( \alpha_1 \), insignificant values for \( \alpha_j \), for \( j > 1 \)). The explanatory power of beta came into question in the late 1970s when researchers identified security characteristics such as the earnings-to-price ratio and market capitalization of common equity with more explanatory power than beta.

This section presents a sample of the more important contributions in this area that collectively stand as a challenge for alternative asset pricing models.

The value effect

The value effect refers to the positive relation between security returns and the ratio of accounting-based measures of cash flow or value to the market price of the security. Examples of the accounting-based measures are earnings per share and book value of common equity per share. Investment strategies based on the value effect have a long tradition in finance and can be traced at least to Graham and Dodd (1940). Ball (1978) argues that variables like the earnings-to-price ratio (E/P) are proxies for expected returns. Thus, if the CAPM is an incomplete specification of priced risk, it is reasonable to expect that E/P might explain the portion of expected return that is compensation for risk variables omitted from the tests. Basu (1977) was the first to test the notion that value-related variables might explain violations of the CAPM. He found a significant positive relation between E/P ratios and average returns for US stocks that could not be explained by the CAPM. Reinganum (1981) confirmed and extended Basu's findings. Rosenberg, Reid and Lanstein (1985), De Bondt and Thaler (1987) and many others have documented a significant positive relation between returns and the book-to-price ratio (B/P). Researchers have also identified a significant relation between security returns and value ratios that use cash flow (earnings plus accounting depreciation expense) in place of earnings in the numerator of the ratio. The value effect in its many forms has been reproduced by numerous researchers for many different sample periods and for most major securities markets around the world (see Hawawini and Keim, 2000, for a review).

Dividend yield, the ratio of cash dividend to price, has also been shown to have cross-sectional return predictability. Although similar in construction to the value ratios, the explanatory power of dividend yields is most often attributed to the differential taxation of capital gains and ordinary income as described in the after-tax asset pricing models developed by Brennan (1970) and Litzenberger and Ramaswamy (1979). Although a positive relation between stock returns and dividend yields has been documented in many studies, interpretation of the results as support for an after-tax pricing model has been controversial. Evidence on the dividend yield effect has been provided by Litzenberger and Ramaswamy (1979), Miller and Scholes (1982) and many others.

The size effect

The size effect refers to the negative relation between security returns and the market value of the common equity of a firm. Banz (1981) was the first to document this phenomenon for US stocks (see also Reinganum, 1981). In the context of eq. (1), Banz found that the coefficient on size has more explanatory power than the coefficient on beta in describing the cross section of returns. Indeed, Banz finds little explanatory power for market betas. Like the value effect, the size effect has been reproduced for numerous sample periods and for most major securities markets around the world (Hawawini and Keim, 2000).

Interpretation of the value and size effects

The separately identified value and size effects are not independent phenomena because the security characteristics all share a common variable – price per share of the firm's common stock. Indeed, researchers have shown a high rank correlation between size and price and between the value ratios and price, and others have documented a significant cross-sectional relation between price per share and average returns. To sort out the relative importance of the different variables, Fama and French (1992) (FF) estimate eq. (1) with...
multiple value and size variables included as explanatory variables (see also Jaffe, Keim and Westerfield. 1989). FF find that B/P and Size provide the greatest explanatory power in describing the cross section of returns, and suggest that B/P and Size are proxies for the influence of two additional risk factors omitted from the CAPM. In this context, the value and size variables can be viewed as capturing sensitivities to the omitted factors, and the coefficients multiplying the value and size variables ($a_j$ in eq. (1)) are estimates of the risk premia required to compensate for that exposure. (A valid question is whether a characteristic like B/P proxies for an underlying (but unknown) risk factor which is the determinant of expected returns or whether the characteristic itself is the determinant of expected returns. Daniel and Titman, 1997, address this issue and conclude that security characteristics appear to be more important than the covariance of security returns with a factor related to the characteristic.) Predicated on this interpretation, Fama and French (1993) propose a three-factor model to describe the time series behaviour of security returns:

$$R_t - r_{ft,t} = \beta_0 + \beta_1 (r_{mt,t} - r_{ft,t}) + \beta_2 SmB_t + \beta_3 HmL_t + \epsilon_t$$

(2)

where $R_t$ is the return on the asset in month $t$, $r_{ft,t}$ is the monthly treasury bill rate, $r_{mt,t}$ is the return on a value-weighted market portfolio, $SmB_t$ is a monthly size premium (Small stock return minus Large stock return), $HmL_t$ is a monthly value premium (High B/P return minus Low B/P return), and $\epsilon_t$ is the error term. As constructed, $SmB$ and $HmL$ are zero net investment portfolios. If these three factors span all sources of common systematic co-movement in security returns, $\beta_0$ (‘alpha’) will on average equal zero. The model has received much empirical confirmation and appears to explain numerous previously reported incidences of anomalous cross-sectional return patterns (that is, such effects have $\beta_0 = 0$ in eq. (2)). As mentioned above, the mean values of the three factors in model (2) can be interpreted as the premium or compensation earned by an investment position for unit exposure to each separate factor. The relative magnitudes of these factor premia are of economic interest. The market risk premium quantifies the return, in excess of a default-risk-free return, provided for investing in a broadly diversified portfolio as represented by the value-weighted market portfolio. Over the period 1927–2005 the average equity market risk premium in (2) is 0.64 per cent per month. Utility-based asset pricing models have difficulty explaining an equity premium of this magnitude – either because the returns on default-risk-free bonds are too low, or the returns on equities are too high. This has been called the equity premium puzzle (Mehra and Prescott, 1985) and has generated an extensive literature trying to reconcile the theory and empirical evidence.

The mean risk premia associated with the size effect ($SmB$) and the value effect ($HmL$) should be zero if the CAPM is correct. Consistent with the research described above, $SmB$ and $HmL$ are both positive. For the period January 1927–December 2005 the monthly mean ($t$-value) is 0.25 per cent (2.01) for $SmB$ and 0.48 per cent (3.64) for $HmL$, and the correlation between the two premia is 0.13. Figure 1 plots the time series of the intra-year monthly means of the two premia. The figure shows that (a) both premia display substantial variability over time and (b) the two series display a considerable common co-movement despite the low estimated correlation.

Figure 1

The value and size premia, 1927–2005
On the first point, there are extended periods when the signs of the risk premia are reversed. This is particularly evident for the size effect – for extended periods in the 1950s and the 1980s large firms outperformed small firms, in contrast to other periods (1930s, 1940s, 1970s, and post-2000) when small stocks outperformed large stocks. Because the estimated magnitudes of the effects are sensitive to the period in which they are measured, it is important to distinguish between unconditional and conditional expected values for the effects. Further, it is relevant to ask whether the 79-year sample we have for the US market (longer than in other developed equity markets) is long enough to capture the ‘long-run’ magnitudes of such volatile effects. (The same caveat has been raised regarding the magnitude of the equity premium.)

On the second point, the visual appearance of common co-movement between the series suggests the two effects are not entirely independent. This possibility is confirmed when the time series plots of $\text{SmB}$ and $\text{HmL}$ are decomposed into separate plots for January and February-to-December observations (Figure 2A and 2B). Much research has shown that the size and value effects are most pronounced in the month of January. This research is discussed in more detail in the next section. For now, we limit discussion to the difference in the

![Graph showing monthly premiums and correlation]

- Monthly mean ($\text{SmB}$) = 0.25% ($t = 2.01$)
- Monthly mean ($\text{HmL}$) = 0.48% ($t = 3.64$)

behaviour of SmB and HmL between January and February–December. First, the mean values for both premia are an order of magnitude larger in January than in February–December. Second, the correlation of 0.40 in January versus 0.06 for February–December demonstrates that the commonality between the two series in Figure 1 arises mostly from their common behaviour in January.

Figure 2A
The value and size premia – January only

Figure 2B
The value and size premia – Feb to Dec
What explains the value and size effects? That both premia reflect some common element which manifests itself only in January is hard to reconcile with a risk compensation story. (Non-risk-based explanations of the January effect are discussed in the section on seasonal patterns in stock returns below.) Much recent research, nevertheless, has characterized the value premium as compensation for financial distress risk. Theoretical models have been developed in which such risk plays a central role, and value (high B/P) stocks accordingly earn higher equilibrium returns than growth (low B/P) stocks. Others have argued that the size effect is actually a liquidity effect in which small-cap stocks are less liquid than large-cap stocks and therefore provide correspondingly higher returns to offset the higher transactions costs (see, for example, Brennan, Chordia and Subrahmanyam, 1998). Still others have suggested that the size and B/P results may be due to survivor biases in the databases used by researchers (see, for example, Kothari, Shanken and Sloan, 1995). One final hypotheses concerns measurement error in the estimated market betas used in the tests. Firms whose stocks have recently declined in price (for example, many high B/P and small-cap stocks), in the absence of a concomitant decline in the value of the debt, have become more leveraged and, other things equal, more risky in a beta sense. Traditional estimation methods produce ‘stale’ betas that underestimate ‘true’ beta risk for such firms. Thus, B/P and size may be viewed as better instruments for ‘true’ market beta risk than traditional estimates of beta, and the value and size effects are simply capturing the measurement error in the traditional beta estimates.

The prior return or momentum effect

Prior stock returns have been shown to have explanatory power in the cross section of common stock returns. Stocks with prices on an upward (downward) trajectory over a prior period of 3 to 12 months have a higher than expected probability of continuing on that upward (downward) trajectory over the subsequent 3 to 12 months. This temporal pattern in prices is referred to as momentum. Jegadeesh and Titman (1993) show that a strategy that simultaneously buys past winners and sells past losers generates significant abnormal returns over holding periods of 3 to 12 months. The abnormal profits generated by such offsetting long and short positions appear to be independent of market, size or value factors, and have persisted in the data for many years. To this end, Carhart (1997) estimates an extension of eq. (2) that includes a momentum factor (in addition to market, size and value factors) defined in the spirit of Jegadeesh and Titman as the difference in returns between a portfolio of ‘winners’ and a portfolio of ‘losers’. The coefficient on the momentum factor is positive and statistically significant, and cannot be explained by the other three factors. Finding a rational risk-related explanation for the momentum effect has proven difficult. A number of researchers have posited behavioural (psychology-based) explanations of momentum that rely on irrational market participants who underreact to news, but these models are hard to reconcile with psychology-based models of overreaction posited to explain the value premium (for example, Lakonishok, Shleifer and Vishney, 1994).

**Predicting returns with past returns I: individual security autocorrelations**

Much research finds that autocorrelations of higher-frequency (daily, weekly) individual stock returns are negative and that the autocorrelations are inversely related to the market capitalization of the stock. The exception is that the largest market cap stocks have positive autocorrelations for daily returns. The inverse relation between individual return autocorrelations and market capitalization is due to the influence of a bid-ask bounce in high frequency stock prices that may induce ‘artificial’ serial dependencies into returns. Niederhoffer and Osborne (1966) find that successive trades tend to occur alternately at the bid and then the ask price, resulting in negative serial correlation in returns. This negative serial dependency is more pronounced for smaller stocks that have lower prices and, consequently, for which the bid-ask spread represents a larger percentage of price. Because of the high variance of individual stock returns, researchers find that past returns explain a trivial percentage of total return variability at high frequencies (typically less than one per cent). And the predictability at high frequencies is economically insignificant: profits from trading strategies attempting to exploit the predictability in individual stocks are indistinguishable from zero.

**Predicting returns with past returns II: aggregate return autocorrelations**

Because of variance reduction obtained from diversification, aggregated or portfolio returns provide more powerful tests of return predictability using past returns. However, this increased power may be offset by upward-biased autocorrelations caused by the infrequent trading of securities in the portfolios (Fisher, 1966). This bias is more serious for portfolios of smaller-cap stocks that contain less frequently traded stocks. In the United States and other global equity markets positive autocorrelations for high-frequency portfolio returns range from 0.4 for small-cap stocks to 0.1 for large-cap stocks. Research has shown, however, that positive portfolio autocorrelations are not due to infrequent trading of the securities in the portfolio. Indeed, many researchers have reported statistically significant positive portfolio autocorrelations for return frequencies up to one month in the United States, an interval over which virtually all securities will have traded. There is no evidence, however, of profitable trading opportunities based on daily, weekly or monthly aggregate return autocorrelations. (Lo and MacKinlay, 1990, reconcile the paradox of positive portfolio autocorrelations and negative individual stock autocorrelations: because the autocorrelation of portfolio returns is the sum of individual security autocovariances and cross-autocovariances, if the cross-autocovariances are sufficiently larger than the autocovariances – empirically, they are – then the cross-autocovariances will overshadow the contribution of the autocovariances.)

Significant predictability – both economically and statistically – has been identified in longer-horizon stock returns. As mentioned in the previous section, Jegadeesh and Titman (1993) identify profitable trading strategies based on past price momentum over 3- to 12-month intervals. De Bondt and Thaler (1985) find that New York Stock Exchange stocks identified as the biggest losers (winners) over a period of three to five years earn, on average, the highest (lowest) market-adjusted returns over a subsequent holding period of the same length of time, a phenomenon that does not seem to disappear when returns are adjusted for size and beta risk. This predictable reversal pattern is often attributed to market ‘overreaction’ in which stock prices diverge from fundamental values because of (irrational) waves of optimism or pessimism before returning eventually to fundamental values. Evidence of this longer-horizon return predictability has been reported in most equity markets around the world. But the significance of negative autocorrelation for long horizon returns is subject to the statistical problems discussed in the next subsection.
**Predicting aggregate returns with predetermined observable variables**

The evidence above shows that past returns contain information about expected returns, but they are a noisy signal. A more powerful test uses predetermined explanatory variables that potentially convey more precise information about expected returns. Much recent research documents such predictability using past information. An incomplete list of the variables in these studies includes expected inflation, yield spreads between long- and short-term interest rates and between low- and high-grade bonds, the dividend-to-price ratio, the earnings-to-price ratio, the book-to-price ratio, and the level of consumption relative to income. Importantly, predictability is stronger when the tests use returns measured over longer horizons, with explanatory power rising to levels of 20–40 per cent at two to four year horizons. Unfortunately, the increased explanatory power does not come without econometric problems. First, the number of independent observations decreases with the return horizon. To accommodate, researchers use overlapping observations, but the adjustments for standard errors to account for this perform poorly for the relatively small sample periods used in these tests. Second, most of the variables listed above are highly persistent (in contrast to lagged returns used in autocorrelation tests), and their innovations are correlated with return innovations, resulting in biased test statistics. Despite these shortcomings, the level of statistical significance and the robust nature of the results – across so many different explanatory variables and across so many worldwide equity markets – strongly argue for a predictable component in aggregate returns.

**Patterns in daily returns around weekends**

Consider an exchange where trading takes place Monday–Friday. If the process generating stock returns operates continuously, then Monday returns should be three times the returns expected on each of the other days to compensate for a three-day holding period. Call this the calendar-time hypothesis. An alternative is the trading-time hypothesis: returns are generated only during trading periods, and average returns are the same for each of the five trading days in the week. Inconsistent with both hypotheses, stock returns in many countries are negative, on average, on Monday (French, 1980). (In Australia, Korea, Japan and Singapore average returns on Tuesday are negative because of time zone differences relative to the US and European markets.)

What causes the weekend effect? That the pattern exists in so many different markets argues persuasively against many institution-specific explanations. Research has shown that the weekend effect cannot be explained by: differences in settlement periods for transactions occurring on different weekdays; measurement error in recorded prices; market maker trading activity; or systematic patterns in investor buying and selling behaviour. That an explanation has been elusive may not be important: in the post-1977 period in the United States and in numerous other markets, the weekend effect has all but disappeared (see Schwert, 2003).

**Patterns in returns around the turn of the year**

Keim (1983) and others document that 50 per cent of the annual size premium in the United States is concentrated in the month of January, particularly in the first week of the year. This finding has been reproduced on many equity markets throughout the world. Blume and Stambaugh (1983) subsequently demonstrated that, after an upward bias in average returns for small stocks (related to the magnitude of bid-ask spreads) had been corrected, the size premium is evident only in January.

What explains this phenomenon? Two hypotheses rely on the buying and selling behaviour of market participants to explain the turn-of-the-year size premium. The first hypothesis attributes the effect to year-end tax-related selling by taxable individual investors of stocks that have declined in price (an attribute shared by many small-cap stocks). In such trades the investor realizes a capital loss which can be used to offset realized capital gains, thereby reducing taxable income. There is much evidence that such tax-related trading occurs at the end of the tax year (which in many countries coincides with the end of the calendar year), but a clear link between such trading and stock return behaviour has not been established. A second hypothesis concerns the impact of institutional ‘window dressing’ at the end of the calendar year – selling off ‘loser’ stocks that have declined in price (again, typically small-cap stocks) so they don’t appear on year-end statements sent to constituent shareholders. Although there is evidence that institutions behave in this fashion, any resulting impact on stock prices is difficult to distinguish from the impact of tax-loss selling. In the end, large bid-ask spreads and high transaction costs for small-cap stocks preclude the profitable exploitation of the short-term return differences between individual small- and large-cap stocks. As a result, the turn-of-the-year size premium continues to be positive in recent years (see Figure 2A).

**Conclusion**

Recent research in finance has revealed stock price behaviour that is inconsistent with the predictions of familiar models. The research on time series predictability, as a whole, is convincing evidence that expected returns are not constant through time. There are reasonable business conditions stories that can account for time variation in expected returns. However, some of the temporal patterns in returns – in particular those relating to calendar turning points – are troubling as they defy economic interpretations.
The evidence on cross-sectional anomalies poses a significant challenge to well-established asset pricing paradigms. Yet, despite mounting evidence, there is little consensus on alternative theoretical models. As such, the focus of future research should be on developing such models. Indeed, one of the most significant contributions of this strand of research has been the recognition of potential alternative sources of risk (for example, risk related to financial distress) and of the potential importance of behavioural models. Importantly, researchers must recognize that the existence of this anomalous evidence does not constitute proof that existing paradigms are ‘wrong’. There is the issue of data snooping – much of the empirical research on financial market anomalies is predicated on previous research that documented similar findings with the same data. And although many of these effects have persisted for nearly 100 years, this in no way guarantees their persistence in the future. More research is necessary to resolve these issues.

Social influence

The metaphor of contagion is central to the early studies of crowd psychology of Mackay (1841), Tarde (1900) and LeBon (1895); and classical early models of disease diffusion were applied to financial markets by Shiller (1984). The modern analysis of social influence starts with Allport and Postman (1946–47) who studied the spread of wartime rumour. They identified four circumstances that facilitate the spread of rumour: two are characteristics of the rumour, two of the population. The topic of the rumour should be important to people and the rumour should be hard to verify individually; while individuals should be credulous, and going through a time of unusual stress. Motivations for neglecting formal Bayesian learning differ between economics and sociology. Sociology emphasizes situations that do not lend themselves to Bayesian updating either through lack of time (is a bank about to fail?), or the nature of the question (what is the one true religion?). Economics, by contrast, emphasizes computational simplicity: rules of thumb make fewer cognitive demands on agents than formal
Kirman (1993) analyses a simple model of influence that is motivated by the foraging behaviour of ants, but applicable, he argues, to the behaviour of stock market investors. Faced with a choice between two identical piles of food, ants switch periodically from one pile to the other. Kirman supposes that there are $N$ ants and that each switches randomly between piles with probability $\varepsilon$ (this prevents the system getting stuck with all at one pile or the other), and imitates a randomly chosen other ant with probability $\delta$.

By the ergodic theorem of Markov chains, there is a unique steady state distribution of ants between piles, and Kirman shows by simulation that the shape of the distribution depends on the relative magnitudes of the imitation parameter $\delta$ and the mutation parameter $\varepsilon$. With weak imitation and strong mutation there is a single peak at $\frac{1}{2}$, with equal numbers of ants at each pile. With stronger imitation and weaker mutation, the steady state distribution has two peaks at 0 and $N$: most ants concentrate on a single pile and switch periodically to the other – the behaviour observed among real ants and possibly stock market participants. In contrast to Bayesian learning models, the absence of martingale convergence allows society continually to flip between beliefs.

The independent work of Weidlich and Haag (1983) in quantitative sociology presents an analogous model in continuous time. Agents switch states with a logistic probability that again depends on the relative social popularity of each choice, but Weidlich and Haag also allow agents to have a personal preference for one of the choices. Again, for sufficiently strong imitative behaviour there is a steady state distribution with two peaks, but now the relative magnitude of the peaks depends on how much agents prefer each choice. Society spends most time at the choice preferred by each agent, but will spend time at the choice that is less popular with everyone, as a consequence of social influence.

Ellison and Fudenberg (1993) look at the role of popularity weighting in choosing between a superior and an inferior technology. They observe that popularity can be a useful summary of the relative past performances of the two technologies – the better technology should be more popular – but that the amount of information conveyed by popularity is diluted the more people rely on it. They therefore look at the likelihood that the better technology is adopted, allowing a fixed fraction of the population to change its choice each period, when the relative weights put on the popularity of the technology versus its performance in the last period are allowed to vary.

Ellison and Fudenberg (1993) show that there is an optimal popularity weighting that causes the system to converge to everyone's using the better technology. If popularity weighting exceeds this optimum, the system converges to a steady state where everyone uses one technology, but which technology depends on the starting number of users of each. With under-weighing of popularity, the inefficient alternative can survive indefinitely.

The competitive exclusion principle, proven in the context of ordinary differential equations by Levin (1970), states that the number of coexisting species cannot exceed the number of resources they compete for. Here there are two competing species or technologies competing for one resource, being used by people, so if the technological choice problem is recast as one of biological competition we know that only one technology will survive. This is done by Juang (2001), who uses an evolutionary selection argument to show how an Ellison–Fudenberg society can reach the optimum when different groups of agents have sufficiently different popularity weightings. In periods when the inferior technology is excessively popular, agents putting low weight on popularity receive higher payoffs and increase in number, while agents who put high weight on popularity do better in periods when the superior technology is popular.

In the popularity weighting models of Kirman (1993), Weidlich and Haag (1983) and Ellison and Fudenberg (1993), every person is equally influenced by every other member of society. In many situations however, we
are influenced more by individuals whom we know and have learned to trust than by strangers. To model the
greater social influence of neighbours, the individual is put into some mathematical space, where he or she is
more likely to interact with individuals close by than far away. Durlauf (1997) looks at the behaviour of
agents in an Ising model (originally developed to model the flipping of magnetic poles of atoms in a crystal)
where agents live on a lattice and change between two actions at a rate that depends logistically on the state of
their nearest neighbours.
If the influence of neighbours lies above a critical value, the system has two steady state distributions (there
are an infinite number of agents so the ergodic theorem of Markov chains does not apply) with all agents
either in one state or the other. If agents have a preference for one state over the other (the physical analogue
is an external magnetic field) however, the system has only one steady state with all choosing the preferred
action.
In Durlauf's model, agents in each state influence each other symmetrically, affecting only their nearest
neighbours. Durrett and Levin (1998) analyse a system where agents of different types can affect others over
different distances. While biologically motivated – Durrett and Levin (1998) are interested in how slow-
growing trees can out-compete rapidly growing grasses – this analysis suggests how propaganda and
advertising can be used to cause bad ideas to drive out good ones.
Suppose that type 0 dominates type 1: an agent of type 0 converts a type 1 neighbour at rate 1, whereas a type
1 agent converts a type 0 only at rate $\delta < 1$. If both types have the same radius of influence then, so long as the
dominant type 0 avoids getting wiped out by an unlucky run at the start, it will take over. However, Durrett
and Levin (1998) show that if the dominant type affects only neighbours in a radius of 1, whereas the
dominated type affects neighbours over a large radius $R$, there is a critical value of the conversion rate $\delta_c < 1$,
above which the dominated type 1 takes over.
It is straightforward to demonstrate the existence of social influence empirically when individuals observe the
overall popularity in society rather than among neighbours. The influence of best-seller lists on book buying is
sufficiently well known for publishers to seek to manipulate them by buying books in stores known to be
tracked by the lists, and a variety of examples of imitative behaviour are given by Bikchandani, Hirshleifer
Testing for the influence of neighbours is more difficult because neighbourhood choice is frequently
endogenous: one must make sure that the behaviour one is attributing to the influence of neighbours is not due
to some individual factor that led the person to choose this neighbourhood over others in the first place.
The classic Ryan and Gross (1943) study, which found that the main factor influencing farmers to adopt
hybrid corn was the number of nearby farmers who had adopted it, passes the exogeneity test: it is unlikely
that farmers chose farms in order to be near other innovative farmers. Sacerdote (2001) uses the random
allocation of roommates to incoming Dartmouth University students to show how roommates influence each
others’ behaviour, finding that roommates have an effect on individual academic performance, while
dormitory effects influence decisions to join fraternities. Kelly and O Grada (2000) look at the behaviour of
Irish immigrants, mostly housemaids and day labourers, in 1850s New York during two bank runs. Since they
are immigrants it is possible to identify their social network from their place of origin in their home country:
newly arrived immigrants tend to associate with people they knew at home. Kelly and O Grada (2000) found
that immigrants from one set of counties in Ireland tended to close their accounts during the panics, while
otherwise identical immigrants from other counties stayed put.

Bayesian learning
Bayesian models of social learning allow individuals to infer the information of other agents from their observed actions in an optimal manner rather than through ad hoc imitation. Bayesian social learning can exhibit pathologies. After the first few agents have chosen, subsequent actions convey little new information and are dominated by idiosyncratic noise. Society converges slowly to the optimal action and, in some circumstances, may become stuck on the suboptimal action. A useful textbook discussion of the literature is given by Chamley (2004).

In Bikchandani, Hirshleifer and Welch (1992) and Banerjee (1992), the world can be in either state $\sigma_0$ or $\sigma_1$. Each agent receives a signal $s_0$ or $s_1$ with symmetric precisions $P(s_0|\sigma_0) = P(s_1|\sigma_1) = p$ and must choose whether or not to invest. Agents choose in a fixed order and, before receiving his private signal, the agent investing in period $t$ observes the history of past investments and uses this to determine their prior probability $\pi_{I_t}$ that the state is 1.

Bikchandani, Hirshleifer and Welch (1992) start with the case where the cost of investment is $\frac{1}{2}$, the payoff in state 1 is 1, and 0 otherwise. Their expected payoff is $p\pi_{I_t}(p\pi_{I_t}+(1-p)(1-\pi_{I_t}))$. After a number of moves there will be a sufficient difference between the number who has invested and those who have not for the agent’s action to be determined solely by his prior belief, irrespective of his signal. Specifically, if the first agent gets a good signal, the second invests if he gets a good signal, and all subsequent agents will then invest irrespective of their signals. If the second gets a bad signal he is indifferent about investing and is assumed to invest, so the third investor again invests regardless of signal, and so on. Once there are two more investors than non-investors, the excess of positive signals outweighs any negative signal an agent might have. Everyone invests regardless of signal, leading to a cascade.

An unlucky series of wrong signals at the start of the game can lead society to fix on the wrong equilibrium. Bikchandani, Hirshleifer and Welch (1992) observe that this wrong equilibrium is fragile, being based on the observations of a handful of early agents, and vulnerable to being overturned by public information available to all agents.

A frequent criticism of cascade models is their reliance on finite signals: all signals are equal and there is no way for a huge negative signal to counteract a series of positive ones. However, the important lesson of the cascade literature is not that society can get stuck at the wrong equilibrium – which requires signals that are finite – but that Bayesian learning when individual signals are observed imperfectly is very slow to converge to the true equilibrium. Vives (1993) shows how adding noise to a Gaussian model slows down its convergence from rate $t^{1/2}$ to rate $t^{1/3}$: 1,000 noisy observations are equivalent to ten clean ones.

The basic intuition of cascades models that imperfectly observed individual information is poorly incorporated into social beliefs is the basis of several other models. Bulow and Klemperer (1994) model rational frenzies in auctions where participants reveal their valuations by bidding. Bidders with high valuations are willing to pay just under the Walrasian clearing price and, being usually inframarginal, all face similar optimization problems. A bid by one agent therefore sets off a chain of bidding by other agents, leading to a pattern of booms and crashes. Caplin and Leahy (1994) look at investment where individuals have Gaussian signals. If the true state is bad, individuals continue to invest, driven by the dominating effect of past actions. Eventually, however, because signals are Gaussian, a few agents get sufficiently bad signals to induce them to stop investing, causing priors rapidly to move to a belief that the state is bad, leading to a market crash and ‘wisdom after the fact’.

While the essence of the cascade literature is that agents transmit a noisy signal of their information, Avery and Zemsky (1998) observe that this is not the case for markets obeying the efficient markets hypothesis where price reflects all publicly available information. In such markets, assuming risk-neutral agents, the price
of an asset worth 1 in the good state and 0 in the bad is the Bayesian prior \( \pi_{It} \), causing agents always to trade according to their private signal. They show that cascades can still occur if extra dimensions of uncertainty are added – specifically if there is event uncertainty (agents know that something important has happened by whether it is good or bad), or compositional uncertainty (agents are uncertain how many informed traders are active in the market).

Underlying Bayesian models of cascades is the obvious but strong assumption that people are Bayesians. Probability is difficult for most people, and conditional probability especially so. Even with trivial problems of the form ‘a family has two children, one of whom is a daughter: what is the probability that the other child is a son?’ most will incorrectly answer \( \frac{1}{2} \) rather than \( \frac{2}{3} \). Similarly, when asked ‘one per cent of the population has a disease. A test detects the disease in 95 per cent of patients when it is present, and generates ten per cent false positives when it is absent. What is the probability that someone who tests positive has the disease?’, most will give answers slightly below 95 per cent rather than the correct 1.05 per cent.

In other words, people appear to ignore base rates, assuming that the probability of a state given a signal equals the probability of the signal given the state \( P(\sigma|s_i) = P(s_i|\sigma) \) even when the probability of the state is considerably lower than the probability of the signal. Agents show overconfidence, focusing excessively on their own signal rather than the history of signals of other agents contained in the prior.

If people neglect priors in this way, cascades cannot occur when private signals are uncorrelated. However, if the signal is common, cascades can still occur. For instance if agents view market price as the signal, a run of rising prices induced by improving fundamentals (such as the good macroeconomic conditions and loose credit that Kindleberger (1978) saw as the preconditions for speculative bubbles) are treated by agents as a positive signal inducing them to buy, driving up price and inducing others to buy, and so on.

**Strategies in coordination games**

Kandori, Mailath and Rob (1993) considered the strategies of players in a coordination game with payoffs
where \( a > c, d > b \) and \( (a-c) > (d-b) \) so \((L, L)\) and \((R, R)\) are Nash equilibria and \((L, L)\) is the risk dominant one. With myopic, best-response play, they show that a small probability of mutation suffices for the risk dominant equilibrium to be chosen.

Ellison (1993) observed that this convergence is slow, requiring many simultaneous mutations, and showed instead that if there is local interaction of players along a line, the \( \frac{1}{2} \)-dominant strategy (the best response if half your neighbours adopt it) spreads rapidly, but not in two dimensions. Blume (1995) shows that non-trivial mixed long run equilibria exist in two dimensional interaction but not in one, while Morris (2000) examines the characteristics of arbitrary networks that permit the risk-dominant strategy to spread. Lee and Valentinyi (2000) look at a game without mutation but where initial strategy choice is random and show that myopic best response to strategies played by immediate neighbours on the lattice causes large populations to coordinate on the risk dominant equilibrium.

**International market contagion**

Large falls in asset values in one country are sometimes followed rapidly by falls in other countries. To the extent that these falls are too great to be explained by interdependence in trade or exposure to common macroeconomic factors, the process is called contagion.

Two main sources of contagion have been proposed: financial fragility and common financial linkages; and pathologies in the diffusion of information. The empirical study of Kaminsky, Reinhart and Vegh (2003) argues that three sources of fragility underlie international contagion: rapid inflows of capital; macroeconomic shocks that occur too rapidly for gradual portfolio rebalancing; and a leveraged common creditor. Allen and Gale (2000) show that if banks in different regions have claims on each other, a fall in asset values in one
region can bring banks in other regions under pressure and lead to falls in asset values in those regions. In Kyle and Xiong (2001) losses suffered by traders who arbitrage between markets dominated by fundamentalists and markets dominated by noise traders cause traders to reduce their positions in both markets, leading to returns becoming more volatile and more correlated. Models of contagion as information transmission abstract away from agents who revise excessively optimistic forecasts of returns in all markets after a fall in one market, and concentrate on rational actors instead. Calvo and Mendoza (2000) show that if there are fixed costs to gathering and processing information specific to one country and limits to short selling in each country, the benefits of acquiring information about each country in one's portfolio fall as the portfolio expands. Agents put more weight on the behaviour of other investors, making portfolio allocation more sensitive to realized returns in each market. In Kodres and Pritsker (2002), portfolio rebalancing by informed investors can set off panics among the uninformed who misinterpret it as negative information about the market. The empirical literature on testing for contagion has focused on increases in the correlation of returns between markets during periods of crisis. Forbes and Rigobon (2002) show the elementary weakness of simple correlation tests: with an unchanged regression coefficient, a rise in the variance of the explanatory variable reduces the coefficient standard error, causing a rise in the correlation of a regression. The regression underlying contagion tests is of the form

\[ y_{it} = \delta_i z_t + \alpha_i x_{it} + \beta I(y_j - z_j) + \varepsilon_{it} \]

where \( y_i \) is asset return in country \( i \), \( z \) are common macroeconomic factors, \( x_i \) are country specific factors, and \( I \) is an indicator of a period of crisis in the originating economy \( j \). As Pesaran and Pick (2007) observe, this is a difficult system to estimate econometrically. To disentangle contagion from interaction effects, county-specific variables have to be used to instrument foreign returns. Choosing the crisis period introduces sample selection bias, and it has to be assumed that crisis periods are sufficiently long to allow correlations to be reliably estimated. In consequence, there appears to be no strong consensus in the empirical literature as to whether contagion occurs between markets, or how strong it is.

financial structure and economic development

Abstract

Most early development economists neglected the financial aspects of development, often restricting them to domestic taxation, the self-finance of enterprises and the negotiation of foreign credits. In the 1970s, a few economists proposed that private financial intermediation, operating with market-set interest rates, improved incentives to save and the availability of credit, and allocated savings more efficiently between borrowers. Against this, new institutional economists have argued that financial intermediation involves considerable risks since banks find it difficult to acquire skills in risk assessment. The relationship between increases in real income and the size and complexity of the financial superstructure remains loose.

Article

The question of how financial structure relates to economic development departs from a distinction between an economy's infrastructure of real wealth – its physical assets produced by human labour and natural resources – and a set of financial claims that exists side by side with it and is somehow connected with it. This set of claims consists of short-term and long-term loans and credits and equity securities. A second distinction is between two types of issuers and holders of these financial instruments: non-financial institutions, such as governments, business enterprises and households, whose assets are mainly – but not exclusively – held in physical form, and financial institutions, whose assets
and liabilities are mainly financial instruments. This second distinction divides the original question into two parts: the link between the real infrastructure and the volume of financial instruments in the economy, and the link between the real infrastructure and the volume of funds held by the financial institutions.

The US economist Raymond W. Goldsmith (1904–88) provided much of the statistical framework and empirical basis for the examination of these questions. In a lifetime of painstaking scholarly labour, he collected data that allowed comparison across countries of key ratios of real and financial assets, and also of how these ratios changed within individual countries over time. His research suggested one – now widely accepted – statistical generalization, that of the \textit{rising financial interrelations ratio}. As expressed by Gurley and Shaw (1967, p. 257), ‘during economic development … countries usually experience more rapid growth in financial assets than in national wealth and national products’. The increase, however, does not continue without limit. This process of financial deepening has been experienced by many of the now developed capitalist countries. However, it tends to be most evident in the early and middle phases of their economic development, after which it levels off. The exceptions to this are higher ratios in periods of repressed inflations during and just after major wars. In the United States, little financial deepening has been noticeable since 1950.

It is also clear that this ratio can be influenced by strategic choices in the quest for development. Countries that adopt state-led development strategies, such as the USSR and its eastern European satellites, exhibited smaller ratios than those of countries that relied on private sector growth to drive their economic development.

As one would expect, developing countries have much lower financial interrelations ratios (between 0.6 and 1.0) than do Europe and North America (between 1.0 and 1.5). This is a reflection of the lower degree of monetization of their economies and the relative lack of separation of the functions of saving and investment. The composition of the value of total financial instruments shows a smaller share of financial institutions in the developing countries, for the same reason (Goldsmith, 1969, pp. 44–7).

\textbf{Compositional changes in financial instruments}

The process of development is associated with compositional change, as well as growth, in the stock of financial instruments. The start of financial development is the diffusion of fiduciary money into the economy through the banking system. This is followed by the growth of banking deposits, and then the share of banking deposits declines as new types of financial institution proliferate – building societies, mortgage companies, insurance companies and pension funds – providing financial services that are tailored to special needs.

The main thrust of early development economics neglected these financial aspects of development. Until the 1980s, the main focus of analysis was on the real economy, particularly the accumulation of real physical capital, the acquisition of new human skills and the expansion of international trade. When the problem of financing ‘real’ development was discussed, it was often restricted to the problem of domestic taxation, the self-finance of enterprises and the negotiation of foreign credits. Michal Kalecki, who greatly influenced the early development literature, explicitly argued that the volume of investment is not subject to financial limits. In the Kaleckian view, financial institutions appear, if at all, as pre-existing constraints on production that have to be removed – for example, rural moneylenders (Kalecki,
financial structure and economic development: The New Palgrave Dictionary of Economics

1972, pp. 145–61; FitzGerald, 1990, p. 184) – or as publicly established agencies for channelling resources to sectors of the economy that were desired to expand (see Eshag, 1983, pp. 186–8 on development banks). Thus financial development was long a secondary consideration, and it was viewed from the perspective of a government deciding which monetary institutions to create and which to destroy.

The McKinnon–Shaw view of financial intermediation

Independently of this dominant post-Keynesian approach, Ronald McKinnon, John Gurley and Ed Shaw in the 1970s elaborated a much more positive view of the role of the growth of private financial intermediaries in development. Using the context of an agricultural sector exhibiting strong technological dualism and lumpy investment, they argued that private financial intermediation, operating with market-set interest rates, improved incentives to save and the availability of credit. It did so by spreading risks and transforming the maturity structure of debt in ways more attractive to both savers and borrowers. Their claim was that financial intermediation would provide the benefits of additional savings and the more efficient allocation of those increased savings between borrowers. On this account, the growth of financial intermediation promotes both capital accumulation and the diffusion of technical progress by spreading risks more widely and in conformity with people's willingness to bear them (Gurley and Shaw, 1960; 1967; McKinnon, 1973; Shaw, 1973).

This positive view of private financial intermediaries has been criticized by post-Keynesians on both theoretical grounds – an incomplete accounting of all the incentive effects of market-determined interest rates – and empirical grounds – the absence of the predicted incentive effects in the savings, investment and interest rate data. However, the most compelling theoretical critique came from the new institutional economists. Rejecting the assumption of perfect information, they showed how various information asymmetries between the knowledge possessed by the private bankers and the knowledge possessed by their clients (savers and investors) generated a radically altered assessment of the potential benefits and dangers of private financial intermediation.

An important conclusion was that, as interest rates rose, the banks’ lending portfolios became riskier. This resulted both from adverse selection, as the marginal borrowers are more liable to default, and from moral hazard, as the marginal borrowers are more likely to invest in high-risk projects. Private banks thus have an incentive to continue to lend at less than the market-clearing rate of interest, and to borrow from depositors at an even lower rate, and then to ration credit (Stiglitz and Weiss, 1981). The benefits to be expected from private financial intermediation under asymmetric information assumptions are smaller than those derived from McKinnon–Shaw perfect information reasoning.

Evidence of financial repression

In the 1980s it became increasingly clear that many existing financial institutions in developing countries were dysfunctional. Moreover, in many cases the cause of the dysfunction was diagnosed as inappropriate government regulation. The analysis of ‘financial repression’ in Shaw (1973) was often borne out in reality. Interest rates were administered and maximum rates held very low, while reserve ratio requirements were set very high to force banks to buy and hold government debt issued at below-
market rates of interest. Banks were treated as a source of government finance, rather than providers of financial services to the private sector. Meanwhile capital controls were in place to stop the flight of private capital seeking better returns abroad.

The consequences of these widespread interventions included banks’ inability to offer attractive rates to depositors; an artificially low level of deposits; a shortage of credit; the rationing of available credit; political pressures directing the allocation of credit; low repayment rates; the accumulation of bad debts; and ultimately the effective insolvency of the banks. The flourishing business of rural moneylenders and ‘kerb’ markets, despite the charging extortionate rates of interest, was simultaneously observed, with puzzlement, complaint or cynicism, as the observer preferred.

The move to financial liberalization

The policy response was that international organizations and national aid donors pressed for the removal of these policy-induced distortions, and the adoption of reforms aimed at financial liberalization. Interest-rate liberalization was adopted as one of the components of structural adjustment programmes in the 1980s and 1990s. Unfortunately, liberalization was not enough by itself to end the effects of financial repression. While deposits did climb as a share of GNP, there was little expansion of credit to the private sector, as many state banks remained in existence, and their habits of directing credit died hard (World Bank, 2005, pp. 207–39). Worse still, financial liberalization led to increasingly frequent financial crises. They were the result of increased competition between private banks, increased opportunities of foreign borrowing for all banks and the serious inadequacy of prudential regulation of the banking system.

As the new institutional economists had pointed out, financial intermediation involves considerable risks, and banks find it difficult to acquire skills in risk assessment, especially when that skill has not been previously salient. Hence, the possibility of miscalculation of risk is ever present. In addition, bank regulation and supervision is itself a risky business, for the by now familiar reason of asymmetric information, and can provoke banking problems as well as prevent them – and can also be vulnerable to corrupt pressures to look the other way. All of this suggests that the building of functional financial sectors is likely to remain a work in progress for the foreseeable future.

Economic and financial development: a loose reciprocal relationship

Few would be inclined to deny that there is a rough parallel between economic and financial development, if periods of several decades are the time period under consideration. As real income and wealth increase, so do the size and complexity of the financial superstructure. Yet this is a loose relationship. The financial intermediation ratio, the share of financial institutions’ assets in the value of all financial assets, is even more loosely tied to the stock of real wealth. Rather, ‘it is to a large extent the result of institutional arrangements and savers’ preferences’ (Goldsmith, 1983, pp. 54).

It is difficult, therefore, to interpret the causal significance of these highly aggregative ratios. It is hard to argue that a given volume or composition of financial assets is a sufficient condition for the development of real sectors of the economy – or even a necessary condition, given that rapid growth has sometimes taken place during periods of deliberate financial repression. We are not, however, obliged to
retreat to a view of finance as purely passive, accommodating growth that is driven by other means. Financial innovation has at times sparked off virtuous circles of growth in particular sectors and regions. The microcredit movement in Bangladesh (and elsewhere) in response to extortionate rural moneylending is one recent example where a new financial technology, carefully managed, has been the spur to the growth of the incomes and welfare of poor borrowers. However, if building a functioning formal sector of financial intermediaries is arduous and costly, the evolution of financial structure and real economic development may well be mutually determined, with causation flowing in both directions (Greenwood and Jovanovic, 1990).

Economic models, which provide relationships between economic variables, are useful in making scientific predictions and policy evaluations. Well-known examples include classical linear regression models, where the explanatory variables are assumed to be non-stochastic (fixed) and the errors are normally distributed, and non-classical models, where these assumptions are violated. These non-classical models are frequently used in empirical work, and they include the simultaneous equations model, models with serial correlation and heteroscedasticity, limited dependent-variables models, panel and spatial models, non-linear models, and models with non-normal errors.

Based on sample data, econometric methods provide techniques of estimation and hypothesis testing related to these and other models. The commonly used estimators are the least squares (LS) or the generalized LS (GLS), the maximum likelihood (ML), the generalized method of moments (GMM), the empirical likelihood (EL) and the quantiles. The hypothesis-testing procedures used are Wald's (W), Rao's score (RS) and the likelihood ratio (LR) methods. Since all these are based on sample information, the statistical properties (unbiasedness, consistency, efficiency, distributions) of these procedures are of great interest for both small and large samples. This has led to the development of asymptotic theory (large sample) econometrics (White, 2001) and finite sample econometrics (Ullah, 2004).

The large sample theory properties may not imply finite sample behaviour of econometric estimators and test statistics, and they can give misleading results for small or even moderately large samples. As an example, consider a regression model
where $y_i$ is a univariate response, $x_i$ is a univariate fixed regressor, $\beta$ is an unknown parameter to be estimated, and $u_i$ is an additive error assumed to be independently and identically distributed (i.i.d.) with mean zero and variance $\sigma^2$. Let $b_1$, and $b_2 = (1 - 1/n)b_1$ be two estimators of $\beta$, where $b_1$ is the LS estimator. Then, the asymptotic distributions of $b_1$ and $b_2$ are

$$\sqrt{n}(b_1 - \beta) \sim N(0, \sigma^2 / m_{xx}), \sqrt{n}(b_2 - \beta) \sim N(0, \sigma^2 / m_{xx}),$$

where $m_{xx} = \Sigma_{i=1}^{n} x_i^2 / n$ as $n$ tends to $\infty$.

Thus, asymptotically, both estimators are unbiased, and they have the same variances and distributions. But these results do not hold for finite samples (small or moderately large), since in this case $Eb_1 = \beta$, $Eb_2 = \beta(1 - 1/n)$, $V(b_1) = \sigma^2 / \Sigma_{i=1}^{n} x_i^2$, $V(b_2) = (1 - 1/n)^2 V(b_1)$, that is, while $b_1$ is unbiased, $b_2$ is biased and their variances are different. Further, the distributions of $b_1$ and $b_2$ are generally not known but, if we assume normality of errors, then both $b_1$ and $b_2$ are normally distributed.

Fisher (1921; 1922) and then the work of Cramér (1946) laid the foundations of statistical finite sample theory on the exact distributions and moments which are valid for any sample size. This exact theory on distributions and moments was brought into econometrics by the seminal work of Haavelmo (1947) and Anderson and Rubin (1949) on the exact confidence regions of structural coefficients, Hurwicz (1950) on the exact LS bias in an autoregressive model, Basmann (1961) and Phillips (1983) on the exact density and moments of the estimators in the structural model, and Ullah (2004) on the exact moments. However, these exact results are often very complicated for drawing meaningful inferences since they are expressed in terms of multivariate integrals or complex infinite series. Also, the results are not derivable for non-classical models, especially for non-linear models or models with non-normal errors.

Another major development took place through the pioneering work of Nagar (1959) on obtaining the approximate moments of the k-class estimators in simultaneous equations. This was followed by Sargan (1975) and Phillips (1980), who rigorously developed the theory and applications of the Edgeworth expansions to derive the approximate distribution functions of econometric estimators. (The idea of the Edgeworth expansions originates from the fundamental work of Edgeworth, 1896.) The approximate distributions and moments provide results which can tell us how much we lose by using asymptotic results and how far we are from the exact results if they are known. Most of the contributions, however, were confined to the analytical derivation of the moments and distributions in the simultaneous equations model and the dynamic first-order autoregressive (AR (1)) model, but with i.i.d. normal
observations. These also included the finite sample results using the Monte Carlo methodology (Hendry, 1984) and advances in bootstrapping (resampling) procedures (see Efron, 1979; Hall, 1992). The analytical and bootstrap results for non-classical models, especially those that are non-linear with non-normal and non-i.i.d. observations, remain a challenging task for future development in this area of research. For the approximate analytical results some development has begun to take place (Rilstone, Srivastava and Ullah, 1996) with a non-i.i.d. extension in Ullah (2004). This provides results which can be used to evaluate the approximate bias and mean-squared error of a class of estimators (ML, LS, GMM) for linear and non-linear models with normal or non-normal errors, and the observations can be i.i.d. or non-i.i.d. In the same spirit Newey and Smith (2004) develop the properties of generalized empirical likelihood estimators. Similarly, there are developments in the bootstrapping procedures for studying the properties of the GMM and extremum estimators in various econometric models with i.i.d. as well as dependent and non-stationary observations (see Horowitz, 2001).

The progress in finite sample econometrics has indeed been ongoing. The developments described provide analytical and simulation-based procedures for finite sample analysis of econometric models. In the broad sense, the frontier of this research area has moved on. With the advances in computer technology this subject will further develop in both the analytical and the bootstrapping domains.

Finley, Moses (1912–1986)

Finley, M.; slavery

Article

Sir Moses Finley had an immense influence on classical studies and particularly ancient history because he brought to them the new disciplines and techniques of the modern social sciences. He was unique among ancient historians in that his early training had been in law, economics and sociology. Born on 20 May 1912, Finley graduated (BA) from Syracuse University at the age of 15 and from Columbia (MA) at 17, his major subjects being psychology and US constitutional law. Westermann encouraged him to try ancient history, and he taught himself Latin and Greek, financing himself with his earnings and those of his wife Mary, a school teacher whom he married in 1932. Theirs was a childless but devoted marriage, Lady Finley dying two days before her husband.

Finley worked from 1930 to 1933 on the Encyclopedia of Social Sciences and was much influenced by the Frankfurt Institute for Social Research; his reading of social theory made him left-wing and at least partly Marxist. He was active on behalf of the Republicans during the Spanish civil war and raised funds for Russian war relief in the Second World War. After founding the American Committee for the Defence of International Freedom against McCarthyism he was dismissed from his post as Assistant Professor of History at Rutgers University. Known by now for his lectures in England, he was given the post of lecturer in classics at Cambridge in 1955, and was a Fellow of Jesus College from 1957 to 1976. He became a British subject in 1962. He succeeded to the chair of ancient history in 1960, and in 1976 became the first Master of Darwin College. Finley's doctoral dissertation, ‘Studies in Land and Credit in Ancient Athens’ (1950), gained him an international reputation. He asked questions that had not been considered before in this field, and saw the ancient world with modern eyes. Classical scholars had used the word ‘economics’ in its ancient and particular sense, as the management of a household and hence of a state; Finley opened up the discipline to the interests of modern social sciences, dealing with matters such as property, contracts, succession, the value of goods and coin and the laws of war. He stepped aside from the traditional track to look at the exact relationship between masters and slaves, the nature of
debt bondage, the consumer society and urban and rural production. He was the first ancient historian to tackle the methodological problems implied by the new style of social history. Finley could appear cantankerous and was famous for his feuds; he enjoyed creating shock waves in the academic world. But at his best he was a new wind blowing through an old and rather old-fashioned subject, and he changed and refreshed the classics more than any other scholar this century.

firm boundaries (empirical studies)

Thomas N. Hubbard

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The empirical literature on the determinants of firms’ boundaries examines relationships between firms’ boundaries and asset specificity, especially how relationship-specific investments create ‘hold-up’ problems that increase the costs of competitive contracting; relationships between firms’ boundaries and the contracting environment, reflecting the role of incomplete contracting in the theoretical literature and the extent to which firms subcontract downstream stages rather than input procurement; and how firms’ boundaries vary with ‘job design’. This literature has established that asset specificity is empirically relevant for understanding integration decisions, and that relationships between subcontracting decisions, the contracting environment, and the division of labour are subtle.

Article

This article discusses empirical work on the determinants of firms’ boundaries, focusing on ‘make-or-buy’ decisions. Examples of such decisions include whether firms procure inputs (or distribute outputs) through in-house divisions or other firms. It concentrates on work that draws on Coase (1937), which depicts firms and markets as alternative means of governing transactions. The theoretical literature in the Coasean tradition is vast, and includes well-known works by Williamson (1975; 1979; 1985), Klein, Crawford and Alchian (1978), Grossman and Hart (1986), and Holmstrom and Milgrom (1994). This contrasts with the neoclassical literature, in which firms’ boundaries are determined by production technology and, perhaps, market power-related issues. This other literature examines how, for example, vertical integration reflects firms’ incentive to eliminate double marginalization, raise rivals’ costs, or protect themselves from competitors’ attempts to raise their own costs.
Firms’ boundaries and relationship-specific assets or investments

By far the largest branch of the empirical literature examines relationships between firms’ boundaries and asset specificity. This branch is primarily motivated by Klein, Crawford and Alchian's (1978) and Williamson's (1979; 1985) analysis of how relationship-specific investments create ‘hold-up’ problems that increase the costs of competitive contracting. On the assumption that such investments do not create as severe problems when transactions take place within firms, it follows that vertical integration should be more prevalent, and outsourcing less prevalent, when transactions involve relationship-specific assets than when they do not.

Several early papers examine this proposition in procurement contexts. Monteverde and Teece (1982) and Masten (1984) examine outsourcing decisions of auto makers and an aerospace firm, respectively, and find that outsourcing is less prevalent when components are firm-specific than not. The latter finds that it is also less prevalent when co-locating production of the component with that of successive production stages is more valuable. Joskow (1985) finds that vertical integration is prevalent when coal-burning power plants are located close to coal mines, but power plants procure coal from outside firms when they are not co-located. These and other correlations uncovered by this early work provided the first evidence that asset specificity is empirically relevant for understanding integration decisions and, more broadly, that analysing firms’ boundaries from a contractual perspective could lead to new empirical insights.

This branch has since developed along several lines. Researchers have found relationships between asset specificity and vertical integration in other industrial contexts, and have explored the empirical limits of this proposition by examining the extent to which asset specificity and integration are correlated in contexts where investments are smaller and less specific than in the contexts discussed above. Still others have investigated the closely related question of how, given that vertical integration is not chosen, contractual relationships vary with asset specificity (see Joskow, 1988, and Klein, 2005, for comprehensive surveys).

There is significant debate over the theoretical interpretation of this evidence. Asset specificity is an important element of many theories in this literature, so correlations between asset specificity and vertical integration need not provide evidence in favour of any one in particular. Whinston (2003) discusses this problem at length, and concludes that, while these theories’ empirical implications are not the same, the data requirements of distinguishing tests are considerable and the existing empirical evidence is not dispositive.

Some recent papers indicate that the relationship between vertical integration and investment can be subtle. Woodruff's analysis (2002) of vertical integration between shoe manufacturers and retailers, and Acemoglu et al.'s analysis (2004) of vertical integration in British manufacturing indicate that whether vertical integration is more or less prevalent when investments are more important depends critically on the source and nature of the investment. Understanding empirical relationships between integration and investment incentives is a major focus of current research.

Firms’ boundaries and the contracting environment
A second branch of the empirical literature examines relationships between firms’ boundaries and the contracting environment. Many theories motivate this research, reflecting the essential role incomplete contracting plays throughout the theoretical literature. This branch typically examines the extent to which firms subcontract downstream stages rather than input procurement. Examples include Anderson and Schmittel's work (1984) on whether manufacturers rely on internal or external sales representatives, Baker and Hubbard's investigations (2003; 2004) of firms’ boundaries in trucking, Brickley, Linck and Smith's analysis (2003) of whether bank offices are independent entities or branches, and some of the research (see Lafontaine and Slade, 1997, for a survey) that examines whether chain outlets are company-owned or franchises. These papers exploit variation in the availability of good measures of downstream individuals’ performance, which, in turn, derives from technological change or differences in the nature of the downstream individual's job. (Work exploiting the latter is classified here rather than below, when authors emphasize differences in the contractibility rather than the number or diversity of tasks.) Results from these papers generally indicate that more (downstream) integration tends to be associated with better performance measures.

These results have several implications. First, they imply that the contracting environment is not organization-neutral. Non-neutrality is not obvious. Agency problems exist between upstream and downstream entities regardless of whether the latter are employees or subcontractors. If contractual improvements reduce agency costs independently of integration-related trade-offs, they should not affect firms’ boundaries. The results indicate otherwise. Second, they imply that the contracting environment affects the costs of transacting within as well as between firms. Some theories, including Coase (1937), propose that coordination takes place ‘by fiat’, and hence the contracting environment is irrelevant, within firms. If so, contractual improvements should always favour market transacting and thus less vertical integration. Again, the results indicate otherwise. Third, they suggest that while contracting problems exist both within and between firms, empirical variation in the availability of good performance measures tends to be related to inefficiencies associated with transacting within firms. Although this conclusion is preliminary, it implies that it is particularly productive for those researching (or making) ‘make-or-buy’ decisions to identify the source of these inefficiencies, because they may have more real-world ‘bite’.

**Firms’ boundaries and the division of labour**

A third, related branch examines how firms’ boundaries vary with the division of labour, or ‘job design’. Holmstrom and Milgrom's (1994) analysis of how multitask agency problems influence firms’ boundaries motivates much of this work. This branch includes analyses of how whether in-house salesmen or sales reps are used depends on whether salesmen are also given non-selling responsibilities (Anderson, 1985), how whether pharmaceutical firms outsource clinical trials depends on whether the work involves more than just data collection (Azoulay, 2004), and how whether restaurants are company-owned or franchised depends on how much food production and service takes place at the restaurant (Yeap, 2005).

Results from these papers indicate that integration tends to be less prevalent when individuals are allocated a narrower set of responsibilities. Combined with the evidence above, they imply that relationships between subcontracting decisions, the contracting environment, and the division of labour
are subtle. The previous subsection suggests that replacing an easily contractible task with a less contractible one tends to make subcontracting more likely. The evidence here suggests that adding a less contractible task to a more contractible one tends to make subcontracting less likely.

Other work has found that the division of labour and firms’ boundaries are related in horizontal contexts as well; for example, Garicano and Hubbard (2003) find that law firms’ field boundaries narrow as market size increases and lawyers become more specialized.

**Firms’ boundaries and economic outcomes**

Most of the literature investigates what determines whether firms integrate rather than what actually happens when they do, but research on the latter is important because it reveals whether integration is an economically important issue.

Some evidence has come from firm or industry case studies. Early work includes Masten, Meehan and Snyder (1991), which concludes that organizational costs make up a significant fraction of production costs in shipbuilding, and that incorrect choices with respect to integration decisions can increase organization-related costs by as much as 70 per cent. More recently, Gil (2004) investigates relationships between how long movies play at a theatre and whether the theatre is owned by the movie's distributor, and finds that movies play two weeks longer at distributor-owned theatres than other, similarly situated theatres.

Perez-Gonzalez (2004) provides cross-industry evidence. This investigates how the elimination of Mexican laws that constrained multinational firms from having majority control of affiliated enterprises affected plant-level investment and productivity. He finds that, within technology-intensive sectors, increases in integration associated with the elimination of these constraints led to significant investment increases and an approximately ten per cent increase in total factor productivity at these enterprises. The allocation of control rights, and thus vertical integration, can have a major impact on investment incentives and productivity. In short, integration decisions can matter a lot.

Article

It is doubtful if there is yet general agreement among economists on the subject matter designated by the title ‘theory of the firm’, on, that is, the scope and purpose of the part of economics so titled. There is, probably, general agreement on the subject matter of economics itself: the allocation and distribution of scarce resources. (Some economists would have us add explicitly ‘and growth’ to ‘allocation and distribution’, but traditionally growth is subsumed under ‘allocation’.) Then we may take it that the purpose of the theory of the firm is to investigate the behaviour of firms as it affects allocation and distribution. We now come immediately to a fork. An economist who believes that a ‘firm’ is a profit-maximizing agent (whether by conscious, rational decision or otherwise), endowed with a known and given technology, and operating subject to a well-defined market constraint, will see no need for any special theory of the firm: the theory of the firm is nothing but the file of optimizing methods (and perhaps market structures). If firms maximize, how they do it is not of great interest or at least relevance to economics. The economist's job is simply to cultivate and apply optimizing techniques. Given this view, it is unnecessary to inquire further: to seek to ‘inquire within’ is otiose, perhaps methodologically misguided. (As we shall see, the theory of the firm has been, and perhaps still is, the battleground for some fierce methodological warfare.) Economists who doubt any of the three critical assumptions see an urgent need to inquire within, but diverge substantially thereafter (for example, managerial utility...
functions, behaviourism). Later on, I shall try to exhibit a systematic tree, although this is not easy since some of the branches are sadly tangled. Before doing that, I want to show that the first fork, referred to above, was recognized a long time ago, and to sketch some of the history of our subject. First, though, I must impose more narrow limits on it.

In most of the work on the theory of the firm it is at least implicitly assumed that the agent whose behaviour is to be examined is a capitalist firm (which may or may not be a joint-stock corporation) engaged in manufacturing, processing or perhaps extraction. Thus the study of financial intermediaries, although they are firms, is conventionally relegated to some other branch of our discipline. Partnerships and cooperatives (labour-managed firms) may be usefully examined with the techniques of the theory of the firm, as may not-for-profit organizations, but their study is conventionally filed under ‘comparative systems’. For convenience and brevity, although not out of conviction, I shall respect these conventions here. It is also necessary to place some demarcation line between the theory of the firm and ‘market structure’ or ‘industrial organization’. For the moment, at least, I think it better to let this one be implicit.

We must also ask why firms exist at all. The classic – and neoclassical – answer was provided by Coase (1937): transactions costs. I call this a ‘neoclassical’ answer because part of the tradition, still embodied in much contemporary general equilibrium theory, is the assumption of constant returns to scale. Some increasingness of returns may be a very good reason for the existence of firms, or at least help to explain their size, but it is obviously vastly convenient to have a sufficient reason which is not inconsistent with constant returns. Coase suggested that the firm was an area (subset of the economy) in which allocation proceeded by direction rather than via markets, because some procedures, such as the allocation of workers to tasks, could be more cheaply done that way – coordination by command rather than by price. The word ‘command’ suggests that some monitoring, enforcement or internal incentive structure will be required, and indeed these matters have been receiving increasing attention. Alchian and Demsetz (1972), in particular, discussed the problem of monitoring, suggesting, in effect, that the need for it explained and justified the existence of the capitalist firm. They posed the question of who monitors the monitor, and suggested that the incentive problem is solved if the ultimate monitor is the residual claimant. O. Williamson (1980) reviewed alternative organizational structures. He suggested that the existence of firms economizes on explicit contracts which, given uncertainty and bounded rationality, are expensive instruments. He also found that ownership and hierarchy are only weakly related.

A recent work to emphasize the reasons for the existence of firms is Aoki’s (1984). He argues that if firms exist because institutional allocation is cheaper than market allocation, reasons for which he explores thoroughly, then firms must enjoy ‘institutional rent’. Furthermore, not all the resources used within the firm will have prices uniquely determined by external markets. Thus the distribution of rewards is not uniquely determined, and there is room for bargaining. Aoki argues that this is best modelled as a cooperative game, the players of which are the stockholders and the workers. Managers are reduced to the role of technocratic mediators (which, in view of recent developments in agency theory, discussed below, is perhaps surprising). This approach proves to be very flexible: Aoki can handle as special cases the neoclassical model (shareholders get all the residual) and the labour-managed firm in which the workers get it all (and even, with some interpretation, managerial models).

In what follows, I shall take the existence of firms for granted and return later to the matter of incentives. The first fork, referred to above, will be familiar to any careful reader of Adam Smith (1776). He relied upon the self-interest of the butcher, the baker and the brewer to provide his dinner. The ‘firms’ in which
he had confidence were small, owner-operated (whether single owner or partnership), without limited liability. He had serious misgivings about joint-stock companies. He pointed out what has become known in this century, thanks to Berle and Means (1933), as the ‘divorce between ownership and control’. And he doubted if the managers had appropriate incentives to try to maximize the owners’ returns; that is, he raised the question of what is now called ‘incentive compatibility’. Thus, in considering the joint-stock company, Smith went unhesitatingly down what I will call the ‘troublemaker's branch’: we do have to inquire within. The joint-stock company is, of course, the predominant contemporary organization.

After Smith, there is not much that can be called ‘theory of the firm’ in classical economics. (Ricardo's firms are Smith's butchers and bakers.) The exception, as so often, is Marx, but there is not space to discuss Marx here. (J.S. Mill, 1848, in the famous chapter ‘On the Probable Futurity of the Labouring Classes’, expressed concern about both the incentive structure and morality of the capitalist form of organization, and recommended a cooperative form instead.) We must notice, however, the startlingly modern work of Cournot (1838). He wrote down a demand function and, in his famous discussion of the mineral spring, employed explicit optimizing methods (and, so far as I know, was the first to do so). Not only this, he carried out a deliberate and formal exercise in comparative statics – in 1838! In applying marginal analysis to the theory of the firm he thus thoroughly anticipated the ‘marginalists’. The ‘marginal revolution’ in due course produced a wholly desirable unification of the theories of production, allocation and distribution, creating the neoclassical branch from the fork, but with little that could be called ‘theory of the firm’. The firm was, however, central in Marshall's (1890) work, and he, characteristically, put a foot on each branch. Formal, mathematical, Marshall is strictly neoclassical, as I employ the term. The informal Marshall, concerned with growth, offered suggestive literary dynamics. Let us consider first the more formal Marshall. His distinction between the short and long runs is essential to much of his work. This distinction is, of course, the one currently in use: in the long run all factors are variable, in the short run one at least (commonly capital) is not. This allowed him to distinguish between fixed and variable costs, and between the effects of adding more labour to a fixed-capital stock and the effects of altering the scale of operations. We now have short-run diminishing returns in industry generally, while there may be increasingness in the long run. Thus Marshall was not limited to the constant coefficients case of his classical predecessors: he was able to offer a thorough analysis of the ‘laws’ of returns. This allowed him to give a fairly complete analysis of the short-run equilibrium conditions for a firm selling in a perfect market. (There is in his analysis an even shorter ‘short run’, the market period in which the price of, say, a catch of herrings is determined. This does not appear to concern us here.) Marshall did not, of course, solve all the problems of the theory of production, costs, supply and distribution in competition. He left room for the important work of Viner (1931) and Stigler (1939).

A further and vital step was Marshall's generalization of Ricardo's theory of rent. He distinguished between a quasi-rent, which would in the long run be competed away, and a true rent, which definitionally could not be. (Both, of course, are any excess of rewards over opportunity cost.) If the quasi-rent is due to an increase in the demand for the product of specific capital equipment, then the long run in which it is competed away and the long run in which all factors are variable are, of course, identical. (That the period in which quasi-rent is competed away and that in which all factors are variable may differ is noted below.) This in turn allowed Marshall to develop the long-run equilibrium
conditions for a competitive industry: quasi-rent must be competed away (or negative profit eliminated by exit) so that the normal profit condition is satisfied. Here he seems to have followed Walras (1874).

Marshall made many other contributions to the theory of the firm. He noted that, if increasingness in returns (to scale, as we should say) is internal to the firm, competition is not viable, whence a downward-sloping competitive supply curve can only be attributed to economies external to the firm (internal to the industry; but he also considered economies external to the industry and internal, perhaps, only to the whole economy). He also offered a formal monopoly model some features of which require remark. The firm's demand curve coincides with the market demand curve for the 'product' (a given primitive of analysis): there is no oligopolistic interaction here. This model is still with us, although the analysis has become more elegant. In his geometry, Marshall had us finding the profit-maximizing output by looking for the biggest profit rectangle: \((AR-AC)q\). Cournot (1838) had written down the marginal revenue function in his discussion of the mineral springs case, but Marshall chose not to follow him. (The discovery of the marginal revenue curve in Cambridge in the 1930s seems to have caused great excitement.)

The less formal Marshall was concerned with growth and the intertemporal behaviour of firms. His firms were joint-stock, but otherwise rather Smithian. He had, loosely speaking, a 'clogs to clogs in three generations' model. The first entrepreneur would be vigorous and innovative, finding some source of quasi-rent. His son would be more passive and probably mistake the quasi-rent for rent itself. The spoiled and idle grandson would certainly make this mistake, the quasi-rent would be competed away, and the cycle would be over.

This is, of course, not a good description of the history of a typical (immortal) joint-stock company. What is important is the link between innovation, quasi-rent and economic growth. Now, of course, the period in which quasi-rent is competed away is not necessarily identical to that in which capital can be varied. It may be possible to copy an innovation very quickly, or necessary to wait for the expiry of a patent. And if the quasi-rent is due to exceptional managerial talent and vigour (really, a rent to ability), it does not get competed away at all, but eventually withers. It was, however, this link between innovation and quasi-rent that Schumpeter (1934) made explicit in his great vision of the source of growth in a capitalist economy: the incessant seeking for quasi-rent via innovation, each source of quasi-rent being in turn competed away by further innovation in the process of 'creative destruction'. One notes, of course, that this model does not depend on the generational cycle of Marshall's family firm: widely owned joint-stock companies can continue to play Schumpeter's game so long as they are appropriately managed.

Marshall had the task of reconciling his view of the intertemporal behaviour of firms with his short-run profit-maximizing conditions and long-run industry equilibrium conditions. His device of the 'representative firm' appears to have been designed to do this. The representative firm would not only be in short-run profit-maximizing equilibrium but would be earning precisely normal profit when the industry as a whole was in equilibrium. This means that the definition of long-run equilibrium needs to be more carefully stated. It is not 'all firms earn normal profit'. It is rather 'there is no tendency for the total number of firms in the industry to alter; the representative firm earns normal profits but others may still be expanding or already withering; in any case the net change is zero.' Here the representative firm is implicitly defined. As Newman (1960, p. 590) put it, in his discussion of Marshall's 'statistical' concept of long-run equilibrium, 'Long-run equilibrium for Marshall meant the equality of long-run demand and supply; just that and no more.' In the 1920s and 1930s there was a considerable literature on
Marshall's value theory, not discussed here (see Newman, 1960, for references). Since the work of Chamberlin (1933) and Joan Robinson (1933), the notion of the representative firm has tended to disappear from the literature. It has become usual to assume that each firm is always, by choice, in short-run equilibrium, and then to consider how Marshall's long-run competitive forces will impose industry equilibrium (normal profit for all firms simultaneously). Newman and Wolfe (1961), on the other hand, followed up the 'statistical' interpretation of Marshall's long-run equilibrium. They were not the first to apply Markov-chain analysis to the behaviour of an industry; but they were the first to integrate it with value theory. (Other more or less contemporary applications of Markov-chain analysis at most appeal to 'Gibrat's Law'. Newman and Wolfe may be thought to have prepared the ground for Nelson and Winter, 1982, discussed below.)

I shall now attempt to describe some other forks and branches of the tree. To do this it is easiest to jump to the present, since so much has happened since the Second World War that needs to be allocated to its appropriate branch. (Chamberlin, 1933, and Joan Robinson, 1933, had, of course, made significant extensions of Marshall's formal models before the war. These contributions are discussed elsewhere.)

We encountered above a fork between what I call the smooth neoclassical branch and the rough and troublesome 'other' branch. There is another possible basis for classification, between optimizing and other models. The advantage of the first is that it gives the neoclassical model the prominence it deserves; the advantage of the second that it brings into prominence the importance of the assumptions we make about information and computational capacity. Perhaps somewhat arbitrarily, I shall classify the models to be considered here as optimizing and 'other'. The optimizing set of models divides again, between profit maximization and the optimization of other (usually managerial) objective functions.

Let us consider some arguments concerning the classes of models we have already identified. The advantages of an optimizing model are clear: it is analytically tractable. We have well-developed techniques to handle it, even if the economic agents considered may not. It may also be thought to have important predictive power, but this is more dubious. The programme of qualitative comparative statics (Samuelson, 1947) has been shown to be more limited than we might have hoped. The objections to optimizing models are well known, but also debatable. They are essentially two. The first is that firms, or the human beings that manage them, cannot optimize: they have neither the information nor the computational capacity, whence the most we can have is Simon's 'bounded rationality' (Simon, 1955; 1959; see also 1979). Nelson and Winter (1982) have recently made a major contribution to this approach, discussed below. The position here is not that we give up the fundamental Smithian assumption of purposeful, self-interested behaviour (with what would we replace it?) but rather that we abandon the optimizing model and consider instead how, in a world of uncertainty, firms (managers) may explore their environment and try to 'make the best of it'. It is not suggested, at least by Nelson and Winter, that we 'inquire within' for the sake of it but rather to improve our understanding of how actual firms, seeking for profit but essentially too ignorant to optimize, may try to allocate resources. The second objection to optimizing models comes from those who have enquired within and report that firms 'just don’t' (see, for example, Hall and Hitch, 1939; Andrews, 1949; Cyert and March, 1963). Many critics of this behaviourist school feel that it says little more than 'firms do what they do', and fails to analyse the relationship between the observed behaviour reported and resource allocation.

An example may show the force of the criticism. It is no longer open to doubt that firms commonly adopt markup pricing routines. In their study of a department store, Cyert and March (1963) report their...
discovery of the markup formula in use. They then congratulate themselves on being able to predict, given the wholesale price of an article, its posted price. They also notice that if profits are not satisfactory, the firm may adjust by altering its product-mix; that is, buying better (more expensive) or cheaper stock. But it is here that the important allocational decisions are taken, and this decision process is not analysed at all. (It should be noted that Cyert and March, 1963, p. 268, place on their agenda matters which do not appear to be relevant to allocation and distribution at all, and which I accordingly exclude from consideration.)

Two related arguments in favour of profit-maximizing models may usefully be noticed now. The first is the ‘biological analogy’: survival of the fittest (see Alchian, 1950; Penrose, 1952; Friedman, 1953; Machlup, 1946; 1967). It is suggested that in a competitive world a firm must maximize to survive. Thus, however decisions are taken, whatever routines are adopted, firms which in fact maximize will prosper and be able, in particular, to retain and attract capital, while those that do not will wither. There are three points to raise here. The first is: how competitive is the environment? (See below.) The second is that to survive, one does not have to be perfect but only good enough to handle the competition. Indeed, Charles Darwin seems to have anticipated this misuse of his argument when he wrote,

> Natural selection tends only to make each organic being as perfect as, or slightly more perfect than, the other inhabitants of the same country with which it has to struggle for existence … Natural selection will not produce absolute perfection … (Darwin, 1859, pp. 201–2)

The third is that, to make effective use of the biological analogy, one has to offer something that can serve as a gene. Nelson and Winter (1982) have recently suggested a candidate (see below). The second, and related, argument is that one can maximize without consciously trying. Thus Day and Tinney (1968) show that a firm can climb to the top of a (suitably concave) profit ‘hill’ by use of a simple feedback algorithm: if an action (change in output) succeeds (increases profit), repeat it; if not, back up. The notion that one may climb the hill ‘driving only by the rear-vision mirror’ must certainly be attractive to those who worry about the firm's information state and computational capacity. Yet obviously this simple feedback process works only if it converges ‘fast enough’ relative to the stability of the environment. Otherwise, it will be necessary to improve the algorithm to speed up convergence; for example, by adding feed-forward loops. The survival argument suggests that it will then be the firms that can do this that will survive. Then the loops (routines) are identified by Nelson and Winter as the genes in the evolutionary process. Notice, however, that this identification was made in 1982, not by those who originally proposed the biological analogy (see also Winter, 1975).

We have now distinguished between optimizing models and ‘other’. We have glimpsed the next two subdivisions, that between profit-maximizing and other optimizing models, and between behaviourism and other non-optimizing models. (We shall soon find another fork on the profit-maximizing branch, too; see below.) We have also noticed some relevant argument. We may now explore some developments along each of these branches.

Developments in and since the Second World War, some emerging from operations research, have extended the scope of optimizing models at a staggering rate. In a few short years, we had linear
programming (for economic applications, see Dorfman, Samuelson and Solow, 1958), and activity analysis (see Koopmans, 1951). Optimizing techniques were extended to inventory control (Whitin, 1953; Simon, 1952). We then had what I will call the ‘dynamic explosion’ as the techniques of optimal control and dynamic programming were increasingly applied to the firm's problems; see, for example, Lucas (1967) and Treadway (1969) on the flexible accelerator, Mortensen (1970) and Brechling (1975) on the demand for labour.

Another major development has been the extension of optimizing models of the firm to include considerations of risk. Risk had been explicitly considered by Knight (1921), who offered an unsurpassed account of the ways in which the institutions of the capital market facilitate risk sharing. Knight tried to distinguish between ‘risk’ and ‘uncertainty’ in a way that many have found unsatisfactory: ‘risk’ was insurable; ‘uncertainty’, any uninsurable residual. Profit was the reward for bearing uncertainty (since risk could be covered by insurance). He was, I believe, the first to make the point that entrepreneurs would have to be less risk-averse than others (their employees) with whom they entered into explicit contracts. Recent work does not, however, follow Knight. It took a new departure from the work of von Neumann and Morgenstern (1944); see particularly Arrow (1971), and for specific applications to the theory of the firm, see for example Sandmo (1971). The main result (Sandmo) is that the risk-averse competitive firm will produce less than a risk-neutral competitive firm or one which knew with certainty that the price was going to be equal to its expected value. Drèze (1985) has used risk as a means of introducing a more realistic model of the firm into general equilibrium theory.

General equilibrium theory is beyond the scope of this essay; but we should note that he does ‘inquire within’ and that his approach has much in common with that of Aoki (1984).

This brings us to a fork on the profit-maximizing branch. The divorce between ownership and control is explicitly recognized and the theory of agency developed to deal with it. The divorce occurs whenever an owner (or principal) submits a risky operation in which he has an interest to an operator (or agent) whose conduct he cannot monitor costlessly. Thus the theory of agency, originally developed in the discussion of sharecropping (risk sharing) and other forms of tenancy (see Stiglitz, 1974) has the widest application, evidently to insurance, and, of particular interest in the present context, to the interior operations of firms, not only the relationship between owners and controllers but even between managers and teams (of employees) (see particularly Ross, 1973; Jensen and Meckling, 1976; Holmstrom, 1982; Grossman and Hart, 1983). It is commonly cheaper to give the operator (whether tenant, car-driver or executive) an incentive to good behaviour than to try to monitor him or her. This, of course, leads to less than optimal risk sharing (collision deductible in automobile insurance). Another incentive to good behaviour in the face of costly monitoring is suggested by Eaton and White (1983): this is to give an employee a bonus, a wage above his or her opportunity cost, so that, in the case that misconduct is detected, dismissal is a genuine penalty (see also Shapiro and Stiglitz, 1984). Thus both carrots and sticks have been considered. When behaviour is unobservable, incentive compatibility may require some surprising forms of contract. Thus Holmstrom has shown that the only way to avoid the free-rider problem in a team in which effort is not observable is a contract which threatens to break the budget: deliver the target, or no member gets anything (someone else takes the full value of whatever is delivered). This raises two immediate problems. First, it may pay the ‘someone else’ to bribe a member of the team to shirk (‘just a little’). Second, if achievement of the target depends on effort and some
random variable(s), how would risk-averse members of the team dare to enter into such a contract?

Above I distinguished between two approaches to the theory of the firm, that of the maximizers and of those who wished to ‘inquire within’. In agency theory we see the two converging. We are ‘within’, but not for its own sake; the agenda is still the allocation and distribution of scarce resources. We are forced within to deal, inter alia, with problems raised by Adam Smith over two centuries ago, in conjunction with our own better understanding of risk.

Let us now consider other optimizing models. These depend not merely upon the divorce between ownership and control but on the idea that there is ‘slack’ within which the controllers may play their own game without being noticed and called to account. This in turn depends on the existence of market imperfections. The usual story has been that large firms are typically in a position to make monopoly rents, and that these rents can be forgone, used up, or ploughed back at the discretion of the controllers. It is acknowledged that rents usually turn out to be quasi-rents, but suggested that the large firms (conglomerates) can, by heavy R&D expenditure, enjoy a perpetual stream of quasi-rents: while one source is being competed away, another is being developed (perhaps patented). Thus there is always some room for discretionary expenditure by the controllers. This room may in turn be limited by the perspicacity of the capital market, but it is suggested (Marris, 1964) that the power of the capital market to discipline controllers is limited by the costs of information and the fact that the supply of capital to potential takeover raiders is not infinitely elastic. Suppose, however, that capital markets were perfect.

So long as the divorce between ownership and control remained, so would the problem of arranging incentive-compatible contracts for managers, whoever owned the equity. How much scope for discretionary behaviour there actually is, then, is an empirical question to which we do not have a final answer. There is, however, no shortage of models of how managers will behave if they have the room – room to maximize their own utility functions, that is. We have Baumol (1959): maximize growth subject to a minimum profit constraint. Marris (1964) and J. Williamson (1966) offer more sophisticated versions. O.E. Williamson (1964) introduces the idea of ‘expense preference’. The controllers can dissipate the rents by padding costs in ways which increase their utility. These ideas (and there are others) have obvious application to regulated industries, at least in the case in which the regulatory standard is a profit ceiling. Marris and J. Williamson both take into account the financial structure of the firm. There is now a large literature on this subject which I shall not discuss here.

The set of ‘other’ models may be seen to subdivide again, between behaviourism, and something more purposeful associated with the work of Herbert Simon (‘don't maximize, Simonize!’). To be sure, the firms in Cyert and March wanted to make a profit: they just do not seem to have been very good at it. Along the ‘Simon branch’ we have purposeful, self-interested behaviour. We may call it rational too, as long as it is understood that optimization is thought to be too difficult, and it is accordingly rational not to try. It does not follow that optimization does not occur: firms may adopt a convergent process, as in Day and Tinney (1968). In a ‘sufficiently stable’ environment, convergence might, of course, be quite common. But convergence must be proved rather than optimization assumed. It is thought rational for the firm to adopt routines or standard operating procedures that work at least ‘well enough’. The meaning of ‘innovation’ is now extended. The introduction of a new routine that successfully handles a
complicated decision that has to be taken with limited information is as much an innovation as a new product or an improvement in the technology. (From this point of view, a new legal or financial instrument that reduces transactions costs is an innovation too.)

It would not, I think, be a good use of space to catalogue all Simon's own innovations and suggestions. (For more recent discussion of bounded rationality, and related matters, see March, 1978.) Instead, I shall consider only a recent contribution on this branch, the work of Nelson and Winter (1982) already referred to. These writers are much concerned with economic growth, perhaps less in static allocational problems. They inherit from Schumpeter, and Marshall, as well as Simon, and they name Cyert and March among their intellectual ancestors, as well as Alchian (1950).

Nelson and Winter argue that firms do not know the well-defined technological choice sets of standard theory. They only know how to do what they do do, and how to make at least local searches to do other things. Thus there is no sharp distinction between the choice set and the choice, and maximization is not an appropriate concept or mode of analysis. Neither is equilibrium for either firm or industry. The configuration of an industry at any time is seen as the outcome of an evolutionary process, whence the appropriate tool is a Markov process (as in Newman and Wolfe, 1961). The ‘genes’ required for biological analogy are the firms’ routines: the standard procedures (in production, marketing, finance, and so on) that it knows how to operate. Its environment is stochastic, and the firm continually has to search for new routines (mutations). Chance enters twice. The search for a new routine may be deliberate, but its success is subject to chance. Once discovered, its application is subject to chance. Thus we have purposeful, self-interested behaviour, but success is a matter of luck. Routines are inherited, but new routines, once discovered, may also be copied by others, which allows the evolutionary process to be much faster than the biological process. There is another important point here. Nelson and Winter show that it may be more profitable to wait and to copy an innovation made by others than to incur the expenses necessary to develop it oneself. This seems to be contrary to the Schumpeterian intuition. There is also a shift in focus from the ‘firm’. For Nelson and Winter the evolution of the industry is the subject of study, and the routines are the genes in the evolutionary process. The ‘firm’, although it is assumed to adopt purposeful, self-interested conduct (to seek profit), is not itself a matter of particular interest: it is something of a transient which happens, at any moment of time, to have inherited some routines, and may or may not succeed in developing some new, successful, ones. As in the earlier biological analogies, success will be rewarded and failure punished, but this is not advanced as an argument for ‘as if’ optimizing behaviour; it is part of the evolutionary process. Indeed, Nelson and Winter offer the first formal proof that, in this process, it is the profitable firms that survive. For other problems (R&D and technological change; Schumpeterian competition), they have to rely on simulation techniques which, however well handled, always leave one a little uncertain about what has been established, or, at least, at what level of generality.

It is now time to return to the question posed at the beginning of this article: what is the scope and purpose of the theory of the firm? Indeed, is there a theory of the firm at all? Perhaps not. There is a file of optimizing models. We may include in this file the theory of agency and much recent work on information and incentives. (There are also inquiries into such organizational matters as integration and the divisional structure of large corporations, which I do not discuss here.) In the ‘other’ branch, profit-seeking but not optimizing, there is the recent work by Nelson and Winter, in which the focus is on the development of the industry (population), and the firm is little more than an agent (unit organism) for the transmission of genes. And there is recent work, very exciting work, exploiting the ideas of capital
commitment and credible threats, much of it in the spatial literature, on the strategic behaviour of firms in small group situations. Much of this work has been associated with developments in game theory. I shall not describe it here on the possibly dubious grounds that it is better filed as ‘Industrial organization’ or ‘theory of market structure’. Demarcation lines are not, of course, well established; it could be argued that, whenever we invoke the ubiquitous Cournot–Nash equilibrium concept, we are taking a game-theoretic approach, and some might wish to interpret theory of the firm more widely than I have done. Be that as it may, there is clearly no such thing as a theory of the firm. But there is a great deal in the file, subdivide it as we will, and since the Second World War we have seen great advances, on many different fronts, albeit differently motivated and with different methodological orientations.

firm-level employment dynamics

Abstract

Firm-level employment dynamics deals with the evolution of firms’ employment decisions when they face costs of creating and destroying jobs. It lies at the intersection of labour economics, industrial organization and macroeconomics. Recent contributions use rational expectations models of labour demand to match salient statistics from establishment-level employment records.

Article

Firm-level employment dynamics is the branch of economics that deals with the evolution of firms’ employment decisions. The static analysis of labour demand equates a firm's marginal product of labour with the wage. Observation suggests that this abstracts from important considerations of employers when expanding or contracting their firms. Recruiting new employees requires effort, and preparing them for the jobs at hand might require training. Employees with substantial tenure might have legal rights that make their dismissal costly. All these realistic constraints make a firm's current employment complementary with its level at any future date. Hence, a firm's employment decisions when properly considered are dynamic. Firm-level employment dynamics is the area of economics that seeks to understand this decision using both theory and measurement. It lies at the intersection of industrial organization, labour economics and macroeconomics. It shares with labour economics a central concern with the employment relationship. Because firm entry and exit plays a substantial role in the evolution of total employment, it shares with industrial organization an interest in entrepreneurship. Firm-level costs of adjusting employment provide one potential source of persistence in economy-wide employment, so the area has contributed to the macroeconomics of business cycles.

Early theoretical treatments of the firm's dynamic employment choices came from the Ph.D. theses of Oi and Rosen. Oi (1962) coined the adjective ‘quasi-fixed’ to describe a factor of production that could be changed from its previous value at a price. He considered the labour demand of a firm facing a constant wage and interest rate that must incur recruiting and training costs when expanding employment. Denote these with $W$, $r$, and $\tau$. Then the firm's first-order condition for labour is $P \times f'(N) = W + r \times \tau$, where the production function holding other inputs constant is $f(\cdot)$, $P$ is the output price, and $N$ is the firm's employment choice. Oi noted two fundamental implications of this equation. First, the marginal product of labour generally exceeds the wage, so wage-setting institutions must support such a gap if the firm is to recover its investment in job creation. Second, unexpected permanent reductions in $P$ leave $N$ unchanged so long as the marginal product of labour remains above the wage. Rosen (1968) extended this by noting that adjusting an employee's hours worked generally costs less than adding or dismissing workers. Hence, fluctuations in hours worked should be more important for workers with high training and recruiting costs. He examined the employment decisions of regulated railways and found that they conform to this pattern. Oi and Rosen intuitively saw many of the fundamental theoretical implications of imposing labour adjustment costs, but the first fully dynamic treatment of the firm's labour demand curve came from macroeconomics. Sargent (1978) considered a firm with a quadratic production function maximizing profit subject to quadratic costs of adjusting employment. Given a stochastic wage, $W_t$, he showed that the firm's optimal labour demand curve takes the form

[http://www.dictionaryofeconomics.com/proxy.library.csi.cuny.edu/article?id=pde2008_F000315&goto=6&result_number=5881]
Here, $N_t$ is the firm’s employment at date $t$, $\mathbb{E}$ is the expectations operator, and $\rho$ and $\lambda$ are positive parameters that depend on the interest rate, the cost of adjustment, and the production function’s concavity. Intuitively, $N_{t-1}$ influences the profit-maximizing choice of $N_t$ because it changes the cost of achieving any given level of employment. The complementarity between current and future employment makes $N_t$ a function of the wage and its expected value at all future dates. This rule for $N_t$ aggregates easily: if all firms follow it, then total employment does so as well. Sargent estimated this using US data on private employment and real wages. His model considered both straight-time and overtime employment. The quarterly data did not contain substantial evidence against the model, but the response of employment to real wage fluctuations in the model was much less than that measured with a vector autoregression.

With quadratic costs of adjustment, firms smooth their employment adjustments across time. This conflicts with the casual observation that firms’ employment adjustment is *lumpy*, that is, they alternate between periods with very little or no employment adjustment and others with high rates of hiring or firing. Further credence to that view came from observations of firm employment collected by national statistical agencies. Using plant-level employment observations from the Dutch economy in 1988 and 1990, Hamermesh, Hassink and van Ours (1996) showed that 28.3 per cent of firms kept employment constant over that two-year period. All these firms changed the identities of their employees. The average hiring rate for these firms was 11.3 per cent, so they apparently face costs of changing the jobs in the firm that are independent of the costs of changing the workers filling them.

With their book-length study of plant-level employment dynamics in the US manufacturing sector Davis, Haltiwanger and Schuh (1996) reinforced the conclusion that firm-level employment adjustment is lumpy. Their data came from the Longitudinal Research Database, an unbalanced panel of quarterly firm-level employment observations created from the surveys underlying the Annual Survey of Manufacturers and the Census of Manufacturing. These are confidential US Census records, but they may be used for approved projects that benefit the US Census at one of several regional census research data centres. Denote the employment of firm $i$ in quarter $t$ with $N_{it}$, and let $N_t = \sum_{i=1}^{M_t} N_{it}$ be the employment of the $M_t$ firms with positive employment in quarter $t$. With these data, Davis, Haltiwanger and Schuh defined the job creation and destruction rates as

$$POC_t = 2 \times \sum_{i} I(N_{it} > N_{it-1}) \frac{N_{it} - N_{it-1}}{N_t + N_{t-1}} \text{NEC}_{it} = 2 \times \sum_{i} I(N_{it} < N_{it-1}) \frac{N_{it-1} - N_{it}}{N_t + N_{t-1}}.$$

So defined, the difference between these two rates equals the rate of employment growth. These authors refer to their sum as employment reallocation.

The examination of these statistics from 1972: IV to 1988: IV yielded the following conclusions. (1) The rates of job creation and destruction are both very large relative to total employment changes. The average annual rates of job creation and destruction equaled 9.1 and 10.3 per cent. (2) The job creation and destruction rates of the population of young and middle-aged plants (less than ten years old) are much higher than those of their older counterparts. (3) Plants’ employment changes are persistent. Some 70 per cent of newly created jobs last at least one year, and 80 per cent of newly destroyed jobs fail to reappear within a year. (4) Employment adjustment is lumpy. Two-thirds of job creation and destruction occurs at plants that adjust their employment by 25 per cent or more. (5) Employment drops in a recession because job destruction increases. Job creation is relatively acyclical. Together, these facts have become the empirical touchstone for firm-level employment dynamics.

These facts motivated the creation of new models of firms’ employment choices that incorporated adjustment costs and lent themselves to aggregation. A pair of papers by Campbell and Fisher (2000; 2004) develops one such model and applies it to explain the job creation and destruction facts of Davis, Haltiwanger, and Schuh. They begin with the labour demand problem of a single plant that produces a homogenous good for sale in a competitive market. The plant uses one factor of production, labour, that comes in fixed shift lengths. The per-period cost of employment measured in units of the output price is $W_t$, and let $n_t$ denote employment at this plant. The plant’s output in period $t$ is $z_t n_t^\alpha$, where $z_t$ is the plant’s idiosyncratic productivity term and $0 < \alpha < 1$. The wage follows a Markov chain over $(W_t, \omega)$ with transition probability $p$, and the idiosyncratic productivity shock follows a random walk with bounded innovation $\epsilon_t$. The production function’s strict concavity could arise from limits to a manager’s effective span of control. When the plant changes its
firm-level employment dynamics: The New Palgrave Dictionary of Economics

employment, it incurs adjustment costs that are proportional to the number of jobs created or destroyed. If employment at the plant expands, the cost per job created in units of lost output is $\tau_c$, and the analogous cost per job destroyed is $\tau_d$.

With these primitives, the profit maximization problem for a plant manager discounting future profits with $\beta$ can be represented as a dynamic programming problem with initial states $n_{t-1}$, $z_t$, and $W_t$. Its associated Bellman equation is

$$
\nu(n_{t-1}, z_t, W_t) = \max_{n_t} z_t n_t^\alpha - W_t n_t - \tau(n_t, n_{t-1}) (n_t - n_{t-1}) + \beta \mathbb{E}_t \left[ \nu(n_{t+1}, z_{t+1}, W_{t+1}) \right].
$$

Here, $\tau(y, x) = \tau_c \times \mathbb{1}(y > x) - \tau_d \times \mathbb{1}(y < x)$ is the per-job adjustment cost incurred. Campbell and Fisher (2000) show that the plant's optimal employment policy has a very simple structure. There exist job creation and destruction schedules, $\underline{n}(z, W) = \bar{n}(z, W) z^{1/(1-\alpha)}$, such that

$$
n_{t+1} = \begin{cases} 
\underline{n}(z, W) & \text{if } n_{t-1} \leq \underline{n}(z, W) \\
\bar{n}(z, W) & \text{if } \underline{n}(z, W) < n_{t-1} < \bar{n}(z, W) \\
\bar{n}(z, W) & \text{if } \bar{n}(z, W) \leq n_{t-1}
\end{cases}
$$

Figure 1 illustrates these policies. On its horizontal axis is $\ln z_t$, while its vertical axis gives $\ln n_{t-1}$ and $\ln n_t$. The three plants labelled $A$, $B$, and $C$ all start with identical values of $n_{t-1}$ but different values of $z_t$. The job creation and destruction schedules are both linear with slopes equal to $1/(1-\alpha)$. Plant $A$ lies above the job destruction schedule, so it reduces employment. Plant $C$ lies below the job creation schedule, so it creates jobs. Plant $B$ lies between the two schedules. Here, the costs of job creation and destruction both exceed their associated benefits, so the plant's optimal employment is unchanged. Thus, this model automatically replicates one of Hammermesh, Hassink, and van Ours's findings: the plant's optimal employment frequently does not change.

Figure 1
Optimal employment policy in Campbell and Fisher (2000)
Davis, Haltiwanger, and Schuh’s finding that job destruction accounts for most cyclical employment variation attracted a great deal of attention in macroeconomics. Campbell and Fisher (2000) show that this simple model can replicate that fact if employment fluctuations arise from variation in $W_t$. To appreciate how this can be, note that the total cost of creating a job is $W_t + \tau_c$, which has an elasticity with respect to $W_t$ that is less than one. The total cost of destroying a job is $W_t - \tau_d$, so its elasticity with respect to $W_t$ exceeds 1. This asymmetry in the costs of job creation and destruction translates into asymmetric responses of the job creation and destruction schedules to changes in $W_t$. When the model is calibrated to match the characteristics of a typical US manufacturing industry, this microeconomic asymmetry produces the observed aggregate dynamics in a large population of such plants: the variance of job destruction exceeds the variance of job creation.

Campbell and Fisher (2004) extend this model to address Davis, Haltiwanger, and Schuh’s finding that the magnitude of job creation and destruction declines with a plant’s age and a related fact: aggregate fluctuations in young and middle-aged plants’ employment exceed those of employment at older plants. To do so, they incorporate a life cycle into the above model. Plants exit exogenously and are instantly replaced by new entrants. All entrants begin life in a ‘volatile’ state with high probability of exit and high idiosyncratic productivity variance. In each period, a plant has a constant probability of transiting to a ‘stable’ state with lower exit probability and idiosyncratic productivity variance. Alone, this change would (mechanically) replicate the finding that young plants display greater job creation and destruction rates than their older counterparts. To generate young plants’ greater business-cycle sensitivity, Campbell and Fisher add ‘unstructured’ jobs. Creating and destroying these jobs is costless, but for a worker to fill such a job is less productive than filling a structured job, which is costly to create and destroy.
Intuition suggests that a plant’s use of unstructured jobs depends on its position in the life cycle. Young firms face high uncertainty about their future productivity and survival, so they find unstructured jobs more attractive than their older more predictable counterparts. This is indeed the case. In the calibrated version of the model that Campbell and Fisher use, firms in the ‘mature’ life-cycle stage never use unstructured jobs. Their employment dynamics qualitatively mimic those in the simpler model. In contrast, young plants’ greater uncertainty induces them to create fewer structured jobs. This increases the marginal product of labour and thereby makes creating unstructured jobs more attractive. Figure 2 illustrates such young firms’ employment choices. As in Figure 1, the four plants labelled A, B, C, and D all have the same previous employment in structured jobs. Job creation and destruction schedules govern these plants’ choices of structured jobs. These are the figure’s solid lines. The dashed line gives the optimal employment in unstructured jobs if structured jobs were not available. Plants A and B do not use unstructured jobs, because they lie above this frictionless labour demand schedule. Plants C and D lie below it, and so they employ workers in both structured and unstructured jobs. Plants B and C both lie between the job creation and destruction schedules, so small changes in productivity induce neither of them to change their employment in structured jobs. However, only plant B would keep total employment constant. Plant C would change its employment in unstructured jobs following a small change in $z_t$. In this sense, the greater uncertainty young plants face leads them to choose more flexible production structures. Campbell and Fisher show in their calibrated version of this model that this greater microeconomic flexibility leads to larger aggregate responses to aggregate productivity shocks. Thus, the microeconomic differences between plants at different stages of the life cycle lead directly to the different aggregate differences in their employment dynamics.

Figure 2
Employment choices when structured and unstructured jobs are used
One aspect of firm-level employment dynamics not captured by Campbell and Fisher's models is the prevalence of very large employment adjustments. To generate this, Bentolila and Bertola (1990) add fixed costs of employment adjustment. This non-convexity complicates the model's analysis, but under certain conditions a plant's optimal employment policy follows a two-sided version of an $(S, s)$ policy familiar from inventory models. Denote the gap between a plant's actual employment and its optimal value without adjustment costs using $g_t$. Then the firm lowers the gap to the target $u$ by destroying jobs whenever it would otherwise exceed the trigger $U$, and it raises it to the target $l$ by creating jobs whenever it would otherwise fall below the trigger $L$. Campbell and Fisher's model can be written in this form, where $u=U$ and $l=L$. Fixed costs of employment adjustment cause the targets to differ from their associated triggers and induce the firm to make only large employment adjustments.

Research on firm-level employment dynamics currently examines areas far removed from the initial focus on US manufacturing. Foote (1998) and Campbell and Lapham (2004) examine the dynamics of employment in service and retail industries. Foote finds that job creation dominates aggregate employment fluctuations in these industries. Consistent with this, Campbell and Lapham find that retail industries expand employment following a demand shock by increasing net entry. The importance of entrepreneurship for retail industries' employment is intuitive, and it suggests that the empirical and theoretical lessons learned from studying manufacturing industries will not apply easily to this important sector.

fiscal and monetary policies in developing countries

David Fielding
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Low levels of economic development constrain fiscal and monetary policy in several ways. Few developing countries are able to raise much direct tax revenue, and so must rely on other sources of funding, including seigniorage. Institutional constraints often lead to a high risk of hyperinflation and currency crises. Credible, effective institutions can be created with appropriate outside help, but there are few examples of this in practice.

Policymakers in developing (low-income, semi-industrialized) countries face particular challenges when setting taxes, interest rates and quantitative monetary instruments. All that follows should be preceded by a caveat: developing countries encompass at least as much economic diversity as the OECD. There is no such thing as a representative developing country; much harm can be (and has been) done by the incautious application of stylized models from development macroeconomics to individual countries. Nevertheless, we can identify those characteristics of developing countries that are likely to impose severe constraints on macroeconomic policy-making.

Fiscal and monetary characteristics of developing countries
The descriptive statistics in Table 1 provide some insight into the ways in which the fiscal and monetary characteristics of many developing countries differ from those of the developed world. The first row of the table contains information about fiscal structure and financial development in the United States. Subsequent rows show equivalent average figures for those low-income countries for which data are available.

*The per capita gross national income (GNI) figures are PPP-adjusted. The averages are constructed from those countries for which complete data are available in World Bank (2003): Algeria, Bolivia, Bulgaria, Congo Republic, Costa Rica, Cote d'Ivoire, Croatia, Dominican Republic, El Salvador, Estonia, Georgia, India, Iran, Jamaica, Jordan, Kazakhstan, Latvia, Lithuania, Madagascar, Mauritius, Mexico, Moldova, Mongolia, Nepal, Pakistan, Paraguay, Peru, Philippines, Poland, Romania, Russia, Sri Lanka, St. Vincent, Swaziland, Tajikistan, Thailand, Tunisia, Turkey, Uganda, Ukraine, Uruguay, Venezuela and Vietnam. Russia and Turkey are included in the figures for Europe. The table indicates some of the structural differences between the developing country average and the United States:

- Direct taxation in developing countries makes up a much smaller fraction of total tax revenue, and import duties make up a larger fraction.
- In Asia and the Americas, total tax revenue makes up a substantially smaller fraction of GDP.
- In Africa and Europe, M1 makes up a much larger fraction of M2.
- M2 makes up a much smaller fraction of GDP.

All these features are more pronounced for countries with a per capita gross national income below $5,000 than for those countries in the $5,000–$10,000 range. The low levels of direct taxation in developing countries reflect that fact that a large fraction of private sector income is non-monetized: for example, many peasant households grow subsistence crops for their own consumption. Even when income is monetized, the administrative costs of direct taxation are often...
fiscal and monetary policies in developing countries: The New Palgrave Dictionary of Economics

relatively high because of, for example, low levels of literacy and limited information technology. Governments are therefore forced to rely to a much greater degree on seigniorage revenue and on import duties. (High tariffs are often motivated by the need for fiscal revenue rather than by import substitution.) Inflation in developing countries is usually far higher than in the OECD. Between 1990 and 2000, the average annual inflation rate for the median developing country in Table 1 was 46 per cent; only five countries had single-digit inflation, and 14 had average inflation rates over 1,000 per cent per annum.

The low levels of broad money demand in developing countries reflect low savings rates and limited access to financial services. Commercial banks are often absent from rural areas, where low per capita income, low population density and poor transport and communication infrastructure entail high costs in financial service provision to individual customers. In many developing countries a large fraction of the total money stock is in the form of cash, and few households have access to interest-bearing assets. One consequence is that the interest elasticities of saving and money demand are often very low; another is that there is limited scope for absorption of public debt by the domestic private sector.

Monetary policy: the neoclassical perspective

Central to the monetarist approach to development macroeconomics is the argument that in developing countries high inflation is always and everywhere a fiscal phenomenon. Agénor and Montiel (1999) provide an extensive survey of this approach. In the standard formulation of the argument, which embodies many of the constraints highlighted above, there is a Cagan money demand function:

\[
\frac{M}{P} = \exp(-\alpha \cdot \pi^\beta)
\]

where \(M\) is the nominal money stock, \(P\) is the price index and \(\pi = \dot{P} / P\). \(M\) is to be interpreted as narrow money. There are no interest-bearing assets and no interest elasticity of money demand, so the opportunity cost of holding money depends just on the inflation rate. There is also a fixed real budget deficit, \(D\), financed entirely by seigniorage:

\[
D = \dot{M} / P = \left[ \frac{M}{P} \right] \cdot \mu
\]

where \(\mu = \dot{M} / M\). This reflects the government's limited access to tax revenue and domestic credit. Combining equations (1) and (2) we have:
Equation (1) entails that an equilibrium with a constant $\pi$ requires $\pi = \mu$, so that $M/P$ is constant. For low enough values of $D$ there will be two such equilibria, solutions to equation (3) with $\pi = \mu$. But for high values of $D$ there is no equilibrium: successively higher levels of inflation lead to lower levels of real money demand, requiring higher rates of monetary expansion to finance the budget deficit, and so yet more inflation.

The first goal of macroeconomic policy is therefore to reduce the budget deficit to a level compatible with a stable inflation rate. In the absence of alternative sources of revenue this entails a reduction in public expenditure, which may have a negative impact on social and economic development. This provides a rationale for foreign aid to subsidize public expenditure in the medium term, while the country develops the institutions that will facilitate a wider fiscal base and a financial sector that will support some public debt. This approach still views the main macroeconomic function of a central bank in a developing country as generating seigniorage revenue. Policy reform is intended to reduce seigniorage, not to zero, but to a range compatible with a stable inflation rate. Indeed, a part of the neoclassical development macroeconomics literature analyses the inflation tax using concepts explicitly drawn from public finance, for example the Laffer Curve. The use of monetary policy for business cycle stabilization is at most a secondary objective.

**Time consistency in monetary policy**

The critique of Kydland and Prescott (1977) can readily be applied to a seigniorage model. The simple model above provides an extreme case. Consider a policymaker for whom $D$ is a variable to be maximized, subject to the equilibrium condition that $\pi = \mu$. From equation (3), the optimal rate of monetary expansion is $[\alpha \cdot \beta]^{-1/\beta}$; rates higher than this will reduce revenue. But if we modify equation (1) so that current money demand is based on a predetermined expectation of inflation, then for a given expectation and a given level of money demand the optimum inflation rate is infinite. The rational expectation of inflation is therefore infinite, in which case money demand and revenue are zero.

The policymaker's problem is how to pre-commit credibly to a rate of expansion equal to $[\alpha \cdot \beta]^{-1/\beta}$. Failure to solve this problem is one suggested reason for the failure of disinflation programmes in developing countries.

The standard solution to the time inconsistency problem in industrialized countries is to delegate control of monetary policy to a central bank governor with a contract to target a given inflation rate. The constraint facing many developing countries is the absence of a political tradition or political institutions that will give people confidence in any laws enacted to create central bank independence. Evidence on the link between central bank independence and inflation in developing countries is very weak. There is no significant correlation between historical inflation rates and historical indices of independence, which are based on the assumption that laws in developing countries have the same force as those in
industrialized countries (Cuckierman, Webb and Neyapti, 1992). One interpretation of these results is that legislation for central bank independence would of little use in many developing countries, either because independence de jure does not entail independence de facto or because underdeveloped political institutions are unable to deliver enough clarity or stability in the decision-making process to allay people's doubts.

A possible alternative to central bank independence legislation is commitment to a credible nominal exchange rate peg. For a given real exchange rate a fixed peg against, for example, the euro or US dollar delivers an inflation rate equal to that of the eurozone or the USA. However, a fixed peg will be credible in the long run only if it is accompanied by an appropriate rate of domestic monetary expansion. Excessive domestic monetary expansion will lead to persistent balance of payments deficits and a loss of official foreign exchange reserves; eventually this will cause a collapse in the demand for domestic currency.

‘First generation’ currency crisis models show that with excessive monetary expansion this collapse can happen long before official reserves are finally depleted (Flood and Garber, 1984). It would be irrational to hold on to domestic currency until reserves were finally depleted: at that point there would be a discrete fall in the value of domestic currency as the exchange rate shifted to a market value unsupported by central bank intervention, and those left holding domestic currency would make a loss. Instead, people will offload domestic currency as soon as monetary expansion has driven the implicit market value without intervention below the pegged rate.

‘Second generation’ models (Obstfeld, 1996) go a step further, explaining currency crises in cases where there is moderate monetary growth, no greater than the rate of growth of the supply of foreign currency. Private sector views on the probability of an imminent abandonment of a peg will depend on an assessment of the likely costs and benefits of the peg for the government. (One example of such a scenario is when seigniorage revenue is higher under a more flexible exchange rate regime, but such flexibility deters foreign investment.) But these views will themselves influence the current level of demand for foreign and domestic currency, and so the opportunity cost of maintaining the peg. Models of such an environment typically imply the existence of multiple equilibria. There may be an equilibrium with a low perceived probability of collapse and a low opportunity cost of maintaining the peg, but this equilibrium is unlikely to be globally stable. The feedback between the perceived probability of collapse and the true opportunity cost of the peg means that some rumour questioning the government's commitment to the peg, however small and baseless, could eventually undermine this commitment, regardless of its fiscal and monetary discipline.

Table 2 illustrates some cases in which monetary and fiscal discipline has not been sufficient for the maintenance of an exchange rate peg. In the three cases shown, the size of the budget deficit in the years prior to collapse was not an excessive fraction of GDP (Bolivia, Honduras), or else seigniorage revenue did not account for a large fraction of the deficit (Zambia).

One interpretation of such examples is that they emphasize the need for monetary institutions free from all domestic political pressures and whose commitment to monetary discipline is without doubt. Lost seigniorage revenue is not the only cost of an exchange rate peg. An appreciation of the euro or US dollar due to idiosyncratic shocks in the eurozone or the USA is likely to create a recession in any country pegging to one of these currencies. These recessions can make the peg very unpopular. If we ignore the question of whether such unpopularity is justified, one suggested route to the creation of politically independent monetary institutions is the establishment of currency boards. In a currency board system the central bank is legally required to back issue of domestic currency one-for-one with reserves in a given foreign currency. In eastern Europe currency boards have met with some success, at least in terms of maintaining a fixed peg. Recent examples are Bosnia–Herzegovina and Bulgaria pegging to the euro, and Latvia and Lithuania pegging to the US dollar. By contrast, the currency board system in Argentina met with spectacular failure, showing that currency board systems can be abandoned with almost as much ease as a conventional fixed peg.

A second suggested route to independent monetary institutions is the formation of monetary unions. A transnational central bank may well be free from many of the political pressures facing the central bank of a single country. In order to exert any political pressure on their central bank, the governments (and populations) of a monetary union would need to coordinate their actions. At any one time, conflicting economic interests are likely to undermine coordination attempts. It is always possible to secede from a monetary union, but in the absence of existing national monetary institutions this is potentially very costly. Given the ill will that secession is likely to generate among the remaining members of the union, it is also likely to be an irreversible decision, unlike the abandonment of a currency board. This irreversibility is likely to deter governments from abandoning their commitment to the monetary union. Currently, there are three major monetary unions among developing countries. These are the East Caribbean Currency Union (ECCU: Anguilla, Antigua, Dominica, Grenada, Montserrat, St Kitts, St Lucia, St Vincent), the West African Economic and Monetary Union (UEMOA: Benin, Burkina Faso, Côte d’Ivoire, Guinea–Bissau, Mali, Niger, Senegal, Togo) and the Economic and Monetary Community of Central Africa (CEMAC: Cameroon, Central African Republic, Chad, Congo Republic, Equatorial Guinea, Gabon). The ECCU has for decades maintained a fixed peg to the US dollar with a currency board arrangement. The two African monetary unions have maintained a fixed peg against the French franc (and now the euro) since the member states’ independence in the 1960s, with just one devaluation in 1994. All three monetary unions have maintained low and stable rates of inflation. However, it is unlikely that these three monetary unions could easily be replicated elsewhere. The ECCU is a group of small island economies where tourism makes up a large fraction of GDP and the US dollar circulates freely anyway; the monetary institutions just formalize pre-existing dollarization. The African monetary unions maintain a peg in cooperation with the French government. The French treasury exchanges euros for the two African currencies at a fixed rate, so the peg does not constrain the two central banks’ use of domestic monetary instruments in the short run. (There are rules to prevent excessive monetary expansion in the long run.) Moreover, the French provide overdraft facilities to the two central banks to help cushion balance of payments shocks. So when the euro appreciates because of...
Macroeconomic shocks specific to Europe, the African countries are not obliged to live through a recession. The feasibility of the peg has relied on an unusually strong (and arguably neo-colonial) economic commitment from the country issuing the anchor currency. Otherwise, it is likely that countries without credible domestic monetary institutions can buy a low inflation rate only at the cost of a fixed peg that periodically generates damaging recessions. Even if ‘second generation’ currency crises can somehow be averted, weak domestic monetary institutions and incomplete information about policymakers’ preferences mean that any relaxation of the exchange rate regime in times of recession will undermine the credibility of the commitment to low inflation.

Monetary policy: alternative perspectives

There is a body of literature that encompasses alternatives to the monetarist approach discussed above. This literature is often labelled ‘heterodox’ in the context of policy formation and ‘structuralist’ in the context of theoretical models, of which Cardoso (1981) is a good example. At its core is the idea that inflationary spirals can be generated by the wage- and price-setting institutions within an imperfectly competitive economy, with the supply of money responding passively to increases in prices. Suppose for example that industrial prices \( p \) in a closed economy are set by monopolistic firms as a mark-up on nominal industrial wages \( w \):

\[
 p = [1 + \theta] \cdot w
\]  

(4)

Workers would like to maintain a fixed real wage, so in equilibrium the ratio of nominal wages to consumer prices will be fixed. If consumption is made up of industrial goods and non-industrial goods in fixed proportions \( \phi, 1 - \phi \), then the constant real wage condition can be written as:

\[
 w = \eta \cdot [\varphi \cdot p + (1 - \varphi) \cdot q]
\]  

(5)

where \( \eta \) is the target real wage and \( q \) is the price of non-industrial goods. (The closed economy and fixed consumption share assumptions are not essential to this class of model.) Together equations (4–5) pin down relative prices:

\[
 \frac{p}{q} = \frac{1 - \varphi}{\eta \cdot (1 + \theta)^{-1} - \varphi}
\]  

(6)
There is a positive relationship between relative prices and the target real wage. Now if the supply of non-industrial goods depends just on relative prices, equation (6) will pin down non-industrial production and hence also, with full employment and a given level of resources, industrial production. In general, these production shares will not be equal to the consumption shares $\phi$ and $1-\phi$, in which case the model is overdetermined and has no equilibrium. An inflationary spiral will exist if non-industrial prices adjust to clear goods markets at a level of $p/q$ less than $[1 - \phi] / \{(\eta \cdot (1 + \theta))^{-1} - \phi\}$, which entails a real wage less than $\eta$. In such a world workers will raise wage demands, so $\dot{w}/w > 0$, but from equation (4) $\dot{p}/p = \dot{w}/w$ and with non-industrial prices adjusting to maintain the initial level of $p/q$ we also have $\dot{q}/q = \dot{p}/p$, so there is no change in the real wage; nominal wages and prices will rise indefinitely.

Various policy prescriptions follow from such a model. A government-imposed nominal industrial wage freeze will halt the inflationary cycle at no cost to industrial workers, since their real wages are constant for all levels of inflation. Alternatively, subsidizing consumption of the non-industrial good will raise the real wage and reduce inflationary pressure. This is the macroeconomic basis for arguments in favour of food subsidies. One criticism of subsidies is that they increase the size of the budget deficit, so in models that integrate monetarist and structuralist elements the impact of subsidies on inflation is ambiguously signed.

Evidence on the effectiveness of heterodox anti-inflation measures, compared with orthodox fiscal and monetary contraction, is very limited. Many of the high-profile programmes designed to tackle hyperinflation in the 1980s (for example, Argentina and Israel in 1985, Brazil in 1986 and Mexico in 1987) combined orthodox fiscal and monetary reforms with heterodox wage and price controls of one kind or another. It is very unclear which elements of these programmes were crucial in determining their success or failure. There is some limited evidence from reduced-form macro-econometric models on the direction of causality between wage growth, price growth and money growth (for example, Montiel, 1989). This suggests that different macroeconomic processes are at work in different countries. On the basis of current evidence, policy prescriptions for any one country should be accompanied by a large caveat.

**Taylor rules in developing countries**

The discussions above relate to the problems developing countries face in achieving a stable fiscal policy environment with a moderate rate of monetary growth. This has been the main focus of the theoretical and empirical literature to date. However, there is also a growing literature that extends the mainstream concerns of the monetary policy literature in OECD countries – in particular, issues surrounding the optimal policy response to exogenous macroeconomic shocks – to developing countries. Certainly, developing countries are at least as vulnerable to external shocks as OECD countries. Many developing countries are small in size, trading a relatively large fraction of their GDP and exporting a narrow range of primary commodities for which world prices are highly volatile. In these countries, yearly changes in the terms of trade can increase or reduce domestic income by several percentage
points. The average value of such changes over 1990–2000 in the developing countries in Table 1 is greater than three per cent of GDP; in the USA it is less than 0.2 per cent. Values in excess of ten per cent have been recorded for some countries in some years. These figures are large relative to the magnitude of supply shocks estimated for most OECD countries. So there is a strong case for advocating an active short-run monetary policy in those developing countries with a stable underlying monetary and fiscal regime.

The current norm in OECD countries is an institutionally independent central bank which regularly adjusts a monetary policy instrument – the quantity of short-term lending to commercial banks, or more frequently the corresponding interest rate – in order to meet an implicit or explicit medium-term inflation target. This target is usually accompanied by an injunction to avoid ‘unnecessary’ volatility in real macroeconomic indicators such as GDP growth or the unemployment rate. The relative weight to be given to the two goals is seldom explicit, but the academic literature – including the research divisions of many central banks, though never their policy statements – interprets the trade-off between output and price stability in terms of the framework introduced by Taylor (1993). That is, the optimal value of the instrument in any one period is derived from the maximization of an objective function including the deviations of inflation and output (or unemployment) from their target values, subject to a constraint embodied in a short-run supply curve (or Phillips curve). Shocks to the supply curve shift the constraint and so change the optimal value of the instrument; the magnitude of the change depends on the weights on the different targets in the objective function. Past central bank behaviour is often interpreted as such a Taylor rule plus inertia reflecting model uncertainty and a random component reflecting unquantifiable information about the economy.

In recent years, some non-OECD countries have introduced explicit inflation targeting with a degree of central bank independence and accountability. These are not countries typical of those in the study of Cukierman, Webb and Neyapti (1992): they have relatively stable political institutions and relatively democratic governments. High-profile examples are Brazil, Chile, the Czech Republic, Poland and South Africa. There are also central banks that lack an explicit inflation target but nevertheless publish policy reports that motivate the adjustment of monetary instruments by reference to short-term movements in inflation and output, accompanied by research division working papers on the application of Taylor rules to their economy. The central banks of the two African monetary unions discussed above, the BCEAO and the BEAC, are examples of this phenomenon. Econometric studies of the evolution of monetary instruments and macroeconomic variables in these counties suggest that in most cases their monetary institutions function in a broadly similar way to those of OECD countries, although the shocks to which they are responding (often normalized in econometric analysis!) are greater in magnitude.

The creation of such institutions is surely endogenous to a country's level of political and economic development. They are the consequence rather than the cause of a stable policy environment and relatively developed financial markets. The former ensures the credibility of monetary institutions; the latter ensures an identifiable monetary transmission mechanism in which interest rate changes can be expected to impact on the economy in a consistent way. Such examples represent one tail of the distribution of institutional quality, in which institutions reduce macroeconomic instability. There are still many countries in which institutions increase macroeconomic instability, as witnessed by the hyperinflation still endemic in many parts of the world. Nevertheless, they indicate that a high level of per capita GDP is not a necessary condition for monetary institutions equally as effective as those in the

Fiscal federalism is concerned with the division of policy responsibilities among different levels of government and with the fiscal interactions among these governments. Public service provision by lower-level governments can be efficiency-enhancing, although competition for mobile resources can also interfere with efficient resource allocation both in the public and private sectors. Intergovernmental transfers affect the overall equity and efficiency properties of public policies. Global economic integration and political and economic reforms in developing and transition economies – which have institutional contexts very different from those of the mature federations – present important challenges for a ‘second generation’ of federalism research.

Fiscal federalism is concerned with the division of policy responsibilities among different levels of government and with the fiscal interactions among these governments.

The institutional context of fiscal federalism

Fiscal federalism has long been a topic of keen interest in the United States and Canada. In both nations, subnational governments have traditionally played major roles in the provision of important public services, notably in the areas of education, health, social services, transportation, public safety, and economic development. In addition to non-tax revenues, subnational governments in both countries have
Fiscal federalism: The New Palgrave Dictionary of Economics

had significant sources of tax revenues, with state/provincial governments relying heavily on retail sales taxes and taxes on personal and business income and with local governments depending on property taxes. Higher-level governments (national in relation to subnational, and state/provincial in relation to local) have supported the finances of lower-level governments with extensive programmes of intergovernmental fiscal transfers in order to promote the provision of particular public goods and services, to supplement (or perhaps displace) lower-level government taxes, and to advance broad social welfare objectives. Although they are subject to constitutional, statutory, and regulatory constraints, state/provincial and local governments exercise substantial fiscal autonomy with respect to expenditures, taxation and borrowing. National and subnational fiscal policies have been developed and implemented within the context of continuously evolving but fundamentally durable market, political, and legal institutions, underpinned by stable democratic constitutional structures.

There are long-established federations (and long traditions of scholarly research on federalism) in other parts of the world as well, but interest in fiscal federalism has become particularly intense in developing and transition economies since the early 1990s, no doubt in part because of broad reform initiatives that have reduced the role of the state in economic planning and control (Wildasin, 1997a, ch. 2). In many of these countries, constitutional, economic, and political reforms have led to significant decentralization of tax, expenditure, and borrowing responsibilities, often accompanied by the development of new systems of intergovernmental fiscal transfers. In contrast to the mature North American federations, the newly (or increasingly) decentralized and liberalized economic and fiscal systems of many developing and transition economies are being implemented in the absence of the background political, legal, and market institutions found in more developed nations. The development and restructuring of federations around the world has presented many practical challenges and, for scholars, important questions regarding the design of federal systems, the implementation of fiscal reforms in such systems, and the interactions between basic social institutions and the public sector in federations.

Fiscal federalism is also a subject of increased interest and concern in the European Union. Fiscal decentralization has accompanied economic and political reforms in several European nations. In addition, the interactions of tax, expenditure, debt, and monetary policies among EU member states continuously raise questions concerning international policy coordination and the development of EU-wide supranational institutions. Controversy surrounds the issues of national sovereignty and the upward transfer of powers from national governments to EU executive, legislative, and judicial bodies. In important respects, however, the EU can be viewed as an emerging federation in which EU-level political and fiscal institutions are gradually developing within the context of an increasingly integrated and expanding system of developed and transition economies. From this perspective, the EU itself is a (so far relatively limited) higher-level government in relation to the national governments of its member states.

Fiscal federalism is thus a subject of great interest throughout the world. Wide international variation in the institutional context of federalism has stimulated what Oates (2005) calls a ‘second generation’ of fiscal federalism research, differentiated from ‘first-generation’ research by its heightened attention to political, constitutional, financial and macroeconomic institutions. For example, issues of fiscal discipline, soft budget constraints, and subnational government borrowing, little discussed within the context of traditional federalism research, have received considerable attention in recent years (Inman, 2003; Wildasin, 1997b; 2004), especially with reference to newly decentralizing fiscal systems. Because the policy issues and institutional context of federalism varies widely throughout the world, a rapidly
growing literature deals with fiscal federalism in an international context, often focusing on unique policy issues facing individual countries (see, for example, Bird and Vaillancourt, 1998; Martinez-Vasquez and Alm, 2003; and Rodden, Eskeland and Litvack, 2003, which contain many studies of federalism problems in developing and transition economies).

As the foregoing remarks suggest, problems of fiscal federalism touch upon almost all aspects of fiscal policy, in almost all nations (especially the large nations and economic regions) of the world. The subject is correspondingly very broad. The following paragraphs highlight recurring themes that have occupied researchers for many years as well as selected issues that are likely to be the subject of active enquiry in coming years. The discussion begins with fundamental issues regarding the economic functions of different levels of government, noting their implications for the organization of the public sector. The potential efficiency gains from decentralized policymaking as well as the limitations of decentralization are discussed next, emphasizing the importance of resource mobility and fiscal competition as a crucial feature of the decision-making environment facing lower-level governments. Finally, directions for new research are briefly discussed.

The organization of the public sector

What economic functions can, do, or should be performed by different levels of government? This fundamental question has been a focus of the federalism literature from its inception. There has been a broad normative consensus (Oates, 1972) that, of Musgrave's (1959) ‘three branches of the public household’, the highest-level government (normally a national government, but possibly a supranational entity like the EU) should take responsibility for stabilization functions (that is, macroeconomic and monetary policies), that allocative functions (the provision of public goods and services and correction of market failures) should be undertaken by governments whose jurisdictional boundaries are co-terminous with the geographical scope of the regions affected by these policies, and that higher-level governments should be responsible for policies that target the distribution of income. Subnational economies are comparatively more open than national economies, which means that the impacts of stabilization policies are diluted through capital, labour, and financial flows when undertaken by lower-level governments; see, for example, Mundell's (1961) classic work on optimal currency areas. Similarly, the mobility of labour and capital constrains the ability of (small, open) subnational governments to alter the net distribution of income. For example, high taxes on the rich in one jurisdiction create incentives for the rich to locate elsewhere, while the provision of generous cash or in-kind benefits for the poor attracts beneficiaries (Stigler, 1957). In addition to distorting the efficiency of resource allocation, the spatial reallocation of resources in response to local redistributive policies limits the set of feasible policies as well as their impact on net incomes. Lower-level governments may, however, serve effectively to provide public goods and services in the amounts that are most efficiently adapted to local benefits and costs, which normally vary among locations in accordance with differences in demographic composition, incomes, and technologies (Oates's ‘decentralization theorem’).

Allocative efficiency at the local level

The decentralization theorem shows that non-uniform provision of public goods, varying in accordance
with local benefits and costs, may be more efficient than uniform provision. In principle, however, an
omniscient and omnipotent central planner could implement optimal non-uniform policies, obviating the
need for distinct administrative units of lower-level government. Such a planner could manage all public
sector functions (in fact, all economic decisions) for the entire world. A key idea in the literature of
fiscal federalism, however, is that lower-level units of government may be better informed about and
more responsive to local demands. The information needed for efficient decision-making, and the
incentives to use this information, may differ by level of government, just as markets provide incentives
guiding decentralized market decisions for households and firms in ways not achievable, in practice, by
central planning mechanisms.
This idea is developed explicitly, if informally, in Tiebout (1956). Tiebout draws the analogy between
consumers shopping for commodities in the marketplace and households choosing residences from
among a collection of localities. Writing soon after and in response to Samuelson's classic contributions
to public goods theory, Tiebout asserts that households reveal their preferences for local public goods
when they choose where to reside. Different localities provide different levels of public services, as
illustrated by local school districts in the United States that offer different qualities of elementary and
secondary education. Households with high valuations for education can outbid others for residences in
localities with good schools, thus leading to a sorting of households by demand for public services.
According to Tiebout, this matching of demand and supply leads to efficient provision of local public
goods.
Tiebout's paper identifies local governments as distinct economic units that can perform important
allocative functions in ways that central governments cannot. Tiebout is not specific, however, about
exactly how local decision-makers determine public goods levels – whether by voting or through some
other mechanism. Many subsequent contributions (see, for example, Wildasin, 1986, for a survey and
references), including both theoretical and empirical analyses, explore in detail the phenomenon of
'Tiebout sorting' and the implications of community stratification, by income, race, religion, age and
other household attributes, for variation in local public expenditures. Median voter models (and variants
thereof) commonly provide a theoretical starting point for empirical analyses of the demand for local
public goods. Linkages between housing markets and local fiscal policies, as revealed by hedonic price
relationships, suggest that local voters have incentives to support policies that preserve property values.
In the extreme, these linkages may obviate altogether the need for households to participate in the
collective decision-making process, by providing profit-maximizing property developers and other
market participants with the information and incentives to make efficient policy choices, resulting in
completely market-driven provision of public goods (Fischel, 2001, discusses land use regulation,
property development and their interactions with community formation and local policymaking).
In addition to the information and incentives that may result from the mobility of households and firms,
emphasized by Tiebout, decentralized policymaking may also provide a framework for experimentation
and learning about policy alternatives and their consequences as well as for learning about the
performance of policymakers themselves (Besley and Case, 1995).

Limits to decentralization: efficiency and distributional considerations

Tiebout's analysis and much subsequent research highlights the potential benefits, especially with
fiscal federalism: The New Palgrave Dictionary of Economics

respect to the efficiency of public good provision, from competition among lower-level governments for mobile households and firms. The potential disadvantages of fiscal decentralization have long been recognized, however. For instance, the economic service areas for local public goods may not closely match jurisdictional boundaries. Local health, educational, or transportation policies may benefit residents of neighbouring localities or society at large, spillover benefits that local decision-makers may ignore. These externalities can potentially be internalized through voluntary policy coordination among neighbouring governments. Such coordination can be costly, however, resulting in inefficient decentralized public good provision. Within a federation, a higher-level government can use intergovernmental grants (generally conditional grants, especially matching grants that reduce the marginal cost of public good provision for recipient governments) in order to induce more efficient provision of externality-generating local public goods and services (Breton, 1965). If the spillover benefits from a public good are sufficiently widespread, a higher-level government may assume complete responsibility for its provision. Such centralization of a governmental function involves a trade-off between the potential benefits from internalization of externalities and the potential informational disadvantages of centralized collective decision-making for a larger and more heterogeneous population (Alesina and Spolaore, 2003).

A second possible drawback of decentralized policymaking arises if there are significant limitations on the fiscal instruments available to lower-level governments. In the competition among lower-level governments for households and businesses, taxes (or non-tax revenue instruments such as user fees or licenses) perform a ‘price like’ function by rationing access to public services. Taxes may also introduce inefficiencies of their own, however, not only through ‘classical’ tax distortions (distortion of in situ labour/leisure, consumption, savings, and investment decisions) but more especially through their effects on the locational choices of households and businesses. For example, subnational government income taxes may inefficiently drive profitable businesses and high-income households into low-tax jurisdictions, and retail sales taxes may encourage inefficient cross-boundary shopping. Fiscal competition for mobile factors of production or consumers may discourage taxation of these resources, changing the composition of the subnational revenue structures toward less-mobile tax bases if these are available and potentially constraining the overall level of government revenues. Underprovision of public goods may result, which, as in the case of spillover benefits, may potentially be remediated with well-designed fiscal transfers from higher-level governments (Wildasin, 2006a; Wilson and Wildasin, 2004; Wilson, 1999). On the other hand, if Leviathan governments are likely to engage in excessive spending, fiscal competition may impose useful constraints on their revenue-raising powers (Brennan and Buchanan, 1980).

A further difficulty for federalized systems arises from the fact that many public policies, by their nature, intermingle allocative and distributional impacts, so that a clean separation of allocative and redistributive functions between higher- and lower-level governments may be unattainable. Health, education, transport, economic development, and many social services involve allocative functions (service delivery for geographically limited areas) but also promote distributional goals. Particularly when competition among lower-level governments results in the formation of communities that are relatively homogeneous (with respect to income, race, age or other socioeconomic characteristics), the efficiency gains from decentralization may be realized in part precisely through increased disparities in public service provision. The demand for education, for example, is a normal good, so that stratification
of localities by income produces disparities in educational quality between rich and poor localities, as efficiency requires. In the United States, concern about the fairness of inequality in education, partly as expressed in state government constitutions, has resulted in extensive litigation leading to judicial mandates for policy reforms, notably including extensive programmes of equalizing fiscal transfers from state to local governments (Inman and Rubinfeld, 1979). More generally, the equalization of fiscal transfers from higher- to lower-level governments provides a mechanism through which to limit horizontal inequities in the fiscal treatment of households in rich and poor jurisdictions and the locational incentives to which they give rise (Boadway and Flatters, 1983).

As noted earlier, factor mobility imposes constraints on the ability of governments to redistribute incomes. The integration of capital and labour markets can improve the efficiency of factor allocations and thus raise output and welfare, an important potential benefit that underpins policy initiatives, such as economic integration within the EU, that seek to remove barriers to factor mobility. Factor mobility also affects factor prices, giving rise to potentially important first-order distributional impacts. Thus, economic integration affects not only the cost of ‘decentralized’ redistribution – which, in a global context with international factor mobility, includes redistribution by national as well as subnational governments. By affecting factor prices and the underlying distribution of income, it also may increase or decrease the benefits of redistributive policies. International capital mobility and the migration of younger workers (both skilled and unskilled) from developing and transition economies to aging developed nations thus create new policy trade-offs, particularly for the extensive redistributive systems of North America and Western Europe (Wildasin, 2006b), the consequences of which will unfold in coming decades.

**Directions for future research**

As noted at the outset, the challenges of policy and institutional reform throughout the world have stimulated new interest in fiscal federalism. The incentives embedded in the institutional structures of the mature federations seem to have ensured that subnational governments maintain sufficient fiscal discipline to avoid major widespread or recurring fiscal crises, while preserving their ability to exercise significant policy autonomy with respect to the level and composition of their taxes, expenditures and debts (Buettner and Wildasin, 2006; Inman, 2003; Wildasin, 2004). Such institutions cannot be taken for granted, however, and many informed observers see potential risks from fiscal decentralization in the evolving federations of the developing and transition economies, including risks from excessive (that is, inefficiently high) spending or borrowing by subnational governments. An appropriate mix of revenue and expenditure assignments, intergovernmental fiscal transfers, borrowing flexibility, and policy autonomy is needed in order to realize the potential efficiency gains from fiscal decentralization (McLure and Martinez-Vasquez, n.d.; Weingast, 2006). The interplay between the market environment (especially financial markets and institutions and capital and labour mobility), the assignment of fiscal and regulatory authorities by level of government, and the constraints that influence political decision-making is not well understood and promises to be the subject of extensive study in coming years.

The integration of national and international markets for labour and capital, of crucial importance for federalism, appears to be increasing over time, and affects the competitive pressures facing governments at all levels. The global configuration of age-imbalanced demographic structures (young poor
populations in developing countries and old rich populations in developed countries) implies that international migration incentives are unlikely to diminish in the foreseeable future. The fiscal systems of developed nations, with their extensive systems of intra- and intergenerational transfers, will face growing challenges in coming decades as a result of population aging, even as competition for capital investment and mobile high-income households may increasing constrain their capacity to finance redistribution (Wildasin, 2006c). Policy coordination, perhaps through newly developed governmental structures (for example, at the EU level), may provide opportunities for national governments to limit the degree of fiscal competition, helping them to finance the liabilities arising under existing redistributive systems. Alternatively, or in addition, national governments may explicitly or implicitly shift some expenditure responsibilities to lower-level governments as they manage growing fiscal imbalances arising from demographic change. In any case, growing fiscal imbalances are likely to form the backdrop for public finance in developed countries in coming decades, offering opportunities for fruitful analysis of the dynamics of factor mobility, factor market integration, dynamic fiscal adjustment, and institutional change within and among nations.

The fiscal theory of the price level (FTPL) describes fiscal and monetary policy rules such that the price level is determined by government debt and fiscal policy alone, with monetary policy playing at best an indirect role. This theory clashes with the monetarist view that states that money supply is the primary determinant of the price level and inflation. Furthermore, many authors have argued that the fiscal rules upon which the FTPL relies are misspecified. We review the sources of disagreement, and highlight aspects upon which some consensus has emerged.

Article
The fiscal theory of the price level (FTPL) describes policy rules such that the price level is determined by government debt and the present and future tax and spending plans, with no direct reference to monetary policy.

In understanding the FTPL and tracing its roots, we start from two simple relations: the velocity equation and the government budget constraint.

The velocity equation defines the velocity of money in period \( t \) \((V_t)\) as the ratio of nominal output (the price level \( P_t \) times real output \( Y_t \)) to nominal money balances \((M_t)\):

\[
V_t = \frac{P_t Y_t}{M_t}
\]
Differences across monetary models arise in the way these four economic variables are determined, and in the specification of which (if any) of these variables is to be treated as exogenous as opposed to endogenous. Prior to the introduction of the FTPL, eq. (1) was viewed as the primary determinant of the price level. As an example, the quantity theory of money states that $V_t$ is fixed and exogenous. In this case, the price level is proportional to the money supply. High prices arise because too much money is chasing too few goods, which is the heart of the monetarist doctrine. In a more sophisticated theory, velocity is itself affected by other macroeconomic variables, chief among them the nominal interest rate. Furthermore, in general, the price level needs to be determined jointly with $M_t$, $Y_t$, and $V_t$ by computing the entire equilibrium path of the economy. The FTPL traces its roots to an incompleteness in the monetarist view of the price level: often, the equilibrium price level fails to be uniquely determined, that is, there are many paths of $P_t$ that satisfy (1) as well as all the other equilibrium requirements (see discussion in Kocherlakota and Phelan, 1999). This is especially true when monetary policy prescribes an exogenous interest rate; Sargent and Wallace (1975) show that the initial price level is then indeterminate, and subsequent inflation is subject to ‘sunspots’, uncertainty driven by self-fulfilling expectations. In the simplest case, an interest-rate peg determines the level of velocity ($V_t$), and real output and interest rates are independent of money and prices; eq. (1) then pins down real money balances ($M_t/P_t$), but it does not specify whether those balances will be attained by high or low nominal money supply and prices.

The FTPL (Woodford, 1994; Sims, 1994) determines prices from a different equation:

$$\frac{B_t}{P_t} = \text{Present value of primary fiscal surpluses as of time } t, \ t = 0, 1, \ldots,$$

(2)

where $B_t$ is the nominal value of government liabilities (debt and money) at the beginning of period $t$. Equation (2) is the government budget constraint, in its present value form: the left-hand side represents real government liabilities, matched by assets on the right-hand side. In its simplest form, the FTPL assumes that the government commits to a fixed and exogenous present value of primary fiscal surpluses; this is a special case of what Leeper (1991) defines as an ‘active’ fiscal policy and Woodford (1995) a ‘non-Ricardian’ fiscal regime. Given an initial condition for debt, $B_0$, a unique price level is consistent with (2): the FTPL successfully selects a unique price level at time 0, even in the case of an interest rate peg, for which the monetarist view offered no prediction. The power of the FTPL is not limited to period 0; the possibility of sunspot equilibria is ruled out in all subsequent periods, since again
a unique level of prices is consistent with a given present value of surpluses and the nominal debt inherited from the past. Nonetheless, monetary policy does have an effect on inflation after period 0: the evolution of nominal liabilities $B_t$ depends on the nominal interest rate, which is affected by monetary policy.

Since its inception, the FTPL has been extremely controversial. I focus here on two main areas of concern.

**The value of money or the value of debt?**

The price level is defined as the inverse of the value of money: how much money it takes to buy a given basket of goods. By contrast, the FTPL is about the inverse of the value of government debt. This is explained particularly clearly in Cochrane (2005). As Buiter (2002) points out, there is no reason in general for the value of debt and the value of money to coincide. To the extent that households anticipate a government default, they may trade government debt at a discount, without necessarily affecting the value of money. This criticism is particularly serious when the central bank adopts a monetary policy that rules out monetization of government debt. As an example, consider the case in which the central bank adopts a constant money supply rule and does not engage in open market operations. In this case, there is no link between government debt and money, and no reason why a maturing T-Bill with a face value of $1,000 should trade at par with ten $100 notes issued by the central bank. Maturing debt and money will trade at par only if fiscal policy is run in such a way that the government will have the appropriate amounts of money to repay its debt, independently of the price level: this requires real tax revenues to adjust to prices, violating the central assumption of the FTPL.

The same criticism does not apply when the monetary policy of the central bank allows unlimited monetization of debt, as in the case of an interest rate peg. In this case, the central bank commits to exchange arbitrary amounts of money and one-period government debt at a fixed price. This commitment is not inconsistent with a second commitment, to redeem all maturing government debt at par, offering money in exchange. Since the central bank has unlimited ability to produce money, a government default on nominal debt is now ruled out. In this case, the FTPL is simply a version of a commodity money standard; money, as well as other government liabilities, is backed by the present value of future government surpluses, just as the value of Microsoft shares is backed by the present value of Microsoft profits (this is the main example in Cochrane, 2005).

While the original treatment of the FTPL was ambiguous (in particular, Woodford, 1995, considers the case of the FTPL under a money supply rule), it is now widely agreed that the FTPL requires an implicit or explicit institutional commitment to prevent a government default (or excess repayments by the government) through an appropriate (de)monetization of debt. In this form, the FTPL bears some similarities with the ‘unpleasant monetarist arithmetic’ of Sargent and Wallace (1981). Under the monetarist arithmetic, a fiscal deficit imbalance will trigger inflation, because seigniorage revenues are necessary to prevent the government from defaulting. Even though monetization of government debt plays a central role in both theories, there are important differences. According to the unpleasant monetarist arithmetic, seigniorage revenues (which are part of the present value of surpluses in eq. (2)) will have to respond to changes in $P_t$ to ensure that the government budget constraint holds; hence, equilibrium occurs through adjustments in the right-hand side of (2). In the FTPL, seigniorage revenues...
on the monetary base play at best a minor role. Under the FTPL, it is the price level that responds to shocks to spending and taxes; its fluctuations cause the real value of debt (the left-hand side of (2)) to appreciate or depreciate to reach an equilibrium.

**Government constraints and equilibrium conditions**

The FTPL is based on the assumption that eq. (2) holds only at an equilibrium. The critics of the FTPL view instead (2) as a constraint that forces the government to match the real value of debt with an appropriate present value of primary surpluses, for all conceivable levels of prices. To better understand the issue, it is useful to note that (2) looks identical to the intertemporal budget constraint of any household in the economy: it is sufficient to relabel $B_t$ as the nominal liabilities of the household, and the right-hand side as the present value of its non-asset income, net of consumption. In the case of a household, there is universal agreement that (2) should be viewed as a constraint: given any value of $P_t$, the household must choose a consumption/income plan that satisfies (2). The critics of the FTPL argue that the government should be no different from any other agent. Unlike the previous criticism, the heated debate that has emerged on this point has not resulted in widespread agreement. As Bassetto (2005) points out, the disagreement stems from a fundamental weakness in the tools that have been used to study this problem. Both critics and supporters of the FTPL adopt the dynamic competitive equilibrium framework. This framework is designed for environments populated by many small players; in the presence of a large and potentially strategic player, such as the government, it offers little guidance in distinguishing between equilibrium conditions and constraints that the large player(s) faces under any circumstances, even away from an equilibrium. While there are many applications for which this ambiguity is not important, a proper account of the distinction is essential to study the uniqueness or multiplicity of equilibria, which is the object of interest in the case of the FTPL.

To overcome this difficulty, Bassetto (2002) explicitly describes the economy as a game, where the actions available to all households and the government at any point in time are clearly spelt out. Bassetto shows that the basic version of the FTPL, with an unconditional commitment to a sequence of primary surpluses, is not a valid government strategy in a well-specified game, at least if the sequence includes a primary deficit at any point in time. Intuitively, a primary deficit is possible only if the government is able to raise revenues through borrowing. Since lending is voluntary (unlike payment of taxes), any plausible game includes the possibility that private agents will not lend; if this circumstance arises, the government is forced to a fiscal adjustment. Bassetto then proves that there exist other government strategies that lead to a unique equilibrium price level that is determined from taxes and spending alone. These strategies paint a very different picture of the conditions under which a FTPL arises: whereas the traditional view relies on the government setting taxes and spending exogenously, with no regard for the evolution of debt, the strategies described by Bassetto require the government to strongly react to incipient ‘debt crises’ by accumulating larger surpluses in present value.

**Empirical studies**

A small empirical literature (for example, Canzoneri, Cumby and Diba, 2001; Cochrane, 2001) has looked into the usefulness of (2) in accounting for the evolution of prices. The results are not very
favourable; in particular, when a government runs an unexpected deficit, the real market price of its debt increases, suggesting that households expect that the government will make up for the shortfall through increased surpluses in the future. If future surpluses were exogenous and fixed, (2) would suggest that an unexpected deficit should have its primary effect through inflation, by depressing the real market value of debt. While these observations cannot refute the central claim of the FTPL, that (2) is only an equilibrium condition, they call into question the usefulness of the FTPL in explaining actual inflationary episodes.

Conclusion

Recent research into monetary policy has looked for interest rate rules that ensure price level determinacy independently of the fiscal policy of the government; this has weakened interest in the FTPL. Though no issue as controversial as the FTPL has emerged since, this recent analysis is still open to ambiguous distinctions between policy rules, which should capture government behaviour in all possible scenarios, and equilibrium relations across the endogenous variables of an economic system. A more complete analysis awaits the development of new tools that are as simple and powerful as dynamic competitive equilibrium, and yet able to appropriately capture the special role of the government.

Irving Fisher was born in Saugerties, New York, on 27 February 1867; he was residing in New Haven, Connecticut at the time of his death in a New York City hospital on 29 April 1947.

Fisher is widely regarded as the greatest economist America has produced. A prolific, versatile and creative scholar, he made seminal and durable contributions across a broad spectrum of economic science. Although several earlier Americans, notably Simon Newcomb, had used some mathematics in their writings. Fisher's dedication to the method and his skill in using it justify calling him America's first mathematical economist. He put his early training in mathematics and physics to work in his doctoral dissertation on the theory of general equilibrium. Throughout his career his example and his teachings advanced the application of quantitative method not only in economic theory but also in statistical inquiry. He, together with Ragnar Frisch and Charles F. Roos, founded the Econometric Society in 1930; and Fisher was its first President. He had been President of the American Economic Association in 1918.

Much of standard neoclassical theory today is Fisherian in origin, style, spirit and substance. In particular, most modern models of capital and interest are essentially variations on Fisher's theme, the conjunction of intertemporal choices and opportunities. Likewise, his theory of money and prices is the foundation for much of contemporary monetary economics.

Fisher also developed methodologies of quantitative empirical research. He was the greatest expert of all time on index numbers, on their theoretical and statistical properties and on their use in many countries throughout history. From 1923 to 1936, his own Index Number Institute manufactured and published price indexes of many kinds from data painstakingly collected from all over the world. Indefatigable and innovative in empirical research, Fisher was an early and regular user of correlations, regressions and other statistical and econometric tools that later became routine.

To this day Fisher's successors are often rediscovering, consciously or unconsciously, Fisher's ideas and building upon them. He can be credited with distributed lag regression, life cycle saving theory, the ‘Phillips curve’, the case for taxing consumption rather than ‘income’, the modern quantity theory of money, the distinction between real and nominal interest rates, and many more standard tools in economists’ kits. Although Fisher was not fully appreciated by his contemporaries, today he leads other

For all his scientific prowess and achievement, Fisher was by no means an ‘ivory tower’ scholar detached from the problems and policy issues of his times. He was a congenital reformer, an inveterate crusader. He was so aggressive and persistent, and so sure he was right, that many of his contemporaries regarded him as a ‘crank’ and discounted his scientific work accordingly. Science and reform were indeed often combined in Fisher's work. His economic findings, theoretical and empirical, would suggest to him how to better the world; or dissatisfaction with the state of the world would lead him into scientifically fruitful analysis and research. Fisher's search for conceptual clarity about ‘the nature of capital and income’ led him not only to lay the foundations of modern social accounting but also to argue that income taxation wrongly puts saving in double jeopardy. Fisher turned his talents to monetary theory because he suspected that economic instability was largely the fault of existing monetary institutions. His ‘debt-deflation theory of depression’ was motivated by the disasters the Great Depression visited upon the world.

Economics was not the only aspect of human and social life that engaged Fisher's reformist zeal. He was active and prolific in other causes: temperance and Prohibition; vegetarianism, fresh air, exercise and other aspects of personal hygiene; eugenics; and peace through international association of nations. Fisher was an amazingly prolific and gifted writer. The bibliography compiled by his son lists some 2000 titles authored by Fisher, plus another 400 signed by his associates or written by others about him. Fisher's writings span all his interests and causes. They include scholarly books and papers, articles in popular media, textbooks, handbooks for students, tracts, pamphlets, speeches and letters to editors and statesmen. They include the weekly releases of index numbers, often supplemented by commentary on the economic outlook and policy, issued for thirteen years by Fisher and assistants from the Index Number Institute housed in his New Haven home.

Fisher was the consummate pedagogical expositor, always clear as crystal. He hardly ever wrote just for fellow experts. His mission was to educate and persuade the world. He took the trouble to lead the uninitiated through difficult material in easy stages. Whenever he was teaching or tutoring students, he wrote handbooks or texts for their benefit – in mathematics and science when he was still a student himself, in the principles of economics when he was the professor responsible for the introductory course. Fisher's economics text was published in 1910 and 1911. Its graceful exposition of sophisticated theoretical material will impress a modern connoisseur, but it was too difficult for widespread adoption. Some of it survived in a leading introductory text of the 1920s and 1930s, by the younger Yale economists Fairchild, Furniss and Buck (1926).

**A Brief Biography**

Irving Fisher grew up and attended school successively in Peace Dale, Rhode Island; New Haven, Connecticut; and St Louis, Missouri. His father, a Congregational minister, died of tuberculosis just when Irving had finished high school and was planning to attend Yale College, his father's *alma mater*. Irving was now the principal breadwinner for himself, his mother and his younger brother. He did have a
$500 legacy from his father for his college education. The family moved to New Haven, and together managed to make ends meet. Irving tutored fellow students during term and in summers. Fisher was a great success in Yale College, ranking first in his class and winning prizes and distinctions not only in mathematics but across the board. He was also determined to make good in the extracurricular college culture so important in those days. His efforts won him election to the most prestigious secret senior society, Skull and Bones, the ultimate reward senior campus leaders bestowed on members of the class behind them. Awarded a scholarship for graduate study, he stayed on at Yale. Graduate Studies were not departmentalized in those days, and Fisher ranged over mathematics, science, social science and philosophy. His most important teachers were Josiah Willard Gibbs, the mathematical physicist celebrated for his theory of thermodynamics, William Graham Sumner, famous still in sociology but at the time also important in political economy, and Arthur Twining Hadley, a leading economist specializing in what is now known as Industrial Organization. As the time to write a dissertation approached, Fisher had still not chosen his life work. Young Fisher's interests and talents were universal. In the seven years at Yale before he finished his doctorate, he had written and published poetry, political commentary, book reviews, a geometry text together with tables of logarithms, and voluminous notes on mathematics, mechanics and astronomy for the benefit of students he was teaching or tutoring. If he had specialized in anything in six years at Yale, it was mathematics, but even in his graduate years he had spent half his time elsewhere. Summer put him on to mathematical economics, and in his third year of graduate study, he finished the dissertation that won him worldwide recognition in economic theory. Fisher's 1891 PhD was the first one in pure economics awarded by Yale, albeit by the faculty of mathematics. Although the university, thanks to Summer, Hadley and Henry W. Farnum, was strong in 'political economy', there was no distinct department for the subject, let alone for 'economics'. This was generally the case in American universities. Venturing into mathematical economic theory, Fisher was very much on his own; and his route into economics was quite different from that of most American economists of his era. The dominant tradition in American political economy was imported from the English classical economists, mainly Smith, Ricardo and John Stuart Mill; it was just beginning to be updated by Marshall. This tradition Fisher's mentors at Yale had taught him well. But the neoclassical developments on the European continent from 1870 on, the works of Warlas and Menger and Böhm-Bawerk, or even those of their English counterparts Jevons and Edgeworth, had been little noticed at Yale or elsewhere in America. At the time, the main challenge in America to classical political economy was coming from quite a different direction. The American Economic Association was founded in 1886 by young rebels against Ricardian dogma and its laissez-faire political and social message. They included Richard T. Ely, J.B. Clark, Edwin R.A. Seligman and other future luminaries of American economics. Many of them had pursued graduate studies in Germany. In the German emphasis on historical, institutional and empirical studies they found welcome relief from implacable classical theory, and in the German faith in the state as an instrument of socially beneficial reform they found a hopeful antidote to the fatalism of economic competition and social Darwinism. Sumner was prominent among several elders who refused to join an Association born of such heresy; he did not relent even though the AEA very soon became sufficiently neutral and catholic to attract his Yale colleagues and other initial holdouts. Fisher, a bit younger than the founding rebels and educated solely at one American university, was not involved. It was his
reconstruction, rather than their revolution, that was destined eventually to replace the classical tradition in the mainstream of American economics.

Fisher stayed at Yale throughout his career. He started teaching mathematics, evidently even before he received his doctorate and was appointed Tutor in Mathematics. His first economics teaching was under the auspices of the mathematics faculty, an undergraduate course on ‘The Mathematical Theory of Prices’. In 1894–5 during his Wanderjahr in Europe, this young American star was welcomed by the leading mathematically inclined theorists in every country. On his return he became Assistant Professor of Political and Social Science and began teaching economics proper. He was appointed full Professor in 1898 and retired in 1935.

Fisher was struck by tuberculosis in 1898. He spent the first three years of his professorship on leave from Yale and from science, recuperating in more salubrious climates. His lifelong crusade for hygienic living dates from this personal struggle to regain health and vigour. The experience powerfully reinforced his determination to gain ‘a place among those who have helped along my science’ and his ambition ‘to be a great man’, as he wrote to his wife (I.N. Fisher, 1956, pp. 87–8). After his recovery the books and articles began flowing from his pen, never to stop until his death at the age of 80.

Fisher participated actively in teaching and in university affairs until 1920. Thereafter his writings and his myriad outside activities and crusades preoccupied him. He taught only half time and had little impact on students, undergraduate or graduate. Thus Fisher had few personal disciples; there was no Fisherian School. The student to whom Fisher was closest, personally and intellectually, was James Harvey Rogers, a 1916 PhD who returned to Yale as a professor in 1930. His career was prematurely ended by his tragic death in a plane crash in 1939 at the age of 55.

Fisher was, on top of everything else, an inventor. His most successful and profitable invention was the visible card index system he patented in 1913. In 1925 Fisher's own firm, the Index Visible Company, merged with its principal competitor to form Kardex Rand Co., later Remington Rand, still later Sperry Rand. The merger made him wealthy. However, he subsequently lost a fortune his son estimated to amount to 8 or 10 million dollars, along with savings of his wife and her sister, when he borrowed money to exercise rights to buy additional Rand shares in the bull market of the late 1920s. More than money was at risk in the market. Fisher had staked his public reputation as an economic pundit by his persistent optimism about the economy and stock prices, even after the 1929 crash. His reputation crashed too, especially among non-economists in New Haven, where the university had to buy his house and rent it to him to save him from eviction. Until the 1950s the name Irving Fisher was without honour in his own university. Except for economic theorists and econometricians, few members of the community appreciated the genius of a man who lived among them for 63 years.

Irving Fisher's marriage to Margaret Hazard in 1893 was a very happy one for 47 years. She died in 1940. They had two daughters and one son, his father's biographer. The death of their daughter Margaret in 1919 after a nervous breakdown was the greatest tragedy of her parents’ lives. Their daughter Carol brought them two grandchildren.

**General Equilibrium Theory**

Fisher's doctoral dissertation (1892) is a masterly exposition of Walrasian general equilibrium theory. Fisher, who was meticulous about acknowledgements throughout his career, writes in the preface that he was unaware of Walras while writing the dissertation. His personal mentors in the literature of

Fisher's inventive ingenuity combined with his training under Gibbs to produce a remarkable hydraulic-mechanical analogue model of a general equilibrium system, replete with cisterns, valves, levers, balances and cams. Thus could he display physically how a shock to demand or supply in one of ten interrelated markets altered prices and quantities in all markets and changed the incomes and consumption bundles of the various consumers. The model is described in detail in the book; unfortunately both the original model and a second one constructed in 1925 have been lost to posterity. Anyway Fisher was a precursor of a current Yale professor, Herbert Scarf (1973) and other practitioners of computing general equilibrium solutions. In his formal mathematical model-building too, Fisher was greatly impressed by the analogies between the thermodynamics of his mentor Gibbs and economic systems, and he was able to apply Gibbs's innovations in vector calculus.

Fisher expounds thoroughly the mathematics of utility functions and their maximization, and he is careful to allow for corner solutions. He uses independent and additive utilities of commodities in his first mathematical approximation and in his physical model; later he was to show how this assumption could be exploited to measure marginal utilities empirically (1927). But the general formulation in his dissertation makes the utility of every commodity depend on the quantities consumed of all commodities. At the same time, he states clearly that neither interpersonally comparable utility nor cardinal utility for each individual is necessary to the determination of equilibrium. Fisher's list of the limitations of his analysis is candid and complete. The supply side of Fisher's model is, as he acknowledges, primitive. Each commodity is produced at increasing marginal cost, but neither factor supplies and prices nor technologies are explicitly modelled.

Finally, Fisher shows his enthusiasm for his discovery of mathematical economics by appending to his dissertation as published an exhaustive survey and bibliography of applications of mathematical method to economics.

**General equilibrium with intertemporal choices and opportunities**

The distribution of income and wealth, and in particular the sources, determinants and social rationales, of interest and other returns to private property, were obsessive topics in economics, both in Europe and North America, at the turn of the century. One important reason, especially in Europe, was the Marxist challenge to the legitimacy of property income. Answering Marx was a strong motivation for the Austrian school, in particular for the capital theory of Böhm-Bawerk and his followers. Neoclassical economics was in a much better position than its classical precursor to respond to the Marxist challenge. The labour theory of value, which Marx borrowed from the great classical economists themselves, neither explains nor justifies functionally or ethically incomes other than wages.

These topics engaged the two leading American economists of the era, John Bates Clark and Fisher. Clark (1899) set forth his marginal productivity theory of distribution, arguing that a generalized factor of production, capital, the accumulation of past savings, has like labour a marginal product that explains and justifies the incomes of its owners.

Fisher attacked these problems in a more elegant, abstract, mathematical, general and ethically neutral manner than Clark, and than Böhm-Bawerk. At the same time, his approach was clearer, simpler and more insightful than that of Walras.

The general equilibrium system of Fisher's dissertation was a single-period model. No intertemporal
choices entered; hence the theory was silent on the questions of capital and interest. But Fisher took up these subjects soon after.

His first contribution, one that should not be underestimated, was to set straight the concepts and the accounting. This he did in (1896) and (1906) with clarity and completeness that have scarcely been surpassed. It's all there: continuous and discrete compounding; nominal versus real rates; the distinction between high prices and rising prices, and its implications for observations of interest rates; the inevitable differences among rates computed in different *numéraires*; rates to different maturities and consistency among them; appreciation, expected and unexpected; present values of streams of in- and out-payments; and so on. Schumpeter calls this work ‘the first economic theory of accounting’ and says ‘it is (or should be) the basis of modern income analysis’ (1954, p. 872).

Perhaps the most remarkable feature is Fisher's insistence that ‘income’ is consumption, including of course consumption of the services of durable goods. In principle, he says, income is psychic, the subjective utility yielded by goods and services consumed. More practically, income could be measured as the money value, or value in some other *numéraire*, of the goods and services directly yielding utility, but only of those. Receipts saved and invested, for example in the purchase of new durable goods, are not ‘income’ for Fisher; they will yield consumption and utility later, and those yields will be income. To include both the initial investment and the later yields as income is, according to Fisher, as absurd as to count both flour and bread in reckoning net output. This view naturally led Fisher to oppose conventional income taxation as double taxing of saving, and to favour consumption taxation instead.

Fisher published his theory of the determination of interest rates in *The Rate of Interest* (1907). A revised and enlarged version was published in 1930 as *The Theory of Interest*. One motivation for the revision was that Fisher's many critics apparently did not understand the 1907 version. They typically concentrated on the ‘impatience’ side of Fisher's theory of intertemporal allocation and missed the ‘opportunities’ side. It was there in 1907 already; the theory is much the same in both versions.

In 1930 Fisher is at pains to label his theory the ‘impatience and opportunity’ theory. ‘Every essential part of it’, he acknowledges, ‘was at least foreshadowed by John Rae in 1834.’ He does claim originality for his concept of ‘investment opportunity’. This turns on ‘the rate of return over cost, [where] both cost and return are differences between two optional income streams’ (1930, p. ix). As Keynes acknowledged, this is the same as his own ‘marginal efficiency of capital’ (Keynes, 1936, p. 140).

In these books Fisher extended general equilibrium theory to intertemporal choices and relationships. This strategy was different from Walras. Walras tried to extend his multicommodity multi-agent model of exchange to allow for production, saving and investment. This maintained his stance of full generality but was also difficult to expound and to understand. Fisher saw that intertemporal dependences were tricky enough to justify isolating them from the intercommodity complexities that had concerned him in his doctoral thesis. Therefore he proceeded as if there were just one aggregate commodity to be produced and consumed at different dates. This simplification enabled him to illuminate the subject more brightly than Walras himself.

The methodology of Fisher's capital theory is very modern. His clarifications of the concepts of capital and income lead him to formulate the problem as determination of the time paths of consumption – that is, income – both for individual agents and for the whole economy. Then he divides the problem into the two sides, tastes and technologies, that are second nature to theorists today. One need only read Böhm-Bawerk's murky mixture of the two in his list of reasons for the agio of future over present consumption...

to realize that Fisher's procedure was not instinctive in those times. Fisher's theory of individual saving is basically the standard model to this day. Undergraduates learn the two-period ‘Fisher diagram’, where a family of indifference curves in the two commodities consumption now $c_1$ and consumption later $c_2$ confront a budget constraint $c_1 + c_2/(1+r) = y_1 + y_2(1+r)$, where the $y$'s are exogenous wage incomes in the two periods and $r$ is the (real) market interest rate. From the usual tangency can be read the consumption choices and present saving or dissaving. This is indeed a Fisher diagram, but of course he went much beyond it.

He stated clearly what we now call the ‘life cycle’ model, explaining why individuals will generally prefer to smooth their consumption over time, whatever the time path of their expected receipts. But he was not dogmatic, and he allowed room for bequests and for precautionary saving. Where Fisher differed from later theorists, and especially from contemporary model-builders, was in his unwillingness to impose any assumed uniformity on the preferences (or expectations of ‘endowments’ – the latter term was not familiar to him though the concept was) of the agents in his economies, and in his scruples against buying definite results by assuming tractable functional forms. In general, many of the advances claimed in present-day theory appear to depend on greater boldness in these respects.

On the side of technology, Fisher's approach was the natural symmetrical partner of his formulation of preferences, equally simple, abstract and general. He assumed that the ‘investment opportunities’ available to an individual (not necessarily the same for everybody) and to the society as a whole can be summarized in the terms on which consumption at any date can be traded, with ‘nature’, for consumptions at other dates. In modern language, we would say that Fisher postulated intertemporal production possibility frontiers, properly convex in their arguments, consumptions at various dates.

All that remained for Fisher, then, was to assume complete intertemporal loan markets cleared by real interest rates, count equations, and show that in principle the equalities of saving and investment at every date determine all interest rates and the paths of consumption and production for all individuals and for the society. Like hundreds of mathematical theorists since, he set the problem up so that it conformed to a paradigm he knew, in this case the Walrasian paradigm of his own doctoral dissertation. A more rigorous proof of the existence of the equilibria Fisher was looking for came much later, from Arrow and Debreu (1954). As we know, the problems of infinity, whether agents are assumed to have infinite or finite horizons, are much more troublesome than Fisher imagined.

In any event, Fisher had an excellent vantage point from which to comment on the controversies over capital and interest raging in his day. His formulation of ‘investment opportunities’ seems to allow for no factor of production one could call ‘capital’ and enter as argument in a production function. For that matter, he doesn't explicitly model the role of labour in production either, or of land. Strangely, in Fisher's insistence that interest is not a cost of production, he seems to say that labour is the only cost, evidently because labour and labour alone is a source of disutility, the loss of utility from leisure, the opportunity cost of the consumption afforded by work. Proceeding in the same spirit, he postulates that, from a position of equality of present and planned future consumption a typical individual will require more extra future consumption than present consumption as compensation for extra work. The difference, the agio, is interest, whether or not it is a ‘cost’. Fisher attributes the agio to ‘impatience’, at the same time scorning the notion that interest is the cost of securing the services of a factor of production called ‘abstinence’ or ‘waiting’.

In the 1890s and 1900s Knut Wicksell, discovering marginal productivity independently of Clark, was modelling production as a function of labour and land inputs with the output also depending on the lags...
between those inputs and the harvests (Wicksell [1911], 1934, vol. I, pp. 144–66). This is an ‘Austrian’ formulation, akin to Böhm-Bawerk's examples of trees and wine, in which time itself appears to be productive. Fisher rightly objects to any generalization that waiting longer increases output. His own intertemporal frontiers are, to be sure, sufficiently general to encompass such technologies. They can also accommodate Leontief input-output tables and Koopmans-Dantzig activity matrices with lags, Hayekian triangular structures with inventories of intermediate goods in process, Solow technologies with durable goods and labour jointly yielding output contemporaneously or later. The only common denominator of these and other representations of technology is that they relate consumption opportunities at different dates to one another, though not necessarily always in the convex trade-off terms Fisher assumed. There does not appear to be any summary scalar measure to which the productivity of a process is generally monotonically related, whether roundaboutness, average period of production, or replacement value of existing stocks of goods.

Fisher describes himself as an advocate of ‘impatience’ as an explanation of interest, although he realizes there are two sides of the saving-investment market, and although he acknowledges that real interest rates can at times be zero or negative. He does appear to believe that in a stationary equilibrium with constant consumption streams, consumers will require positive interest, and that only those technologies and investment opportunities affording a ‘rate of return over cost’ equal to this pure time preference rate would be used. He does not face up to Schumpeter's argument in 1912 that in such a repetitive and riskless ‘circular flow’, rational consumers would not care whether a marginal unit of consumption occurs today or tomorrow (Schumpeter [1912], 1934, pp. 34–6). Like Böhm-Bawerk, Fisher appeals to the shortness and uncertainty of life as a reason for time preference. For life-cycle consumers, however, time preferences are entangled with age preferences, and it is hard to defend any generalization as to their net direction. Fair annuities take care of the uncertainty.

### Monetary theory: the equation of exchange and the quantity theory

Irving Fisher was the major American monetary economist of the early decades of this century; the subject occupied him until the end of his career. Here especially Fisher combined theorizing with empirical research, both historical and statistical. The problems he encountered led him to invent statistical and econometric methods – index numbers and distributed lags in particular – to apply for the purposes at hand to the data he and his assistants compiled. (He even studied the turnover of cash and checking accounts of a sample of Yale students, professors and employees.)

Money was a big subject in American economic literature in the 19th century, before Fisher came on the scene. The monetary events of the times – the inconvertible greenbacks issued during the Civil War, their redemption in gold in 1879, the demonetization of silver, the rapidly increasing importance of banks – stimulated research and controversy. Nevertheless, monetary theory was relatively undeveloped and unsystematized, both in Europe and in America. Fisher's treatise (1911a) was an ambitious attempt to organize with the help of theory a large body of historical and institutional information.

Yet for all its theory, statistics and index numbers, *The Purchasing Power of Money* is a tract supporting Fisher's proposal for stabilizing the value of money. This came to be known as the ‘compensated dollar’, the gold-exchange standard combined with a rule mandating periodic changes in the official buying and selling prices of gold inverse to changes in a designated commodity price index. In 1911 Fisher proposed that the gold price changes be uniform and synchronous in the currencies of all countries
linked by fixed exchange parities, in proportional amounts related to an international price index. Later he was willing to accept as second best that the United States adopt the scheme on its own. Keynes proposed a similar but less formal rule for the United Kingdom (1923).

The proposal is an early example of a policy rule, another Fisherian idea ahead of its time, more likely to be popular among economists today than it was with Fisher's contemporaries. Indeed, some rules recently proposed are quite Fisherian, for example Hall (1985).

The ‘compensated dollar’ is but one of several proposals Fisher advanced over the years for stabilizing price levels or mitigating the effects of their unforeseen variation. In the 1911 book he also writes favourably of the ‘tabular standard’, which meant no more operationally than facilitating price-indexed indexed contracts. In the 1920s he launched a crusade for 100 per cent reserves against checkable deposits, culminating in 100% Money (1935). This idea is also beginning to resurface in the 1980s as a preventive defence against the monetary hazards of bank failures. In Schumpeter's view, Fisher's zeal for monetary reforms lost him some of the attention and respect his scientific contributions to monetary economics deserved, and made him come across as more monetarist than his own analysis and evidence justified (Schumpeter, 1954, pp. 872–3).

The Purchasing Power of Money is a monetarist book. Fisher asserts the quantity theory as earnestly and persuasively as Milton Friedman. There are two species of quantity theories. One is a simple implication of the ‘classical dichotomy’ : since only relative prices and real endowments enter commodity and factor demand and supply functions, the solution values for real variables in a general equilibrium are independent of scalar variations of exogenous nominal quantities. While Fisher mentions this implication of general equilibrium theory, he does not dwell upon it as one might expect. Anyway, it does not quite apply to a commodity money system like the gold standard, which Fisher was analysing. Fisher's theory is mainly of the second kind, based on the demand for and supply of the particular nominal assets serving as media of exchange.

Fisher is usually given credit for the Equation of Exchange, although Simon Newcomb, a celebrated figure in American astronomy as well as an economist, had anticipated him (1886, pp. 315–47). The Equation is the identity $MV = PT$, where $M$ is the stock of money; $V$ its velocity, the average number of times per year a dollar of the stock changes hands; $P$ is the average price of the considerations traded for money in such transactions; and $T$ is the physical volume per year of those considerations. It is an identity because it is in principle true by definition. Actually Fisher, of course, recognized the heterogeneity of transactions by writing also $MV = \sum p_i Q_i$, where the $p_i$ and $Q_i$ are individual prices and quantities. His interest in index numbers was substantially a quest for aggregate indexes $P$ and $T$ derived from the individual $p_i$ and $Q_i$ in such a way that the two forms of the equation would be consistent.

Much of the book (1911a), both text and technical appendices, is devoted to this quest. Here and in later writings, particularly (1921) and (1922), Fisher was looking for the ‘best’ index number formula. He postulated certain criteria and evaluated a host of formulas, investigating their properties both $a$ $priori$ and from applications to data. Since the criteria inevitably conflict, there can be no formula that excels on all counts. Although Fisher was mainly interested in measuring movements of the aggregate price level, naturally he wanted a price index $P$ and a quantity index $T$ to have the property that $P_1 T_1 / P_0 T_0 = (\sum p_1 Q_1) / (\sum p_0 Q_0)$, where the subscripts represent two time periods at which observations of $p$'s and $Q$'s are available.

This and various other desirable consistency properties are not hard to meet. The difficult question is the
choice of weights in the two indexes, especially when a whole series of consistent period-to-period comparisons is desired, not just one isolated comparison. For a price index, should the quantity weights be those of a fixed base year, yielding what we now call a ‘Laspeyres’ index \( \left( \sum p_1 Q_0 \right) / \left( \sum p_0 Q_0 \right) \)? Or should the weights be those of the ever-changing current period, yielding a ‘Paasche’ index \( \left( \sum p_1 Q_1 \right) / \left( \sum p_0 Q_1 \right) \)? The indicated correlate quantity indexes would be the opposites, respectively ‘Paasche’ and ‘Laspeyres’. In 1911 Fisher opted for the Paasche price index. He also seemed to approve the idea of chain indexes, in which the period 0 of the above formulas is not fixed in calendar time but is always the prior period, even though these violate one possible desideratum, that the relative change between two periods should be independent of the base used. He also wrote favourably of the practical advantages of an entirely different procedure, namely taking the median of an expenditure-weighed distribution of percentage price changes from one period to the next.

In 1920, however, Fisher proposed as the ‘Ideal Index’ a candidate he had not ranked high in 1911, namely the geometric mean of the Laspeyres and Paasche formulas. This formula has the pleasant property that the correlate of an Ideal price index is an Ideal quantity index. Correa Walsh, another index number expert, on whose comprehensive treatise (1901) Fisher relied heavily from the beginning of his own investigations, reached the same conclusion independently at about the same time (Walsh, 1921). These index number issues do not seem as important to present-day economists as they did to Fisher. Knowing that they are intrinsically insoluble, we finesse them and use uncritically the indexes that government statisticians provide. But Fisher's explorations have been important to those practitioners.

In Fisher's Equation of Exchange (1911a) the \( T \) and the \( Q_i \) are measures of all transactions involving the tender of money, intermediate goods and services as well as final goods and services, old goods as well as newly produced commodities, financial assets as well as goods. The corresponding velocity is likewise comprehensive, much more so than the ‘income’ or ‘circuit’ velocity preferred by some monetary theorists, notably Alfred Marshall and his followers in Cambridge (England), who count only transactions for final goods, for example for Gross National Product.

Fisher elaborated the equation to distinguish the quantities \( M \) and \( M' \) of the two media currency and checking deposits and their separate velocities \( V \) and \( V' \): \( MV+M' V' = PT \). This was a bow to the rising importance of bank deposits relative to currency as transactions media. Previous practice counted only government-issued currency as money, in modern parlance high-powered or base money, and regarded bank operations as increasing its velocity rather than adding to a money stock. How does the quantity theory come out of the Equation of Exchange? Fisher argues that the real volume of money-using transactions \( T \) is exogenous; that the velocities are determined by institutions and habits and are independent of the other variables in the equation; that the division of the currency supply, the monetary base in current terminology, between currency and bank reserves is stable and independent of the variables in the equation; that banks are fully ‘loaned up’ so that deposits \( M' \) are a stable multiple of reserves, determined by the prudence of banks and by regulation; that exogenous changes in currency supply itself are the principal source of shocks, which, given the preceding propositions, move price level \( P \) proportionately. The many qualifications for transitional adjustments are conscientiously presented, but the monetarist message is loud and clear.

The argument is familiar to modern readers, but certain features deserve notice:

1. (1) Fisher gives the most illuminating account available of the institutions and habits that
generate the society's demand for transactions media relative to the volume of transactions. He rightly emphasizes the fact that, and the degree to which, receipts and payments are imperfectly synchronized. He seeks the determinants of velocity in such features of social and economic structure as the frequency of wage and bill payments and the degree of vertical integration of firms. His belief that these institutions change only slowly supports his contention that velocities are exogenous constants.

2. Much ink has been spilled on the difference between Fisher's velocity approach to money demand and the Cambridge (England) 'k' formulation. The latter, like Walras's encaisse désiré, directs attention to agents' portfolio decisions. To Fisher's critics that seems behavioural, while velocity is mechanical. The issue is overblown; the same phenomena can be described in either language. If the other variables in the equation are defined and measured the same way, then \( V \) and \( k \) are just reciprocals each of the other. Fisher himself discusses hoarding. Fisher's explicit attention, in discussing economy-wide demand for circulating media in distinction to other stores of value, to the fact that money 'at rest' soon takes 'wing' to fly from one agent to another seems to be a merit of his approach.

3. As already noted, Fisher resolved a question current in his day, whether banks' creation of deposit substitutes for currency should be regarded as increasing the velocity of basic money or as enlarging the supply of money. His choice of the latter course compels attention to the structure, behaviour and regulation of banks. He could not be expected to foresee that the proliferation of future candidates for designation as 'money' would create the monetarist ambiguities we see today.

4. For the most part later writers have not followed Fisher in his preference for a comprehensive concept and measure of transactions volume. It is hard to attach meaning to the real volume of financial transactions, and therefore to see why a \( T \) that includes them should be a constant or exogenous term in the equation. On the other hand, modern students of money demand tend simply to forget transactions other than those on final payments.

5. Fisher ignores the possibility that other liquid assets can serve as imperfect substitutes for money holdings because they can be converted into means of payment as needed, though at some cost. Partly for this reason, he ignores interest rate effects on demand for transactions media. In his day there may have been more excuse for these omissions than there was later. But they are still surprising for an author who elsewhere pays so much attention to the effects of interest rates and opportunity costs on behaviour.

6. When Fisher was writing, the United States was on the gold standard; the exchange parities of the dollar with sterling and other gold-standard currencies were fixed. Fisher discusses in detail the implications of foreign transactions for the elements of the Equation of Exchange and for the quantity theory. He recognizes that tendencies towards purchasing-power parity, even though imperfect, make money supplies in any one country endogenous, tie prices to those of other countries and enhance quantity adjustments to monetary shocks in the short run. Much of the 1911 book applies, therefore, to the gold standard economies in aggregate. Indeed, Fisher finds the increase in gold production after 1896 to be the main cause of price increases throughout the world.
The quantity theory by no means exhausts Fisher's ideas on macroeconomics. His views were much more subtle than straightforward monetarism, but they are scattered through his writings and not systematically integrated. Consider the following non-neutralities emphasized by Fisher:

(1) Probably Fisher's principal source of fame, especially among non-economists, is his equation connecting nominal interest \( i \), real interest \( r \) and inflation \( \pi \): \( i = r + \pi \). It is frequently misused. Like the Equation of Exchange, it is first of all an identity, from which, for example, an unobservable value of \( r \) can be calculated from observations of the other two variables. More interesting, certainly to Fisher, is its use as a condition of equilibrium in financial markets; for this purpose \( \pi \) must be replaced by expected inflation \( \pi_e \), another unobservable. In a longer run, as Fisher recognized, steady-state equilibrium would also be characterized by equality of actual and expected inflation: \( \pi = \pi_e \).

The Fisher equation is frequently cited nowadays in support of complete and prompt pass-through of inflation into nominal interest rates. Fisher's view throughout his career was quite different. For one thing, neither Fisher's theory of interest nor his reading of historical experience suggested to him that equilibrium real rates of interest should be constant. Moreover, from (1896) on he believed that adjustment of nominal interest rates to inflation takes a very long time. This he confirmed by sophisticated empirical investigations, regressions in which the formation of inflation expectations was modelled by distributed lags on actual inflation. During the transition, inflation would lower real rates; nominal rates would adjust incompletely. The effect was symmetrical; he attributed the severity of the Great Depression to the high real rates resulting from price deflation. Moreover, Fisher was quite explicit about the effects of these movements of real interest rates on real economic variables, including aggregate production and employment. In *The Purchasing Power of Money* these transitional effects are mentioned, but minimized in the author's zeal to convince readers of the importance of stabilizing money stocks. But in Fisher's writings on interest rates, the transitions turn out to be long. In his accounts of cyclical fluctuations in business activity, and especially of the Great Depression, they play the key role.

(2) An assiduous student of price data, Fisher knew that some prices were more flexible than others, that money wages were on the sticky side of the spectrum, and that the imperfect flexibility of the price level meant that the \( T \) on the right-hand side of his Equation of Exchange would absorb some of the variations of the left-hand side.

In the early 1930s he came to a very modern position. Real variables like production and employment are independent of the level of prices, once the economy has adjusted to the level. But they are not independent of the rate of change of prices; they depend positively on the rate of inflation. He even calculated a ‘Phillips’ correlation between employment and inflation (1926). He was just one derivative short of the accelerationist position (Friedman, 1968); in a little more time he would have made that step, aware as he was of the difference between actual and expected inflation. Anyway, his policy conclusion was that stabilizing the price level would also stabilize the real economy.

(3) During the Great Depression, observing the catastrophes of the world around him, which he shared personally, Fisher came to quite a different theory of the business cycle from the simple monetarist version he had espoused earlier. This was his ‘debt-deflation theory of depression’ (1932), summarized in the first volume of *Econometrica*, the organ of the international society he helped to found (1933). The essential features are that debt-financed Schumpeterian innovations fuel a boom, followed by a recession which can turn into depression via an unstable interaction between excessive real debt burdens
and deflation. Note the contrast to the Pigou real balance effect, according to which price declines are the benign mechanism that restores full-employment equilibrium. The realism is all on Fisher's side. This theory of Fisher's has room for the monetary and credit cycles of which he earlier complained, and for the perversely pro-cyclical real interest rate movements mentioned above.

Fisher did not provide a formal model of his latter-day cycle theory, as he probably would have done at a younger age. The point here is that he came to recognize important non-monetary sources of disturbance. These insights contain the makings of a theory of a determination of economic activity, prices, and interest rates in short and medium runs. Moreover, in his neoclassical writings on capital and interest Fisher had laid the basis for the investment and saving equations central to modern macroeconomic models. Had Fisher pulled these strands together into a coherent theory, he could have been an American Keynes. Indeed the ‘neoclassical synthesis’ would not have had to wait until after World War II. Fisher would have done it all himself.

His practical message in the early 1930s was ‘Reflation!’ When his Yale colleagues and orthodox economists throughout the country protested against public-works spending proposals and denounced Roosevelt's gold policies, Fisher was a conspicuous dissenter. He was right. Characteristically, he crusaded vigorously for his cause – in speeches, pamphlets, letters and personal talks with President Roosevelt and other powerful policy-makers. Characteristically too, as his letters home (I.N. Fisher, 1956, p. 275) disclose, he saw clearly and unapologetically that in lobbying for what was good for the country he was also hoping to rescue the Fisher family finances.

Addressing the President of Yale shortly after Fisher's death, Joseph Schumpeter and eighteen colleagues in the Harvard economics department wrote, ‘No American has contributed more to the advancement of his chosen subject. The name of that great economist and American has a secure place in the history of his subject and of his country.’ According to his son, this is the eulogy that would have pleased Irving Fisher the most (I.N. Fisher, 1956, pp. 337–8). Today, four decades later, economists can confirm the judgement and prediction of that eulogy.

Author's Note: Fortunately Fisher's son, Irving Norton Fisher, preserved the memory of his father in two indispensable publications, a biography and a comprehensive bibliography (1956, 1961). I have also relied extensively on Professor John Perry Miller's biographical essay (1967) and Professor William Barber's account (1986) of political economy at Yale before 1900. My review of Fisher's contributions to general equilibrium theory, the theory of capital and interest, monetary theory and macroeconomics draws heavily and often literally on a recent essay of my own (Tobin, 1985).

R.A. Fisher was born in London on 17 February 1890, the son of a fine-art auctioneer. His twin brother was stillborn. At Harrow School he distinguished himself in mathematics, despite being handicapped by poor eyesight which prevented him working by artificial light. His teachers used to instruct by ear, and Fisher developed a remarkable capacity for pursuing complex mathematical arguments in his head. This manifested itself in later life in his ability to reach a conclusion whilst forgetting the argument; to handle complex geometrical trains of thought; and to develop and report essentially mathematical arguments in English (only for students to have to reconstruct the mathematics later).

He entered Gonville and Caius College, Cambridge, as a scholar in 1909, graduating BA in mathematics in 1912. Prevented from entering war service in 1914 by his poor eyesight, Fisher held several jobs before being appointed Statistician to Rothamsted Experimental Station in 1919. In 1933 he became Galton Professor of Eugenics at University College London, and in 1943 Arthur Balfour Professor of Genetics in Cambridge and a Fellow of Caius College. He retired in 1957 and spent his last few years in Adelaide, Australia, where he died from a post-operative embolism on 29 July 1962.

He married Ruth Eileen Guiness in 1917 and they had two sons and six daughters. He was elected a Fellow of the Royal Society in 1929 and was knighted in 1952 for services to science.

Fisher made a most profound contribution to applied and theoretical statistics and to genetics. He had been attracted to natural history, and especially the works of Darwin, at school, and he had bought Bateson's *Principles of Genetics*, with its translation of Mendel's paper, in his first term as an undergraduate. Before graduating he had already remarked on the surprisingly good fit of Mendel's data, published a paper introducing the method of maximum likelihood, and given a proof of the distribution of the ‘$t$’ statistic which Student had only conjectured.

In 1915 Fisher published the distribution of the correlation coefficient; in 1918 the seminal work in...
biometrical genetics, ‘The correlation between relatives on the supposition of Mendelian inheritance’, in which he introduced the word ‘variance’ and foreshadowed his later development of the analysis of variance; and in 1922 ‘On the Mathematical Foundations of Theoretical Statistics’, a paper which revolutionized statistical thought.

As Statistician at Rothamsted he founded the subject of experimental design based on randomization, pursued vigorously the development of statistical estimation theory and invented – or, at least, captured – the quixotic notion of fiducial probability. Moving to London the pace did not slacken, for in addition to pioneering genetical work, especially in connection with the human blood groups, Fisher's statistical explorations revealed the likelihood principle, conditional inference and the concept of ancillarity. The Second World War found him embattled on many fronts. Unhappy at home, he found his scientific activity disrupted by wartime conditions including the evacuation of his department from London. The profundity of his work on statistical inference was ill-appreciated in America, where preoccupation with wartime problems encouraged an excessively mathematical and operational view with which Fisher had little sympathy. In mathematical genetics there were similar difficulties as the American school, starting from his ‘fundamental theorem of natural selection’, developed ideas of ‘adaptive topographies’ with false analogies to physical systems. It was not until well after his death that in both statistical inference and mathematical genetics the criticisms which he had advanced came to be appreciated.

After the war, from the relative peace of Cambridge, Fisher saw his theoretical work in both subjects suffer further temporary eclipse. He made great, but ultimately unsuccessful, efforts to establish biochemical genetics in his department and to secure for Cambridge the national laboratories for human blood-group work. When close to retirement, he was amongst the first to realize the significance of Watson and Crick's discovery of the structure of DNA (1953), and to apply the new computers to a biological problem (1950).

Perhaps embittered by his post-war experiences (though he never relaxed his scientific work), he found some consolation in the Presidency of Caius College from 1956 to 1959, a post second to the Master, and further happiness in retirement in Adelaide.

Fisher wrote five books and published a famous set of statistical tables jointly with F. Yates. An extremely informative and admirably objective biography was published by one of his daughters in 1978 (Box, 1978).

In the field of economics Fisher's name would be remembered for his contributions to statistics alone, so fully chronicled in Box's biography, but we may here draw attention to three other areas not emphasized in the biography but which are especially relevant.

First, the ‘fundamental theorem of natural selection’ (1930). Although this is specifically directed at a genetical problem, it relies on a simpler implicit theorem of widespread relevance wherever discussion centres on differential growth rates, namely ‘the rate of change in the growth-rate is proportional to the variance in growth-rates’. This precise theorem, which is easily proved mathematically, captures the notion that the growth rate of the fastest-growing sub-population (or economic sector, and so on) will come to dominate the overall growth rate.

Secondly, the modern preoccupation with ‘socio-biology’ has as one of its origins The Genetical Theory of Natural Selection (1930), a fact that only surprises those who have not studied the book and Fisher's other writings on human affairs in the two decades before the Second World War.

Thirdly, Fisher not only introduced the theory of games into evolutionary biology (at the suggestion of Dr Cavalli, later Professor Cavalli-Sforza), but he discovered and published the idea of a randomized or
‘mixed’ strategy as early as 1934, independently of von Neumann. The problem was the card game ‘Le Her’, though if Fisher had gone to the primary source (the correspondence between Montmort and Nicholas Bernoulli, published in 1713) rather than relying only on Todhunter’s *History of the Mathematical Theory of Probability* (1865), he would have found that his solution had already been given by Waldegrave.

Marine fisheries throughout the world continued to be severely overexploited throughout the 20th century and beyond. Even under intensive ‘scientific’ management many important fisheries have collapsed, some never to recover. Vast overcapacity of fishing fleets is also widespread. Both outcomes can be attributed to the common-pool aspect of fishery resources. One method of countering these developments, individual transferable catch quotas (ITQs), is currently in use in several countries. Provided this instrument is combined with resource taxes (royalties), an efficient and equitable management system is feasible. (Owing to lack of jurisdiction, deep-sea fisheries seem destined to continue to suffer from overfishing.)

By the end of the 1970s, most of the world's coastal states had declared 200-nautical-mile zones of extended fisheries jurisdiction (EFJ zones) over marine fisheries. These zones allowed coastal states to exert full control over fishing activities. Over 90 per cent of global marine fishery landings thus came under the control of coastal states.

The need to regulate fishing activities arises from the common-pool nature of marine fish (and other living-resource) populations. In simple terms, under unregulated open-access conditions any fish stock that can be profitably harvested will in fact be exploited. Whether such exploitation eventually leads to biological depletion and reduced harvest levels depends on a number of circumstances, including demand for the product, cost of fishing, and the distribution, abundance and behaviour of the fish.
Using a simple graphical model, H.S. Gordon (1954) argued that an unregulated fishery would achieve 'bionomic' equilibrium, reaching a stock level at which the revenue from catching and selling fish would just balance the opportunity costs of fishing. Populations with high price–cost ratio would thus be heavily exploited, while those with low ratio would remain lightly exploited or unexploited. Countless actual examples support this prediction.

The next obvious question is whether bionomic equilibrium is undesirable and, if so, what can be done about it. Early commentators largely agreed that, because bionomic equilibrium results in the dissipation of economic rents, it is economically undesirable, independent of any biological consequences. But in many cases bionomic equilibrium also implies biological overfishing, defined as the reduction of the fish population to a level at which net annual biological productivity is below the maximum that could be generated. Indeed, in extreme cases overfishing can lead to the collapse of the fishery, with little or no recovery after fishing is terminated (Dulvy, Sadovy and Reynolds, 2003). Pauly et al. (1998), Myers and Worm (2003) and other scientists have documented the historical decline of marine fish stocks on a worldwide scale, especially over recent decades. Even many stocks within 200-mile EFJ zones have continued to be overfished. The reasons for this outcome are only beginning to be generally understood.

Fisheries management has traditionally been based on the objective of determining and achieving the maximum sustainable yield (MSY) available from each population. In its own right, this approach is beset with difficulties generated by unobservability and uncertainty pertaining to marine populations and ecosystems (Caddy and Seijo, 2005). Management difficulties also arise because the MSY paradigm overlooks all economic aspects of fishing.

To be more specific, until recently most fishery management programmes have been based almost exclusively on the total allowable catch (TAC) method. The annual TAC is calculated on the basis of an accepted model, and the fishery is managed so as to achieve this quota, usually by means of restricted annual openings of the fishery. If correctly calculated and implemented, this method can indeed prevent overfishing and produce positive economic rents – temporarily.

But *positive rents attract additional fishing effort* – this is the basis of Gordon's original theory. If annual effort is controlled through TAC-based seasonal openings, the response is that either the fishermen increase the power and capacity of their vessels, or additional vessels enter the fishery, or both. Further shortenings of the fishing season are then needed, and so on. A new regulated bionomic equilibrium is reached when the average capital costs of expanding fishing capacity are just equal to the average present value of net operating revenues. Rents in a TAC-managed fishery are then dissipated through over-expansion of fishing capacity rather than via overfishing. Extreme overcapacity of fishing fleets worldwide is today considered to be a major impediment to rational management.

It seems natural, therefore, to attempt to control fishing capacity. In cases where excess capacity has already developed, vessel buy-back programmes have often been used to reduce fleet size. However, such buy-back programmes, which can be very costly, do nothing to eliminate the incentives for additional expansion. Indeed, if buy-backs are anticipated by fishermen, they may actually induce a higher level of initial overcapacity than would otherwise occur (Clark, Munro and Sumaila, 2005).

Two possible approaches to resolving the joint problems of overfishing and overcapacity are, first, taxes or royalties, and second, individual fishing quotas (IFQs). Although these are usually considered as alternatives, they can in fact readily be used in combination. By the early 21st century IFQs and related programmes were in effect in several countries, with generally positive results (Cunningham and
IFQs can be envisioned as a form of quasi-property rights, an interpretation that is strengthened if the quotas are tradable (that is, individual transferable quotas, ITQs). Its owner considers an ITQ as a productive asset, whose value will be enhanced if the resource is protected and well-managed. It also seems likely (though this remains to be demonstrated in practice) that ITQ owners will favour risk-averse management strategies, such as conservative TACs and the use of marine reserves. Various economic distortions can arise, however, if ITQs are awarded free of charge. For example, the initial recipients of the quotas may become greatly enriched. This possibility being well known to fishermen, the anticipation of a forthcoming ITQ programme may attract extra entry into the fishery, dissipating much of the future rents in advance. Besides this there is the question of social equity – why should the government award special access privileges to a publicly owned resource to a chosen few individuals? Charging significant catch royalties can reduce rent-seeking incentives, while also compensating the resource owner, namely, the general public.

During the current transitional phase from managing ocean fisheries as common-pool resources to managing them with individual quotas, royalty charges will probably remain minimal. But, once a profitable fishery develops, it seems likely that the public will expect and demand a fair share of the resource rents – as is already the case with other natural resource assets. Whatever system is used, the management of marine fisheries will always face high levels of uncertainty. Marine ecosystems are complex, poorly observable, and subject to unpredictable, environmentally induced fluctuations. Finely tuned management, intended for example to maximize some specified objective, will remain elusive. The threat of overfishing persists, even for closely monitored and managed stocks. Also, recent experience has shown that the recovery of depleted stocks can often be slow or non-existent (Hutchings, 2000).

For these reasons it is now widely agreed that a precautionary management approach is needed (Charles, 2001). Conservative annual catch quotas are necessary to protect against inadvertent overfishing. In addition, breeding stocks need to be strongly protected, as do sea-floor and estuarine habitats, and marine ecosystems in general. Furthermore, fishing activities that damage and degrade the marine environment, leading to long-term reductions in productivity, need to be controlled or eliminated. Marine reserves, permanently protecting substantial areas of the ocean from harvesting activities, can provide a valuable hedge against management error resulting from biological uncertainty or from imperfect control of fishing operations. Such reserves can protect breeding stocks, ensuring a continued supply of recruits even when stocks are overfished elsewhere. Reserves are not a substitute for well-designed and operated traditional management systems; rather, they need to be used in conjunction with normal management methods.

Space limitations preclude the discussion of other important issues such as: ocean pollution, aquaculture, illegal fishing and non-regulated deep-sea fisheries, and ecosystem-based management programmes.

fixed effects and random effects

Badi H. Baltagi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Unobservable individual effects in panel data models are employed to control for heterogeneity. These can be thought of as random variables that are uncorrelated with the regressors, thus generating a random effects model. Alternatively, these random individual effects are allowed to be completely correlated with the regressors, thus generating a fixed effects model. The choice between these two alternatives is usually settled using a Hausman (1978) test. This article argues that one should interpret a rejection by the Hausman test as a rejection of the random effects model, not necessarily an endorsement of the fixed effects model.

Article

One of the major benefits from using panel data as compared to cross-section data on individuals is that it enables us to control for individual heterogeneity. Not controlling for these unobserved individual specific effects leads to bias in the resulting estimates. Consider the panel data regression

\[ y_{it} = \alpha + X'_{it} \beta + u_{it}, \text{ } i = 1, ..., N; \text{ } t = 1, ..., T \]  

(1)
fixed effects and random effects: The New Palgrave Dictionary of Economics

with \( i \) denoting individuals and \( t \) denoting time. The panel data is balanced in that none of the observations is missing whether randomly or non-randomly due to attrition or sample selection. \( \alpha \) is a scalar, \( \beta \) is \( K \times 1 \) and \( X_{it} \) is the \( it \)th observation on \( K \) explanatory variables. Most panel data applications utilize a one-way error component model for the disturbances, with

\[
  u_{it} = \mu_i + v_{it} \tag{2}
\]

where \( \mu_i \) denotes the unobservable individual specific effect and \( v_{it} \) denotes the remainder disturbance. For example, in an earnings equation in labour economics, \( y_{it} \) will measure earnings of the head of the household, whereas \( X_{it} \) may contain a set of variables like experience, education, union membership, sex, or race. Note that \( \mu_i \) is time-invariant and it accounts for any individual specific effect that is not included in the regression. In this case we could think of it as the individual's unobserved ability. The remainder disturbance \( v_{it} \) varies with individuals and time and can be thought of as the usual disturbance in the regression. If the \( \mu_i \)'s are assumed to be fixed parameters to be estimated, we get the fixed effects (FE) model. If the \( \mu_i \)'s are assumed random variables independent of \( X_{it} \) and \( v_{it} \), for all \( i \) and \( t \), we get the random effects (RE) model.

For the fixed effects model, the regression equation in (1) becomes

\[
  y_{it} = \alpha + X_{it}'\beta + \mu_i + v_{it} \tag{3}
\]

where the \( \mu_i \)'s can be estimated as coefficients of dummy variables, one for each individual. This model is also known as the least squares dummy variables (LSDV) model. Note that only \((\alpha + \mu_i)\) is estimable and that is why it is sometimes denoted by \( \alpha_i \). For large labour or consumer panels, where \( N \) is very large, LSDV regressions like (3) may not be feasible. In this case, one is including \((N-1)\) dummy variables in the regression and therefore inverting a huge matrix of dimension \((N + K)\) rather than \((K+1)\) as in (1). In addition, this FE regression suffers from a large loss of degrees of freedom, since we are estimating \((N-1)\) extra parameters, and too many dummies may aggravate the problem of multicollinearity among the regressors. In particular, this FE estimator cannot estimate the effect of any time-invariant variable like gender, race, religion which may be of prime interest for the researcher especially in attempting to estimate wage differentials among men and women or whites and non-whites, with other factors held constant. In fact, these time-invariant variables are spanned by the individual dummies in (3) and therefore any OLS regression attempting to estimate (3) will fail, signalling perfect multicollinearity. Averaging (3) over time yields

\[
  \bar{y}_{it} = \bar{\alpha} + \bar{X}_{it}'\bar{\beta} + \bar{\mu} + \bar{v}_{it}
\]

Subtracting (4) from (3) gives

\[ \bar{v}_{it} - \bar{v}_i = (X_{it} - \bar{X}_{i.})' \beta + (v_{it} - \bar{v}_i). \]

(5)

One can show that the FE estimator of $\beta$ (denoted by $\hat{\beta}_{FE}$) obtained from the sometimes infeasible LSDV regression in (3) can be alternatively obtained from the simpler regression given in (5). The latter regression is known as the within-regression since it is based on the within variation in the data. Regression (4), which is a cross-section regression, is known as the between-regression since it is based on the between variation in the data. If (3) is the true model, FE is the best linear unbiased estimator (BLUE) as long as the remainder disturbances (the $v_{it}$'s) are independent and identically distributed (i.i.d.). Of course, here we are assuming that the $X_{it}$'s are independent of the $v_{it}$ for all $i$ and $t$. The fixed effects model is deemed appropriate when one is focusing on a specific set of $N$ countries, states, counties, regions or firms. Inference in this case is conditional on the particular $N$ firms, countries or states that are observed. Note that, if $T$ is fixed and $N \to \infty$ as typical in short labour panels, then only the FE estimator of $\beta$ is consistent; the FE estimators of the individual effects ($\alpha_i$) are not consistent since the number of these parameters increases as $N$ increases. This is the incidental parameter problem discussed by Neyman and Scott (1948) and reviewed more recently by Lancaster (2000). Note that, when the true model is fixed effects as in (3), pooled OLS on (1) yields biased and inconsistent estimates of the regression parameters. This is an omission variables bias because OLS deletes the individual dummy variables when in fact they are relevant. One could test the joint significance of these dummies, that is, $H_0: \mu_1 = \mu_2 = \ldots = \mu_{N-1} = 0$, by performing an $F$-test. This is a simple Chow test with the restricted residual sums of squares (RRSS) being that of OLS on the pooled model and the unrestricted residual sums of squares (URSS) being that of the LSDV regression in (3) or equivalently the residual sum of squares from the within-regression in (5). In this case

\[ F_0 = \frac{(RRSS - URSS) / (N - 1)}{URSS / (NT - N - K)} \sim F_{N-1, N(T-1) - K}. \]

(6)
One computational caution for those using the within-regression computed from (5). The \( s^2 \) of this regression as obtained from a typical regression package divides the residual sums of squares by \( NT-K \) since the intercept and the dummies are not included. The proper \( s^2 \), say \( s^*2 \) from the LSDV regression in (3), would divide the same residual sums of squares by \( N(T-1)-K \). Therefore, one has to adjust the variances obtained from the within-regression by multiplying the variance-covariance matrix by \( (s^*2/s^2) \) or simply by multiplying by \( [NT - K] / [N(T - 1) - K] \). For robust estimates of the standard errors for the FE model, see Arellano (1987).

For the random effects model, \( \mu_i \sim \text{IID}(0, \sigma^2_{\mu}) \), \( \nu_{it} \sim \text{IID}(0, \sigma^2_{\nu}) \) and the \( \mu_i 's \) are independent of the \( \nu_{it} 's \). In addition, the \( X_{it} 's \) are independent of the \( \mu_i \) and \( \nu_{it} \), for all \( i \) and \( t \). The random effects model is an appropriate specification if we are drawing \( N \) individuals randomly from a large population, and we have no endogeneity between the regressors and the disturbances. For household panel studies, special attention is usually taken in the design of the panel to make it ‘representative’ of the population we are trying to make inferences about. In this case, \( N \) is usually large, and a fixed effects model would lead to an enormous loss of degrees of freedom. The individual effect is characterized as random, and inference pertains to the population from which this sample was randomly drawn. But what is the population in this case? Nerlove and Balestra (1992) emphasize Haavelmo's (1944) view that the population ‘consists not of an infinity of individuals, in general, but of an infinity of decisions’ that each individual might make. They argue that the fixed effects model may be more appropriate in cases where the population is sampled exhaustively (like data from geographic regions over time), whereas the random effects model is more consistent with Haavelmo's view given above. They argue that what differentiates individuals, who make the decisions with which we are concerned, is largely historical. Taking a leaf from Knight (1921), they argue that these inheritances from the past are material goods and appliances, knowledge and skill, and morale. In a dynamic context, this means that the primary reasons for heterogeneity among individuals is the different history each one has.

The random effects model implies a homoskedastic variance \( \text{var}(u_{it}) = \sigma^2_{\mu} + \sigma^2_{\nu} \) for all \( i \) and \( t \), and an equi-correlated block-diagonal covariance matrix which exhibits serial correlation over time only between the disturbances of the same individual. In fact,

\[
\text{cov}(u_{it}, u_{js}) = \sigma^2_{\mu} + \sigma^2_{\nu} \text{ for } i = j, t = s = \sigma^2_{\mu} \text{ for } i = j, t \neq s
\]

and zero otherwise. This also means that the correlation coefficient between \( u_{it} \) and \( u_{js} \) is

\[
\rho = \text{corr}(u_{it}, u_{js}) = 1 \text{ for } i = j, t = s = \sigma^2_{\mu} / (\sigma^2_{\mu} + \sigma^2_{\nu}) \text{ for } i = j, t \neq s
\]
and zero otherwise. In this case, the BLUE of the regression coefficients is GLS which can be obtained from a least squares regression of $\hat{y}_{it} = \gamma_{it} - \theta \bar{y}_{i}$, on $X_{it}^* = X_{it} - \overline{X}_{i}$. and a constant (see Fuller and Battese, 1974). The GLS estimator of $\beta$ for this random effects model will be denoted by $\hat{\beta}_{RE}$. Here $\theta = 1 - (\sigma_u / \sigma_1)$ and $\sigma_1^2 = T \sigma_u^2 + \sigma_v^2$. Note that (i) if $\sigma_u^2 = 0$ then $\theta = 0$ and $\hat{\beta}_{RE}$ reduces to $\hat{\beta}_{OLS}$ since $\hat{y}_{it}^*$ reduces to $y_{it}$; (ii) if $T \rightarrow \infty$, then $\theta \rightarrow 1$ and $\hat{\beta}_{RE}$ tends to $\hat{\beta}_{FE}$ since $\hat{y}_{it}^*$ reduces to $\bar{y}_{it}$. The variance components can be estimated from the between- and within-variation of the disturbances:

$$\hat{\sigma}_1^2 = \frac{T \sum_{i=1}^{N} \hat{u}_{it}^2}{(N - K - 1)}$$

(7)

and

$$\hat{\sigma}_v^2 = \frac{\sum_{i=1}^{N} \sum_{t=1}^{T} \hat{y}_{it}^2}{N(T - 1) - K}$$

(8)

where $\hat{u}_{it}^*$ denotes the between-residuals from (4). Note that (7) is $T$ times the $s^2$ of the between-regression obtained in (4). Also, $\hat{y}_{it}$ denotes the FE residuals from (5). So, (8) is the $s^2$ of the FE regression obtained in (5). Substituting these estimates for the variance components in $\theta$ and running $\hat{y}_{it}^*$ on $X_{it}^*$ yields a feasible GLS or RE estimator suggested by Swamy and Arora (1972). For alternative estimators of the variance components, see Baltagi (2005). These are implemented using standard econometric software, including EViews, Stata, TSP, RATS and LIMDEP, to mention a few.

After this discussion of the fixed effects and the random effects models and the assumptions underlying them, the reader is left with the daunting question: which to choose? This is not as easy a choice as it might seem. In fact, the fixed versus random effects issue has generated a hot debate in the biometrics and statistics literature, which has spilled over into the panel data econometrics literature. Economists cannot perform natural experiments of, say, the effect of fertilizer brand on crop yield controlling for the effect of land and other inputs. We have to deal with human subjects whose individual effects may be correlated with the regressors even when we randomly draw these individuals. Mundlak (1961) and Wallace and Hussain (1969) were early proponents of the fixed effects model, and Balestra and Nerlove (1966) were advocates of the random effects model. The modern econometric interpretation of the $\mu_i$'s
is that they are random variables but in the RE model the $E(\mu_i | X_{it}) = 0$. This implies that the individual effects are uncorrelated with the regressors. This is a strong assumption given economists preoccupation with endogeneity issues. For example, in an earnings equation, $\mu_i$ may denote the unobservable ability of the individual and this may be correlated with the schooling variable included as a regressor. In this case, $E(\mu_i | X_{it}) \neq 0$ and the RE estimator $\hat{\beta}_{RE}$ becomes biased and inconsistent for $\beta$. However, the within-transformation wipes out these $\mu_i$'s and leaves the FE estimator $\hat{\beta}_{FE}$ unbiased and consistent for $\beta$. Hausman (1978) suggested comparing $\hat{\beta}_{RE}$ and $\hat{\beta}_{FE}$, both of which are consistent under the null hypothesis $H_0: E(\mu_i | X_{it}) = 0$. In this case, the contrast $\hat{\gamma} = \hat{\beta}_{RE} - \hat{\beta}_{FE}$ will have $\text{plim} \hat{\gamma} = 0$ under $H_0$. However, if $H_0$ is not true, $\text{plim} \hat{\gamma} \neq 0$ and the Hausman test statistic is given by

$$
m = \hat{\gamma}' [\text{var}(\hat{\gamma})]^{-1} \hat{\gamma}
$$

Under $H_0$ this is asymptotically distributed as $\chi^2_K$ where $K$ denotes the dimension of slope vector $\beta$. For significant values of $m$, we reject the consistency of the RE estimator. Since $\hat{\beta}_{RE}$ is the efficient estimator under the null hypothesis $H_0$, one can show that the $\text{cov}(\hat{\gamma}, \hat{\beta}_{RE}) = 0$ and that the $\text{var}(\hat{\gamma}) = \text{var}(\hat{\beta}_{FE}) - \text{var}(\hat{\beta}_{RE})$. This makes the computation of (9) simple. Nevertheless, Hausman (1978) suggested an alternative asymptotically equivalent test to (9) that can be obtained from the augmented regression

$$
Y^* = X \beta + \tilde{X}Y + W
$$

where $Y^*_{it} = Y_{it} - \theta \bar{Y}_{i.}$, $X^*_{it} = X_{it} - \theta \bar{X}_{i.}$ and $\tilde{X}_{it} = X_{it} - \bar{X}_{i.}$. Hausman's test is now equivalent to testing whether $Y = 0$. This is a standard Wald test for the omission of the FE regressors $\tilde{X}$ from the RE regression. For an alternative variable addition test that produces a Hausman test which is robust to autocorrelation and heteroskedasticity of arbitrary form, see Arellano (1993).

Note that the FE model allows for endogeneity of the regressors and the individual effects, whereas the RE model does not. This is why the FE model is more popular among economists. Mundlak (1978) assumed that the individual effects are a linear function of the averages of all the explanatory variables across time, that is,
fixed effects and random effects: The New Palgrave Dictionary of Economics

\[ \mu_i = \bar{X}_i' \pi + \varepsilon_i \]

(11)

where \( \varepsilon_i \sim \text{IIN}(0, \sigma^2_\varepsilon) \) and \( \bar{X}_i \) is a vector of observations on the explanatory variables averaged over time. These effects are uncorrelated with the explanatory variables if and only if \( \pi = 0 \). In fact, a test for \( \pi = 0 \) yields the Hausman (1978) test based on the contrast between the FE and the between-estimators. Mundlak (1978) shows that GLS on (3) augmented with (11) yields \( \hat{\beta}_{\text{FE}} \). Only if \( \pi = 0 \) does it yield \( \hat{\beta}_{\text{RE}} \). This all-or-nothing choice of correlation between the individual effects and the regressors prompted Hausman and Taylor (1981) to suggest a model where some of the regressors are correlated with the individual effects. They proposed an instrumental variable estimator, denoted by HT, which uses both the between- and within-variation of the strictly exogenous variables as instruments. More specifically, the individual means of the strictly exogenous regressors are used as instruments for the time invariant regressors that are correlated with the individual effects (see Baltagi, 2005, for more details). The over-identification conditions are testable. In fact, this is a Hausman test based upon the contrast between the FE and the HT estimators.

Most applications in economics since the 1980s have made the choice between the RE and FE estimators based upon the standard Hausman test. If this standard Hausman test rejects the null hypothesis that the conditional mean of the disturbances given the regressors is zero, the applied researcher reports the FE estimator. Otherwise, the researcher reports the RE estimator. Unfortunately, applied researchers have interpreted a rejection as an adoption of the fixed effects model and non-rejection as an adoption of the random effects model. Chamberlain (1984) showed that the fixed effects model imposes testable restrictions on the parameters of the reduced form model and one should check the validity of these restrictions before adopting the fixed effects model (see also Angrist and Newey, 1991). For the applied researcher, performing fixed effects and random effects and the associated Hausman test, it is important to carry this analysis a step further. Test the restrictions implied by the fixed effects model derived by Chamberlain (1984) before accepting the FE estimator and check whether a Hausman and Taylor (1981) specification might be a viable alternative.

fixed factors

Walter Y. Oi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Small firms invest relatively less in custom-made machines and specifically trained employees. The overhead costs of fixed-capital assets are relatively larger for big firms that engage in the volume production of standardized products. Large firms also incur higher fixed employment costs to recruit and train a specialized workforce. Workers in large firms are paid higher wages designed to reduce labour turnover rates. These phenomena could not be explained without a formal analysis of fixed and quasi-fixed factors. A continuum of degrees of fixity makes for a richer theory of factor markets than a dichotomy of fixed versus variable factors.

In moving from one market equilibrium to another, a firm may choose to hold fixed the rate of employment of one or more factors of production. The presence of fixed factors and their associated overhead costs will affect the firm's responses to changing market conditions. The residually determined quasi-rents which constitute the returns to the fixed factors must, in the long run, cover their overhead costs; otherwise, the inputs of fixed factors have to be contracted. The importance of fixed factors and overhead costs, which varies across firms and industries, was analysed by J.M. Clark (1923), who emphasized the first of the following three questions: (1) How do fixed factors affect the behaviour of prices, outputs and inputs of variable factors? (2) What determines whether a factor of production will be fixed or variable? (3) How do the fixed employment costs of quasi-fixed labour inputs affect
contractual arrangements in labour markets?

In the short run, certain paths of adjustment are barred to the firm. The usual assumption is that the input of one or more factors is fixed. Total unit costs, which include the outlays for fixed factors, lie above average variable costs so that price, in the short run, can remain well below the minimum long-run average cost. If fixed costs in an industry are high, they can pose a barrier to entry of new firms and could result in wide short-run fluctuations in price. Further, the upper-bound constraint on inputs of fixed factors affects the firm's demand for the remaining variable inputs in a manner analogous to the theory of rationing of consumer goods analysed by E. Rothbarth (1941). An increase in the demand for the final product raises the shadow price of the fixed factor, which increases the demand for variable factors that are substitutes for the fixed factor and decreases the demand for complementary variable factors. This result could explain the greater cyclical volatility in the demand for unskilled labour relative to skilled labour if unskilled labour is a closer substitute for the fixed factor, capital. Moreover, the smaller the elasticity of substitution of labour for capital, the steeper is the slope of the marginal cost curve, implying larger cyclical swings in product prices.

A firm will fix the input rate of a factor if (a) the factor is specific to the firm in the sense that employment in this firm constitutes its highest valued use, or (b) reallocation to some higher-valued use is precluded by some contractual agreement or by a prohibitively high transaction cost. In the former case, equipment, buildings and even labour can be specialized to fit into a firm's idiosyncratic production methods. The internal values of such specialized resources are likely to exceed their external values to outside users. These resources are more likely to be owned (rather than hired or leased), because of their specificity. Long-term contracts that account for some fixed factors occur where there are gains from risk-sharing or high costs of transferring resources to other firms.

A richer theory of factor markets can be developed if the dichotomy of fixed versus variable factors is replaced by a continuum of degrees of fixity. The discipline of labour economics has now accepted the principle that labour is a quasi-fixed factor. The cost of hiring and training workers constitutes the fixed component of the full cost of labour, while the variable component is the wage paid to the employee. In long-run equilibrium, the expected marginal value product which depends on the expected product price $P^*$ and labour's marginal physical product $f_N$, is equated to the full labour cost:

$$P^* f_N = W + q, \quad q = \left( \frac{F}{r} \right) \left( 1 - e^{-rT} \right)$$

where $W$ is the wage, and $q$ is the periodic rent that amortizes the fixed employment cost $F$ at a discount rate $r$ over the worker's expected period of employment $T$. The gap between the wage and labour's marginal value product will be relatively larger, the higher is the degree of fixity which can be measured by $f = q / W + q$.

The cyclical behaviour of the labour market is characterized by an uneven incidence of unemployment, a compression of occupational wage differences in the upswing, persistent differences in labour turnover rates, hiring/firing practices that smack of discrimination. The quasi-fixity of labour goes a long way in explaining these phenomena. In the downswing, the product price falls below its long-run level $P^*$. If
labour is a completely variable input, meaning that $q = F = 0$, its marginal value product $Pf_N$ will be equated to the wage in each period. Hence, when $P$ falls, the demand for this grade of labour is contracted until $f_N$ climbs to restore equilibrium in both factor and product markets. However, if labour is a quasi-fixed factor, the periodic amortization of the fixed cost drives a wedge between the wage and marginal value product. For a small decline in product price, the firm will not contract the demand for a quasi-fixed grade of labour as long as its short run MVP exceeds the wage, which is the variable cost of labour; that is, if $Pf_N > W$ even though $Pf_N < (W + q)$, the input of this grade of labour will not be reduced in the downswing. There is, for each quasi-fixed factor, a trigger price $P_t$ at which the firm will choose to reduce employment. The trigger price which induces a decline in factor demand will be lower for factors with higher degrees of fixity. In the early stages of a downturn, labour with low degrees of fixity will become unemployed, while other workers will be retained until the drop in product price $P$ is driven below $P_T$. At the trough of a cycle, most grades of labour satisfy a short-run equilibrium condition where labour's MVP is equated to its variable cost, $Pf_N = W$. As $P$ rises in the recovery, a firm will increase its demand for a quasi-fixed factor if the price rise is such that labour's MVP exceeds its full cost; that is, employment is expanded if and only if $Pf_N > (W + q)$. In the upturn, the rightward shift in factor demand will be greater for factors with lower degrees of fixity. Employment will be more stable, and the incidence of unemployment will be lower for those workers in occupations with higher degrees of fixity.

Some firms find that it is profitable to incur the fixed employment costs of assembling a firm-specific workforce. Recruiting is the means by which an employer identifies more productive individuals and ascertains whether an applicant will meet prescribed hiring standards. Recruitment for high-wage positions usually entails higher costs because of the variability of individual productivities. Employers who have well-defined internal labour markets and who organize production around teams also incur higher recruiting costs. In an internal labour market, workers are hired at a limited number of ports of entry and are typically given on-the-job training to adapt them to the firm's idiosyncratic production methods. Larger investments in firm-specific human capital are indicative of the greater specialization of the labour input. Firm-specific training is less profitable when labour turnover rates are high due either to the high separation propensities of workers or the low survival odds of firms. Smaller firms spend less on recruiting and appear to invest less in formal training. The estimates reported by Oi (1962) and Parsons (1972) reveal that employers incurred substantially higher fixed employment costs for workers in higher skill levels. The degree of fixity, $f = q / (W + q)$, is positively related to the wage rate $W$, and this relation allows us to test the implications of a theory of labour as a quasi-fixed factor. Employees in high-wage occupations experience greater employment stability over the cycle. Occupational wage differentials widen in the downswing and narrow in the upswing. Labour turnover rates are lower, and recruiting costs are higher in large firms whose workforces exhibit a higher degree of fixity.

The persistence of unemployment and the failure of wages to clear labour markets call for an explanation. Some unemployed workers are in a state of pseudo-idleness while they look for work:

‘When actively searching for work, the situation is that he is really investing in himself by working on his own account without immediate remuneration. He is prospecting’ (Hutt, 1977, p. 83). The time and money spent by new entrants and disemployed workers in their search for suitable job matches constitute a fixed cost which has to be recovered over the course of the employment relation. Each job is, in a very real sense, specialized to the worker–firm attachment. In a search model, unemployment can
be efficient in two senses. First, it may be the least-cost means of finding a durable job. Second, a worker on a temporary layoff may stay in a state of availability awaiting recall rather than seeking work. Labour turnover is costly, both to the employer for whom labour is a quasi-fixed factor due to the fixed investments in hiring and training, as well as to the employee for whom this job is specific due to the fixed costs of search. Both parties have incentives to form an implicit contract that can raise the returns to these fixed employment costs by lengthening the expected period of employment.

Long-term employment contracts could be the result of risk-averse workers seeking job security. An employer can reduce his full labour costs by providing a tacit agreement in which the risks of income variability are shared. Such long-term agreements end up increasing the fixity of labour. Implicit, long-term contracts may also result from an employer's desire to discourage shirking and dishonesty. Firms will incur monitoring and enforcement costs to deter dysfunctional behaviour and malfeasance. These enforcement costs can be reduced by designing compensation packages which reward workers with separation pay and pensions if they perform in accordance with prescribed work standards. Stable and durable employment relations make sense only when there are fixed costs of forging and maintaining specific jobs defined by worker–firm attachments.

When physical or human capital is specialized to a firm, it must capture any quasi-rents that it can because the fixed investments in these specialized resources cannot be reallocated to some alternative use. Fixed, firm-specific factors only make sense in a world of heterogeneous firms. In Oi (1983) I advanced the thesis that firm-specific capital was systematically related to firm size. Small firms with low survival odds do not invest in custom-made machines and specifically trained employees. They are more likely to purchase used assets and to hire inexperienced workers with general human capital. The overhead costs of fixed-capital assets are relatively larger for big firms that engage in the volume production of standardized products. Large firms also incur higher fixed employment costs to recruit and train a specialized workforce. Workers in large firms are paid higher wages and are provided with employee compensation packages that are designed to reduce labour turnover rates. These phenomena could not be explained without a formal analysis of fixed and quasi-fixed factors.

fixed point theorems

Abstract

This article gives statements of the Tarski fixed point theorem and the main versions of the topological fixed point principle that have been applied in economic theory. Pointers are given to literature concerned with proofs of Brouwer's theorem, and with algorithms for computing approximate fixed points. The topological results are all consequences of a slightly weakened version of the Eilenberg–Montgomery (1946) fixed point theorem. The axiomatic characterization of the Leray–Schauder fixed point index (which is even more powerful) is also stated, and its application to issues concerning robustness of sets of equilibria is explained.

Article

The Brouwer (1910) fixed point theorem and its descendants are key mathematical results underlying the foundations of economic theory.

Let \( f : X \to X \) be a function from a space to itself. A **fixed point** of \( f \) is a point \( x^* \in X \) that is mapped to itself by \( f : f(x^*) = x^* \). A **fixed point theorem** is a result asserting that, under some hypotheses, the set of fixed points of \( f \) is nonempty. A simple example with many applications is:

**Theorem 1:** (contraction mapping th). If the metric space \((X, d)\) is complete (recall that this means that every Cauchy sequence is convergent) and there is a number \( c \in (0,1) \) such that

\[ d(f(x), f(x')) \leq c d(x, x') \text{ for all } x, x' \in X, \]

then \( f \) has a unique fixed point.

Another example illustrating the importance of the general notion of completeness, but otherwise based on quite different principles, is:

**Theorem 2:** (Tarski's (1955) fixed point theorem). Let \((X, \leq)\) be a complete lattice: \( \leq \) is a partial ordering of \( X \) and every subset of \( X \) has a greatest lower bound and a least upper bound. If \( f : X \to X \) is monotone – that is, \( f(x) \leq f(x') \) whenever \( x \leq x' \) – then there are fixed points \( y, z \in X \) such that \( y \leq x \) whenever \( x \leq f(x) \) and \( x \leq z \) whenever \( f(x) \leq x \).

This result is foundational for the theory of strategic complementarities – for example, Milgrom and Shannon (1994); Echenique (2005) – and has been applied to growth theory by Hopenhayn and Prescott (1992).

The rest of our discussion is devoted to results related to Brouwer's fixed point theorem. A topological space has the **fixed point property** if every continuous map from the space to itself has a fixed point. Brouwer's theorem states that a nonempty compact convex subset of a Euclidean space has the fixed point property. This celebrated result underlies many of the advanced results of topology, and was a pivotal event in the development of algebraic topology, which has influenced many areas of mathematics. In the half-century following Brouwer's paper the theory of fixed points was extended in various directions, yielding several generalizations of Brouwer's result that are themselves famous theorems. Early in the
Fixed point theorems were used by Arrow and Debreu (1954), McKenzie (1959), Nash (1950; 1951), and Debreu (1952) to prove the fundamental equilibrium existence results of theoretical economics: every economy with finitely many goods and agents has a competitive equilibrium; every finite normal form game has a Nash equilibrium. Fixed point theory continues to play an important role in the extensive body of research that grew out of these fundamental discoveries.

Useful books devoted to fixed point theory include Border (1985), which emphasizes results used in economic theory, Brown (1971), which develops the theory of the fixed point index using the methods of algebraic topology, and Dugundji and Granas (2003), which comprehensively surveys the topic from the point of view of applications to analysis and topology. The latter book features extensive historical information concerning the development, and the developers, of the subject.

Proofs and algorithms

Since Brouwer's theorem is a breakthrough result, one should expect proofs to reveal deep mathematical principles, and in fact Brouwer's work was a major stimulus to the development of the subject that is now known as algebraic topology. Eventually Sperner (1928) distilled a relatively simple combinatoric argument out of the topological ferment of that era. Although this argument is the most popular in graduate education in economics, in the author's opinion the exposition in Milnor (1965) of an argument due to Hirsch is worth whatever additional effort it entails, because the student also learns Sard's theorem, which is another fundamental result of the 20th century with important applications in economic theory. Although the substance of the argument in Milnor (1978) appears to be less useful, its brevity and elementary character are stunning. The proof of McLennan and Tourky (2005) is also relatively simple, and displays how Kakutani's theorem follows easily from the existence of Nash equilibrium for a special class of two-person games, which is one of the simplest manifestations of the fixed point principle.

Computation of approximate fixed points has many applications in economics and other fields, and is an important topic of research. Iteration of a function is guaranteed to work only when the function is a contraction, as in Theorem 1, but this method is often practical for functions that do not satisfy this condition. Other methods are derived from proofs of Brouwer's theorem. The method pioneered by Scarf (1973; Doup, 1988) is a method of moving through the simplices of a simplicial subdivision of the simplex. It is justified by a refinement of the proof of Sperner's lemma. The proof derived from Sard's theorem points towards homotopy methods, which have a huge literature (Garcia and Zangwill, 1981; Algower and Georg, 1990). The proof in McLennan and Tourky (2005) also points towards algorithms in which the equilibria of certain two-person games give rise to approximate fixed points.

Variants

We will give statements of the main forms in which the fixed point principle is applied in economic theory. Let $X$ and $Y$ be metric spaces. A correspondence $F: X \rightarrow Y$ assigns a nonempty $F(x) \subseteq Y$ to each $x \in X$. When $Y = X$, a point $x^*$ is said to be a \textit{fixed point} if $x^* \in F(x^*)$. If $P$ is any property of sets, then $F$ is \textit{P valued} if each image $F(x)$ has property $P$. It is \textit{upper semicontinuous} (u.s.c.) if it is compact valued and, for each $x \in X$ and each neighborhood $V$ of $F(x)$, there is a neighborhood $U$ of $x$ such that $F(x') \subseteq V$ for all $x' \in U$. It is not hard to show that if $Y$ is compact, then $F$ is u.s.c. if and only if its graph

$$G(F) = \{(x, y) \in X \times Y : y \in F(x)\}$$

is closed. We think of a function as a singleton-valued correspondence, in which case upper semicontinuity coincides with the usual notion of continuity.

Economic models frequently give rise to sets of optimal individual choices that are convex, but may have more than one element. For this reason the most prominent fixed point theorem in economic applications is:

\textit{Theorem 3: (Kakutani, 1941).} If $X$ is a nonempty compact convex subset of a Euclidean space and $F: X \rightarrow X$ is a u.s.c. convex valued correspondence, then $F$ has a fixed point.

The following variant is tailored for applications in general equilibrium theory, where one is searching for a price vector that equates supply and demand in all markets.

\textit{Theorem 4: (Debreu–Gale–Kuhn–Nikaido lemma).} Let
Δ: = \left\{ p \in \mathbb{R}^n_+ : \sum_{j=1}^n p_j = 1 \right\}

be the n−1 dimensional simplex. If \( Z: \Delta \rightarrow \mathbb{R}^n \) is a u.s.c.c.v. correspondence satisfying \( p \cdot Z = 0 \) for all \( p \in \Delta \) and all \( z \in Z(p) \), then there is a \( p^* \in \Delta \) and \( z^* \in Z(p^*) \) such that \( z^* \leq 0 \).

The following result of Shapley (1973a; 1973b; see also Herings, 1997, and references cited therein) generalizes the famous K–K–M theorem of Knaster, Kuratowski and Mazurkiewicz (1929). It has important applications to the theory of the core and other aspects of cooperative game theory and general equilibrium theory.

**Theorem 5:** (K–K–M–S th). Let \( N = 2 \{ 1, \ldots, n \} \setminus \emptyset \), and for \( S \in N \) let \( \Delta^S = \{ x \in \Delta : x_i = 0 \text{ for all } i \in S \} \). If \( \{ C^S \} \subseteq N \) is a collection of closed sets such that \( \Delta^T \subseteq \cup S \in T C^S \) for all \( T \subseteq N \), then there is \( \lambda_S \geq 0 \) for \( S \in 2^N \) such that \( \sum_{i \in S} \lambda_S = 1 \) for all \( l = 1, \ldots, n \) (such a \( \lambda \) is called a balanced collection) and \( \cap S \in 2^N C^S \neq \emptyset \).

The original K–K–M theorem is the special case in which \( C^S = \emptyset \) whenever \( S \) has more than one element. That is, \( C_1 \cap \ldots \cap C_n \neq \emptyset \) whenever \( C_1, \ldots, C_n \subset \Delta \) are closed sets satisfying \( \Delta^T \subseteq \cup S \in T C^S \) for all \( T \subseteq N \).

**Generalizations**

During the first half of the 20th century there emerged a sequence of increasingly general versions of Brouwer's theorem. Let \( X \) and \( X' \) be metric spaces, and let \( \phi: X \rightarrow X' \) be a homeomorphism. A point \( x^* \in X \) is a fixed point of a continuous function \( f: X \rightarrow X \) if and only if \( \phi(x^*) \) is a fixed point of \( \phi \circ f \circ \phi^{-1} \), so the fixed point property is invariant under homeomorphism. Compactness and continuity are invariant properties, but the assumptions of convexity and finite dimensionality in Brouwer's theorem seem too strong, as does the assumption of convex valuedness in Kakutani's theorem. One is led to search for weaker, topological assumptions that imply the fixed point property.

Let \( Y \) be another metric space. A continuous function

\[ h: X \times [0, 1] \rightarrow Y \]

is called a homotopy. For each \( 0 \leq t \leq 1 \) let \( h_t = h(\cdot, t): X \rightarrow Y \). We think of ‘continuously deforming’ \( h_0 \) into \( h_1 \), with the variable \( t \) representing time, and we say that \( h_0 \) and \( h_1 \) are homotopic. The space \( X \) is contractible if the identity function on \( X \) is homotopic to a constant function. If \( X \) is convex, then for any \( x_0 \in X \) the function

\[ h(x, t) = x_0 + (1 - t)(x - x_0) \]

is such a homotopy, so convex sets are contractible. It was conjectured that nonempty compact contractible sets have the fixed point property, but eventually counterexamples were discovered by Kinoshita (1953) and others.

A retract of \( X \) onto a subset \( A \) is a continuous function \( r: X \rightarrow A \) whose set of fixed points is \( A \), so that \( r(a) = a \) for all \( a \in A \). In this circumstance we say that \( A \) is a retract of \( X \).

One point of interest is that if \( X \) has the fixed point property, then so does \( A \): if \( g: A \rightarrow A \) is continuous, then \( g \circ r: X \rightarrow A \) has a fixed point \( x^* \), and \( x^* = g(r(x^*)) = g(x^*) \) because \( x^* \) must be in \( A \).

The subspace \( A \) is a neighbourhood retract if there is an open \( U \supset A \) and a retract \( r: U \rightarrow A \). A continuous function \( e: X \rightarrow Y \) is an embedding if it is injective and \( e^{-1}: e(X) \rightarrow X \) is continuous, that is, \( e \) is a homeomorphism onto its image. A metric space \( X \) is an absolute neighbourhood retract (ANR) if \( e(X) \) is a neighbourhood retract whenever \( e: X \rightarrow Y \) is an embedding of \( X \) in a metric space \( Y \). The class of ANRs is large, encompassing many important types of spaces such as manifolds, simplicial complexes, and convex sets, and there is an extensive theory (for example, Borsuk, 1967) that cannot be described here. One may think of an ANR as a space that has bounded complexity, in a certain sense, in a
neighbourhood of each of its points. (An example of a space that is not an ANR is the union \( X \) of the unit circle centred at the origin in \( \mathbb{R}^2 \) and the set \( \{(1-\theta^{-1})(\cos \theta, \sin \theta) : 1 \leq \theta < \infty \} \). If \( X \) was an ANR, then there would exist a retraction of a neighbourhood \( U \subset \mathbb{R}^2 \) onto \( X \), and the retraction would take small connected neighbourhoods of \((1, 0)\) in \( U \) to small connected neighbourhoods of \((1,0)\) in \( X \), but small neighbourhoods of \((1,0)\) in \( X \) are disconnected.)

Eilenberg and Montgomery (1946) gave a fully satisfactory generalization of Brouwer's theorem: \( F \) has a fixed point whenever \( X \) is a nonempty compact acyclic ANR and \( F : X \to X \) is a u.s.c. acyclic valued correspondence. Acyclicity is a concept from algebraic topology that cannot be defined here; the important point for us is that contractible sets are acyclic, and that the loss of generality in passing from acyclicity to contractibility is of slight concern in economic theory.

Contractible valued correspondences that are not convex valued appear in McLennan (1989a) and Reny (2005). There are many applications in economics of the special case of the Eilenberg–Montgomery theorem in which \( X \) is convex (but possibly infinite dimensional) and \( F \) is convex valued, for which relatively simple and direct proofs were given by Fan (1952) and Glicksberg (1952). In turn this result is more general than both Kakutani's theorem and the well known Schauder (1930) fixed point theorem.

**The Leray–Schauder fixed point index**

Consider the fixed points of the function from \([0,1]\) to itself shown in Figure 1. The points \( A \) and \( C \) are qualitatively similar, and qualitatively different from \( B \). In the one-dimensional setting one can easily see that, if the function is differentiable and its graph is not tangent to the diagonal at any of its fixed points, then the number of fixed points of the first type must be one greater than the number of fixed points of the second type. In particular, the number of fixed points must be odd. These properties extend to smooth functions \( f : \mathbb{R} \to \mathbb{R} \), where \( C \) is an \( n \)-dimensional convex set, that intersect the diagonal in the ‘expected’ manner: the Jacobian of \( \text{Id}_C - f \) is nonsingular. Debreu (1970) used Sard's theorem (for example, Milnor, 1965) to show that for an exchange economy with fixed preferences, the excess demand function generated by a ‘generic’ endowment vector has well-behaved equilibria, and Dierker (1972) showed that the qualitative conclusions described above hold in this circumstance. Mas-Colell (1985) summarizes the extensive literature descended from these seminal contributions.

**Figure 1**
The Leray–Schauder fixed point index generalizes these aspects of the theory to correspondences, to sets of fixed points that are not singletons, and to general ANRs. Suppose $X$ is a nonempty compact ANR, $U \subset X$ is open and $\overline{U}$ is its closure. A correspondence $F: U \to X$ is index admissible if it is u.s.c. and does not have any fixed points in its boundary $\overline{U}\setminus U$. Let $\mathcal{F}:X$ be the set of index admissible contractible valued correspondences $F: \overline{U} \to X$ where $U \subset X$ is open. A homotopy $h: \overline{U} \times [0, 1] \to X$ is index admissible if each $h_t$ is index admissible.

The next result gives an axiomatic characterization of a number $\Lambda_X(F)$. When there are finitely many fixed points the Additivity axiom allows us to think of $\Lambda_X(F)$ as the sum of their indices. When $X \subset \mathbb{R}^n$, $f: \overline{U} \to X$ is a smooth function, and $x$ is a fixed point in the interior of $X$ with $\text{Id}_{\mathbb{R}^n} - Df(x)$ nonsingular, the index of $x$ is $+1$ or $-1$ according to whether the determinant of $\text{Id}_{\mathbb{R}^n} - Df(x)$ is positive or negative.
Theorem 6: There is a unique function $\Lambda X : \mathcal{F} X \to \mathbb{Z}$ satisfying:

1. (A) (Normalisation) If $\varepsilon : X \to X$ is a constant function, then $\Lambda X(\varepsilon) = 1$.
2. (B) (Additivity) If $F : \overline{U} \to X$ is in $\mathcal{F} X$, $U_1, \ldots, U_r$ are disjoint open subsets of $U$, and $F$ has no fixed points in $\overline{U}\setminus (U_1 \cup \ldots \cup U_r)$, then

$$\Lambda X(F) = \sum_{i=1}^r \Lambda X(F|_{U_i}).$$

3. (C) (Homotopy) If $h : \overline{U} \times [0, 1] \to X$ is an index admissible homotopy, then

$$\Lambda X(h_0) = \Lambda X(h_1).$$

4. (D) (Continuity) For each $F : \overline{U} \to X$ in $\mathcal{F} X$ there is a neighborhood $W \subset \overline{U} \times X$ of $\text{Gr}(F)$ such that $\Lambda X(F') = \Lambda X(F)$ for all $F' : \overline{U} \to X$ with $F' \in \mathcal{F} X$ and $\text{Gr}(F') \subset W$.

The index is closed related to the Brouwer degree of a function between manifolds of the same dimension. These ideas evolved from the time of Brouwer's work until O'Neill (1953) achieved the axiomatic expression of the concept (for functions) given above.

Theorem 1 has many important consequences. To begin with note that if $F \in \mathcal{F} X$ has no fixed points, then Additivity implies that

$$\Lambda X(F) = \sum_{i=1}^r \Lambda X(F|_{U_i}) = 0.$$

Therefore $F$ must have a fixed point whenever $\Lambda X(F) \neq 0$. If $\varepsilon : X \to X$ is a continuous function, then $\Lambda X(\varepsilon)$ is called the Lefschetz number of $f$. The famous Lefschetz (1923) fixed point theorem states that $f$ has a fixed point if its Lefschetz number is nonzero, and provides connections to algebraic topology that give tools for computing the Lefschetz number.

We now use the following approximation result to recover the weak version of the Eilenberg–Montgomery theorem stated above, thereby showing that Theorem 6 embodies the fixed point principle. This result generalizes Kakutani’s method of passing from Brouwer’s theorem to his result, and it plays an important role in one method of proving Theorem 6.

Theorem 7: (Mas-Colell, 1974; McLennan, 1989b). If $X$ is a compact ANR, $U, V \subset X$ are open with $\overline{V} \subset U$, $F : \overline{U} \to X$ is a u.s.c. contractible valued correspondence, and $W \subset \overline{U} \times X$ is a neighbourhood of $\text{Gr}(F)$, then there is a continuous function $f : \overline{V} \to X$ with $\text{Gr}(f) \subset W$.

Suppose that $F : X \to X$ is a u.s.c. contractible valued correspondence. Applying the last result with $U = V = X$ and $W$ as in (14), we find that there is a continuous function $f : X \to X$ with $\Lambda X(f) = \Lambda X(F)$. If $X$ is contractible, so that there is a homotopy $h : X \times [0, 1] \to X$ with $h_0 = \text{Id}_X$ and $h_1$ a constant function, then $j(x, t) = f(h(x, t))$ is a homotopy with
Recall that a subset $C$ of a metric space $Y$ is connected if there do not exist open sets $V_1, V_2 \subset Y$ with $V_1 \cap V_2 = \emptyset$ and $V_1 \cap C \neq \emptyset \neq V_2 \cap C$. A subset of $Y$ is a connected component if it is the union of all connected sets containing some point $y$. Each connected component is connected, and the connected components partition $Y$.

Suppose that $X$ is a compact contractible ANR, that $F: X \to X$ is in $\mathcal{F}$, and that the set of fixed points of $F$ has finitely many connected components $C_1, \ldots, C_r$. Additivity implies that each component $C_i$ has a well-defined index $\lambda_i$ that depends on the restriction of $F$ to an arbitrarily small neighbourhood of $C_i$. Suppose that it is possible to show that $\lambda_i = 1$ for each $i$. Since additivity implies that $\sum \lambda_i = \lambda(X(F)) = 1$, it follows that $r = 1$. This style of proof of uniqueness is applicable to many economic settings, but usually more elementary methods are available. At present no alternative to its application in Eraslan and McLennan (2005) is known. It is more common to use the index to prove nonuniqueness: it suffices to display a connected component whose index is different from one.

The fixed point index has two other important properties.

**Theorem 8: (Multiplication).** If $X$ and $Y$ and compact ANRs, $U \subset X$ and $V \subset Y$ are open, and $f: \overline{U} \to X$ and $g: \overline{V} \to Y$ are index admissible contractible valued correspondences, and $F \times G: \overline{U} \times \overline{V} \to X \times Y$ is the correspondence that takes $(x,y)$ to $F(x) \times G(y)$, then

$$\Lambda_{X \times Y}(F \times G) = \Lambda_X(F) \cdot \Lambda_Y(G).$$

**Theorem 9: (Commutativity).** If $X$ and $Y$ are compact ANRs and $f: X \to Y$ and $g: Y \to X$ are continuous functions, then

$$\Lambda_X(g \circ f) = \Lambda_Y(f \circ g).$$

There is a more general version of Commutativity for functions defined on subsets of $X$ and $Y$, but its statement involves technical complications. In view of the uniqueness asserted in Theorem 6, Multiplication and Commutativity are, in principle, consequences of (A)–(D), but it is not known how to prove them in this way. In practice these properties are treated as axioms and shepherded up the ladder of generality, one rung at a time, along with everything else. In fact Commutativity (which was introduced by Browder, 1948, for this purpose) plays a critical role at one stage of this process.

**Essential sets of fixed points**

The two fixed points in Figure 2 are qualitatively different. Arbitrarily small perturbations of the function have no fixed point near $A$, but this is not the case for $B$. In the terminology introduced by Fort (1950) $A$ is inessential while $B$ is essential. Let $X$ be a compact contractible ANR, let $F: X \to X$ be a u.s.c. contractible valued correspondence, and let $C$ be the set of fixed points of $F$. Kinoshita (1952) extended Fort's ideas to correspondences, and to sets of fixed points, defining an essential set of fixed points of $F$ to be a compact $C' \subset C$ such that for any neighbourhood $U$ of $C'$ there is a neighbourhood $W$ of $\text{Gr}(F)$ such that any continuous function $f: X \to X$ with $\text{Gr}(f) \subset W$ has a fixed point in $U$.

Figure 2
For any neighbourhood $U$ of $C$ we can find a neighbourhood $W$ of $\text{Gr}(F)$ that cannot have any fixed points outside of $U$, so $C$ is essential. That is, without some additional condition, essentiality does not distinguish some fixed points from others. Following Kohlberg and Mertens (1986), one is led to consider minimal essential sets, which exist by virtue of the following argument. Let $B_1, B_2, \ldots$ be a listing of the open balls of rational radii centred at points in some countable dense subset of $X$. Define a sequence $K_0, K_1, K_2, \ldots$ inductively by setting $K_0 = C$ and, for $j \geq 1$, setting $K_j = K_{j-1} \setminus B_j$ if this set is essential and otherwise setting $K_j = K_{j-1}$. We claim that $K_\infty = \bigcap_j K_j$ is a minimal essential set. Any neighbourhood $U$ of $K_\infty$ contains some $K_j$ (the accumulation points of a sequence $\{x_j\}$ with $x_j \in K_j \setminus U$ must be outside $U$ but also in each $K_j$, by compactness, hence in $K_\infty$) and each $K_j$ is essential, so $K_\infty$ is essential. If there was a smaller essential set there would be some $j$ such that $K_\infty \setminus B_j$ was essential, but then $K_{j-1} \setminus B_j$ would also be essential, in which case $K_\infty \cap B_j \subset K_j \cap B_j = \emptyset$.

Kinoshita (1952) showed that minimal essential sets are connected when $X$ is convex and $F$ is convex valued. Otherwise one could find a minimal essential set $C_1 \cup C_2$, where $C_1$ and $C_2$ are nonempty, compact, and disjoint. Then $C_1$ and $C_2$ are inessential, so there is a perturbation of $F$ that has no fixed points near $C_1$ and another such perturbation of $F$ has no fixed points near $C_2$. The main idea of Kinoshita's argument is that these can be combined, by using convex combination with locally varying weights, to give a perturbation of $F$ that has no fixed point near $C_1 \cup C_2$, thereby contradicting the assumption that $C_1 \cup C_2$ is essential.

Kinoshita's theorem is pertinent to the literature on refinements of Nash equilibrium that began with the introduction in Selten (1975) of perfect equilibrium. An important technique is to give a privileged status to those Nash equilibria that can be approximated by fixed points of certain perturbations of the given correspondence. In particular, it has important connections to the notion of strategic stability of Kohlberg and Mertens (1986).

The fixed point index also has implications for essential sets. For the sake of simplicity assume that $C$ consists of finitely many connected components $C_1, \ldots, C_r$. (This condition holds in the application to Nash equilibrium.) Any $C_i$ with nonzero index is essential, by Continuity. Since the sum of the indices is one, some $C_i$ must have nonzero index, so a connected essential set exists. Harder arguments, which apply the Hopf theorem (Milnor, 1965) to 'transport' fixed points of perturbations to a desired location, and to eliminate pairs of fixed points of opposite index, show that any proper subset of a $C_i$ is inessential, and that $C_i$ is inessential if its index is zero. Thus the minimal essential sets are precisely those $C_i$ with nonzero index.

fixprice models

Joaquim Silvestre

Abstract

The general competitive theory of markets (Walras, Arrow–Debreu) presupposes that no agent has market power and that prices and wages instantaneously adjust to equilibrate price-taking supply and demand. Fixprice models follow its emphasis on the interactions across markets, but under the more realistic assumption that markets frequently operate under excess demand or supply, with prices often exceeding marginal costs because prices and wages adjust slowly, or because of market power. The original fixprice models, which adopted the short-run method with static expectations, are the precursors of neo-Keynesian dynamic macroeconomics based on market power and the stickiness of wages or prices.

Article

The canonical fixprice model (Benassy, 1975; 1976; 1982; Drèze, 1975; Younès, 1975) was born at the interface of two extensions of general equilibrium theory: the study of out-equilibrium price dynamics, and the incorporation of price-setting behaviour by firms. Fixprice analysis aimed at providing microfoundations for macroeconomic theory and policy. Accordingly, it first generated static macroeconomic models of the interaction between the labour and the output markets at given prices and wages with or without explicit market power. Later, it exerted a diffuse influence on the more recent dynamic macroeconomic models with market power and/or wage or price stickiness.

Many wages and prices appear to change infrequently and fail to respond quickly to shocks. Casual observation suggests that the wages of many workers are fixed in nominal terms for at least several months, and do not drop quickly in response to adverse shocks in demand. This observation is well supported by quantitative studies (Taylor, 1999) as well as by the in-depth interviews of Bewley (1999). For instance, Cecchetti (1984) found that, even when the rate of inflation was high, union wages were fixed at nominal levels for an average of one year. Later researchers, such as Card and Hyslop (1997), have obtained similar results for non-union workers. Bewley (1999) finds that wage rigidity is stricter in long-term, full-time jobs (the 'primary sector') than in short-term, part-time ones, and emphasizes downwards rigidity over upwards rigidity, an asymmetry that is quaked by Taylor (1999).

Price rigidity has also been subject to extensive inquiry (Andersen, 1994; Taylor, 1999). Even though one may presume that prices are less rigid than wages, and many commodities are indeed sold at continuously changing prices, several studies have found that, on the average, prices may stay fixed for relatively long periods (Carlton, 1986; 1989; Cecchetti, 1986; Blinder et al., 1998). In Taylor's (1999, p. 1020) words, ‘... the studies suggest that price changes and wage changes have about the same average frequency – about one year’ (emphasis in original.) Later work has found shorter, but still ample, average periods (Baharad and Eden, 2004).

In addition, prices seem to systematically exceed marginal costs in many industrial markets. These observations challenge the relevance of models where wages and prices are assumed to adjust instantaneously to their Walrasian equilibrium values.
Theoretical roots of the canonical fixprice model

Out-of-equilibrium price dynamics

The Walrasian approach postulates that prices adjust very rapidly in response to excess demand or supply, so that no transactions occur before equilibrium is reached. A rigorous formulation of this idea is the Walras–Samuelson tâtonnement process. Consider an exchange economy with two commodities and two traders, Trader $i$ being initially endowed with $\omega_{ij}$ units of commodity $j$ ($i, j = 1, 2$). Let the aggregate Walrasian excess demand functions be $z^j(p_1, p_2|\omega)$, $j = 1, 2$. (Here the vector $\omega = (\omega_{ij})$ is fixed.) As long as $z^1(p_1, p_2|\omega) \neq 0$ or $z^2(p_1, p_2|\omega) \neq 0$, no transactions occur and prices adjust according to the differential equation:

$$\frac{dp_j}{dt} = z^j(p_1(t), p_2(t)|\omega), \quad j = 1, 2.$$ 

Walrasian excess demands provide the ‘market signals’ for the adjustment of prices in the Walras–Samuelson tâtonnement. Of course, the Walrasian excess demand functions express plans made under the conjecture that any quantities can be bought and sold at the going prices. If transactions did occur at non-Walrasian prices, then such a conjecture would be falsified, since some agents would be unable to realize their plans (see Arrow, 1959). This led Patinkin to postulate that disequilibrium transactions in a market create spillover effects on others, so that, for example, ‘the pressure of excess demand in the one market affects the price movements in all other markets’ (1956, p. 157). Patinkin’s formulation was imprecise (Negishi, 1965; Clower, 1965), but his search for the ‘relevant market signals’ motivates Clower’s (1965) ‘dual decision hypothesis’. This idea, generalized by Barro and Grossman (1971; 1976), is central to Benassy’s fixprice model.

It was discovered in the late 1950s that the Walras–Samuelson tâtonnement process fails to converge unless some restrictive assumptions are imposed, motivating the non-tâtonnement adjustment process. Here two simultaneous movements occur: the distribution of the endowments changes according to some rule for trading at non-Walrasian prices, and prices adjust in response to Walrasian excess demands at the current endowments, for example, for some rule $g_{ij}$:

$$\frac{d\omega_{ij}}{dt} = g_{ij}(p_1(t), p_2(t)|\omega(t));$$

$$\frac{dp_j}{dt} = z^j(p_1(t), p_2(t)|\omega(t)), \quad i, j = 1, 2.$$ 

This process is hard to interpret except possibly as depicting the sequential exchange of durable goods, and, as just argued, the appeal to Walrasian excess demand in the price-adjustment equation is unjustified. But some conditions on the functions $g_{ij}$ (Hahn and Negishi, 1962; Uzawa, 1962) originally meant to guarantee the convergence of the non-tâtonnement process inspired the fixprice model of Younès (1975).

General equilibrium with market power
The monopolistic general equilibrium analysis pioneered by Negishi (1960) led to the construction of simple models where firms or workers had price- or wage-setting capacity (Benassy 1976; 1977; 1982; 1991; Hart, 1982; Silvestre, 1990; 1993). This work revealed intimate connections between market power and the fixity or stickiness of prices and wages. First, oligopoly displays formal parallelisms to excess supply, and oligopsony to excess demand (Madden and Silvestre, 1991; 1992; Silvestre, 1986). Second, an imbalance between supply and demand gives temporary market power to agents on the short side who then face non-horizontal demand or supply curves for large enough quantities (Arrow, 1959; Negishi, 1974; 1979; Hahn, 1978; John, 1985). Third, a firm with market power experiencing frequent demand or productivity shocks may optimize by changing prices at discrete intervals even if the costs of changing prices are small (Sheshinski and Weiss, 1977; Akerlof and Yellen, 1985; Mankiw, 1985; Parkin, 1986; Caplin and Spulber, 1987; Blanchard and Kiyotaki, 1987), and the resulting stickiness is magnified by strategic complementarities among the pricing decisions of firms (Fishman and Simhon, 2005).

Fixprice allocations

Trading at non-Walrasian prices

Fixprice analysis postulates a common medium of exchange (money) in each market. Thus, there are \( n + 1 \) goods (from 0 to \( n \)) in the case of \( n \) markets, the zero good being money. The analysis addresses two qsts. First, given a price vector \( p \) (normalized with respect to money), what allocations are compatible with it? Second, given a \( p \) and an allocation compatible with it, which is the type of disequilibrium in each market? The answers are derived from three basic principles: (a) voluntary trading; (b) absence of market frictions, and (c) effective demand. The last requires the explicit recognition of the interaction among markets. The first two impose conditions on the trades carried out in a market, namely, that, at the going price, (a) no trader may gain by trading less; (b) no pair formed by a buyer and a seller may gain by trading more.

The fixprice model provides a general framework (which includes Walrasian markets as a limit) for price-guided allocation mechanisms. It has several applications: (a) short-run analysis, which assumes that it takes time for prices and quantities to adjust; (b) market power (imperfect or monopolistic competition); (c) price (or wage) controls; this in particular motivates Drèze's formulation; and (d) price (or wage) negotiation (representatives of buyers and sellers negotiate prices that are taken as given by individual traders: see Silvestre, 1988). Fixprice analysis can be viewed as abstracting from specific features and focusing instead on basic market principles common to alternative specifications.

The definitions of fixprice equilibrium due to Bénassy, Drèze and Younès vary in form and motivation, but turn out to be equivalent under some assumptions (Silvestre, 1982; 1983). Fixprice analysis can be viewed as abstracting from specific features and focusing instead on basic market principles common to alternative specifications.

Rather than reproducing them in all generality, we exemplify the common concepts in two simple but important cases.

Differentiable exchange economies

There are \( n + 1 \) goods, indexed 0, 1, ..., \( n \) (i.e. \( n \) markets). There are \( m \) traders: trader \( i \) is endowed with an \((n + 1)\) dimensional vector \( \omega_i \) of initial endowments and a differentiable utility function \( u_i(x_{i0}, x_{i1}, ..., x_{in}) \). A net trade allocation is an \( m \)-tuple of \( n \)-dimensional net trade vectors \((z_j^*; j = 1, ..., n)\), one for each trader, satisfying: \( \sum_j z_j^* = 0 \). It is understood that, for \( j = 1, ..., n \), if \( z_j^* > 0 \) (or \(< 0 \)) then trader \( i \) is buying (or selling) in market \( j \). The (normalized) price vector \( p = (p_1, ..., p_n) \) is given.

The definitions of fixprice equilibrium due to Bénassy, Drèze and Younès vary in form and motivation, but turn out to be equivalent under some assumptions (Silvestre, 1982; 1983). Rather than reproducing them in all generality, we exemplify the common concepts in two simple but important cases.

Definition 1: A net trade allocation \((z_j^*; j = 1, ..., n)\) is a fixprice equilibrium for \( p \) if, writing \( \mu_{ij}^* = \mu_{ij}(p, z_j^*) \),

1. (a) Voluntariness: For \( i = 1, ..., m \), \( z_j^* \cdot \mu_{ij}^* \geq 0 \).
2. (b) Absence of market frictions: For \( j = 1, ..., n \) and for any pair of consumers \( i, h \), \( \mu_{ij}^* \cdot \mu_{jh}^* \geq 0 \).

The straight line through points \( \omega \) and \( A \) depicts the budget constraints. Allocations in the segment \([\omega, A]\) violate condition (b). Those in the segment \([A, B]\) (in particular the Pareto efficient point \( D \)) violate condition (a) for Trader 1.

Figure 1 illustrates the case of \( n = 1 \) and \( m = 2 \) in an Edgeworth box: point \( A \) represents the (unique) fixprice equilibrium at the price vector \( p \); there Trader 1 is a buyer (\( z_{11} > 0 \)).
The more complex case of \( n = m = 2 \) is illustrated in Figures 2a–d. Figure 2(a) depicts Trader 1's budget set in \( \mathbb{R}^3 \). Rather than drawing a three-dimensional Edgeworth box, we graph first separately (Figure 2(b–c)) and then together (Figure 2(d)) the two-dimensional budget triangles of the traders. Figure 2(a–b) also depicts the intersections of some indifference surfaces of Trader 1 with her budget set, \( Q_1 \) being her most preferred point in the budget set. At point \( A \) she is selling in both markets (that is, \( z_{11} < 0 \) and \( z_{12} < 0 \); she gets money in exchange), with \( \mu_{12} < 0 \) (she would like to sell more in market 2) and \( \mu_{11} = 0 \). Figure 2(c) corresponds to Trader 2: at point \( A \) she is buying in both markets (i.e., \( z_{22} > 0 \) and \( z_{21} > 0 \)), with \( \mu_{21} > 0 \) and \( \mu_{22} = 0 \). Figure 2(d) superimposes the two graphs (with the axes corresponding to Trader 2 reversed, and with the initial endowment points coinciding at \( \omega \)). Points \( A \) in Figures 2(b–c) have been chosen so that they also coincide in Figure 2(d), i.e., \( z_{2j} + z_{2j} = 0 \), \( j = 1, 2 \). These trades constitute a fixprice equilibrium.
The three-good model

The model originated in Barro and Grossman (1971; 1976) and was further elaborated by Benassy (1977; 1982; 1986) and Malinvaud (1977) among others. Let there be three goods: money, denoted by $M$, initially available in $M_0$ units; labour, denoted by $L$, initially available in $L_0$ units, and output, denoted by $Y$, which is produced by labour according to the production function $Y = f(L)$. There are two markets, the labour market, with (nominal) wage $w$, and the output market, with price $p$. There is one firm and one consumer, with preferences represented by the homogeneous utility function $U(Y, M)$, who owns $M_0$ and $L_0$, and receives all profits. The labour supply is fixed at $L_0$.

Define the marginal rate of substitution as $\frac{Y'}{M'} = \frac{\partial U/\partial Y}{\partial U/\partial M}$, with derivatives evaluated at $(Y, M_0)$. Define the marginal cost curve as $C'_W(Y) = \omega f^{-1}(Y)$, and the full employment output as $Y_0 = f(L_0)$.

Definition 2: The level of output $Y$ is a fixprice equilibrium output for the price–wage pair $(p, w)$ if

$$Y = \min \left\{ (Y') - 1(p), (C'_W) - 1(p), Y_0 \right\}$$

This equality embodies in a compact way four conditions. First, $Y \leq Y_0$, that is, output cannot exceed the full employment level. Second, $Y \leq (Y')^{-1}(p)$, or alternatively $p \leq Y'$: the consumer cannot gain by buying less output at the going price (it is a condition of voluntary trading for the consumer). Third, $Y \leq (C'_W)^{-1}(p)$, or $p \geq C'_W(Y)$: the price cannot be lower than the marginal cost, or, in other words, profits cannot increase by selling less at the going price (it is a condition of ‘voluntary trading’ for the firm). Finally, at least one of these weak inequalities must be an equality: this is the condition of frictionless markets.

Figure 3 partitions the $(p, w)$ plane according to which one of the three possible equalities determines output (solid lines). In region $E$ (full employment), $Y = Y_0$. In region $K$ (Keynesian unemployment), $p = Y'$, and in region $C$ (classical unemployment of full capacity), $p = C'_W(Y)$. In the boundaries between regions the two relevant equalities hold. At the Walrasian point $W$ all three equalities hold. There is full employment in region $E$ and unemployment outside it. The dashed lines are isoemployment loci, with the arrows indicating the directions of increasing employment.

Figure 3
The labour market is in excess supply (or excess demand) in the interior of regions $K$ and $C$ (or region $E$), and the output market is in excess supply (or demand) in the interior of region $K$ (or regions $C$ and $E$). At the Walrasian point $W$ both markets are balanced. In the Keynesian region the condition $p = v'(y)$ for determination of output can be rewritten in terms of the consumption function as in the textbook Keynesian multiplier model. The homogeneity of $U$ implies that demand for output, as a function of $p$ and wealth $I$, can be written as $h(p)I$, where the function $h(p)$ satisfies: (a) $b U(h(p)) < 1$ and (b) the marginal equality $(\partial U / \partial y) / (\partial U / \partial h) = p$ whenever the consumption vector is a multiple of $(h(p), 1 - ph(p))$. By setting $l = M^e + p^e$ we obtain the effective demand for output $C(y) = h(p)(M^e + p^e)$: this is the traditional consumption function, with marginal propensity to consume equal to $b U(h(p)) < 1$. The satisfaction of effective demand requires $Y = C(y)$, that is, $Y / M^e = h(p) [1 - ph(p)]$, which by the above marginal equality implies that $p = v'(y)$.

The distinction between the two types of excess supply of labour has important implications for policy and for comparative statics. Output is determined in region $C$ by the condition ‘price=marginal cost’. Hence, lowering wages (nominal or real) will increase employment, whereas an increase in demand will have no effect on employment. But in region $K$ a decrease in the nominal wage has no effect on employment: only lowering the price or otherwise stimulating demand will work. This analysis also offers insights on the effects of different kinds of shocks (Malinvaud, 1977): a business cycle driven by demand shocks will fluctuate between Keynesian unemployment and full employment, whereas productivity shocks will yield fluctuations between the Keynesian and the classical types of unemployment.

**Welfare analysis**

The budget equality and the market institution impose constraints on trades. Thus, the resulting allocation may very well be Pareto dominated by other allocations that do not satisfy these constraints. The study of such inefficiencies is important for the normative analysis of the situations covered by fixprice theory (short-run market disequilibria, price controls, monopolistic market power). On the other hand, to the extent that these constraints cannot be circumvented, they are for policy purposes as effective as physical and resource constraints, motivating the study of efficiency subject to these additional constraints (‘second best’).

**Inefficiency relative to the set of physically attainable allocations**

Consider Figure 1. Note that the allocation given by $A$ is not Pareto efficient: both traders would be better off at $C$, but $C$ cannot be reached without violating some budget constraint. A similar phenomenon may occur if there are two traders in one side of the market. Modify the example of Figure 1 by duplicating Trader 2: that is, Traders 1 and 2 are unchanged, but now there is a Trader 3 with the same preferences and endowments as Trader 2. Let $z_{21} = (-1/4)z_{11}$ and $z_{31} = (-3/4)z_{11}$. Then there are mutually beneficial reallocations between Traders 2 and 3, but they violate the budget constraint.

One can say that this type of inefficiency is caused by ‘wrong prices’. Note, however, that trade at non-Walrasian prices does not per se imply inefficiency. Point $D$ in Figure 1, for instance, is Pareto efficient, and all budget constraints are satisfied there. (A general treatment of allocations of this type is given by Balasko, 1979, and Keiding, 1981.) But there is forced trading at point $D$. It is the combination of non-Walrasian prices and the voluntariness condition that implies inefficiency (Silvestre, 1985).

**Inefficiencies relative to allocations satisfying the budget constraint**

When there is only one market (see Figure 1), the absence of frictions guarantees that no allocation that satisfies the budget constraint is Pareto superior to a fixprice equilibrium; that is, a fixprice equilibrium is efficient relative to allocations that satisfy the budget constraints. This ceases to be true with several markets: for instance, point $B$ in Figure 2(d) Pareto dominates point $A$ and satisfies all budget constraints. (Note that point $B$ violates voluntariness.) Such inefficiencies have been studied in Benassy (1975; 1977; 1982) and Younès (1975). A particularly striking case occurs in Keynesian allocations of the three-good model: the markets for labour and output are in excess supply, and a direct barter of labour against output would benefit both the firm and the worker, and improve welfare. This phenomenon was viewed by Clower (1965) as a failure of coordination among markets.

**Undominated price-wage pairs**

Suppose that, in the three-good model, wages and prices are determined by negotiation between representatives of labour and business, and then taken as given by individual firms and workers, so that a fixprice allocation results. If bargaining is efficient, any movement away from the negotiated price-wage pair $(p, w)$ will make somebody worse off, in which case we say that $(p, w)$ is *undominated*. Do there exist undominated price-wage pairs besides the Walrasian pair? Note that this question is different from the ones addressed in the previous paragraphs: there, we compared allocations at a given $(p, w)$, whereas now we compare price-wage pairs.

The answer depends on the rationing of unemployment, that is, on whether unemployment falls uniformly on workers, or, on the contrary, some workers are dismissed whereas others...
experience no rationing (Silvestre, 1988; 1989). In the first case, the answer is affirmative under some assumptions, in which case the set of undominated price–wage pairs is a segment of the Keynesian–classical boundary of Figure 3, implying that the output market is balanced. Non-uniform rationing of unemployment typically expands this set to a band of the Keynesian region adjoining the Keynesian–classical boundary.

The analysis is extended to a dynamic model by Jacobsen and Schultz (1990; 1991), who characterize the conditions for unemployment at undominated wages under the assumptions that unemployment is uniformly rationed, and that the output market is always balanced.

**Wage and price rigidities in dynamic macroeconomic models**

Dynamic stochastic macroeconomic models were first developed under the Walrasian assumptions of price taking and market clearing in models labelled ‘real business cycle’ (Kydland and Prescott, 1982; King and Plosser, 1984) aimed at mimicking business cycle regularities. Later developments have improved the fit, in particular for the persistence of real effects of monetary shocks, by introducing, singly or in combination, market power, or price or wage rigidity.

Here we focus on rigidities. (See Silvestre, 1995, for an early account of market-power, dynamic macroeconomic models; Svensson, 1986, combines market power with sticky prices in a dynamic model.) A first departure from Walrasian market clearing is the assumption that nominal wages are predetermined in the short run, before technological or monetary shocks are experienced. For instance, they may be preset at the expected Walrasian level (Gray, 1976), so that expected demand equals expected supply, whereas actual discrepancies between supply and demand are resolved in favour of demand: workers supply the amount of labour demanded by firms at the predetermined wage. (This simplifying assumption conflicts with the voluntariness condition of the canonical fixprice model, as described above. Benassy, 1995b; 2002, modifies the dynamic model of preset wages by postulating that unions maximize a utility function subject to the voluntariness condition.) This form of rigidity or stickiness yields predictions quite different from the Walrasian model: it grants monetary shocks the ability to generate large effects on employment and output, allowing for contemporary money shocks to generate countercyclical behaviour of the real wage, as well as cyclical behaviour of prices (Benassy, 1995a). The determinants of the accompanying welfare costs are studied in Cho, Cooley and Phaneuf (1997). A shortcoming of this approach is that monetary shocks show relatively little persistence, limited by the length of the period in which wages are fixed (Taylor, 1999).

This limitation, together with the observation that wage contracts are not synchronized across firms, led to the models of staggered wages or prices. In their simplest form (Taylor, 1979; 1980), wages are fixed for a given number $N$ of dates, but in each date $1/N$ firms renew their contracts, so that at any moment the average wage is defined by the current contract plus the ones set in the last $N-1$ dates. More complex versions allow for various contract lengths. An influential formulation is that of Calvo (1983), who postulates that the contract length is stochastic: a given contract remains unchanged at each date with probability $\pi$, and terminated and reset with probability $1-\pi$. This approach typically yields propagation mechanisms and persistence characteristics capable of matching stylized facts of economic fluctuations (Benassy, 2002; 2003; Yun, 1996). Christiano, Eichenbaum and Evans (2005) show that wage staggering performs better than price staggering in generating the observed type of persistence, confirming Andersen's (1998) analysis in a model based on staggered prices or wages with fixed contract length.

Fleming was born on 13 March 1911 at Bathgate, Scotland, and died on 3 February 1976. He was educated at Edinburgh University, where he received the degrees of MA (Honours) in history in 1932 and MA (First Class Honours) in political economy in 1934. He was a graduate research fellow at the Institut Universitaire des Hautes Etudes Internationales in 1934–5, and a graduate student at the London School of Economics in 1935.

At the end of 1935, he joined the Secretariat of the League of Nations, Economic Intelligence Section, as a research economist, and assisted Gottfried Haberler in the latter's Prosperity and Depression (first published by the League in 1937). During the Second World War, he served with the UK Ministry of Economic Warfare from 1939 until 1942, and then joined the Economic Section of the Cabinet Office under Lord Robbins, rising eventually to the position of Deputy Director of the section. He was also a member of the UK Delegation to the San Francisco Conference in 1945; a member of the Preparatory Commission of the United Nations in 1946; a member of the International Trade Conference Preparatory Commission, 1947; and UK Representative to the Economics and Employment Commission, United Nations in 1950. From 1951 to 1954 Fleming was Visiting Professor at Columbia University, New York. He joined the International Monetary Fund in 1954 as a division chief, and in 1964 became the Deputy Director of the Research Department.

His academic contributions are mostly in the fields of welfare theory and trade and exchange policies. The most notable of his contributions was the seminal article ‘On Making the Best of Balance of Payments Restrictions on Imports’ (1951), which, in James Meade's words, was ‘the begetter of the analysis of the second best’ (Meade, 1978), which rapidly became a fashionable new topic in welfare theory during the 1950s.

The flypaper effect results when a dollar of exogenous grants-in-aid leads to significantly greater public spending than an equivalent dollar of citizen income: money sticks where it hits. Viewing governments as agents for a representative citizen voter, this empirical result is an anomaly. Four alternative explanations have been offered. First, it is a data problem; exogenous aid is mismeasured. Second, it is an econometric problem; important explanators of spending correlated with aid or income are excluded from the specification. Third, it is a specification problem; the representative citizen misperceives aid and the rational voter model misses this point. The empirical evidence suggests none of these explanations is sufficient. A fourth explanation seems most promising: it is politics. Rather than an anomaly, the flypaper effect is best seen as an outcome of political institutions and the associated incentives of elected officials.

Article
In the late 1960s James Henderson (1968) and Edward Gramlich (1969) changed the direction of empirical research on how local governments tax and spend. While all prior work detailed the demographic and economic correlates with government budgets, Henderson and Gramlich sought an explanation for those correlations. To them as economists, the answer was clear. Citizens
demand services from their elected officials, and elected officials respond subject to the availability of government resources. Resources come from citizen incomes and from fiscal transfers given by the central government as grants-in-aid. From this perspective, Henderson and Gramlich specified and estimated demand equations based on the maximization of a representative citizen's utility subject to that citizen's 'full income' constraint specified as the sum of personal income and the citizen's share of the government's unconstrained fiscal transfers. So specified, personal income and the citizen's share of fiscal transfers should impact spending identically – money is money. The empirical analyses of Henderson and Gramlich revealed something unexpected, however. An extra dollar of personal income increased government spending on the order of $0.02 to $0.05, but an equivalent extra dollar of grants-in-aid increased government spending by from $0.30 to often as much as a full dollar. When Gramlich first presented his results, his colleague Arthur Okun called this larger effect of lump-sum aid on government spending a 'flypaper effect', noting that 'money seems to stick where it hits'. The label stuck too, as has the puzzle of why intergovernmental transfers are so stimulative. A Google search reveals that over 3,500 research papers – excluding those studying the effects of real flypaper on insect populations – have now been written documenting and seeking to explain the flypaper effect.

Why do we care about this apparent anomaly? There are two reasons. First, as a matter of policy, understanding how recipient governments spend intergovernmental transfers is essential for the design of efficient fiscal policy in federal economies. Second, as a matter of science, understanding why governments spend citizens' incomes as they do provides valuable insights into how citizen preferences are represented in government policies. The taxation of citizen incomes and the allocation of grants-in-aid provide two 'tracers' as to the inner workings of political decision-making, one (taxes) that is directly observed and controlled by citizens, and the other (grants) perhaps only imperfectly so.

The benchmark for both the policy and political economy literatures is how a politically decisive citizen would like to see government resources allocated, specified by the maximization of that representative citizen's welfare over private (x) and public (g) goods, indexed by $U(x, g)$, subject to a current period budget constraint specified as:
\[ Y = \{I + h \cdot z\} = x + p_g \cdot g \]

where \( I \) is the citizen's private income (or tax base), \( h \) is the citizen's share of \textit{unconstrained or lump-sum} intergovernmental transfers per capita \((z)\) specified as \( h = l / \bar{l} \) with \( \bar{l} \) equal to the average income (or tax base) in the citizen's political jurisdiction, and \( p_g \) is the 'tax price' for government services \((g)\) equal to \( c \cdot (1 - m) \cdot h \) where \( c \) is the per unit production cost of \( g \) and \( m \) is the matching rate for open-ended matching federal aid. Private goods cost $1. \( Y \) is called the citizen's 'full income'. The citizen's preferred allocations will be \( x = x(1, p_g, Y) \) and \( g = g(1, p_g, Y) \), where:

\[ \Delta g_I = (\delta g / \delta Y) \cdot (\delta Y / \delta I) \cdot \Delta I = (\delta g / \delta Y) \cdot (\Delta I = \$1), \]

for an extra dollar of personal income and:

\[ \Delta g_z = (\delta g / \delta Y) \cdot (\delta Y / \delta z) \cdot \Delta z = (\delta g / \delta Y) \cdot h \cdot (\Delta z = \$1) \]

for an extra dollar of aid, implying that estimated marginal effects of aid to income should be related as \( \Delta g_z / \Delta g_I = h \). In most political jurisdictions the representative citizen has a tax base (often specified as the median tax base) less than the average tax base; thus, in most cases, if our representative citizen has had her way, then we should expect \( \Delta g_z / \Delta g_I = h < 1 \). The overwhelming empirical evidence summarized by Gramlich (1977), Inman (1979), Fisher (1982) and Hines and Thaler (1995) shows just the opposite, however; \( \Delta g_I \) ranges from $0.02 to $0.05 while the companion estimates of \( \Delta g_z \) typically fall between $0.30 to $1.00. Income to the citizen stays with the citizen; grants to the government stay with the government. Money sticks where it hits. Why?

http://www.dictionaryofeconomics.com/ezproxy.bu.edu/article?id=pde2009... 2009-6-24
Four explanations have been offered. First, the answer is in the data. Researchers mismeasure intergovernmental aid by confusing matching grants that lower the marginal price of public services \((p_g)\) with lump-sum aid \((z)\) that shifts outward the representative citizen's budget constraint. Matching aid has a price effect, lump-sum aid an income effect. For local politics controlled by a representative citizen, consumer theory predicts that a matching grant's price effect will stimulate more government services than an equivalent dollar of lump-sum aid. If the dollar transfer received from matching aid is erroneously classified as lump-sum aid, then \(\Delta g_z > \Delta g_I\) will result; see Moffitt (1984), Megdal (1987), and Baker, Payne and Smart (1999). Even after correctly classifying aid programmes and measuring \(p_g\) and \(z\) appropriately, however, the flypaper effect remains; see for example Wyckoff (1991).

The second explanation sees the anomaly as an econometric problem. Researchers may have omitted important determinants of government spending likely to be correlated with citizen income or intergovernmental aid, leading to biased estimates of \(\Delta g_I\) and \(\Delta g_z\). Bruce Hamilton (1983) and Jonathan Hamilton (1986) attribute the flypaper effect to misspecifications of the technology or costs of providing local services. Bruce Hamilton argues that estimated demand equations omit important variables such as the citizen's talents or willingness to volunteer which are positively correlated with citizen income and also contribute to the provision of government services. If these omitted effects are substitutes for (negatively correlated with) purchased government inputs, then the estimated coefficient for income will be biased downward, perhaps sufficiently so that \(\Delta g_z > \Delta g_I\). Jonathan Hamilton suggests the misspecification arises from a failure to account correctly for residential exit from high tax jurisdictions leading to a loss of tax base when specifying the price of government services. Local taxes are inefficient and the correctly specified price of local services must reflect this fact. If citizens tend to reside in localities of comparable income, and higher-income residents are more mobile, then the representative citizen's income will be positively correlated with the correct price, which is negatively correlated with government services. Again, there is a downward bias in the estimated income effect, with \(\Delta g_z > \Delta g_I\) as a possible result.

Neither of the Hamiltions's biases are likely to fully explain estimated flypaper effects, however. A plausible upper estimate for \(\Delta g_I\) can be obtained as \(\Delta g_I = (\delta g/\delta Y) = \varepsilon_{g,Y} \cdot (g/Y)\), where \(\varepsilon_{g,Y}\) is the income elasticity of demand for

http://www.dictionaryofeconomics.com/ezproxy.bu.edu/article?id=pde2009... 2009-6-24
government services and $g/Y$ is the average rate of spending by recipient governments. This ratio for the US state and local government sectors combined from 1970 to 2008 – the period used for most all studies – is at most 0.15. Since most state and local services are arguably necessities, $\varepsilon_{g,Y} \leq 1$ seems reasonable. If so, then $\Delta g_I \leq (g/Y) = 0.15$ bounds an unbiased income effect. Since most estimates of $\Delta g_z$ exceed 0.15, the flypaper effect remains. Perhaps then the explanation lies in an upward bias in the estimates of $\Delta g_z$?

Here the results of four recent studies are particularly instructive. Each takes advantage of a plausibly exogenous, or “natural experiment”, change in lump-sum national aid to state or local governments. Gordon (2004) uses US federal legislation's required changes in Title I education aid caused by state-level (exogenous to the local budget) demographic changes before and after census years as her measure of exogenous aid. She finds strong evidence of a flypaper effect for local school districts in the first year after the change in Title I aid – $\Delta g_z = 1.00$ – but that this effect evaporates after three years, with most of the new aid returned to voters as lower local tax revenues. In contrast, Ladd (1993) and Singhal (2008) find evidence for a significant and quantitatively large flypaper effect for US state governments, as do Dahlberg et al. (2008) in their study of national aid to municipalities in Sweden. Ladd uses windfall tax revenues to state governments following the Tax Reform Act of 1986 as her exogenous measure of aid, and estimates $\Delta g_z = 0.40 > \Delta g_I = 0.03$. Singhal (2008) uses outside revenues received by state governments from a recent legal settlement with the tobacco industry as her measure of $z$, and finds $\Delta g_z = 0.20$ for spending on tobacco control programmes, compared with an estimate of $\Delta g_I \approx 0$ for income's effects on the same programmes. Dahlberg et al. (2008) exploit a discontinuity in the national aid formula that gives significant additional assistance to communities that experience more than 2 per cent outmigration over the previous ten years; communities just below the threshold receive no additional aid, those just above do. The analysis includes community and time fixed effects – there is no direct estimate of $\Delta g_I$ – and they find $\Delta g_z = 1.00$ and no local tax relief. Ladd's, Singhal's and Dahlberg's estimated flypaper effects remain over time.

The flypaper effect appears to be a real phenomenon. As a third explanation, then, perhaps our model of citizen fiscal choice is misspecified. First, voters
may not understand the complexity of grant programmes. Both Courant, Gramlich and Rubinfeld (1979) and Oates (1979) conjecture that the representative citizen misperceives lump-sum aid's income effect as an average price effect. They conjecture that the voter uses taxes paid per unit of services received – \((p_g \cdot g - z)/g\) or \(p_g - (z/g)\) – as their estimate of the true marginal tax cost of government services, \(p_g\). If so, lump-sum aid \((z)\) will impact spending as a price subsidy, and the estimated effect aid on spending will imply that \(\Delta g_z > \Delta g_I\). Wyckoff (1991) and Turnbull (1998) test this hypothesis by including both \(p_g\) and \([p_g - (z/g)]\) as competing explanators of local spending. They find plausible (negative) marginal price effects but implausible (positive) effects of the misperceived average price. Estimated flypaper effects are comparable to those of previous studies. From this evidence, it is unlikely that price misperception provides the explanation for the flypaper effect.

Filimon, Romer and Rosenthal (1982) and Hines and Thaler (1995) provide alternative versions of the voter ignorance hypothesis. For Filimon, Romer and Rosenthal the representative voter fails to see through the veil of government budgets; he does not know the level of aid received by the local government. For Hines and Thaler, the representative voter sees through the veil but budgets using mental accounts; there is a ‘public budget’ that is the responsibility of government officials and a ‘private budget’ that is the citizen's responsibility. Both hypotheses need a theory of public budgets to explain \(\Delta g_z\). Hines and Thaler leave this an open question, but Filimon, Romer, and Rosenthal are quite explicit: public officials are budget maximizers and therefore \(\Delta g_z = 1\). They test their theory for a sample of Oregon school districts, and cannot reject the null hypothesis that \(\Delta g_z = 1\) for state education aid.

In Romer, Rosenthal, and Munley (1992), the authors replicate their analysis for a sample of New York school districts, and here the conclusion varies by the size of the school district. Large districts (>20,000 students) show budget-maximizing behaviour and a full flypaper effect: \(\Delta g_z = 1\). In smaller districts, however, the estimated aid and income effects are about equal: \(\Delta g_z \approx h \cdot \Delta g_I\). These results parallel those from Ladd and Singhal for larger state governments and from Gordon for local school districts. Together, this evidence is sufficient to reject a strict version of the mental accounting
explanation. It leaves open, however, the question of why the flypaper effect remains for larger governments.

Here a fourth explanation for the flypaper effect seems the most promising: it is politics. This approach assumes that voters are informed and rational, but conceal their preferences when it is strategically useful to do so. Such strategic behaviours require the use of less than efficient institutions for preference revelation, such as majority rule or representative legislatures. From this perspective, the flypaper effect is a consequence of an inability of citizens to write complete ‘political contracts’ with their elected officials. Consistent with the results of Ladd, Singhal, and Romer, Rosenthal and Munley, we might expect these contracting problems to be greater, and the flypaper effect more likely, for large governments.

Chernick (1979) and Knight (2002) offer specifications of a political contract between a donor central government and recipient local governments as a way to understand the flypaper effect. Chernick (1979) specifies donor-recipient contracting as an auction. Assuming an exogenous level of federal aid, local governments bid for the right to provide aided services by offering to share the costs of provision. Beginning with the highest offer price, the central government selects recipient local governments until its grants budget is exhausted. The resulting allocation will equalize the marginal contribution of each local government to the incremental benefits from the provision of the local service. Local governments with the highest valuations will provide more services and receive more aid. Chernick offers evidence in support of this prediction from the US federal Water and Sewer Grant programme. Importantly, any reduced form estimate of $\Delta g_z$ for this programme that did not account for the auction that sets aid would be biased upward and imply a strong flypaper effect.

Knight (2002) specifies and estimates a model of political contracting for grants policy that sets both the aggregate size of the aid budget and its allocation. The budget is chosen to ensure its passage and to maximize local constituent net benefits for the central government's agenda-setter. Again, the allocation process is an auction. Legislators bid to be part of the winning coalition by offering to vote for the grants budget in return for intergovernmental aid. The agenda-setter picks the smallest 51 per cent of the bids. He then sets his own grant award to maximize the net benefits to his own constituents. Those legislators whose state or local governments value the aided local service most highly make the winning offers. The result is again a positive correlation between grants awarded and local spending. Failure to
control for this correlation will lead to an upward bias in the estimate of $\Delta g_z$.

For a statistically consistent estimate of $\Delta g_z$, we need instruments that both predict grants ($z$) and are independent of constituents' demand for the aided service. Legislative institutions that select agenda-setters independent of constituent preferences will serve this purpose. Knight uses the legislators' tenures and majority party memberships as his instruments in his empirical study of highway grants and state highway spending. Least squares estimation of grants' effect on spending shows $\Delta g_z = 1$; instrumental variables estimation rejects that extreme flypaper result but cannot reject a partial effect ($1 > \Delta g_z > \alpha \cdot \Delta g_I$). In a companion piece, Knight (2004) estimates that this agenda-setting process for highway grants imposes an allocative inefficiency of $0.40$ per dollar of aid.

Over the first decade of the 21st century, the devolution of economic responsibilities to lower-tier governments has become increasingly important, not only in formally federal states but in unitary states as well. Central governments typically grant fiscal assistance to these local governments for the provision of those services. Knowing how grants will be spent is important for the appropriate design of central government transfer policies. Credible estimates of aid's effects on local spending requires good instrumental variables to predict aid, or ideally 'natural experiments' providing truly exogenous measures of central government assistance. Knowing how money is spent as it is helps us to understand allocative performance of intergovernmental transfers, given federal and local political institutions. Knowing why grant money is spent as it is, is just as important. Here the specification and estimation of structural models of central government transfer spending and local government allocations of transfer incomes are essential. This information provides a basis for reforming these important institutions, and there is perhaps no more striking example of the benefits of such structural analyses of the aid process than the work of Reinikka and Svensson (2003, 2004) on the allocation of Ugandan central government aid to local schools. Initially, only $0.15$ of each centrally allocated school aid dollar found its way into the local schools; $0.85$ was 'captured' by the district bureaucracy for its own use. The problem was inadequate information and weak local political organizations. Reforms publicized aid allocations and empowered village councils to monitor that spending. The end results was to reduce district capture to $0.15$ per aid dollar – a plausible administrative cost – and to increase local school resources by $0.85$ per aid dollar.
Once viewed as an anomaly, the flypaper effect should now be seen as a reality of fiscal politics, and its study as an opportunity to fashion central government transfer policies and intergovernmental fiscal institutions that better reflect citizen preferences for local public goods.

Abstract

A pioneer in the development of cliometrics, Robert Fogel has always focused on linking economic analysis to the study of historical problems and on the need for large-scale data collection and analysis. Based on this approach, he found that slavery was profitable and viable even on the eve of the American Civil War; and he used information on height to draw inferences on food consumption by slaves. Fogel has since become involved in the economics of aging and longevity, the impact of the expansion of leisure time in the developed world, and the increasing burden of health care.

Article

Robert William Fogel is one of the pioneering figures in the development of cliometrics or the new economic history during the 1950s, a contribution for which he was awarded, with Douglass C. North, another innovator, the 1993 Nobel Prize in economic science. As of 2005 they are the only two economic historians to obtain this honor. Fogel was born in New York City on 1 July 1926, and graduated from Cornell University in 1948. Active politically in left-wing organizations for several years, he did not begin graduate work in economics until after 1956. He received a master's degree from Columbia University writing under the supervision of Carter Goodrich. He then went to the John Hopkins University, receiving a Ph.D. under the direction of Simon Kuznets in 1963. He has held teaching positions at the University of Rochester, the University of Chicago, and Harvard University, being the Charles R. Walgreen Distinguished Professor of American Institutions at the University of Chicago since 1981.

Fogel's career has always focused on the linking of economic analysis to the study of historical problems. The application of economic theory to specific historical questions has characterized his
writings since he began graduate work. Also characteristic of his work has been a concern with empirical data, at first the use of quantitative data to study specific problems, and later, with developments in computer technology, with attention given to the collection and analysis of large datasets of economic and demographic evidence.

Railroads

Fogel's first book, *The Union Pacific Railroad: A Case in Premature Enterprise*, based on his master's thesis, was published in 1960. The basic question asked was whether the building of the Union Pacific in the 1860s, with government subsidy, led to corruption and abnormal profits earned by the railroad's builders and promoters. It had long been a staple of historical scholarship about the Union Pacific that the charges of corruption were true, and that the Union Pacific was to be viewed as part of America's late 19th-century ‘Great Barbecue’ and the ‘Gilded Age’. Fogel's extensive primary research permitted some more accurate accounting measures of the profits, and he used data on bond prices and related information to estimate the anticipated ‘risk of failure’ at the time of financing. By adjusting the accounting profits and pointing to the great measured risk in this pioneering transcontinental venture, Fogel argued that the extent of abnormal profits was overstated, but also that the mixture of public and private financing may not have been the most effective way to undertake construction. The novel historical application of economic theory here was in the measuring of the market assessment of risk on the basis of standard financial models.

Fogel's next book, *Railroads and American Economic Growth: Essays in Econometric History*, was based upon his doctoral dissertation. Published in 1964, it has become one the two early classics of cliometrics, the other being the study of the economics of American slavery by Alfred H. Conrad and John R. Meyer (1958). This work, aimed at estimating the contribution of the railroad to American economic growth in the 19th century, something that many contemporaries had discussed, led to significant debates about both economic techniques of measurement and the methodological principles of historical analysis. Fogel's book (and that published a few years later by Albert Fishlow, 1965) asked, on the basis of considerable empirical information, what the estimated difference in costs was between shipping goods by railroad and shipping them by the next-best alternative: road, canal, river, or lake. This was used to measure what Fogel called the ‘social savings’ based on the difference in costs of shipping between railroads and alternatives, and was to be the basic measure of the railroads’ contribution to economic growth in 1890. That the number came out smaller than expected led to some critiques of the analysis, but in a controversial next step Fogel argued that this was too high, since it did not allow for possible structural adjustments in the economy to the absence of a railroad, including the building up of a canal network that never existed, but seemed feasible, if necessary, and for which ample amounts of water existed. Also, following the development economics of the period, Fogel estimated the contribution of the railroad via backward linkages (for inputs) and forward linkages (for outputs). In general none made the contribution of the railroad as large as expected, a point that has been used to argue that no single innovation can itself explain much growth, and that for an economy to be successful there has to be a broad spread of productivity gains within the economy. Whatever the specific criticisms, the overall fruitfulness of Fogel's method of analysis is seen in the number of country studies undertaken using his approach for the study of the economic effects of the railroad. Some studies
indicate a small growth contribution, although in several cases (particularly Mexico) the measured effects were large due to the lack of good alternative means of transportation.

A major debate concerning the use of so-called ‘what if’ or counterfactual history in Fogel's analysis arose primarily among historians. To economists used to drawing supply and demand curves and discussing the impact of changes, this approach was rather standard and not questioned, and one might have felt that, given the form of most historical analysis, the same general acceptance would be expected among historians. This was not, however, a general view, and the explicit use of counterfactuals led to much debate. In some cases there was, as there should be, a questioning of the appropriateness of the particular counterfactuals used, since, as argued later, a counterfactual based on Napoleon using an atomic bomb is of doubtful usefulness. In other cases, however, the criticism was of the general use of the approach, with the implications that no ‘what if’ statement can be used at any time. This debate has disappeared in recent years, with apparent agreement that counterfactuals have long been part of the historian's approach to the past, and their use is a generally accepted, if not necessary, part of any historical study.

**Economics of slavery**

Fogel's next major project concerned one of the major issues of American historiography, the economics of slavery in the United States South. This project led to numerous publications, including several books and many articles, over a 30-year period by Fogel, his colleagues, and his students. The first major publication, in 1974, was the two-volume *Time on the Cross* (co-authored with Stanley Engerman); the first volume subtitled *The Economics of American Negro Slavery*, aimed at a large audience, and the second subtitled *Evidence and Methods: A Supplement*, which contained more detailed descriptions of data and analysis, aimed primarily at a professional, scholarly readership. These works presented findings from numerous types of primary data located in southern archives as well as census publications and manuscripts, and used many research assistants to collect and analyse the primary data, a practice then not typical in either history or economics. Earlier work on manuscript data from the federal census of 1860, prepared by William N. Parker (1970) and Robert E. Gallman (1970), was also of particular use, and the works of numerous historians and economists, in previous decades as well as that available from the then booming area of slavery studies, was important in shaping the arguments.

Both because of its heavy use of quantitative methods and also because of several of its major findings that seemed to go against some then commonly held views, *Time on the Cross* attracted an unexpected amount of attention and criticism for an academic publication, and there emerged a rather extended series of debates on many of the questions studied, leading to the publication of several books and many articles developing these disagreements. As before, some of the debate was about the nature of questions asked and some about the specifics of the substantive analysis.

The major economic findings in *Time on the Cross* were that slavery was profitable and was expected, by southerners and others, to be viable even on the eve of the Civil War. These findings were based on standard measures of profitability and price–rental ratios, but the calculation required collections of data on slave prices (by age, sex, and so on), slave productivity, slave demography, and the material consumption allowed to the slaves by their masters. While profitability and viability had not always been widely accepted, by the time the debates ended they did seem to be acceptable, suggesting that slavery would not collapse under of its own weight, that southern planters had behaved in a manner that
indicated a responsiveness to economic incentives, and, moreover, with the use of related evidence, that the South was doing quite well economically on the eve of the Civil War. Two other arguments were, and remain, still somewhat debated. A straightforward economist's measure of the relative productivity of northern and southern agriculture in 1860, used to answer a question long-discussed by contemporaries and many subsequent scholars, compared agricultural output with inputs of land, labour, and capital, and indicated that southern agriculture was more ‘efficient’ than northern agriculture and that within the South it was the larger slave-using plantations (over 16 slaves) that were more ‘efficient’ than were the small, free white farms and smaller slave farms. The concept of efficiency was interpreted by some, not as a standard concept of economic measurement, but as a measure with distinct moral overtones. The findings for the South led a discussion of economies of scale in slave plantations in the United States and in Caribbean sugar production, and the importance of scale has been seen to be significant for understanding slave societies as well as for evaluating the economic adjustment to the emancipation of slaves. A second continuing controversy concerned what was regarded as the favorable material treatment allowed slaves, based upon estimates of consumption allowed by masters, and the argued-for limited impact on slave family and cultural life. The former argument was based on demographic and related evidence. These questions have now become more important, and the ability of slaves to defeat masters’ attempts to exercise complete power over slaves is now more widely argued for in slave studies. Nevertheless, some disagreements on these issues remain.

In the aftermath of the *Time on the Cross* debates various articles by its co-authors and others were written for conference presentation and for publication. In 1989 Fogel published a new book on slavery, *Without Consent or Contract: The Rise and Fall of American Slavery*, which covered some of the earlier themes but also provided much new information on the politics of abolition in Britain and the United States. In general Fogel expanded on several discussions, particularly on cultural and demographic matters, but he still maintained most of the basic positions of his earlier writings on slavery, and the book is more of a defence than a revision of those arguments. In 1992 three edited volumes of earlier papers and notes by Fogel and others were published, adding greatly to the information and analysis of *Without Consent or Contract*. Fogel was invited to give the William Lynwood Fleming Lectures at Louisiana State University in 2001, published in 2003 as *The Slavery Debates, 1952–1990*. This brief, non-technical volume reviews the many debates on slavery, examines the trends and shifts in the study of slavery in the United States, and provides a very useful summary of changes in views over a 50-year period.

**Heights and demographic history**

One of the debates concerning the material conditions of slave life related to the issue of food consumption and nutrition. Only after the publication of *Time on the Cross* did Fogel and his collaborators become aware of the valuable information provided by information on height. The collection of this data from coastal shipping manifests of slaves carried in the interstate movement between 1808 and 1865, and other sources such as military records and the registrations of free blacks, turned out to be exceptionally important, both for comparisons of the heights of southern slaves with other populations, supporting the argument of basically adequate consumption by slaves, and in opening another major project for Fogel and for other economic historians, historians, and economists. There were, of course, some difficulties in making inferences about food consumption from information on
height, given differences in work regimen and disease environments and some truncations introduced by height requirements. Nevertheless, so widespread were available data on heights in many countries over long periods of time, mainly from military records, that the study of height and its use as an alternative (or complementary) measure of welfare became widely used by economic historians in many different countries. Studies by Floud, Wachter and Annabel (1990), Komlos (1994), Steckel (1995), Goldin and Rockoff (1992), and Steckel and Floud (1997), among others, frequently utilized measures for comparative purposes across countries, as well as for studying long-term trends within specific countries. Some unexpected patterns developed, such as long-period cycles in height, rather than simply monotonic change, and periods of time in which heights and per capita incomes move in different directions. Fogel used the study of heights as a method of approaching a number of different problems, such as long-term variations in longevity and health and their contributions to economic growth, changes in diseases and patterns of aging, and the economics of the health care industry. As earlier, several of these projects were based on extensive data retired from archival sources, and required collaborative work with many scholars from different disciplines.

In 1996 Fogel gave the McArthur Lectures at Cambridge University and these were published in 2004 as *The Escape from Hunger and Premature Death, 1700–2100: Europe, America, and the Third World*. In these essays he was concerned with changes in productivity due to improvements in human capacity to perform. He focused on changes in the 20th century in health, the dramatic change in the caloric input of the French and British populations from their earlier limited available energy, and also the great increases in available leisure time. Such benefits of health and leisure have not yet occurred in much of the Third World today, where people adapt to limited energy by a smaller body size, limiting the prospective productivity in these societies relative to that in the developed world.

Fogel's most recent project, based on extensive data collection from archival sources and involving many students and scholars in collection and analysis, concerns long-term longitudinal studies of health, diseases, and the role of socio-economic and biomedical factors. The initial major data-set was based on the pension records of the Union army in the Civil War, which present very detailed medical histories of veterans from childhood until death, and run from the Civil War into the 20th century. These data, with more recent information, provide a basis for examining not only changes in life expectation and health, but also the nature of the changing pattern of diseases over time. These studies had been supplemental by other longitudinal data-sets, including sampling of births and of babies born between 1910 and 1934, to examine inter-generational factors in health and longevity. As a result of these studies Fogel has become involved in the analysis of the economics of aging and longevity, the impact of the expansion of leisure time in the developed world, and the increasing burden of health care and the complexities of achieving equity in health care in recent years, arguing that these issues reflect social and economic progress, not new difficulties. He has also estimated, based on the work of Dora Costa (2003) and others, the magnitude of the continued increase in the length of life in the 20th century.

Fogel has also made other important contributions to the study of economics and history, to the study of methodology in the social sciences and in history, as seen in his debate with Geoffrey Elton, *Which Road to the Past? Two Views of History* (1983), and to the study of the relations among religious, economic, and political changes. His 2000 book, *The Fourth Great Awakening and the Future of Egalitarianism*, studied the emergence of a religious belief in egalitarianism over time, and how the periodic bursts of awakening influenced the political and economic worlds, as well as what were the
major changes in measured inequality in the United States over time.
In addition to his numerous contributions to economics and economic history, Fogel has been a leading
figure in proselytizing for cliometrics in economics and in history (including the publication of a 1971
collection of cliometric essays, *The Reinterpretation of American Economic History*, coedited with
Stanley Engerman), has been influential in advocating large-scale data collection and analysis, and has
been a major producer of scholars for the next generation of economic history. Honours, besides the
Nobel Prize, include membership in the National Academy of Science and the American Academy of
Arts and Sciences; presidencies of the Economic History Association, the Social Science History
Association, and the American Economic Association; the Bancroft Prize; and the Pitt Professorship of
American History and Institutions at the University of Cambridge. He was the first director of the

French economist, industrialist and inspector of commerce, Forbonnais was born at Le Mans in 1722 and died in Paris in 1800. After initial employment in industry and trade in Nantes, his desire to obtain an official position in the government services (successful in 1756 when he was appointed general inspector of currency) inspired his career as a writer on economic and financial subjects. These all have a strong mercantilist flavour, and also display considerable antagonism to the Physiocrats. Forbonnais contributed a number of economic articles to the Encyclopédie and provided translations of some important writings on commerce. These include King's The British Merchant (1721) and Uztariz's Theory and Practice of Commerce (1724), the former translation according to Morellet (1821) inspired by Gournay.

Forbonnais' major works are his Elémens du commerce (1754) and his Principes et observations oeconomiques (1767). The Elémens has the distinction of being the first French work on economics using mathematical argument. This is his analysis of equilibrium conditions with respect to the rates of exchange between more than two countries and in situations of bimetallism where there are differences in the price ratios of gold and silver (Theocaris, 1961). The Principes is a polemical work in which the major part is devoted to criticism of Quesnay's Tableau économique and his Encyclopédie articles on Farmers and Corn after an elucidation of general principles. Forbonnais' criticism of Physiocratic analysis is noteworthy because it was directed at its empirical foundations. In the discussion of general principles he develops arguments on the interdependence of production and trade, the balance of trade, the balance of trade doctrine in relation to money supply and employment, the beneficial consequences of gradual price rises, and the advantages of paper credit.

forced saving

Björn Hansson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The forced saving doctrine proposes that an increase in the amount of money may be favourable to capital accumulation at the cost of a reduction in consumption of certain individuals, who have not saved voluntarily. A consensus emerged that new credit might lead to additional, at least temporary, investment even in a full employment situation via an increase in the price level, though Lindahl and Keynes did not consider the extra saving to be forced. However, it was generally thought unwise and unjust to rely on credit inflation as a means of increasing capital accumulation.

Article

The doctrine of forced saving proposes that an increase in the amount of money may be favourable to capital accumulation at the cost of a reduction in consumption of certain individuals, but the latter have not saved voluntarily and they do not receive any immediate benefit. The doctrine was developed in the early 19th century by Thornton (1802) and Bentham (1804). They used the terms ‘defalcation of revenue’ and ‘forced frugality’ respectively. It was Mises who coined the term ‘forced saving’ (erzwungenes Sparen).

Thornton published his Paper Credit (1802) during the debate on the suspension of gold payments by the Bank of England in 1797; the debate concerned the possible existence of a natural tendency to keep the circulation of the Bank of England within the limits which would prevent a dangerous depreciation. An excessive issue of paper money could, according to Thornton, at least temporarily increase the price
level of commodities while the money wage and other fixed incomes stayed the same. This would not only lead to a general rise in prices but also to some increase in real capital, since the real consumption of the labourers and recipients of fixed incomes would be reduced, which was the meaning of ‘defalcation of revenue’.

Jeremy Bentham, in the manuscript ‘Institute of Political Economy’ of 1804, some of which had already been written in the years 1800 and 1801, analysed the effects of an increase of paper money in a situation where all hands were employed in the most advantageous manner. If the money in the first instance were used for productive expenditure, that is, buying inputs for producing capital goods, then it would add to real capital. In the second round the money would be exclusively used for consumption and only prices would be affected. The extra real capital was due to the ‘forced frugality’ of the possessors of fixed income which was engineered by the decrease in the value of money; it operated exactly like an indirect tax upon pecuniary income. But the effect of ‘forced frugality’ was probably quite small. It was also an unjust mechanism for increasing national wealth, and under normal circumstances voluntary sacrifices would be sufficient to augment the mass of real wealth. It is obvious in these early enquiries that the forced saving by receivers of fixed incomes came from a decrease in the amount of their real consumption, while the total amount of their money expenditures was kept the same and there was no change in the amount of hoarded funds.

During the course of the Bullionist Controversy, Malthus raised the issue in his 1811 review of Ricardo's *High Price of Bullion* (1810). Malthus proposed that if a new issue of notes came into the hands of the productive classes (described as a change in the distribution of the circulating medium), then capital accumulation would increase. The mechanism of forced saving worked via the increase in the price level, which reduced the share of the annual produce of those classes who were only buyers and not sellers. Ricardo replied, in an appendix to the fourth edition of *The High Price of Bullion* published in 1811, that Malthus's results were based upon the assumption that those who lived on fixed incomes must consume their whole income. In the case of money saving it was possible that the issue of banknotes and the ensuing inflation merely transferred saving from the receivers of fixed incomes to those who had borrowed from the banks. Thus Ricardo saw no reason why it should add anything to the productive classes.

Later, comments on forced saving are found in the works of J.S. Mill and Walras, but the doctrine became important once again when it was incorporated into the pre-Keynesian analysis of credit and business cycles. The analysis took off from Wicksell's brief mention that during a cumulative process rising prices might force people living on fixed money income to reduce their consumption, an ‘involuntary saving’ which could lead to the production of new real capital. Mises (1912) and later Hayek (1929) developed Wicksell's analysis, and forced saving was used to explain the upswing in the so-called ‘over-investment’ theories of cyclical movements. An overextension of credit, since the money rate of interest was too low, and the ensuing cumulative process led to a distortion of the vertical structure of production. Production of producers’ goods outstripped the production of consumers’ goods since means of production were transferred from the latter to the former. The increase in real capital took place because of forced saving, which worked through prices rising faster than disposable income of wage-earners and the rigidity of certain incomes. The intermediate result was the same as for voluntary saving. Consumers were forced to forgo what they used to consume so as to give the entrepreneurs, who had received the additional money, command over resources for the production of extra capital goods. However, no permanent increase of real capital was possible with the help of
inflationary credit expansion and forced saving, and the new capital built during the upswing would necessarily be destroyed during the downturn.

Dennis Robertson made a most detailed analysis of different forms of saving or ‘lacking’ in *Banking Policy and the Price Level* (1926). He introduced the term ‘automatic lacking’: an involuntary reduction in planned consumption, which came about when the price level increased because newly created money was added to the daily stream of money which competed for the daily stream of marketable goods. Parts of the doctrine of forced saving were questioned with the publication of Keynes's *Treatise on Money* (1930) and his subsequent debate with Hayek and Robertson. Robertson had, according to Keynes, no distinct definition of voluntary saving, which was related to a confusion concerning the definition of income, and it implied a deficient view of the meaning of forced saving. Keynes defined saving as the difference between income or normal costs and expenditure on consumption, which could differ from investment since saving and investment were decisions taken by different agents, windfall profits and losses being the balancing figure between investment and saving. Forced saving or automatic lacking existed when investment exceeded saving and purchasing power was redistributed by the accompanying inflation; it was represented on the one hand by the increased amount of money which spenders had to pay for that part of consumption which they continued to enjoy, and on the other hand by the extra investment provided out of the windfall gains of the entrepreneurs. Hence Keynes did not challenge the fact that an increase in net investment took place via the redistribution of purchasing power, but it was not an involuntary act.

At the same time, Erik Lindahl presented a similar analysis in *The Rate of Interest and the Price Level* (1930). The rising prices during an upward cumulative process had to change the distribution in favour of those who had a strong incentive to save, until the total saving in the community corresponded to the value of real investment, which was primarily determined by the rate of interest. This saving was mainly voluntary, since an individual was free to consume as much as he liked and the only limit was his credit standing. Keynes had the same view in the *General Theory*: this type of saving was in complete agreement with the free will of the individual to save what he chose irrespective of what he or others might be investing, since no individual could be compelled to own the additional money (corresponding to the new bank-credit) unless he deliberately preferred to hold more money rather than some other form of wealth. Lindahl reserved forced saving for the possibility that the individual has to limit planned consumption out of income (defined as the rate of interest on the capital value of all capital goods including human capital) because he is not able to obtain credit, which might be explained by banking rules concerning the collateral for loans, i.e. it is not a perfect capital market.

Once the notions of *ex ante* and *ex post* were introduced all these problems could be solved. A fall in the money rate leads to an excess of planned and realized investment over planned saving (related to planned income), and the subsequent increase in prices would imply higher incomes *ex post* for the entrepreneurs, which is the same as Keynes's concept of windfall gains in the *Treatise*. This unexpected windfall, which could not be spent during the period, would contribute the extra necessary saving, since investment *ex post* had to be equal to saving *ex post*. Lindahl denoted this as ‘unintentional saving’ and he found ‘forced saving’ to be an inappropriate term. However, Keynes seemed to have changed his position slightly in *How to Pay for the War* (1940). The process could be successful only if wages lagged behind prices, for otherwise an unlimited inflation would take place. As such it was a method of compulsorily converting a part of workers’ earnings, which they do not plan to save voluntarily, into the
voluntary saving of the entrepreneurs. From an analytical point it was voluntary saving, but it was ‘a matter of taste’ whether this was a suitable name.
To sum up: there was a consensus that new credit might lead to an additional, at least temporary, investment even in a full employment situation via an increase in the price level. But the most recent contributions – for example, Lindahl and Keynes – did not consider the extra saving to be forced. At the same time almost all of them found it unwise and unjust to rely on credit inflation as a means of increasing capital accumulation. However, after Keynes’s analysis in the General Theory the problem seems to have disappeared from the agenda.

forecasting

Clive Granger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Providing timely and useful forecasts is among the most relevant tasks of economists. The choice among
the many techniques and approaches depends on the variables being forecast and the length of the
forecast horizon. Providing confidence intervals around the point forecasts is becoming standard
practice, as are sophisticated attempts at evaluating the quality of the forecasts and the intervals.
Forecasts are often combined, raising questions about the appropriate cost functions to use in the
evaluation process. Economists once concentrated on forecasting the mean of a process, then moved to
time variance, and now consider quantities and the whole distribution.

Article

Decisions in the fields of economics and management have to be made in the context of forecasts about
the future state of the economy or market. As decisions are so important as a basis for these fields, a
great deal of attention has been paid to the question of how best to forecast variables and occurrences of
interest. There are several distinct types of forecasting situations, including event timing, event outcome,
and time-series forecasts. Event timing is concerned with the question of when, if ever, some specific
event will occur, such as the introduction of a new tax law, or of a new product by a competitor, or of a
turning point in the business cycle. Forecasting of such events is usually attempted by the use of leading
indicators, that is, other events that generally precede the one of interest. Event outcome forecasts try to
forecast the outcome of some uncertain event that is fairly sure to occur, such as finding the winner of an
election or the level of success of a planned marketing campaign. Forecasts are usually based on data
specifically gathered for this purpose, such as a poll of likely voters or of potential consumers. There clearly should be a positive relationship between the amount spent on gathering the extra data and the quality of the forecast achieved.

A time series \( x_t \) is a sequence of values gathered at regular intervals of time, such as daily stock market closing prices, interest rates observed weekly, or monthly unemployment levels. Irregularly recorded data, or continuous time sequences may also be considered but are of less practical importance. When at time \( n \) (now), a future value of the series, \( x_{n+h} \), is a random variable where \( h \) is the forecast horizon. It is usual to ask questions about the conditional distribution of \( x_{n+h} \) given some information set \( I_n \), available now from which forecasts will be constructed. Of particular importance are the conditional mean

\[
\hat{f}_{n,h} = E[x_{n+h}|I_n]
\]

and variance, \( V_{n,h} \). The value of \( f_{n,h} \) is a point forecast and represents essentially the best forecast of the most likely value to be taken by the variable \( x \) at time \( n+h \). With a normality assumption, the conditional mean and variance can be used together to determine an interval forecast, such as an interval within which \( x_{n,h} \) is expected to fall with 95 per cent confidence. An important decision in any forecasting exercise is the choice of the information set \( I_n \). It is generally recommended that \( I_n \) include at least the past and present of the individual series being forecast, \( x_{n-j}, j \geq 0 \). Such information sets are called proper, and any forecasting models based upon them can be evaluated over the past. An \( I_n \) that consists just of \( x_{n-j} \), provides a univariate set so that future \( x_i \) are forecast just from its own past. Many simple time-series forecasting methods are based on this information set and have proved to be successful. If \( I_n \) includes several explanatory variables, one has a multivariate set. The choice of how much past data to use and which explanatory variables to include is partially a personal one, depending on one's knowledge of the series being forecast, one's levels of belief about the correctness of any economic theory that is available, and on data availability. In general terms, the more useful are the explanatory variables that are included in \( I_n \), the better the forecast that will result. However, having many series allows for a confusing number of alternative model specifications that are possible so that using too much data could quickly lead to diminishing marginal returns in terms of forecast quality. In practice, the data to be used in \( I_n \) will often be partly determined by the length of the forecast horizon. If \( h \) is small, a short-run forecast is being made and this may concentrate on frequently varying explanatory variables. Short-term forecasts of savings may be based on interest rates, for example. If \( h \) is large so that long-run forecasts are required, then slowly changing, trending explanatory variables may be of particular relevance. A long-run forecast of electricity demand might be largely based on population trends, for example. What is considered short run or long run will usually depend on the properties of the series being forecast. For very long forecasts, allowances would have to be made for technological change as well as changes in demographics and the economy. A survey of the special and separate field of technological forecasting can be found in Martino (1993) with further discussion in Martino (2003). If decisions are based on forecasts, it follows that an imperfect forecast will result in a cost to the
decision-maker. For example, if $f_{n, h}$ is a point forecast made at time $n$, of $x_{n+h}$, the eventual forecast error will be

$$e_{n, h} = x_{n, h} - f_{n, h},$$

which is observed at time $n+h$. The cost of making an error $e$ might be denoted as $C(e)$, where $C(e)$ is positive with $C(0)=0$. As there appears to be little prospect of making error-free forecasts in economics, positive costs must be expected, and the quality of a forecast procedure can be measured as the expected or average cost resulting from its use. Several alternative forecasting procedures can be compared by their expected costs and the best one chosen. It is also possible to compare classes of forecasting models, such as all linear models based on a specific, finite information set, and to select the optimum model by minimizing the expected cost. In practice the true form of the cost function is not known for decision sequences, and in the univariate forecasting case a pragmatically useful substitute to the real $C(e)$ is to assume that it is well approximated by $ae^2$ for some positive $a$. This enables least-squares statistical techniques to be used when a model is estimated and is the basis of a number of theoretical results including that the optimal forecast of $x_{n+h}$ based on $I_n$ is just the conditional mean of $x_{n, h}$. Machina and Granger (2006) have considered cost functions generated by decision makers and then find implications for their utility functions. This is just one component of considerable developments in the area of evaluation of forecasts; see West (2006) and Timmermann (2006), for example.

When using linear models and a least-square criterion, it is easy to form forecasts under an assumption that the model being used is a plausible generating mechanism for the series of interest. Suppose that a simple model of the form

$$x_t = \alpha x_{t-1} + \beta y_{t-2} + \varepsilon_t$$

is believed to be adequate where $\varepsilon_t$ is a zero-mean, white noise (unforecastable) series. When at time $n$, according to this model, the next value of $x$ will be generated by

$$x_{n+1} = \alpha x_n + \beta y_{n-1} + \varepsilon_{n+1}.$$ 

The first two terms are known at time $n$, and the last term is unforecastable. Thus
\[ f_{n,1} = \alpha x_n + \beta y_{n-1} \]

and

\[ \epsilon_{n,1} = \epsilon_{n+1}. \]

\( x_{n+2}, \) the following \( x, \) will be generated by

\[ x_{n+2} = \alpha x_{n+1} + \beta y_n + \epsilon_{n+2}. \]

The first of these terms is not known at time \( n, \) but a forecast is available for it, \( \alpha f_n; \) the second term is known at time \( n, \) and the third term is not forecastable, so that

\[ f_{n,2} = \alpha f_{n,1} + \beta y_n \]

and

\[ \epsilon_{n,2} = \epsilon_{n+2} + \alpha(x_{n+1} - f_{n,1}) = \epsilon_{n+2} + \alpha \epsilon_{n+1}. \]

To continue this process for longer forecast horizons, it is clear that forecasts will be required for \( y_{n+h-2}. \) The forecast formation rule is that one uses the model available as though it is true, asks how a future \( x_{n+h} \) will be generated, uses all known terms as they occur, and replaces all other terms by optimal forecasts. For non-linear models this rule can still be used, but with the additional complication that the optimum forecast of a function of \( x \) is not the same function of the optimum forecast of \( x. \)

The steps involved in forming a forecast include deciding exactly what is to be forecast, the forecast horizon, the data that is available for use, the model forms or techniques to be considered, the cost function to be used in the evaluation procedure, and whether just one single forecast would be produced or several alternatives. It is good practice to decide on the evaluation to be used before starting a sequence of forecasts. If there are several alternative forecasting methods involved, a weighted
The central problem in practical forecasting is choosing the model from which the forecasts will be derived. If a univariate information set is used, it is natural to consider the model developed in the field of time-series analysis. A class of models that has proved to be successful in short-term forecasting is the autoregressive (AR) model class. If a series is regressed on itself up to $p$ lags, the result is an AR($p$) model. These models were originally influenced by Box and Jenkins (1970) as a particularly relevant subclass of their ARMA ($p$, $q$) models, which involve moving average components. The number of lags in an AR($p$) can be chosen using a selection criterion; the most used are the Bayes information criterion (BIC) and the less conservative Akaike information criterion (AIC).

The natural extension was to vector autoregressive models. Later, when it was realized that many series in macroeconomics and finance had the property of being integrated, and so contained stochastic trends, the natural multivariate form was the error-correction model. It is quite often found that error-correction models improve forecasts, but not inevitably. There are a variety of ways of building models with many predictive variables, including those with unobserved components and using special data, such as survey expectations, real-time macro data, and seasonal components.

In recent years the linear models have been joined by a variety of nonlinear forms (see Terasvita, 2006), including switching models and neural networks as well as linear models with time varying coefficients estimated using Kalman filters.

Traditionally, forecasters concentrated on the mean of the predictive distribution. Towards the end of the 20th century considerable attention was given to forecasting the variance of the distribution, particularly in the financial area, often using Engle's (1995) ARCH model or one of its many generalizations (see the survey by Andersen et al., 2006). Recently forecasts of the whole distribution have become more common in practice, both in finance and in macroeconomics: see Corradi and Swanson (2006) for a recent discussion. These forecasts will include discussions of quantiles, and the use of copulas gives a way into multivariate distribution forecasts. The topics mentioned in this paragraph are covered by chapters in Elliot, Granger and Timmermann (2006).

Foreign aid has evolved significantly since the Second World War in response to a dramatically changing global political and economic context. This article (a) reviews this process and associated trends in the volume and distribution of foreign aid; (b) reviews the goals, principles and institutions of the aid system; and (c) discusses whether aid has been effective. While much of the original optimism about the impact of foreign aid needed modification, there is solid evidence that aid has indeed helped further growth and poverty reduction.

Article

Foreign aid and its usefulness in promoting economic development in developing countries has been a topic of intense controversy ever since Rosenstein-Rodan (1943) advocated aid to eastern and south-eastern Europe. Early optimism and confidence in the impact of foreign aid have been tempered with time, but aid continues to loom large in the public discourse; and aid remains squarely on most policy agendas concerned with poverty and inequality in Africa and elsewhere in the developing world.

What is foreign aid? Loosely, it covers governmental transfers to poor countries that are mainly destined for developmental purposes. For a more precise definition it is useful to turn to the Development Assistance Committee (DAC) of the OECD. DAC is the principal body through which the OECD deals
with issues related to cooperation with developing countries, and DAC publishes the most comprehensive data available on foreign aid (OECD, 2004). DAC countries also account for almost 95 per cent of all aid flows. In 2002 the total amount of foreign aid disbursed by donors to developing countries and multilateral organizations reached $61.5 billion (Table 1). Multilateral organizations disbursed some 30 per cent (Table 2), and Table 3 shows that international development assistance is an important resource for many developing countries.

The term ‘foreign aid’ or ‘development assistance’ refers to financial flows that qualify as Official Development Assistance (ODA). ODA is defined as grants and loans to aid recipients that are: (a) undertaken by the official sector of the donor country, (b) with promotion of economic development and welfare as the main objective, (c) at concessional financial terms, where the grant element is equal to at least 25 per cent.

Conventionally the market rate of interest used to assess a loan is taken as ten per cent. Thus, while the grant element is nil for a loan carrying an interest rate of ten per cent, it is 100 per cent for a pure grant, and lies between these two limits for a soft loan. In addition to financial flows, technical cooperation costs are included in ODA; but grants, loans and credits for military purposes are excluded, and transfer payments to private individuals are in general not counted. The same goes for private charity, hard loans and foreign direct investment (FDI).

While the OECD operates with a consolidated list of recipient countries to capture all aid flows, this list is divided into two parts. Only aid to ‘traditional’ developing countries counts as ODA. For these (Part I) countries there is a long-standing United Nations (UN) target that they should receive 0.7 per cent of donors’ gross national income (GNI) as aid. Assistance to the ‘more advanced’ eastern European and developing (Part II) countries is recorded separately as ‘official aid’ (OA), which is not included as part of ODA.

Historical background

Foreign aid emerged out of the disruption that followed the Second World War. The international economic system had collapsed, and war-ravaged Europe faced a critical shortage of capital and an acute need for physical reconstruction. The response was the European Recovery Programme, commonly known as the Marshall Plan. During the peak years the United States devoted some two or three per cent of its national income to helping restore Europe. This objective was achieved on schedule, and fuelled optimistic expectations about the future effectiveness of foreign aid.

After the success of the Marshall Plan, the attention of industrialized nations turned to the developing countries, many of which became independent around 1960. Economic growth in a state-led planning tradition became a key objective during the 1950s and 1960s, and it was widely believed that poverty and inequality would eventually be eliminated through growth and modernization (‘trickle down’). A major part of the rapidly increasing bilateral flows during the 1950s came from the United States, but colonial ties remained strong, and developing regions continued to receive bilateral (country-to-country) support from the former colonial powers, notably France and the United Kingdom. Yet the 1960s was also the decade when a range of new bilateral donor agencies was established in, for example, the Nordic countries. They accounted for much of the increase in aid flows in the 1970s.

A transition toward more independent, multilateral relations began to emerge during the 1960s. Hjertholm and White (2000) argue that this created, a constituency for foreign aid, and the non-aligned
movement of developing countries gave a focus to this voice, as did the various organs of the UN, which accounted for around one-third of multilateral assistance during 1960–73. The International Bank for Reconstruction and Development (IBRD, or World Bank), established at the Bretton Woods Conference in 1944, is central in multilateral development assistance, especially following the creation of the International Development Association (IDA) in 1960. IDA channels resources to the poorest countries on ‘soft’ conditions alongside the regional development banks, formed from 1959 to 1966, and the European Commission.

The original Marshall Plan was built around support to finance general categories of imports and strengthen the balance of payments (that is, programme aid), but from the early 1950s project aid became the dominating aid modality. Some donors continued to supply programme aid (including food aid), but aid was increasingly disbursed for the implementation of specific capital investment projects and associated technical assistance to support advances in infrastructure and productive sectors.

The multilateralism of aid became somewhat more pronounced after the mid-1970s, when the UN, the World Bank and other multilateral agencies expanded their activities quite considerably; since then the share of multilateral aid in total aid has remained close to 30 per cent. The 1970s also saw an increased focus on employment, income distribution, and poverty alleviation as essential objectives of development and foreign aid. The effectiveness of trickle-down was widely questioned, and new strategies referred to as ‘basic human needs’ and ‘redistribution with growth’ were formulated. Nevertheless, the typical project aid modality remained largely unchanged.

During the 1960s and 1970s, economic progress was visible in much of the developing world. This era came to an abrupt end at the beginning of the 1980s. The international debt crisis erupted in association with macroeconomic imbalances in many countries, and it soon became evident that the downturn would be long-lasting, not temporary as in 1973. On the political scene Ronald Reagan and Margaret Thatcher came to power in the USA and UK, and at the World Bank Anne Krueger became Vice-President and Chief Economist, replacing Hollis Chenery. This change was symbolic and substantive (Kanbur, 2003).

Economic circumstances in the developing countries and the relations between the North and South had changed radically. The crisis hit hard, especially in many African countries; progress over previous decades ground to a halt, inflation got out of control and the deficit in the balance payments could not be financed on a sustainable basis. Focus in development policy shifted to internal domestic failures, and achieving macroeconomic balance (externally and internally) became widely perceived as an essential prerequisite for renewed development.

‘Rolling back the state’ turned into a rallying call in the reform efforts, and reliance on market forces, outward orientation, and the role of the private sector, including non-governmental organizations (NGOs), was emphasized by the World Bank and others. In parallel, poverty alleviation somehow slipped out of view in mainstream agendas for economic reform, but remained at the centre of attention in more unorthodox thinking, such as the ‘adjustment with a human face’ approach of the UN Children’s Fund (Cornia, Jolly and Stewart, 1987).

At the same time, bilateral donors and international agencies grappled with how to channel resources to the developing world. Channelling fresh resources to developing countries in the form of discrete investment projects had become increasingly difficult. Project rates of return did not seem to justify the investments. Various kinds of quick-disbursing macroeconomic programme assistance, such as balance of payments support and sector budget support, which were not tied to investment projects and which could be justified under the headings of stabilization and adjustment, appeared to be an ideal solution to
Financial programme aid and adjustment loans (and eventually debt relief) became fashionable and policy conditionality more widespread. A rationale had been found for maintaining the flow of resources, which corresponded well to the orthodox guidelines for good policy summarized by the ‘Washington consensus’ (Williamson, 1997).

Meanwhile, total aid continued to grow steadily in real terms until the early 1990s, and more than tripled as a share of the growing national income of the donor community during 1970–90. After 1992, total aid flows started to decline in absolute terms (especially in the USA). Many reasons account for the fall in aggregate flows after 1992, including the decline of communism and the end of the cold war. Weakening patron–client relationships among the developing countries and the former colonial powers also played a role, and the traditional support for foreign aid by vocal interest groups in the industrial countries receded. Bilateral and multilateral aid institutions were subjected to criticism, and at times characterized as blunt instruments of commercial interests in the industrial world or as self-interested, rent-seeking bureaucracies. Moreover, acute awareness in donor countries of cases of bad governance, corruption, and ‘crony capitalism’ led to scepticism about the credibility of governments receiving aid. Aid fatigue became widespread during the second half of the 1990s.

Aid allocation

Foreign aid has over the years been justified in public policy pronouncements in widely differing ways, ranging from pure altruism to the shared benefits of economic development in poor countries and to the political ideology, foreign policy and commercial interests of the donor country. Few dispute that humanitarian sentiments have motivated donors. Action following severe natural calamities, which continue to be endemic in poor countries, is an example. Food and emergency relief also remains an important form of aid. In addition, the data available in Table 3 suggest that donors allocate relatively more ODA to the poorest countries. The broader validity of this casual observation is confirmed in cross-country econometric work (Alesina and Dollar, 2000). While studying bilateral aid only, they conclude that most donors give more aid to poorer countries, ceteris paribus. They stress as well that there is considerable variation among donors.

Emphasis on the needs of poor countries was a prominent characteristic – and the underlying economic rationale – in much of the policy literature on foreign aid in the 1950s and 1960s. Here the focus was on estimating aid requirements in the tradition of the two-gap model (Chenery and Strout, 1966). With time, development concerns have broadened. The two-gap model has become somewhat unfashionable, at least in academia, and the role of aid has changed to a much more multi-dimensional set of concerns (Thorbecke, 2000). Nevertheless, economic development in aid-receiving countries continues as a yardstick both in its own right (at least for some donors) and as a necessary condition for the realization of other development aims.

A second observation from Table 2 is that large, populous countries, such as China and India, receive relatively small amounts of aid in per capita terms. Smaller countries such as Mali, Ghana, Bolivia and Sri Lanka are given more favourable per capita treatment. This finding is confirmed econometrically by Alesina and Dollar (2000). They stress, however, the critical and complex importance of political and strategic considerations in aid allocations.

It is not news that selfish motives are critical in donor decisions. In the past, the cold war was used as a...
foreign aid: The New Palgrave Dictionary of Economics

powerful justification for providing aid to developing countries to stem the spread of communism. Similarly, aid from socialist governments was motivated to promote socialist political and economic systems. Other strategic interests play a role as well. The USA has over the years earmarked very substantial amounts of aid to Egypt and Israel; being a former colony is an important determinant in getting access to French aid; and voting behaviour in the UN can affect aid allocation both bilaterally (Alesina and Dollar, 2000) and through the multilateral system (Andersen, Harr and Tarp, 2004).

In sum, there is often a wide gap between donor rhetoric and practice when attention is on the size and allocation of foreign aid. This gap is illustrated by the fact that the donor countries are indeed very far from contributing the 0.7 per cent of their national income as ODA, which was agreed as a UN target in 1970. As shown in Table 1, only the group of Nordic countries and the Netherlands have consistently met this target, while the USA contributed around 0.1 per cent of the US GNI in 2002. Finally, Table 3 shows that total ODA, ODA per capita, ODA as a share of GNI and ODA as a share of total flows actually vary considerably in real terms in many aid-receiving countries. Economic management in general, and management of aid inflows in particular, are not easy tasks in developing countries.

The impact of foreign aid

If the economic development rationale for foreign aid is taken seriously, it is of interest to ask whether aid-receiving countries benefit from such transfers and, if so, how. What are the mechanisms through which aid works, and what are the potential negative effects associated with foreign aid? Over the past 60 years a vast amount of empirical work has (a) studied the impact of aid at micro-, meso- and macroeconomic level; (b) relied on cross-country as well as single-country data; and (c) included broad surveys of a qualitative and interdisciplinary nature as well as more strict quantitative econometric work. Many surveys are available; see for example Cassen (1987) and Tarp (2000).

An influential literature focused on cross-country econometric approaches to the analysis of aid effectiveness. This literature has gone through three generations (Hansen and Tarp, 2000); and from the early 1990s macro-econometric studies came to dominate the academic and public discourse. This work was motivated in part by the availability of much better data across a range of countries and in part by insights emerging from new growth theory and the rapidly increasing number of general empirical studies of growth.

The simple Harrod–Domar model (and the two-gap Chenery–Strout extension) was used extensively in the past as the analytical framework of choice for assessing aid impact. The underlying idea was simple. Assume physical capital is the only factor of production (so investment is the key constraint on growth), and assume as well that all aid is invested. Then it is straightforward to calculate the growth impact of additional aid. If aid corresponds to six per cent of the gross national product and the capital–output ratio is estimated at 3.0, then aid adds 2.0 percentage points a year to the growth rate. The impact of aid is clearly positive, and aid works by helping to fill a savings or a foreign exchange gap.

The Achilles heel in this type of calculation is, first, that it is a tall order to expect that all aid is invested. Aid is provided for many reasons. In addition, the share of aid that ends up being invested (rather than consumed) will, in even the best of circumstances, depend on the degree of fungibility of the foreign aid transfer. Yet, even if aid adds to domestic savings and investment on less than a one-to-one basis, aid does continue to have a positive impact on growth in the traditional line of thinking – as long as total
A second line of critique of the Harrod–Domar and two-gap approach has been the argument that growth is less related to physical capital investment (including aid) than often assumed (Easterly, 2001). If the key driver of the productive impact of aid is related more to incentives and relative prices and more generally to the policy environment, then it becomes important to consider potentially distortionary effects of aid on incentives and economic policies in the aid-receiving system, and vice versa. An example is ‘Dutch disease’, and domestic demand and resource allocation can certainly be twisted in undesirable directions following an aid inflow. One concrete example is that aid donors often pay much higher wages to national experts and staff than equally important national institutions. Another illustration is change in the structure of domestic demand following the aid inflow.

Third, a large and growing literature on the political economy of aid (see Kanbur, 2003, and Gunning, 2005, for references) has argued that, if aid allows a recipient government (local elites) to pursue behaviour that is in any way anti-developmental, then the potential positive impact of aid can be undermined. There are many such examples available in practice ranging from outright misuse of aid to more subtle issues such as the potential negative impact of aid on domestic taxation (Adam and O’Connell, 1999).

The fear that foreign aid can generate undesirable aid dependency relationships persisted throughout the 1990s and into the 21st century, and gradually the perception that policy conditionality was failing to promote policy reform started to assert itself (Kanbur, 2000, and Svensson, 2003). This perception prompted a keen interest in new kinds of donor–recipient relationships. One outcome was calls for increased national ownership of aid programmes. Another was that World Bank and independent academic researchers started digging into the aid–growth relationship using modern analytical techniques.

Much of the recent debate has roots in Mosley’s (1987) micro–macro paradox. He suggested that, while aid seems to be effective at the microeconomic level, identifying any positive impact of aid at the macroeconomic level is harder or even impossible. Along with the implementation of adjustment programmes during the 1980s, traditional evaluation methods such as calculating the internal rate of return of projects came under severe criticism. The perception spread that aid channelled through sovereign governments is fully fungible. The internal rate of return approach also became problematic as donors started to embrace wider social goals for aid. The wave of cross-country work during the 1990s and the later, more extensive use of randomized programme evaluation (Duflo, 2004) are ways of trying to come to grips with these issues.

The cross-country analysis by Boone (1996) suggested that aid does not work at all and is simply a waste of resources. This was followed up with an analysis by Burnside and Dollar (1997; 2000). They argue that some aid does work, and provided an attractive solution to the micro–macro paradox. Aid works, but only in countries with ‘good policy’. They based this conclusion on an aid-policy interaction term that emerged as statistically significant in their analysis of the relationship between aid and growth. Burnside and Dollar, and more recently Collier and Dollar (2001; 2002), have used the foregoing framework as a basis for suggesting that aid should be directed to ‘good policy’ countries to improve aid’s impact on poverty alleviation. This recommendation is partly justified by reference to the seeming inability of aid to change policy, a finding that has emerged from other Bank-funded research (Devarajan, Dollar and Holmgren, 2001). While the Bank’s Monterrey document (World Bank, 2002)
toned down these recommendations, the basic thrust in much of the international aid debate remains that macroeconomic performance evaluation and policy criteria (established by the World Bank) should play a key role in aid allocation.

The work of Burnside, Collier, and Dollar led to discussions about what constitutes good policy. In many ways these discussions are extensions of more general debates and views about development strategy and policy, and the World Bank has gradually expanded the good policy concept to include a wider and more complex set of characteristics than originally considered. Nevertheless, if the variation in aid effectiveness across countries is not policy-induced but rather a result of poor initial conditions, a different aid allocation rule would maximize the impact of foreign aid. Moreover, the empirical finding that aid is effective, but only when accompanied by good policy, turns out to be delicate. It is robust neither to alternative specifications of the regression model (Hansen and Tarp, 2001) nor to new data (Easterly, Levine and Roodman, 2004).

Clemens, Radelet and Bhavnani (2004), Dalgaard, Hansen and Tarp (2004) and Roodman (2004) offer up-to-date accounts. It emerges that the single most common result of recent empirical studies is that aid has a positive impact on per capita growth. There is also strong evidence to suggest that the importance of ‘deep’ structural characteristics is not yet fully understood. In sum, the accumulated cross-country evidence is encouraging, and Dalgaard and Hansen (2005) estimate that the aggregate real rate of return on foreign aid financed investments is in the range of 20–25 per cent. Attention should turn to how the effectiveness of aid can and should be improved rather than concentrating on whether aid works. This implies, for example, that focus should shift from aggregate aid to different forms of aid and their application in different types of aid receiving countries – modalities matter.

**Future prospects**

After many years when the project modality was the main vehicle for transferring aid, stabilization and broad structural reforms with associated programme aid were promoted vigorously in the early 1980s. A decisive shift from the state to the market as the key driver behind development was pursued. The East Asian financial crisis in 1997 signalled that the time had come for a rethink of the Washington consensus; and it is now widely agreed that quick-fix and single-actor approaches to development – focusing on either the state or the market – are not going to work. The state and the market have complementary roles to play in the struggle against poverty and inequality.

Aid fatigue is still evident in the international aid community, but it does seem that aid is gradually being rehabilitated from the low point of the mid-1990s. The empirical evidence that ‘aid works’ has been mounting steadily, and recent calls have been made for a ‘big push’ or a ‘Marshall Plan’ for Africa (World Economic Forum, 2005), and foreign aid flows seem to have picked up considerably after 2002. The UN has established a target of halving world poverty by 2015 in the context of its Millennium Development Goals (MDG) (UN, 2002), and the USA has embarked on a $5 billion Millennium Challenge Account (MCA) meant to stimulate aid to poor countries (Bush, 2005).

All of this should not detract attention from the fact that many key challenges remain to be effectively addressed. The institutional set-up for bilateral aid delivery remains complex, uncoordinated and overburdened with many diverse tasks and aims; and calls for reform of the UN have become common. Moreover, it is far from settled where the balance between selectivity and conditionality is situated. An
underlying dilemma here is that it remains disputed how the balance between real or perceived needs on the one hand and development potential and performance on the other should be struck. Various proposals and guidelines exist (including the existing IDA aid allocation formula), but much of this relies ‘too heavily on a uniform model of what works in development policy’ (Kanbur, 2005). Past experiences provide many useful lessons about foreign aid (Robinson and Tarp, 2000), but the search for more effective answers to these kinds of questions is far from complete.

Finally, aid has gradually become a much smaller player in the world economy than private capital flows. Foreign aid decision makers are well advised to try to sharpen their implementation skills and develop complementary relationships with, among others, private capital markets and NGOs (Roland-Holst and Tarp, 2004). In an increasingly global world, possibilities and challenges are also opening up in the arena of international public goods. Foreign aid analysts would do well to explore these possibilities alongside more traditional investment and programme support activities, targeted on the provision of domestic public goods in poor countries.

foreign direct investment

Abstract

Foreign direct investment (FDI) occurs when an individual or firm acquires controlling interest in productive assets of another country. We review the literature on FDI, which can be divided into two broad categories. The first is the inquiry into why multinational production occurs and the factors that determine the patterns of worldwide FDI. The second is the impact that FDI and multinational enterprises (MNEs) have on the parent and host countries, including economic growth, returns to factors of production, and externalities.

Article

Foreign direct investment (FDI) occurs when an individual or firm acquires a controlling interest (typically defined as at least ten per cent ownership) in productive assets in another country. This contrasts with portfolio investment, which includes purchases of foreign bonds, currencies, and stocks in amounts that do not provide control. The most common method of FDI is through the acquisition of a firm. Construction of a new plant is also common and typically referred to as ‘greenfield’ FDI. Other forms of FDI include partnerships in a foreign joint venture and earnings reinvested in an existing
foreign affiliate. Firms with affiliates in more than one country are termed ‘multinational enterprises’ (MNEs).

While real world GDP grew at a 2.5 per cent annual rate and real world exports grew by 5.6 per cent annually from 1986 through 1999, real world FDI inflows grew by 17.7 per cent over this same period (Giorgio and Venables, 2004). Additionally, Bernard, Jensen and Schott (2005) find that 90 per cent of US exports and imports flow through MNEs, with roughly 50 per cent of US trade flows occurring between affiliates of the same MNE, or what is termed ‘intra-firm trade’. While the majority of FDI flows are between developed countries, FDI accounted for the majority of capital flows to less-developed countries from 1990 to 2003 (UNCTAD, 2004).

The study of FDI can be divided into two broad categories. The first is the inquiry into why multinational production occurs and the factors that determine the patterns of worldwide FDI. The second is the impact that FDI and MNEs have on the parent and host countries, including economic growth, returns to factors of production, and externalities for innovative activity.

Understanding what motivates FDI by MNEs

Theory

Theoretical treatment of FDI and MNEs in the economics profession can be traced back to the 1970s, when researchers began to consider why some firms choose to locate production abroad rather than serve such markets through exports or licensing. A key insight is that MNEs may be distinguished by their ownership of firm-specific assets for which market failures can make exporting or licensing arrangements less attractive to the firm than FDI. For example, a foreign licensee may not offer full value in negotiations over a contract if the firm-specific asset is intangible and not fully revealed (for example, a unique production process), but the licensor firm will not want to reveal the asset fully until a contract is finalized. The costs associated with this inherent hold-up problem may then lead the firm to set up its own affiliate in the foreign market. This is termed ‘internalization’ in the literature, and forms the key element in the ‘ownership-location-internalization’ (OLI) theory of MNEs that developed out of this era and has been surveyed recently by Dunning (2001).

The OLI theory is an international business concept that was never formally represented in a mathematical model. As such, the international economics literature continued to treat FDI as simply another capital flow until the mid-1980s, even though its features and patterns differed from those of other capital flows. This changed with papers by Markusen (1984) and Helpman (1984) that developed general equilibrium models of MNEs. Both papers focused on another feature of firm-specific assets, namely, the public-goods aspect of many firm-specific assets that can be applied simultaneously in production across all plants owned by the firm. This feature of firm-specific assets makes it more attractive for a firm to build multiple plants, though something else must be added to a model to explain locating plants into foreign countries. In Helpman (1984) this is accomplished by assuming that MNEs can be separated into two types of activities: a skill-intensive headquarters that generates the firm-specific assets, and a low-skill-intensive production process. If endowment differences are sufficient across countries, MNEs will vertically separate the firm between headquarter services in the skill-abundant parent country and production in the low-skill host country. This type of model is called a
vertical FDI model. In contrast, Markusen's (1984) model generates multi-plant MNEs through the introduction of trade costs (that is, transportation costs, trade barriers, and so on) that are large enough that an MNE chooses to replicate itself in the foreign country to serve the market there. This type of model is termed 'horizontal FDI'.

These models have become the main theoretical MNE frameworks for trade economists, as recent literature has extended these models. Brainard (1997) develops and tests hypotheses from a simplified horizontal MNE model assuming monopolistic competition. Markusen et al. (1996) develop an MNE model that blends both the horizontal and vertical models into what is termed the 'knowledge-capital' model. More recently, Helpman, Melitz and Yeaple (2004) have developed a model that can explain the coexistence of both exporting and MNEs in the same industry by allowing for heterogeneity across firms; other papers have developed models that formalize the role of transactions costs and theory of the firm (for example, Antras and Helpman, 2004; Feenstra and Hanson, 2005).

Empirics

Empirical work on the factors that determine FDI patterns has focused primarily on the effect of government policies and macroeconomic phenomena such as exchange rates and taxes. Most of these studies motivate their analyses with a partial equilibrium model of firm behaviour responding to these various factors. Only recently have empirical studies examined the more fundamental long-run drivers of total FDI activity, such as country size and factor endowments, as predicted by the general equilibrium modelling discussed above. Availability of micro-level data has been an issue for the literature as well. Testing theories of firm-level models with industry- or country-level data requires strong assumptions about firm characteristics. While firm-level data is being employed more often in recent work, much of the literature has examined more aggregate data.

Exchange rates

The effects of exchange rate movements on FDI are not immediately obvious. If a host country's currency depreciates relative to the parent country's currency, this lowers the price of host-country assets. However, if the asset generates returns in the host country's currency, these returns have likewise depreciated in the parent-country currency. Froot and Stein (1991) and Blonigen (1997), however, provide theoretical links that predict that host-country depreciations increase inbound FDI; and empirical evidence generally supports this. A related literature has examined how exchange rate expectations may affect FDI decisions. Campa (1993) provides theory and evidence that exchange rate uncertainty will decrease FDI, while Cushman (1985) and Goldberg and Kolstad (1995) conclude that quite opposite results can be expected and found depending on the firm's trade linkages across markets. On a final note, there has been recent work on the impact of exchange rate crises on FDI. Surprisingly, FDI is relatively stable through currency crises in host countries and, in fact, Aguiar and Gopinath (2005) show that MNEs opportunistically increase their investments in these host countries.

Taxes
Like exchange rate movements, the effect of taxes on FDI has not proven to be straightforward either. While there is an array of taxes that may affect FDI, the primary focus has been on corporate income tax rates in host countries. The natural hypothesis is that higher host-country tax rates discourage FDI, and a survey by de Mooij and Ederveen (2003) finds a median elasticity of tax rates on FDI of minus 3.3 across 25 different empirical studies. However, the literature has also shown that the effects of taxes on FDI can vary substantially depending on the type of taxes, the form of FDI (see, for example, Hartman, 1985), and the influence of government policy.

Perhaps the most explored issue in this literature has been the issue of how parent countries deal with the ‘double taxation’ issue – taxation in both host and parent countries. The common distinction is between territorial countries that do not tax any income outside of the parent country, exempting foreign-earned income from tax liability, and a worldwide tax method which considers all earned income by its parent firms potentially taxable, but may treat foreign income in a number of ways to avoid double taxation of the MNE. The standard treatment to deal with this double taxation issue is for the home country to offer a credit or a deduction of foreign tax payment made by the MNE. A number of studies of the US 1986 tax reform find mixed evidence for differences in FDI behaviour under different parent-country tax regimes (for example, Scholes and Wolfson, 1990; Swenson, 1994). Much stronger results come from work by Hines (1996) which finds that US taxation decreases FDI more for non-credit-system foreign investors than for credit-system foreign investors.

A final significant literature in this area is tax competition between countries competing for FDI (for example, Janeba, 1995) and the impact of bilateral tax treaties between countries (for example, Chisik and Davies, 2004). Hines (1999) and Gresik (2001) have excellent surveys of the FDI and taxation literature.

Other factors

A variety of other smaller literatures have investigated the effect of other factors on FDI. These include the effects of host-country institutions (Wei, 2000), trade protection policies, and agglomeration and information externalities (Head, Ries and Swenson, 1995; Blonigen, Ellis and Fausten, 2005).

Examination of general-equilibrium model predictions

More recently, empirical efforts have been made to more closely match empirical specifications of country-level FDI activity with general-equilibrium models of MNEs. Most previous empirical work uses gravity-based variations to model country-level FDI patterns where size of countries and distance between them are key regressors. Carr, Markusen and Maskus (2001) instead lay out an empirical specification based on the knowledge-capital model of MNE activity which suggests that factor endowment differences are an important control not found in gravity-based specifications. These endowment differences are important as they proxy for vertical MNE motivations. While Carr, Markusen and Maskus (2001) find that the data fit the knowledge-capital model, follow-up work has found specification issues that call into question evidence of vertical motivations for FDI (see Blonigen, Davies and Head, 2003; Braconier, Norback and Urban, 2005). Alternative approaches by Yeaple...
(2003b) and Hanson, Mataloni and Slaughter (2005), however, have confirmed vertical motivations in the data, at least for certain sectors such as electronics and transportation equipment. Another concern pointed out by Yeaple (2003a) is that third country interactions may matter for FDI patterns. Recent empirical work by Baltagi, Egger and Pfaffermayr (2007) suggests that such effects are important empirically.

The economic impact of FDI and MNE activity

A second significant part of the FDI literature is the examination of FDI impacts on parent and, particularly, host countries. The primary areas of study have been on the effect of FDI on host country wages, technology spillovers, and economic growth. Studies of FDI effects on host-country wages typically begin with the hypothesis that MNEs raise wages in the host country. Part of this is ascribed to the fact that the value of marginal product will be higher with MNEs due to productivity advantages and, thus, MNEs pay higher wages. However, an argument can also be made that MNEs need to pay higher efficiency wages than local firms to attract quality workers in an environment which they are relatively uninformed. Regardless of the explanation, the empirical evidence clearly shows that MNEs pay higher wages in both developed countries (for example, Globerman, Ries and Vertinsky, 1994) and less-developed ones (for example, Aitken, Harrison and Lipsey, 1996).

The more intriguing question is whether there are wage spillovers, in the sense that MNEs raise the wages paid by local firms as well. Spillovers are inherently difficult to identify in the data. Virtually all of the studies rely on interpreting a positive correlation between the presence of foreign firms in a local industry and the wages of local firms as evidence of spillovers. Not surprisingly, the evidence is decidedly mixed across numerous studies, as discussed by Lipsey and Sjöholm (2005). The theoretical development behind this issue is also relatively undeveloped in the literature as to when and where we should expect such wage spillovers.

A related issue is the effects of FDI on wage inequality. If MNEs have different technologies that demand different types of labour from local firms, increased FDI can lessen or exacerbate existing wage inequality. There are a number of cross-country studies that find a variety of FDI effects on wage inequality for the host country. Results for the United States using more detailed industry-level data likewise indicate little to no impact of outbound or inbound FDI on US wage inequality (Slaughter, 2000; Blonigen and Slaughter, 2001). Feenstra and Hanson (1997) provides a model to show how FDI can increase the difference between skilled and unskilled workers’ wages in both host and parent countries with empirical work that finds strong impacts of US FDI activity on Mexican wage inequality. The literature on productivity spillovers from FDI is vast compared with the one on wage spillovers, yet the evidence is decidedly mixed as well (see Görg and Strobl, 2001, for a survey). This is not surprising in many ways. First, theory is ambiguous on this issue. Foreign firms are presumably more efficient than the average local firm. Thus, FDI lowers market shares for local firms, which can lead to productivity losses for these firms, particularly if economies of scale are important. However, better technologies of foreign firms may ultimately leak to local firms through, for example, former employees or common suppliers. The second likely reason for mixed evidence is again the difficulty of identifying spillovers in the data (see Aitken and Harrison, 1999, for a discussion).
There is also a significant literature that attempts to gauge the overall impact of FDI on a host economy's economic growth. Like the trade and growth literature, this is difficult because of the obvious endogeneity issue, which is difficult to overcome. Such a question also relies on aggregate cross-country data, which is often quite poor. Most papers in the literature do not adequately control for these issues, and Carkovic and Levine (2005) points out the statistical sensitivity of these studies’ results.

There are much smaller literatures on a variety of other host- and parent-country effects of FDI. This includes the impact of FDI on parent-country investment and employment (Blomström, Fors and Lipsey, 1997), the effects of FDI on host-country trade policies (Blonigen and Figlio, 1998), and differences in how MNEs adjust to local factor prices (Giorgio, Checci and Turrini, 2003).

Research on foreign exchange market microstructure focuses on the idea that trading is an integral part of the process whereby information relevant to the pricing of foreign currency becomes embedded in spot rates. Micro-based models of this process produce empirical predictions that find strong support in the data. Micro-based models can account for a large proportion of the daily variation in spot rates. They also supply a rationale for the apparent disconnect between spot rates and fundamentals. Micro-based models provide out-of-sample forecasting power for spot rates that is an order of magnitude above that usually found in exchange-rate models.

Models of foreign exchange (FX) market microstructure examine the determination and behaviour of spot exchange rates in an environment that replicates the key features of trading in the FX market. Traditional macro exchange-rate models pay little attention to how trading in the FX market actually takes place. The implicit assumption is that the details of trading (that is, who quotes currency prices and how trade takes place) are unimportant for the behaviour of exchange rates over months, quarters or longer. Micro-based models, by contrast, examine how information relevant to the pricing of foreign currency becomes reflected in the spot exchange rate via the trading process. According to this view, trading is not an ancillary market activity that can be ignored when one considers exchange rate behaviour. Rather, trading is an integral part of the process through which spot rates are determined and evolve. Recent micro-based FX models also differ from other areas of microstructure research in their
focus on the links between trading, asset price dynamics and the macroeconomy. Recent research on exchange rates stresses the role of heterogeneity (for example, Bacchetta and van Wincoop, 2006; and Hau and Rey, 2006). Micro-based exchange-rate models start from the premise that much of the information about the current and future state of the economy is dispersed across agents (that is, individuals, firms and financial institutions). Agents use this information in making their everyday decisions, including decisions to trade in the FX market at the prices quoted by dealers. Dealers quote prices (for example, dollars per unit of foreign currency) at which they stand ready to buy or sell foreign currency; they will purchase foreign currency at their bid quote, and sell foreign currency at their ask quote. Agents that choose to trade with an individual dealer are termed the ‘dealer's customers’. The difference between the value of purchase and sale orders initiated by customers during any trading period is termed ‘customer order flow’. Importantly, order flow is different from trading volume because it conveys information. Positive (negative) order flow indicates to dealers that, on balance, their customers value foreign currency more (less) than their asking (bid) price. By tracking who initiates each trade, order flow provides a measure of the information exchanged between counterparties in a series of financial transactions.

Trading in the FX market also takes place between dealers. In direct inter-dealer trading, one dealer asks another for a bid and ask quote, and then decides whether he wishes to trade. When the dealer initiating the trade purchases (sells) foreign currency, the trade generates a positive (negative) inter-dealer order flow equal to the value of the purchase (sale). Inter-dealer trading can also take place indirectly via brokerages that act as intermediaries between two or more dealers. In recent years electronic brokerages have come to dominate inter-dealer trading, but the inter-dealer order flow generated by brokered trades plays the same informational role as the order flow associated with direct inter-dealer trading.

Micro-based exchange rate determination

At first sight, the pattern of FX trading activity seems far too complex to provide any useful insight into the behaviour of exchange rates. However, on closer examination two key features emerge. First, the equilibrium spot exchange rate does not come out of a ‘black box’. Instead, it is solely a function of the foreign currency prices quoted by dealers at a point in time. This is a distinguishing feature of micro-based exchange rate models and has far-reaching implications. Second, information about the current and future state of the economy will impact on exchange rates only when, and if, it affects dealer quotes. Dealers may revise their quotes in response to new public information that arrives via macroeconomic announcements. They may also revise their quotes based on orders they receive from customers and other dealers. This order flow channel is the means through which dispersed information concerning the economy affects dealer quotes and hence the spot exchange rate. The role played by order flow in transmitting information to dealers, and hence to their quotes, is another distinguishing feature of micro-based exchange rate models.

Micro-based models incorporate these two features of FX trading into a simplified setting. Canonical multi-dealer models, such as Lyons (1997) and Evans and Lyons (2002a), posit a simple sequence of quoting and trading. At the start of each period, dealers quote FX prices to customers. These prices are assumed to be good for any amount and are publicly observed. Each dealer then receives orders from a subset of agents, his customers. Dealers next quote prices in the inter-dealer market. These prices, too,
are good for any quantity and are publicly observed. Dealers then have the opportunity to trade among themselves. Inter-dealer trading is simultaneous and trading with multiple partners is feasible. In this trading environment, optimal quote decisions take a simple form; all dealers quote the same FX price to both customers and other dealers. We can represent the period-

\[ s_t = (1 - b) \sum_{i=0}^{\infty} b^i E[f_{t+i}|\Omega^D_t], \]

where \( 0 < b < 1 \). \( s_t \) is the log price of foreign currency quoted by all dealers, and \( f_t \) denotes exchange rate fundamentals. The form for fundamentals differs according to the macroeconomic structure of the model. For example, in Evans and Lyons (2004b) \( f_t \) includes home and foreign money supplies and household consumption. In models where central banks conduct monetary policy via the control of short-term interest rates (that is, follow Taylor rules), \( f_t \) will include variables used to set policy. More generally, \( f_t \) will include a term that identifies the foreign exchange risk premium.

While eq. (1) takes the present value form familiar from standard international macro models, here it represents how dealers quote the price for foreign currency in equilibrium. All dealers choose to quote the same price in this trading environment because doing otherwise opens them up to arbitrage, a costly proposition. (Recall that quotes are publicly observed and good for any amount, so any discrepancy between quotes would represent an opportunity for a riskless trading profit.) Consequently, the month-\( t \) quote must be a function of information known to all dealers. Equation (1) incorporates this requirement with the use of the expectations operator, \( E[. | \Omega^D_t] \), that denotes expectations conditioned on information common to all dealers at the start of month \( t \), \( \Omega^D_t \). This is not to say that all dealers have the same information. On the contrary, the customer order flows received by individual dealers represent an important source of private information, so there may be a good deal of information heterogeneity across dealers at any one time. The important point to note from eq. (1) is that, due to the ‘fear of arbitrage’, individual dealers choose not to quote prices based on their own private information. In this trading environment dealers use their private information in initiating trade with other dealers, and, in so doing, contribute to the process through which all dealers acquire information.

The implications of micro-based models for the dynamics of spot rates are most easily seen by rewriting (1) as

\[ \Delta s_{t+1} = \frac{1-b}{b} (s_t - E[f_t|\Omega^D_t]) + \epsilon_{t+1}, \]

\[ (2) \]
where $\Delta s_{t+1} = s_{t+1} - s_t$, and

$$
\epsilon_{t+1} = \frac{1-b}{b} \sum_{i=1}^{\infty} b^i \left( E[s_{t+i}|\Omega_t] - E[s_{t+i}|\Omega_t^D] \right).
$$

Equation (2) decomposes the change in the log spot rate (that is, the depreciation rate for the home currency) into two components: the expected change $E[\Delta s_{t+1}|\Omega_t^D]$ identified by the first term, and the unexpected change, $\epsilon_{t+1} = s_{t+1} - E[s_{t+1}|\Omega_t^D]$, shown in eq. (3). Both terms contribute to exchange rate dynamics in micro-based models. In equilibrium, dealers’ period-$t$ quote must be based on expectations, $E[\Delta s_{t+1}|\Omega_t^D]$, that match the risk-adjusted returns on different assets. This means that variations in the interest differential between home and foreign bonds can contribute to the volatility of the depreciation rate via the first term in (2). The second term, $\epsilon_{t+1}$, identifies the impact of new information received by all dealers between the start of periods $t$ and $t+1$. Equation (3) shows that new information impacts on the FX price quoted in period $t+1$ to the extent that it revises forecasts of the present value of fundamentals based on dealers’ common information.

As an empirical matter, depreciation rates are very hard to forecast, so the dynamics of spot rates are largely attributable to the effects of news. Here micro-based models have a big advantage over their traditional counterparts because their trade-based foundations provide detail on how news affects spot rates. In particular, as eq. (3) indicates, micro-based models focus on how new information about the fundamentals reaches dealers and induces them to revise their FX quotes.

News concerning fundamentals can reach dealers either directly or indirectly. Common knowledge (CK) news operates via the direct channel. CK news contains unambiguous information about current and/or future fundamentals that is simultaneously observed by all dealers and immediately incorporated into the FX price they quote. In principle, macroeconomic announcements (for example, on GDP, industrial production or unemployment) could be a source for CK news, but in practice they rarely contain much unambiguous new information. In fact, CK news events appear rather rare. The indirect channel operates via order flow and conveys dispersed information about fundamentals to dealers. Dispersed information comprises micro-level information on economic activity that is correlated with fundamentals. Examples include the sales and orders for the products of individual firms, market research on consumer spending, and private research on the economy conducted by financial institutions. Dispersed information first reaches the FX market via the customer order flows received by individual dealers. These order flows have no immediate impact on dealer quotes because they represent private information to the recipient dealer. The information in each customer flow will impact on quotes only when it is known to all dealers. Inter-dealer order flow is central to this process. Individual dealers use their private information to trade in the inter-dealer market. In so doing, information on their customer orders is aggregated and
spreads across the market. This process is known as ‘information aggregation’. Dispersed information is incorporated into dealer quotes once this process is complete.

**Empirical evidence**

The appeal of micro-based models is not solely based on their theoretical foundations. In marked contrast with traditional exchange-rate models, micro-based models have enjoyed a good deal of empirical success. Evans and Lyons (2002a) first demonstrated their empirical power when studying the relation between depreciation rates and inter-dealer order flow at the daily frequency. In particular, they show that aggregate inter-dealer order flow from trading in the spot dollar/deutschmark market on day 0 accounts for 64 per cent of the variation in the depreciation rate, \( \Delta s_{d+1} \), between the start of days 0 and 1. This is a striking result because macro models can account for less than one per cent of daily depreciation rates. It is also readily explained in terms of eqs. (2) and (3). Aggregate inter-dealer order flow during day 0 trading provides a measure of the market-wide information flow that dealers use to revise their quotes between the start of days 0 and 1. This contemporaneous relationship between depreciation rates and inter-dealer order flows appears robust. It holds for many different currencies and for different currency-order flow combinations (for example, Evans and Lyons, 2002b; Payne, 2003; and Froot and Ramadorai, 2005). It is also worth emphasizing that order flow’s impact on spot rates is very persistent. There is very little serial correlation in the daily depreciation rates for major currencies, so the order flow impact on current FX quotes persists far into the future.

While consistent with the idea that dispersed information is impounded into spot exchange rates via inter-dealer order flow, these results do not provide direct evidence on the ultimate source of exchange rate dynamics. According to micro-based models, the analysis of customer order flows should provide the evidence. In particular, if inter-dealer order flows measure the market-wide flow of information concerning fundamentals originally motivating customer orders, customer orders should also have explanatory power for depreciation rates. This is indeed the case. Evans and Lyons (2004b) show that a significant contemporaneous relationship exists between depreciation rates and the customer order flows of a single large bank. Moreover, the strength of this relationship increases as we move from a one-day to a one-month horizon. This, too, is consistent with micro-based models: At longer horizons, customer flows from a single bank should be a better proxy for the market-wide flow of information driving spot rates.

Micro-based models also make strong empirical predictions about the relationship between order flows and fundamentals. According to eq. (1), dealers are forward-looking when quoting FX prices, so spot rates embody their forecasts for fundamentals based on common information, \( \Omega^D_t \). One empirical implication of this observation is that spot exchange rates should have forecasting power for fundamentals. While there is some evidence that this is true for variables that comprise fundamentals in many models (Engel and West, 2005), the forecasting power is rather limited. Micro-based models also have implications for the forecasting power of order flows. If order flows convey information about fundamentals that is not yet common knowledge to all dealers (that is, not in \( \Omega^D_t \)), then they should have incremental forecasting power for fundamentals, beyond the forecasting ability of any variable in \( \Omega^D_t \).
This is a strong prediction: it says that order flow should add to the forecasting power of all other variables in $\Omega^D_t$, including the history of spot rates and the fundamental variable itself. Nevertheless, Evans and Lyons (2004b) find ample support for this prediction using customer order flows and candidate fundamental variables such as output, inflation and money supplies. These findings provide direct evidence on the information content of customer order flows, and provide a new perspective on the link between exchange rates and fundamentals.

Dispersed information concerning fundamentals need not come only from the activities of individuals, firms and financial institutions. Scheduled announcements on macroeconomic variables (for example, GDP, inflation or unemployment) can also be a source of dispersed information. If agents have different views about the mapping from the announced variable to fundamentals, then the news contained in any announcement, while simultaneously observed, will not be common knowledge. For example, two firms may interpret the same announcement on last quarter's GDP as having different implications for future GDP growth. Differing interpretations about the implications of commonly observed news will be a source of customer order flows because they imply heterogeneous views about future returns, which in turn induces portfolio adjustment. Thus, micro-based models raise the possibility that the exchange rate effects of macro announcements operate via both a direct channel (that is, when the announcement contains CK news) and an indirect channel. Love and Payne (2003) and Evans and Lyons (2003; 2005b) find evidence that both channels are operable. Evans and Lyons estimate that roughly two-thirds of the effect of a macro announcement is transmitted indirectly to the dollar/deutschmark spot rate via order flow, and one-third directly into quotes. With both channels operating, macro news is estimated to account for more than one-third of the variance in daily depreciation rates. This level of explanatory power far surpasses that found in earlier research analysing the impact of macro news on exchange rates (for example, Andersen et al., 2003). It also further cements the link between spot rates and the macro variables comprising fundamentals.

**Order flows, returns and the pace of information aggregation**

The process by which the information contained in the customer flows becomes known across the market, and hence embedded into FX quotes, is complex. The individual customer and inter-dealer orders received by each dealer contain some dispersed information about the economy, but extracting the information from each order constitutes a difficult inference problem. Under some circumstances the inference problems are sufficiently simple for every dealer to learn all there is to know about fundamentals in a few rounds of inter-dealer trading. In this case, the pace of information aggregation is very fast, so that new information concerning fundamentals is quickly reflected in dealer quotes whether the news is initially dispersed or common knowledge. The resulting dynamics for exchange rates over weeks, months or quarters will be indistinguishable from the predictions of macro models. Under other circumstances, the inference problem facing individual dealers is sufficiently complex to slow down the pace of information aggregation. Here it takes many rounds of inter-dealer trading before the dispersed information concerning fundamentals becomes known across the market. This scenario is much more likely from a theoretical perspective. Evans and Lyons (2004a) show that the conditions needed for fast information aggregation are quite stringent. Of course, because inter-dealer trading takes places continuously, dispersed information could be completely embedded in FX quotes in a short period of
calendar time (for example, a day), even if the pace of information aggregation is slow. In principle, dealers might be able to learn a good deal from the multitude of orders they receive in a typical day, even if individual orders are relatively uninformative. The question of whether it takes significant amounts of calendar time before dispersed information is embedded in FX quotes can be answered only empirically.

If the pace of information aggregation is slow, customer order flows across the market contain information that will become known to all dealers only at a later date. So, if the customer orders received by an individual bank are representative of the market-wide flows, they should have forecasting power for the future market-wide flow of information that drives quote revision. Recent empirical findings support this possibility. Evans and Lyons (2005b; 2005c) show that customer order flows have significant forecasting power for future depreciation rates both in and out of sample. These results are qualitatively different from the contemporaneous empirical link between order flows and depreciation rates discussed above. In the context of eqs. (2) and (3), the market-wide flow of information from period-\(t\) trading impacts on the depreciation rate, \(\Delta s_{t+1}\), via \(\xi_{t+1}\). The contemporaneous link arises because period-\(t\) inter-dealer order flows measure the market-wide information flow, \(\xi_{t+1}\). In contrast, the forecasting power of customer flows for the depreciation rate arises because \(\xi_{t+1}\) contains information that was originally in the customer orders received by individual banks before period-\(t\) trading.

These forecasting results are surprising in terms of both their horizon and strength. In particular, out-of-sample forecasts based on customer flows from month \(t - 1\) can account for roughly 16 per cent of the variation in next month's depreciation rate, \(\Delta s_{t+1}\). This finding suggests that the pace of information aggregation is far, far slower than was previously thought; it seems to take weeks, not minutes, for dispersed information to be fully assimilated across the market. The level of forecasting power is also an order of magnitude above that usually found in exchange rate models. For example, the in-sample forecasting power of interest differentials for monthly depreciation rates is only in the two to four per cent range.

The slow pace of information aggregation may shed light on one of the long-standing puzzles in exchange rate economics; the disconnect between spot exchange rates and fundamentals over short and medium horizons (Meese and Rogoff, 1983). The idea is quite simple. If changes in fundamentals are reflected in spot rates only when information concerning the change is recognized by dealers across the market, the slow pace of information aggregation will mask the link between the depreciation rate and the change in fundamentals over short horizons, because the latter is a poor proxy for the market-wide flow of information. Simulations in Evans and Lyons (2004a) show that this masking effect can be quite substantial. Fundamentals account for only 50 per cent of variation in spot rates at the two-year horizon even though information aggregation takes at most four months.

One factor that might contribute to the slow pace of information aggregation is the presence of price-contingent order flow generated by feedback trading. Stop-loss orders, for example, represent a form of positive feedback trading in which a fall in the FX price triggers negative order flow from customers wishing to insure their portfolios against further losses. Feedback trading of a known form does not complicate the inference problem facing dealers because the orders it generates are simply a function of old market-wide information. However, when the exact form of the feedback is unknown it makes inferences less precise and so slows down the pace of information aggregation. Osler (2005) argues that
feedback trading will be an important component of order flow when quotes approach the points at which stop-loss orders cluster. A fall in FX quotes at these points can trigger a self-reinforcing price cascade where causation runs from quotes to order flow. Some economists argue that the early empirical findings linking order flow and the depreciation rate reflected the presence of positive feedback trading rather than the transmission of dispersed information. Indeed, there is no way to tell whether intra-day causation runs from order flows to quotes or vice verse from just the contemporaneous correlation between order flow and the deprecation rate measured in daily data. However, the new evidence on the forecasting power of order flow for both deprecation rates and fundamentals firmly points to order flow as the conveyor of dispersed information. This is not to say that feedback trading is absent. Portfolio insurance and other price-contingent trading strategies (such as liquidity provision) undoubtedly contribute to order flows, and their presence may actually explain why the pace of information aggregation is so slow.

Future research

Exchange rate research based on micro-based models is still in its infancy. The past few years have seen a rapid advance in theoretical modelling and some surprising empirical results. Advances on the empirical side will be spurred by the greater availability of trading data. On the theoretical side, micro-based modelling may provide new insights into the determinants of the foreign-exchange risk premium, the efficacy of foreign exchange intervention, and the anatomy of financial contagion.

Foreign exchange transactions, known in classical antiquity, developed into markets in the Middle Ages. Italian dealers dominated the market until the 16th century, when they started being replaced by the Dutch and English. The City of London has been the centre of world forex markets since the 18th century and remains dominant even today. Transaction modes have been revolutionized by information technology. Volume has also grown enormously. But personal contact is still important, hence financial centres persist. Article

‘Foreign exchange markets’ is an expression that people normally associate with foreign currency transactions, whether in notes or coins. That association is correct, but foreign exchange markets trade in all transactions concerning debt instruments denominated in foreign currencies. This is not a modern development, even if it is true that debt instruments and the transactions associated with them have multiplied as economies have become more complex and more open to one another.

Origins and causes

Trade in coins and debt instruments denominated in foreign currency is an ancient activity. Reference to it is found in ancient literatures and inscriptions belonging to many different cultures. From what one
can glean from these ancient texts, it was always a type of trade organized by dealers, who were sometimes only brokers but more often than not traded for their own account, and often mixed foreign exchange dealing with merchandizing and lending.

In the development of foreign exchange activities, it is impossible to exaggerate the importance exercised by the Aristotelian prohibition of usury, which the Koran and scholastic doctrine perpetuated in Muslim and Christian lands. Aristotle thought that only living beings could bear fruit. Money, not a living being, was by its nature barren, and any attempt to make it bear fruit (tokos, the Greek for ‘bearing fruit’, also means ‘interest’) was a crime against nature.

The need for intertemporal planning of economic activities requires the use of lending and its remuneration. Human ingenuity discovered, very soon after the Aristotelian prohibition, that while lending gave rise to interest (which was against nature), the sale of one asset against another, including coins, was a legitimate activity. Hence, the price at which that sale occurred could very appropriately hide a lending transaction. There followed an enormous diffusion of asset sales–purchases, which, after the break-up of the Roman Empire in the fifth century AD and the fragmentation of the Roman currency area into many smaller zones, often became foreign exchange transactions. The fluctuation of exchange rates between currencies provided a convincing case of risk associated with foreign exchange activities, and further reduced the possibility of transactors being accused of usury.

Raymond De Roover (1954) attributes to the Aristotelian prohibition the redirection of banking towards foreign exchange transactions that occurred from the early Middle Ages onwards. Since lending and borrowing at interest were outlawed, they had to be hidden inside more and more imaginatively devised foreign exchange transactions. This is a perfect case of financial innovation spurred by legal prohibition, which acquires a momentum of its own, generating a huge crop of by-products. Most of these by-products, and foreign exchange contracts and practices devised in the Middle Ages, are still present in today's markets, often even keeping their original names.

The most typical case is that of the bill of exchange, which is a transaction between two or more agents, giving rise to an exchange of foreign currency to be effected in different places at different times. The multiplicity of transactors, and of the contract's attributes, allows the fashioning of the contract in a remarkable number of different ways, following the needs of the transactors and the development of commercial and banking habits.

The fact that foreign exchange transactions are sales–purchases of assets denominated in foreign currencies, and that for a long time what could easily have been transacted in one currency had to be hidden behind a foreign exchange transaction, contributed from early on to the weaving of foreign exchange theory into an intricate web, as trade flows were recognized to be just one of the factors determining foreign exchange rates. Asset transactions obviously contributed at least as much to their determination. But while trade was visible, asset sales–purchases were not easily detected and recorded, and it was much more difficult to attribute exchange rate oscillations to their influence. This was especially so if, as we have already noted, a great number of such foreign exchange transactions, giving rise to a large volume of bills of exchange, actually hid domestic lending activity.

**Foreign exchange in the Middle Ages: the rise of Italian market supremacy**

The fragmentation of the Roman Empire gave rise in Italy to a fragmentation of monetary sovereignty and to the accompanying early specialization of Italian merchants in foreign exchange transactions. The
fact that the papacy was also seated in Italy made the adherence to religious prohibitions of usury superficially stricter; but, with the help of scholastic doctors, merchants were able to devise ways to circumvent the prohibitions.

All this ended up in helping Italian merchants to develop a vast body of knowledge about foreign exchange banking, which they tried to keep to themselves for as long as they could. Thus they became specialists in the transfer of funds from one place to another. Difficulty and danger connected with travel discouraged the physical transportation of metallic money, which was a scarce good anyway, at least until the diffusion of fiat currency in the 19th and especially the 20th centuries. Whoever could transfer titles to assets between geographically distant places stood to gain a great deal of money and power. Italians became masters of these arcane practices. First Florentine and Venetian bankers, then the Genoese, practically cornered this market for several centuries. They developed an enormous clearing network, encompassing most relevant trading places, where they kept agents and correspondents. As a result they could effect transfers everywhere. Sovereign rulers, who had to transfer vast sums because of their military operations in foreign lands, were the Italian bankers’ best and worst clients. They tried to escape from the bankers’ clutches, and to foster competition, but more often than not they were forced back into the bankers’ hands by the superiority of the Italians’ skills and by the bankers’ monopoly of power. Philip II of Spain confided in a letter his dismay at not being able to understand foreign exchange problems. He had tried to get rid of the Genoese, but had to accept soon after that only they were able to transfer his American treasure from Spain to Flanders, and thus circumvent the maritime power of the English.

The market shift to Atlantic Europe

With the decline of the religious condemnation of usury, and the shift of trade from the Mediterranean to the Atlantic, the Italians’ tight monopoly on the foreign exchange market faded away and was transferred first to Belgium and the Low Countries and then to Great Britain, or, more precisely, to London. It is quite remarkable how this skill always managed to bypass France, despite its being the richest country in Europe. Champagne fairs were dominated by foreign merchants, who monopolized exchange transactions. The same was true in Lyons. In fact, even the transfer of foreign exchange transactions to the shores of the North Sea and the Atlantic should be seen largely as a physical relocation of foreign exchange specialists to the places where trade had flourished. Foreign exchange transactions have remained a footloose activity, practised by a close-knit coterie of specialists who can move their show to where conditions are favourable, decamping without much ado from places where regulators have become too nosy or fiscal requests too oppressive. This is true even in this day of huge national banks and powerful central banks. It was even more apparent when those institutions were in their infancy and international bankers roamed the world free, holding sovereign rulers in their power.

The City of London’s market supremacy

The monopoly that the Italians held over foreign exchange transactions was reproduced in more modern times by the City of London, where even today the largest concentration of such transactions takes place. British bankers have presided over most of the innovations that have taken place in this market because of the development of modern technologies. Everybody has heard of the homing pigeon
informing the House of Rothschild of the outcome of Waterloo – such was the state of information transmission at the beginning of the 19th century. In the second half of that century, however, technical progress in this field advanced by leaps and bounds, revolutionizing foreign exchange technology.

Distance between markets and the slow flow of information had meant that interest rate differentials between different financial markets could remain open for months before being noticed and closed by foreign financial flow. Arbitrage activity had thus been linked, more than to anything else, to seasonal patterns, as one easily discovers by reading contemporary treatises. It was noticed that money was recurrently scarce in one particular month or season in one specific market. Merchants would contribute to fill the gap, if enough profit was expected from transferring money from other places. Alternatively, or concurrently, the Humean specie-flow mechanism would intervene to transform this money scarcity into increased exports and imports. With faster flow of information made possible first by the steam engine, then by the telegraph, then by the international and intercontinental cable, and finally by the radio and telephone, the arbitrage margins between different financial markets came to be closed at speeds that could not be compared with earlier times. This became particularly apparent from the end of the 19th century. However, the vast increase in the speed and volume of foreign exchange transactions which has accompanied innovation in information technology appears to have given just as much chance to foreign exchange speculation, linking together asset markets that had previously remained purely domestic, and by mixing speculation in foreign exchange with commodity speculation in a volume that could not have been attained in previous times.

**Inception of foreign exchange controls**

Given the advances in information technology, the prevalence of speculation over arbitrage could have generated major international financial crises and so endangered the work of the international economy as much as the advances in information technology had enhanced it. The realization of these dangers, and the palpable loss of monetary sovereignty which the linking of financial markets brought in its train, convinced economic authorities in the period between the two world wars to try to isolate their respective national financial markets by foreign exchange restrictions. Although they were practised with great fervour and severity in Britain too, after the Second World War the City of London managed to persuade the authorities to get rid of them and give the City a chance to go back to its earlier domination of the commodities and exchange markets. In spite of the emergence of New York, Tokyo, and Frankfurt as prime financial markets, the hold British bankers have managed to keep over commodities and exchange transactions is indeed remarkable, and can be considered equal in length of time, breadth and intensity only to that previously exercised on the same activities by the Italian bankers.

**Persistence of London's supremacy**

This persistence, in the face of the obvious decline of British and previously Italian economic power, is extremely interesting. The commodities and foreign exchange markets seem to have successfully ridden, and to have used to their benefit, the momentous advances in information technology which came in waves in the 19th and 20th centuries. It was expected for these advances to enhance the diffusion of such transactions, by de-concentrating and de-monopolizing them. This of course has happened, but not nearly to the extent that was expected. Technical innovations have also been used to reinforce market
Having the dollar as a reserve currency has not seemed to help New York become the home of the commodities and foreign exchange markets. Nor does the demotion of sterling seem to have unduly penalized the City as far as those markets are concerned. It is obvious that some of the reasons that have brought merchants to congregate in certain places ever since early times persist even in the age of global real-time transactions. Physical proximity and cultural affinity are still powerful enhancers of smooth and successful transactions, as is the confidence that the government will not disturb operations with crippling regulations or with oscillatory behaviour, which destroys certainty. It is perhaps this unique mix of factors that makes for the permanence of foreign exchange markets in certain places. Other pillars of economic power, like a great industrial structure, seem to be somewhat inimical to the permanence of commodities and foreign exchange markets in a given place. Industry certainly generates exports and foreign exchange transactions; but it soon also develops credit needs of its own, and possibly protectionism, both of which work against the permanence of a foreign exchange market. Governments are asked by industry to adopt policies that go against the total freedom that commodities and exchange markets require in order to thrive. Their adoption of such policies induces the community of foreign exchange dealers to pitch its tents elsewhere.

**Market growth since the 1980s**

This plea for continuity in history must not, however, be to the detriment of realism – and realism imposes a thorough appreciation of the huge increase the foreign exchange market has experienced since the 1980s. As we have already noticed, computer power increased prodigiously in the 1980s and permitted the real-time connection of forex markets across time zones, in a temporal and geographical continuum. Computer power also allowed ever more sophisticated forex contracts to be priced in real time and thus to be executed very rapidly. Among the more exotic contracts, so-called derivatives must be mentioned, which further contributed to increasing the size of forex markets. The size of the market in 2007 is estimated by the Bank for International Settlements (BIS) to be around two trillion dollars. As we noted above, continuity remains a feature of this huge market. London is still the place where more than 25 per cent of all transactions are processed, with New York coming a distant second, and Tokyo an even more distant third. And, in spite of the huge size of the market, a few giant international banks concentrate a remarkable percentage of total transactions. The ten largest dealers account for 70 per cent of total transactions. Six of them are commercial banks and four are investment banks.

**How the market looks today**

At the turn of the millennium, the euro was introduced, an important novel type of currency, not the expression of a sovereign state, but issued by the European Central Bank on behalf of the European Union. This innovation profoundly changed the forex market, as it marked the disappearance of all transactions denominated in the currencies of the European Monetary Union member states, and it meant the arrival of a dominant currency pair the euro/US dollar pair, which in 2004 already accounted, according to the BIS (2004), for 28 per cent of all forex transactions, followed by the US dollar/Japanese yen pair, which accounted for 18 per cent of all transactions. Remarkably, in 2004 14 per cent of all...
transactions were still taking place between the US dollar and the British pound. Since 1985 most British merchant banks have been swallowed up by foreign financial institutions, mostly commercial banks, but the British pound, and London, remain foreign exchange favourites.

The present situation in the forex market thus bears an important echo of past power, in the persistence of the British pound, a testimony of recent world economic events, with the arrival and very rapid establishment of the euro as dominant instrument for forex transactions, and of the Japanese yen as the third most important currency. Almost no trace is yet to be seen in the forex market of the meteoric rise of China on the world economic scene. The Chinese currency has recently gained some current account convertibility, but it will be years before it becomes fully convertible. Until then, it will not be able to form important currency pairs with the other dominant currencies. This should come as no surprise if we remember how many years it took the yen to establish itself in the position it now enjoys in the forex market. It should also constitute a final and conclusive piece of evidence in favour of what was noted above on the international foreign exchange community's susceptibility to national fetters and regulations.

The educator and heterodox monetary economist William Trufant Foster was born in Boston, Massachusetts, on 18 January 1879, and died in Winter Park, Florida, on 18 October 1950. After his father's early death, Foster worked his way through high school and Harvard University, graduating first in his class in 1901. After teaching at Bates College in Lewiston, Maine, he returned to Harvard to take an A.M. in English in 1904, followed by a Ph.D. from Teachers College of Columbia University. His exceptional success as a teacher of rhetoric and a textbook author, and the vision of an ‘ideal college’ presented in his doctoral dissertation (published in 1911), led to his remarkably early promotion from instructor to full professor at Bowdoin College in Brunswick, Maine, in 1905, and his appointment at the first president of Reed College in Portland, Oregon, in 1910. Foster served as an inspector with the American Red Cross in France after US entry into the First World War. Health problems from overwork, together with controversy over his pacifism, led Foster to resign from Reed College in December 1919. He then became director of the Pollak Foundation for Economic Research, founded in Newton, Massachusetts, by his Harvard classmate Waddill Catchings, an investment banker. The Pollak Foundation was a vehicle for expounding the heterodox monetary theories of Foster and Catchings, and, through Houghton Mifflin, published their books on *Money* (1923), *Profits* (1925), and *Business without a Buyer* (1927). They held that recessions, such as that of 1920–1, happen because a monetary economy does not automatically generate enough consumption to buy potential output. Saving, which enriches the individual saver, contributes to recessions both by reducing consumption and, through investment, by adding to the potential output to be purchased. Because of this paradox of thrift and their support for counter-cyclical public works, Foster and Catchings had been considered as possible forerunners of Keynesian macroeconomics, while their emphasis on a steadily increasing rate of...
investment as a prerequisite for stable growth has been related to later Harrod–Domar growth theory (see Gleason, 1959; Carlson, 1962). Their support for the proposal by Carl Snyder of the Federal Reserve Bank of New York that the volume of currency and credit be increased by a steady four per cent a year has been suggested as an anticipation of monetarist policy rules (Tavlas, 1976). In late 1928, with President-elect Hoover's endorsement and with Foster as his expert witness, Governor Ralph Brewster of Maine submitted to the annual governors’ conference a plan for standby credit authorization for $3 billion of federal, state and local public works to be undertaken once a federal board certified the imminence of a recession (Dorfman, 1959; Barber, 1985). Although Foster and Catchings promoted this as the ‘Hoover Plan’, once the Depression hit President Hoover felt that budget deficits precluded such large-scale counter-cyclical public works.

The Pollak Foundation offered a $5,000 prize for the best adverse criticism of Foster and Catchings's Profits, with the competition judged by the two most recent presidents of the American Economic Association, Wesley Mitchell and Allyn Young, and by Owen Young of General Electric. The competition attracted 431 submissions, and the four winning essays were published with a reply by Foster and Catchings as Pollak Prize Essays (1927). Also in 1927, the magazine World's Work offered a $1,000 prize for the best essay on a series of articles by Foster and Catchings in the magazine. These prizes brought Foster and Catchings considerable professional attention, as did the Pollak Foundation's publication of substantial studies of index numbers by Irving Fisher and of real wages by Paul Douglas (who had been Foster's student at Bowdoin and junior colleague at Reed). Foster and Catchings also found a more popular audience: The Road to Plenty (1928), presented as a conversation aboard a train, sold 58,000 copies, while Progress and Plenty (1930) reprinted 206 of their 400 two-minute talks on economic problems distributed by the McClure Newspaper Syndicate in 1929 and 1930.

Financial difficulties forced Catchings to withdraw from active participation in the Pollak Foundation during the Depression. Foster continued to direct the foundation, and for three years in the 1930s wrote a syndicated daily newspaper column on economics for the layperson. He served on the Consumers Advisory Board of the National Recovery Administration from 1933 to 1935 (recommended by Paul Douglas) and was an economic adviser at the International Labor Conference in Geneva in 1938.

Fractals have become increasingly useful tools for the statistical modelling of financial prices. While early research assumed invariance of the return density with the time horizon, new processes have recently been developed to capture nonlinear changes in return dynamics across frequencies. The Markov-switching multifractal (MSM) is a parsimonious stochastic volatility model containing arbitrarily many shocks of heterogeneous durations. MSM captures the outliers, volatility persistence and power variation of financial series, while permitting maximum likelihood estimation and analytical multi-step forecasting. MSM compares favourably with standard volatility models such as GARCH(1,1) both in- and out-of-sample.

Article
The word ‘fractal’ was coined by the French mathematician Benoît Mandelbrot (1982) to characterize a wide class of highly irregular scale-invariant objects. It originates from the Latin adjective *fractus*, meaning ‘broken’ or ‘fragmented’. The defining characteristic of fractals is that their degree of irregularity remains the same at all scales. This invariance permits parsimonious modelling of complex objects, and has been useful for analysing a wide variety of natural phenomena. The entry reviews the use of fractals in economics and finance, and more specifically their application in the statistical modelling of asset returns, which has been a remarkably active field since the early 1960s. Consider the price $P(t)$ of a financial asset, such as a stock or a currency, and let $p(t)$ denote its
logarithm. The process \( p(t) \) is said to be self-similar if there exists a constant \( H > 0 \) such that for every set of instants \( t_1 \leq \cdots \leq t_k \) and for every \( \lambda > 0 \), the vector \( \{ p(\lambda t_1), \ldots, p(\lambda t_k) \} \) has the same distribution as \( \lambda^H \{ p(t_1), \ldots, p(t_k) \} \), that is,

\[
\{ p(\lambda t_1), \ldots, p(\lambda t_k) \} \overset{d}{=} \lambda^H \{ p(t_1), \ldots, p(t_k) \}.
\]

The constant \( H \) is called the self-similarity index.

Three classes of self-similar processes have been widely used in finance: the Brownian motion, Lévy-stable processes and the fractional Brownian motion, which are successively discussed. The Brownian motion (Bachelier, 1900), with self-similarity index \( H = 1 / 2 \), pervades modern financial theory and notably the Black–Merton–Scholes approach to continuous time valuation. Its lasting success arises from several appealing properties, including tractability and consistency with the financial concepts of no-arbitrage and market efficiency.

The stable processes of Paul Lévy (1924) are characterized by thicker tails than the Brownian motion. They are thus more likely to accommodate the outliers exhibited by financial series, as was pointed out by Mandelbrot in a series of seminal papers (for example, 1963). The increments of Lévy-stable processes are stationary and have stable distributions, where stability refers to invariance under linear combinations (see Samorodnitsky and Taqqu, 1994). Tails are Paretian:

\[
\mathbb{P}\{ p(\Delta t) > x \} \sim c x^{-\alpha} \text{ as } x \to + \infty,
\]

with index \( \alpha = 1 / H \in (0; 2) \). The variance of a Lévy-stable process is infinite, which is at odds with both empirical evidence and mean-variance asset pricing. Furthermore, stable processes have independent increments and thus cannot account for volatility clustering.

The fractional Brownian motion (Kolmogorov, 1940; Mandelbrot, 1965; Mandelbrot and Van Ness, 1968) with \( H > 1 / 2 \) is a self-similar process with strongly dependent returns. Increments are stationary, correlated, and normally distributed. Their autocorrelation declines at the hyperbolic rate

\[
\text{Cov}[r(t); r(t + n)] \sim c (2H - 1) n^{2H - 2} \text{ as } n \to \infty,
\]

where \( r(t) = p(t) - p(t - \Delta t) \) denotes the return on a time interval of fixed length \( \Delta t \). Hyperbolic
autocorrelation is the defining property of long-memory processes, whose use in economics was advanced by the discrete-time fractional integration approach of Granger and Joyeux (1980). While research on long memory has generally been very fruitful in economics (see Baillie, 1996, for a review), the fractional Brownian motion rarely represents a practical model of asset prices. Specifically, long memory in returns is both empirically inaccurate in most markets (Lo, 1991) and inconsistent with arbitrage-pricing in continuous time (Maheswaran and Sims, 1993). There is, however, abundant evidence of long memory in the volatility of returns (for example, Dacorogna et al., 1993; Ding, Granger and Engle, 1993).

In all the above self-similar processes, returns observed at various frequencies have identical distributions up to a scalar renormalization:

\[ p(t + \lambda \Delta t) - p(t) \sim \lambda^H p(\Delta t). \]

Most financial series, however, are not exactly self-similar, but have thicker tails and are more peaked in the bell at shorter horizons. This observation is consistent with the economic intuition that high-frequency returns are either large if new information has arrived, or close to zero otherwise. Thus, self-similar processes do not capture in a single model the most salient features of asset returns.

A partial solution to these difficulties is provided by the multifractal model of asset returns (MMAR; Calvet, Fisher and Mandelbrot, 1997; Calvet and Fisher, 2002a). This approach builds on multifractal measures (Mandelbrot, 1974), which are constructed by the iterative random reallocation of mass within a time interval. The MMAR extends multifractals from measures to diffusions. The asset price is specified by compounding a Brownian motion with an independent random time-deformation:

\[ p(t) = B(\Theta(t)), \]

where \( \Theta \) is the cumulative distribution of a multifractal measure \( \Theta(t) = \mu[0, t] \). Returns are uncorrelated and the price \( p \) is a martingale in MMAR, which precludes arbitrage. The time deformation induces sharp outliers in returns and long memory in volatility. The MMAR also captures nonlinear changes in the return density with the time horizon (Lux, 2001).

The price \( p \) inherits highly heterogeneous time-variations from the multifractal measure. Its sample paths are continuous but can be more irregular than a Brownian motion at some instants. Specifically, the local variability of a sample path at a given date \( t \) is characterized by the local Hölder exponent \( \alpha(t) \), which heuristically satisfies

\[ |p(t + dt) - p(t)| \sim \epsilon_t(dt)^{\alpha(t)} \text{ as } dt \to 0. \]
Traditional jump diffusions impose that $\alpha(t)$ be equal to 0 at points of discontinuity, and to $1/2$ otherwise. In a multifractal process, however, the exponent $\alpha(t)$ takes a continuum of values in any time interval.

Asset returns at different frequencies satisfy the moment-scaling rule:

$$E[|p(\Delta t)|^q] = c_q(\Delta t)^{\tau(q) + 1},$$

which holds for every (finite) moment $q$ and time interval $\Delta t$. These moment restrictions represent the basis of estimation and testing (Calvet, Fisher and Mandelbrot, 1997; Calvet and Fisher, 2002a; 2002b; Lux, 2004). The MMAR provides a well-defined stochastic framework for the analysis of moment-scaling, which has generated extensive interest in econophysics (for example, LeBaron, 2001). The multifractal model is also related to recent econometric research on power variation, which interprets return moments at various frequencies in the context of traditional jump-diffusions (for examples, Andersen et al., 2001; Barndorff-Nielsen and Shephard, 2004).

Despite its appealing properties, the MMAR is unwieldy for econometric applications because of two features of the underlying measure: (a) the recursive reallocation of mass on an entire time-interval does not fit well with standard time series tools; and (b) the limiting measure contains a residual grid of instants that makes it non-stationary.

The Markov-switching multifractal (MSM) resolves these difficulties by constructing a fully stationary volatility process that evolves stochastically through time (Calvet and Fisher, 2001; 2004). MSM builds a bridge between multifractality and regime-switching, which permits the application of Bayesian filtering and maximum likelihood estimation to a multifractal process. Volatility is driven by the first-order Markov state vector $M_t = (M_{1,t}, M_{2,t}, \ldots; M_{K,t}) \in R^K_+$, whose components have unit mean and heterogeneous persistence levels. In discrete time, returns are specified as

$$r_t = \sigma(M_{1,t}M_{2,t}\ldots M_{K,t})^{1/2}\varepsilon_t$$

(2)

where $\sigma$ is a positive constant and $\{\varepsilon_t\}$ are independent standard Gaussians.

Volatility components follow independent Markov processes that are identical except for time scale. Given the volatility state $M_t$, the next-period multiplier $M_{K,t+1}$ is drawn from a fixed distribution $M$ with probability $\gamma_k$, and is otherwise left unchanged.
Components differ in their transition probabilities $\gamma_k$ but not in their marginal distribution $M$. The transition probabilities are tightly specified by $\gamma_k = 1 - (1 - \gamma_1)^{b k^{-1}}$, which is approximately geometric at low frequency: $\gamma_k \sim \gamma_1 b^{k^{-1}}$. In empirical applications, a unique scalar $m_0$ typically determines the distribution $M$. The return process (2) is then specified by the four parameters $(m_0, \sigma, b, \gamma_1)$. Since the number of frequencies $k$ can be arbitrarily large, MSM provides a tight specification of a high-dimensional state space. The approach conveniently extends to continuous time (Calvet and Fisher, 2001) or a multivariate setting (Calvet, Fisher and Thompson, 2006).

When $M$ has a discrete distribution, the state space is finite and MSM defines a stochastic volatility model with a closed-form likelihood. It then bypasses the estimation problems of traditional stochastic volatility settings based on smooth autoregressive transitions. On the other hand when $M$ has a continuous (for example, lognormal) distribution, estimation can proceed by simulated method of moments (Calvet and Fisher, 2002b), generalized method of moments (Lux, 2004), or simulated likelihood via a particle filter (Calvet, Fisher and Thompson, 2006).

MSM tends to substantially outperform traditional models both in and out of sample. Calvet and Fisher (2004) thus report considerable gains in exchange rate volatility forecasts at horizons of 10 to 50 days as compared with GARCH-type processes. Lux (2004) obtains similar results with lognormal MSM using linear predictions. Furthermore, bivariate MSM compares favourably with multivariate GARCH under criteria such as the likelihood function, integral transforms and value-at-risk (Calvet, Fisher and Thompson, 2006).

The integration of multifrequency models into asset pricing is now at the forefront of current research. Calvet and Fisher (2005a) thus introduce a parsimonious equilibrium set-up in which regime shifts of heterogeneous durations affect the volatility of dividend news. The resulting return process is endogenously skewed and has significantly higher likelihood than the classic Campbell and Hentschel (1992) specification. Calvet and Fisher (2005b) similarly illustrate the potential of MSM for building parsimonious multifrequency jump-diffusions.

France, economics in (after 1870)

Abstract

After 1870, classical liberals gradually lost their influence. Political economy began to be taught in university faculties of law, and also in some of the engineering schools. This laid the foundations for a long-standing divide between two groups of economists. Professors of political economy in the law faculties often inclined to an institutionalist approach, and opposed the mathematical approach to political economy that economic engineers and some mathematicians adopted. This antagonism abated after the Second World War as French economists strengthened their relations with foreign colleagues.

The publication of Léon Walras's *Éléments d'économie politique pure* in 1874 marks an important turning point in the history of economic analysis. But for many years his ideas remained misunderstood. Recognition of the importance of his work on the part of French economists followed a lengthy and difficult period, in which the publication of Maurice Allais's *À la recherche d'une discipline économique, l'économie pure* in 1943 marks a vital stage. Allais introduced the analysis of risk and intertemporal choice to the theory of general equilibrium and in this way posed new questions to which Gérard Debreu, Marcel Boiteux, Edmond Malinvaud and many others would respond. Nonetheless, many French economists had considerable reservations about the theory of general equilibrium. They favoured an emphasis upon the role of institutions, and the need to integrate the various elements of the social sciences – economics, sociology and history – if economic phenomena were to be understood.

From 1870 to 1943

In the years after 1870 the domination of the liberal school was increasingly questioned, and this was largely the consequence of institutional developments (Le Van-Lemesle, 2004). The teaching of political economy was introduced into the faculties of law in 1877, but the professors in law in charge of this teaching progressively became scientifically independent. In 1887 they founded the *Revue d'Économie Politique* so that the new political economy might be more widely diffused, and this quickly became far more influential than the liberal *Journal des Économistes*.

Classics liberals and institutionalists

The best known of the last classical liberals, Gustave de Molinari and Paul Leroy-Beaulieu, sought to defend very different positions. Liberals had maintained that the state should limit itself to the provision of individual security but de Molinari (*L'évolution politique et la révolution*, 1884) argued that it was necessary to go much further. All branches of production, including the judiciary, the police and defence, should be freed from state control. If a need for security exists and if the state does not foresee it, then this need will be met by private initiative, and so much the better. Leroy-Beaulieu did not challenge the principle that a state had its prerogatives and that it would exercise them. However, while Molinari defended the classical theory of distribution, Leroy-Beaulieu (*Essai sur la répartition des richesses*, 1881) thought it necessary to abandon this theory. The consequences which it foresaw – a fall in the rate of profit, an increase in the rate of rents, and a reduction of wages to subsistence levels – were refuted by factual evidences: wage rates were increasing, and rents were diminishing in proportion. Institutionally Leroy-Beaulieu belonged to the group of older classical liberals, but he abandoned the propositions basic to this school.
Charles Gide occupied a leading place among the professors of the law faculties. He was a staunch eclectic, which led him to reject extreme theses in favour of an intermediate synthesis. In studying prices and distribution he made use of ideas borrowed from Jevons and Walras, but played down their contribution. If Jevons's analysis of value was ingenious, it was nonetheless not new; Condillac had long before made clear that the utility of an object determined its value. Gide was somewhat reluctant to make use of the notion of marginal productivity, since he did not consider that the distribution of revenues to be solely determined by economic factors, and he argued (*Principes d'économie politique*, 1901) that social relations among agents also played a part.

Adolphe Landry and François Simiand were part of a very small group of philosophers educated at the École Normale who chose to become economists. In his *Révolution démographique* (1934) Landry distinguished three types of regulation as of importance to the study of demographic development. First, under the ancien régime, parents did not concern themselves with the consequences of the birth of children. Mortality played the principal role in regulating the population. Second, during the transitional phase, men and women chose their age of marriage so that they might maintain the standard of living to which they had become accustomed, and there was no voluntary birth control in marriage. Third, in modern times, on the contrary, the timing and number of births had become a matter of choice. Landry used this argument to persuade parliament to vote through, in 1932, 1939 and 1946, the three laws which determine the allocations of family support: for if the birth rate is the product of choice, then one can hope to end demographic decline with the aid of a system of financial incentives.

French positive economics developed with the work of François Simiand (*La méthode positive en science économique*, 1912). He rejected both the approach of the German Historical School as well as what he termed ‘orthodox’ economics, referring in this way to French liberals, the Austrian School and mathematical economics. The German Historical School, he suggested, lacked principles and had produced nothing but an empty accumulation of knowledge. ‘Orthodox’ economists constructed theories that were poorly founded, since they drew upon incomplete or implicit observations. Simiand, by contrast, made use of long statistical series, analysing them in terms of models that described the behaviour of social groups. He applied this method to the study of the development of wages and prices in his major works of the 1930s (*Recherches anciennes et nouvelles sur le mouvement des prix du 16ème au 19ème siècle*, 1932, et *Le salaire, l'évolution sociale et la monnaie*, 1932). In these works he argued that variations in the money supply drove the cycle and that cyclical fluctuation was a necessary part of economic progress. This approach influenced Ernest Labrousse (*Esquisse du mouvement des prix et des revenus au 18ème siècle*, 1933) who, on the basis of meticulously constructed statistical series, put forward a simple theory of the crisis of the ancien régime as engendered by the agricultural cycle: bad harvests brought about a rise in the price of wheat, consumers spent an increasing proportion of their revenues on agricultural goods and so the crisis was transmitted to industry.

Albert Aftalion (*Les crises périodiques de surproduction*, 1913) and Jean Lescure (*Des crises générales et périodiques de surproduction*, 1906) took their inspiration from Say and their analysis of crises from Juglar. They retained Say's Law of Markets. From Juglar they drew three lessons. Their analysis rested upon study of empirical data. They used price movements to determine the phases of the cycle. The crisis was defined as the point at which prices ceased rising, inevitably followed by a fall in prices – it was only one phase of the cycle. But whereas Juglar put forward a monetary theory of crises, Aftalion and Lescure proposed a real theory. At the bottom of a recession production had difficulty satisfying needs. The marginal utility of consumer goods and their prices would thus rise. To meet this demand,
machinery is needed. The price of machinery rises and in turn stimulates production. However, when the new production goods come into service consumer goods become over-abundant. Their final utility and value collapse and this has repercussions for the price of machinery. The crisis becomes almost, or entirely, general. Lescure placed the emphasis on the role of profits and on the interdependence between activities. At the end of an expansionary phase, costs rise faster than prices and new enterprises that have paid a high price for their means of production face losses. Their insolvency brings about the crisis, which spreads from one branch to another. The crisis is not general, but generalized.

Over a lengthy period, French economists had criticized the version of the quantity theory of money advocated by partisans of the Currency School, and this continued after 1870. Bertrand Nogaro (*Contribution à une théorie réaliste de la monnaie*, 1906) noted that money was the object neither of demand nor supply; the general price level is not determined, as the quantity theory supposed, by the relation between the money stock and desired cash holdings, but by global demand for goods, or as argued by Aftalion (*Monnaie, prix et change*, 1927), by the relationship between monetary revenue and the volume of production. The consequences of a variation in the stock of money depended for its effect upon the demand and supply of goods, and hence on the way that it is introduced into the system.

Nogaro and Aftalion rejected the idea that variations in the price of goods explained variations in the exchange rate. The direction of causality was not necessarily from prices to exchange rates. The current exchange rate depended upon the expected future rate and, since it affected producer costs and agents’ revenues, domestic prices are determined by psychological factors.

**Walras, the mathematicians and the statisticians**

For many years both mathematicians and engineers had reservations about the idea of general equilibrium. They considered partial equilibrium quite adequate for the study of most problems. Walras's use of mathematics seemed quite superfluous. Even when the importance of Walras's work gradually became more generally accepted, his successors remained critical of his methodology. Instead they shared Pareto's view that the criterion of a theory's truth lies in its correspondence to reality. They did not attempt to resolve the theoretical difficulties presented by the Walrasian construct. Instead, they were interested in understanding the instruments which permitted the analysis of facts while using economic theory. The procedure followed by Albert Aupetit, the leading disciple of Walras, is quite typical. His dissertation, *Essai sur la théorie générale de la monnaie* (1901), presents itself both as a development of Walrasian monetary theory and as verification of its empirical relevance.

The tradition of engineer–economists continued with Clément Colson. His works (*Cours d’économie politique*, 1901–7) drew more on Dupuit's analysis than on Walras's, but he encouraged François Divisia, René Roy and Jacques Rueff to study Walrasian theory since he was aware of the importance of the interdependence of markets. It was not possible to study the determination of wages independently of that of the rate of interest. Since labour and capital are substitutes, the proportions in which they should be employed depended both upon the wage rates and interest rates. Here one can see at work the fundamental idea that had driven Walras to use mathematics and make use of models of general equilibrium.

Divisia's analysis of monetary phenomena illustrates this connection of theory to empirical research. It had sometimes been thought that the quantity equation implies that prices vary with the quantity of money. Divisia rejected this idea, arguing that the transactions equation is an identity. Appealing to
statistical observation for verification is an absurdity, but it does allow the definition of what should be an indicator of prices. Weights are quantities of goods and services exchanged, not quantities produced or consumed. Divisia (*L'indice monétaire et la théorie de la monnaie*, 1925–6) explained that it is not possible to set these weights; the index should be a chain index. In order to determine the value of money in 1900 relatively to its value in 1800, it is not enough to know the quantities of goods and services bought in 1800 and 1900, all the intermediate values should also be known. René Roy followed the same line of argument. He introduced (*De l’utilité, contribution à une théorie des choix*, 1942) the idea of the indirect utility function to demonstrate that the consumer price index is the number by which primary prices have to be multiplied to render the satisfaction of an individual (under the assumption of constant monetary income) equal to his satisfaction at current prices.

Even while invoking Walras, Rueff appeared above all to be the defender of classical arguments against attack by Institutionalists and by Keynes. Contrary to Nogaro, he argued (*Théorie des phénomènes monétaires*, 1926) that price variations are determined by effective holdings of cash relative to desired holdings. He based his arguments on a reformulation of the theory of purchasing power parity in dealing with the problem of transfers. Contrary to Keynes, he maintained that the sole levy that would enable the Germans to pay reparations to France would be a rise in taxes. Of course, in the flexible exchange rate regime that was then prevailing, the D-Mark would depreciate and the wage rates of German workers expressed in foreign currency would diminish; but the price of German products would diminish in proportion, so that real wages remained unchanged. It was, however, his analysis of unemployment that made him famous. Following the First World War, unemployment rose in Great Britain and changed in nature: instead of being cyclical, it became permanent. Drawing upon the relation he had put forward between unemployment and the real wage rate, Rueff suggested that this development followed from the emergence of a system of unemployment relief which checked the fall in the money wages despite the existence of an excess labour supply.

The establishment of a more direct link between theory and empirical research involved the development of statistics. Lucien March was the first Frenchman to make Karl Pearson's work known, and he took (*Les principes de la méthode statistique*, 1930) from Pearson three fundamental techniques: the method of moments, the system of curves, and correlation analysis. Marcel Lenoir's 1913 doctoral dissertation (*Etudes sur la formation et le mouvement des prix*), which dealt with price formation and price movements, marked the beginning of econometrics. He not only made careful use of correlation and regression, but he posed, and resolved, the problem of identification. If one had a time series of quantities exchanged and their prices it was possible to plot a path on a graph, but not to interpret this graph as a supply or a demand curve. Lenoir, using moving averages, plotted the long-run trend of cyclical fluctuations. He then calculated regression coefficients and interpreted his results by introducing the idea that short-run variations in prices reflected shifts of the demand curve, while long-term variations were more indicative of shifts in the supply curve and the influence of monetary factors.

Apart from the engineers, French mathematicians took hardly any interest in political economy. Two of them however, Louis Bachelier and Émile Borel, did, at the beginning of the 20th century, make fundamental contributions to the development of economic science. The arguments advanced in Bachelier's *Théorie de la speculation* (1900) lie at the origins of the mathematical analysis of finance: here can be found the essentials of the theory of efficient markets and the premises of the notion of Brownian motion which he developed in 1913. Borel's point of departure is the analysis made by Joseph Bertrand of the game of baccarat in his *Calcul des probabilités* (1889). Bertrand highlighted the
existence of a strategic interdependence between the players similar to that which, he suggested, Cournot had wrongly ignored in his analysis of duopoly. But Borel in turn accused Bertrand of overlooking the case where players determined their strategy by drawing lots. He argued that, if one were to reveal the psychological mechanism governing choices, then it had to be connected to the notion of probability: at each moment, each player chooses his or her strategy with a given probability. The player's mathematical hope of gain depends on the way in which the probabilities are allocated to each alternative. In a symmetric game no information can provide one of the players with the certainty of the gain advantage. The best strategy is to distribute probabilities so that one does not lose whatever the opponent does. Borel demonstrated in *La théorie du jeu et les équations intégrales à noyau symétrique* (1921) that a solution exists for a game in which two players could choose between three ways of playing. Nonetheless, it was von Neumann who in 1928 demonstrated at a general level the theorem of the minimax. Jean Ville suggested in 1938 a more simple demonstration, and showed that the result applied to continuous variables.

**From 1943 to the present day**

The publication in the early 1940s of books by Robert Marjolin (*Prix, monnaie et production*, 1941), Maurice Allais (*À la recherche d’une discipline économique*, 1943), François Perroux (*La valeur*, 1943) and by Jacques Rueff (*L’ordre social*, 1945) all testify to a shift in the analyses of French economists. But if they were all certain of the need for a break with traditional liberalism, their work led in different, even contradictory, directions.

**Liberals, Keynesians and Institutionalists**

If, despite the efforts of Daniel Villey and Louis Baudin, the heritage of French classical liberalism was fading, after 1940 liberalism experienced a renaisance, but it was a liberalism quite different from that of Molinari and Leroy-Beaulieu. Its most typical representatives, Rueff and Rist, admired Walras for the manner in which he showed that variations in prices always led to equilibrium, since they continued up to the point where they stabilized. René Courtin took up exactly this point in his *Cours de théorie économique* (1950) when he accused Keynes of having assumed absolute rigidity of prices, and of nominal wages in particular. If such a rigidity exists (a doubtful interpretation of Keynes's book), it is never absolute, for while it is capable of explaining unemployment in the short run, it cannot explain its persistence. According to Rueff, the modern social order rests on two institutions: property rights which prevent appropriation by violence, and the market, with its characteristic flexibility of prices which mutually adjust to the point where equilibrium is reached. A property right should be understood as a pool of value, of known volume, which can be filled with whatever wealth offered on the market at the behest of its owner. In so far as the value of this pool corresponds to the value of the goods that it contains, one can say that the right is a real one. But if this is not so, then the right is false. Rights of this sort can be introduced in a number of ways. The simplest example is that of a budget deficit financed by the creation of money. The state, by buying goods or leasing services, creates rights for its creditors. When these expenditures are covered by taxes the rights are real; but if they are not so covered then they are false rights – state creditors hold paper claims to wealth which does not exist. Inevitably, policies of this kind lead to inflation. And in so conducting itself the government weakens the judicial system that
protects the social order. Some individuals are not able to provide the rights which they hold with the volume of their choice. The unconditional character of the law is irremediably compromised. Soon after the publication of the General Theory, several works inspired by Keynes appeared, in particular the works of Marjolin (Prix, monnaie et production, 1941), Claude Gruson (Esquisse d’une théorie générale de l’équilibre économique, 1949) and Alain Barrère (Théorie économique et impulsion keynésienne, 1952). They touched on Keynes's work in a very specific manner. Their common problem was the construction of dynamic analysis. They had doubts about the analysis that Keynes had developed in the General Theory, but his book had the merit of addressing – even if not fully consciously – the economic problems of growth, and the most fundamental economic policy issue, that of growth coordinated by deliberate and conscious policy. They showed little interest in the models that Modigliani and Hicks had introduced to analyse short-term monetary and budgetary policy. The IS–LM model was for many years neither taught nor discussed in France.

The majority of university economists remained distanced from both liberal arguments and Keynesian ideas. They argued that it was barely possible to understand economic choices without studying its social, cultural and institutional determinants. They argued for a concrete and positive economics closely linked to other social sciences such as sociology and history. The will to renew the link to positive economics was expressed with the foundation in 1950 of the Revue Économique, which quickly became the most important of French academic journals. Aftalion was among the founders, alongside historians such as Braudel and Labrousse. This conception of economic science led them to place the study of structure, defined as an ensemble of relations characteristic of a social and economic system – following the example of André Marchal's Systèmes et structures (1959) – at the centre of their studies. This method was applied in particular to the analysis of distribution (as in Jean Marchal and Jacques Lecaillon, La répartition du revenu national, 1958–70), production structures, spatial organization and the relationships between national economies.

François Perroux played an important role after the Second World War. He created and directed the Institut de Sciences Économiques Appliquées, which for many years was the leading centre for economic research in France. He became a professor at the Collège de France, the most prestigious French scientific institution. Perroux was open to different influences, and which sometimes appeared to conflict. His first works, in particular his book La valeur, revealed the influence Austrian marginalists had played in his thinking. Économie appliqué, the journal that he edited, was one of the important channels for the diffusion of Keynes’ thinking in France. But his masters were Chamberlin and Schumpeter. He admired Schumpeter as the theorist of innovation, and of creative destruction. What interested him about Chamberlin was the detailed criticism of hypotheses regarding pure and perfect competition. He proposed a general theory of the impact of domination at the level of enterprise, industry and national economy. He saw in this analysis a first and indispensable step towards a much larger synthesis between a theory of the economy and a theory of force, power and of constraints. And so following the Second World War French economists sought to reconnect with the tradition of positive economics founded with Aftalion and Simiand. This institutionalist project collapsed at the end of the 1960s when the new generation turned to either Marxism or the theory of general equilibrium. Nonetheless, institutionalism has remained an active force within French political economy up to the present day with the Convention School (André Orléan, Analyse économique des conventions, 1994) and the theory of regulation (Robert Boyer, La théorie de la régulation: une analyse critique, 1986; Boyer and Saillard, Théorie de la régulation: l’état des savoirs, 1995). In both schools there is agreement that
political economy has to collaborate with other social sciences, history and sociology. The conventionalists are interested in situations where existing prices are insufficient to coordinate the activity of agents on account of uncertainty concerning the future and the quality of products. It is necessary to take account of conventions, understood as legitimate routines of interpretation on the part of agents. The theory of regulation has much larger ambitions: the development of an economic theory which presents an alternative to orthodox theory. Its key concept is the mode of regulation, that is, the manner in which several institutions (the financial system, the wage relation, forms of competition) join together to form a system. Hence the Fordist mode of regulation is characterized by oligopolistic competition, the development of credit, the growth of productivity in mass production and the indexation of wages to gains in productivity. The theory of regulation addresses itself to the description and explanation of different forms of regulation and the specificity of the crises which characterize it.

Reformulations of general equilibrium theory

Divisia and Roy had not profoundly modified the basic framework of Walrasian analysis. In 1943 Allais had put forward some new directions for research by introducing intertemporal economies, where each good is defined by the location and date at which it becomes available, and in which there exist markets for all future goods. He demonstrated, making use of Walrasian tâtonnement, that the equilibrium was stable. He established the two propositions fundamental to the theory of welfare. In 1947, in Économie et Intérêt, he developed a synthesis combining the theory of interest, prices and money. He put forward the first proof of the golden rule. He noted that the existence of transaction costs explained why agents hold money rather than stocks and shares. On this basis he showed that the demand for money is a function of income and of the rate of interest. To illustrate the influence of basic elements of the theory of interest, he introduced a model of overlapping generations. The third fundamental contribution by Allais was the development of a theory of decisions in a state of uncertainty. He showed in Le comportement de l'Homme rationnel devant le risque (1953) that, if one wants to account for the behaviour of agents, it is necessary to take account of characteristics of the index of utility other than its average. Finally, in his La théorie générale des surplus (1981), Allais put forward a complete modification of the frame of reference: in place of the Walrasian market model he put forward a model of markets founded upon the decentralized search for realizable surpluses.

Debreu was trained as a mathematician; he had been the pupil of Henri Cartan and through him had come under the influence of the Bourbaki group which had an axiomatic approach to mathematics. It was through the study of Allais's book À la recherche d'une discipline économique that he was initiated into the theory of general equilibrium. If Debreu found in his reading of Allais the point of departure for his own studies, the reorientation is significant. Up to that point economic analysis consisted in maximizing differentiable functions and deriving the characteristics of maxima from first-order conditions. Debreu abandoned this approach; differential calculus gave way to topological arguments which quite clearly increased the generality and simplicity of theory. But it was not only the mathematical tools that changed. Allais had maintained that ‘in the last analysis it was experience, and only experience, which could determine whether a theory had merit or whether it must be rejected’ (Allais, 1943, p. 116). In the work of Debreu, the concern for rigour dominates: he stipulated that the axiomatic form of analysis or of theory was, strictly speaking, logically entirely disconnected from its interpretations. In his Théorie de la valeur (1954) Debreu took up the analytical framework
employed by Allais in 1943. He demonstrated the existence of an equilibrium and established the two theorems of welfare through the use of convex sets. But he refrained from discussing the problem of stability which was central to Allais's preoccupations. The uniqueness of equilibrium posed a problem. At the end of the 1960s it became evident that the hypotheses under which the uniqueness of equilibrium could be established were too restrictive and that it was necessary to make do with an analysis of local equilibrium. Debreu (1970) demonstrated that, using the hypothesis of differentiability, the number of economies that did not have a local equilibrium was ‘negligible’, that is, ‘contained in a closed set of Lebesgue measure zero’. This result, gained by using the concepts and techniques of differential topology, was the origin of the theory of regular economies that Yves Balasko in particular developed. Following the Second World War the problems of reconstruction, of developing a system of indicative planning, and the management of public enterprises lent Allais, Pierre Massé and their pupils occasion to apply the theoretical propositions that they had elaborated. Among the contributions that French economists made during this period to the theory of the efficient allocation of resources and to the study of public policy, Jacques Drèze (1964) underlined the importance of two themes: the management of public enterprises and the analysis of the conditions under which the accumulation of capital is socially effective.

Edmond Malinvaud (1953) explicitly introduced time into the model of general equilibrium. From this he derived an analysis of the determination of the rate of interest and the meaning that it gives to the proposition that the rate of interest is equal to the marginal productivity of capital. One can only regret that the economists who became involved in the controversy that led to the theory of capital did not always record the results that they arrived at.

Marcel Boiteux (1956) suggested a new approach to the management of public monopolies constrained by budgetary equilibrium. He sought to define a rule for the management of public monopolies by adding to natural connections a new constraint: the budgetary equilibrium. He then defined the shadow prices which were the solution to the problem. Public monopolies should maximize their profits in terms of these shadow prices. The gap between real prices and shadow prices is proportional to the inverse of the price elasticity of compensated demand. While Dupuit and Colson referred to marginal costs, Boiteux took account of shadow marginal costs and prices.

What remains to be determined is whether the enterprise or the regulator is the better at determining tariffs. Jean Tirole and Jean-Jacques Laffont analysed systematically this type of problem by using the theory of contracts. The central idea is that information at the disposal of the managers of a public monopoly is greater than that available to the regulator. It is therefore necessary to determine the nature of the contract which the regulator is able to propose to the enterprise to minimize the costs of production of the good which it produces, while explicitly taking account of the capacity of the agent to manipulate the information.

In Debreu's model, all agents have, \( \textit{ab initio} \), access to a complete system of forward markets and adjustments are made solely by price. All contracts are concluded on the starting date; there is no incentive to reopen markets at a later date. The model is essentially atemporal; the role of money cannot be explained, nor the existence of a market for stocks nor the underemployment of resources. Lindahl and Hicks suggested that a partial equilibrium framework was appropriate for dealing with this kind of problem. Michel Grandmont, in a series of articles published in the course of the 1970s, took up and then systematically developed this notion by assuming that agents formed, at every moment, expectations of the future states of the economy that were not necessarily realized. It was in this
framework that, in the 1970s, Jean-Pascal Benassy, Drèze, Malinvaud and Yves Younès built their theory of disequilibrium. More recently, this framework was used to study the relations between value and money (Grandmont, *Money and value*, 1983), between competition and underemployment (Claude D’Aspremont, Louis Gérard-Varet, Rodolphe Dos Santos, *On Monopolistic Competition and Involuntary Unemployment*, 1990, and Benassy, *The Economics of Imperfect Competition and Underemployment*, 2002) and rational expectations (Roger Guesnerie, *Assessing Rational Expectations*, 2001).

Until the 1970s, French economics had a flavour of its own with engineer–economists interested in planning and the management of public enterprises, and with many professors still following the French institutionalist tradition. Thereafter, this distinctiveness disappeared and, with the exception of the Regulation School, French economists became thoroughly integrated into an international economics profession.

France, economics in (before 1870)

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

From the late 17th century onwards, French economists were major contributors to the rise of economic liberalism, developing many of the analytical tools of political economy. After the Revolution, their major concern was the growth and stability of what they called ‘industrial society’; and a distinction arose between those who claimed that such a society needed to be regulated (the Saint-Simonians) and those in favour of a more decentralized and market-oriented system. After 1848, French economists became deeply involved in the struggle against socialism, and devoted a great deal of energy to the diffusion of sound principles of political economy.

The term *économie politique* first appeared in French in Antoine de Montchrestien's *Traicté de l’économie politique* of 1615. However, during the 17th century there was no French counterpart to English mercantilist thought, nor the kind of economic administration formed on cameralist principles found in Austria and Germany, despite Colbert's attempt to promote the wealth and power of the monarchy through the regulation of commerce. Censorship and the weakness of the French merchants as a class could explain this situation. By the end of the 17th century reflection on economic matters was just beginning, and the monarchy was increasingly conscious of the gravity of the problems that recurrent dearth and high levels of debt represented. This created the conditions for the questioning of economic policy with respect to both the provisioning of markets and taxation.

Vauban argued in his *Dixme royale* (1707) that the principal cause of the monarchy's economic distress was the way its fiscal system was organized. Taxation, he wrote, should be raised in kind as a proportion of the gross yield from the annual harvest. Such a tax would therefore be proportional to agricultural wealth. For commerce and industry he anticipated light taxes that could be passed on in trade.

Boisguilbert's proposal (*Le détail de la France*, 1695) goes much further, even though his attention was likewise directed to taxation. His theory of markets derived from Jansenist moral philosophy, according to which a society in which behaviour was founded upon interests would also be ordered in the same way as a society composed of charitable and pious people. Boisguilbert endorsed laissez-faire as the sole condition permitting the emergence of the ‘proportionate price’, a price at which each gained from participating in exchange and in which each party to the exchange adhered to his budget constraint. He argued that both good and bad harvests disrupted economic activity because they would bring about violent price changes if, as was then the case in France, free competition were absent. Since the wheat market determined the level of agents’ revenues (the remuneration of agricultural capital, the payment of rents), variations in the price of wheat affected other markets. Moreover, the price of wheat was vital to the subsistence of populations. Expectations on the part of agents, whether justified or not, disturbed the economy, and government intervention was not capable of stabilizing the market since such intervention was in turn perceived to be the sign of an even more serious crisis.

After the death of Louis XIV in 1715, the regent accepted John Law's arguments concerning financial policy. According to Law (*Considérations sur le commerce et l’argent*, 1720), France's poor economic performance was due to an inadequate money supply. In 1716, he founded a bank which had the creation of paper money as its principal function; this paper money was supposed to substitute for coins and to permit a refinancing of government debt. Here Law's ideas were at variance with those of Boisguilbert, but Law also went on to argue that money could also be backed by land or by shares, that is, by productive capital. These ideas were given shape with the formation of a commercial company that was granted an exclusive right to trade with Louisiana. The company's shares could be purchased only with *billets d’Etat* (government securities) at their face value instead of being discounted about 70 per cent, but the public could hope for capital gains if the company's trade was well managed. The company gained in this way an exclusive right to the exploitation of vast wealth, and the state transformed its floating debt into long-term debt with a lower interest rate. The merging of the company and the bank permitted monetary expansion and at the same time boosted the value of the company's own shares. At the end of 1719 Law became Comptroller General of Finance – money issue was strong (around a million *livres*) and the rate of interest touched a low point of two per cent. The price of the company's
own shares was stabilized by an office which intervened in the market. The system collapsed as soon as agents sought to exchange their shares and securities for cash. Law's collapse had a lasting impact. The chance of modernizing the public finances had been missed, and for the entire 18th century the collapse weighed heavily on the capacity of the French monarchy to finance its military conflicts with Britain. In addition, a marked suspicion of fiduciary money and banking prevailed right up to the Revolution.

Discussion of monetary matters and Law's system continued in the early part of the 18th century, but gave way to an interest in commerce from the perspective of the legislator, as for instance in Richard Cantillon's *Essai sur la nature du commerce en général* (written around 1728–30 and published in 1755) and Jean-François Melon's *Essai politique sur le commerce* (1736). Cantillon's text is the more notable of the two on account of his theory of price (measured in land) and his general theory of the circulation of goods founded upon the behaviour of the entrepreneur. The theory of the balance of trade is modified by taking account of the value in land of the products exchanged, and Cantillon associates with it an automatic equilibrating mechanism mediated by modifications to the expenditures of landed proprietors. The science of *commerce politique* was given a decisive boost in 1751 with Vincent de Gournay's accession to the post of Supervisor of Commerce. The intention was that France should follow the example of England in supporting mercantile activity, but Gournay's economic thinking was not that original: it remained close to the brand of mercantilism advanced by Josiah Child and which saw in a low rate of interest the best way of promoting commerce. His significance, rather, lay in the fact that he gathered around himself young administrators (such as Véron de Forbonnais, the abbé Morellet, and Turgot) who would be influential up to the time of the Revolution.

The science of commerce that crystallized in de Gournay's writings and those of his group, or in Montesquieu's *Spirit of Laws*, can be characterized by four features. First, trade is composed of flows of goods between nations which exchange their surplus thanks to the practical knowledge of traders. Second, trade depends upon self-interested behaviour, and it implies that the trader has an interest, both economic and symbolic, in keeping to his particular station in life rather than in achieving nobility. Third, trade is the most important form of economic activity. And fourth, the particular interest of the trader could be opposed to that of the state.

1756–1789: From Physiocratic Philosophie économique to Condorcet's social mathematics

From 1750, economic publications multiplied and this growth accelerated in the years leading up to the Revolution. New contributors to the genre emerged with François Quesnay and the Physiocrats during a troubled political period including the Seven Years' War (1756–63) and the Treaty of Paris, under which a large part of the French colonial empire was lost.

Diderot and d'Alembert's *Encyclopédie* presented Forbonnais with the opportunity of writing a series of entries which were then brought together in his influential *Eléments du commerce* (1754). This publicized the views of the group around de Gournay on the importance of monetary flows and a low rate of interest. But there were two other important contributors to the *Encyclopédie*. Rousseau argued that the General Will was the first principle of political economy and the basic rule of government. This proposition opposed republican virtue to wealth and interested behaviour. The abbot Mably took this argument up in criticism of the Physiocrats (*Doutes présentés sur l'ordre légal et essentiel des sociétés politiques*, 1767). The same argument was revived during the Revolution, when the most radical of the Montagnards reclaimed for themselves ancient republican egalitarianism in order to promote the right of
property and economic development through the market.

Quesnay came to political economy from medicine. There he had encountered the then contemporary notion of animal economy – economy understood as a harmonious organization of diverse phenomena which came together in one coherent whole: the body. He transferred this notion, as was fashionable at the time, to the level of the state so that he was able to talk of economic government, a concept vital to the presentation of his ideas. The task of economic government was to administer resources – men, land, money – in such a way that the nation would enjoy abundance; under-employment of resources was not to be attributed to individuals, but to the errors of economic government. According to Quesnay (Grains, 1757), economic government should leave the decision of what is best in matters of culture or trade to the interested behaviour of men. It should limit itself to providing an institutional context favourable to interested behaviour; commercial freedom and a predictable tax levied upon the net product (and not on the gross product as in Vauban) so that productive capital might be maintained. The latter was later elevated to the status of the central variable in the economy since the amount of the net product is always fixed as a proportion of farmers’ circulating capital.

Quesnay elaborated the advantages of free trade in the market for wheat in arguments that Dupont de Nemours and Turgot then adopted. He explained how free trade blunted brutal market fluctuations – a phenomenon noted by Gregory King and elaborated by Charles Davenant (Essay upon the Probable Methods of Making a People Gainers in the Balance of Trade, 1699) in the 17th century – by allowing compensating adjustments between nations. The consumer enjoyed the benefits of more stable prices. The producer who would benefit from a better price will be prompted to produce more – so long as the price did not fall too far as a consequence of a good harvest. These interests conjoin those of the consumer (in the security of provision) and those of the state (enhanced wealth and increased fiscal returns).

In 1758 Quesnay converted to his camp Count Mirabeau, whose L’ami des hommes (1758) on population and commerce had been well received. Their subsequent close collaboration led to the major doctrinal publications of Physiocracy – Théorie de l’impôt (1760) and La philosophie rurale (1763) – in which Quesnay elaborated his idea of the single tax payable by sole proprietors on the grounds that they were the sole recipients of agricultural rent. But the theoretical landmark of this period is the Tableau Économique, which appeared in different versions between 1758 and 1767. There are echoes in the Tableau of Cantillon's approach, his text having circulated in manuscript before 1755. Flows between rural and urban classes are conceived at the highest level of abstraction so that the relation of these classes to each other might be clearly demonstrated. The key difference is that Cantillon was interested in monetary phenomena and commercial uncertainty, matters neglected by Quesnay.

In the initial versions of the Tableau, Quesnay showed how landowners’ expenditures made possible the circulation of the wealth produced by farmers and artisans. The later versions, more ‘macroeconomic’ in form, showed under what conditions the monetary expenditure of a society restricted to three classes (farmers, landowners and artisans) allowed the reproduction of the conditions of agricultural wealth at an optimal level. This final version of the Tableau also allowed the impact on the amount of the net product of accrued luxury expenditures, or of indirect taxation, to be studied; it hence made possible an estimation of their importance to the nation as a whole.

The Physiocratic School gained in importance during the 1760s and played a role in economic administration. In 1764–5 the Comptroller General, Bertin, liberalized trade in wheat and in flour; together with Turgot, Inspector in Limousin, and Pierre Paul Le Mercier de la Rivière, Inspector in the

Antilles, the highest reaches of administration opened up to Physiocracy. The doctrine spread abroad: to Baden, Austria, Poland, Russia and Sweden. However, a succession of poor harvests in the later 1760s put an end to those tentative efforts at trade liberalization. Quesnay lost interest in political economy; the baton was taken up by a small number of writers, among whom Turgot was pre-eminent.

Turgot is close to Physiocracy, but he differs in theoretical points and practical matters. He was close in so far as he was a strong advocate of a complete freedom of trade, distancing himself from Gournay's slogan ‘liberty and protection’; and he adopted Quesnay's analysis of the price of wheat in respect of the theory of the net product and the single tax. But Turgot never made use of the Tableau Economique; he was, he said, happy to employ its metaphysics, meaning the competitive process upon which it was founded.

Turgot's originality is evident from his Réflexions sur la formation et la distribution des richesses, published in 1766 in the Physiocratic journal Ephémérides du citoyen, and can also be appreciated from many of his writings of this period that were either never completed, or remained unpublished, such as his essay Valeur et monnaie. His approach is based upon sensualist philosophy, and this orients him to a subjective theory of value and utility. The economic thought of abbé de Condillac, the principal theorist of sensualism in France, was similar in this respect, for in his Le gouvernement et le commerce considérés relativement l’un à l’autre (1776) Condillac defined value in terms of judgement and opinion made in respect of the scarcity and utility of a good – combining this with a more thorough study of the competitive process.

This led Turgot to a number of significant findings: the formation of markets upon the foundation of mutual interest between buyers and sellers constrained by transport costs (Foyères et marchés, 1757); a theory of price (estimated value) proceeding from a discussion of the scarcity (quoted value) of a good for parties to an exchange – although Turgot stopped at two agents and two goods (Valeur et monnaie, 1769); the justification for interest upon loans and its determination according to market forces (Mémoire sur le prêt à intérêt, 1770); a theory of the formation of a uniform rate of profit, or a stable hierarchy of such rates (Réflexions, 1766). If one adds to this list the discovery of the principle of decreasing returns to capital in agriculture it is clear that Turgot's theoretical contribution was a considerable one, especially in view of the fact that he had heavy responsibilities in his various administrative posts – as Inspector in Limoges (1761–74), then Navy Minister (1774), and finally Comptroller General for Louis XVI (1774–6).

In this last appointment, together with a small number of loyal supporters (Dupont de Nemours, Condorcet) Turgot worked to re-establish the freedom of trade in grain, which gave rise to a dispute with Jacques Necker (Sur la législation et le commerce des grains, 1775), Necker opposing to Turgot's liberalism a more flexible and pragmatic conception of the administration of trade for which the anticipations and beliefs of agents were vital, a factor neglected by Turgot.

Political economy thus assumed an explicitly political dimension. For Quesnay and Le Mercier de la Rivière (L'ordre naturel et essentiel des sociétés politiques, 1767) the community of economic interests shared by different groups secured the harmony of the social body, provided that the legislator surrounded himself with experts in the science of economics. Mirabeau and Turgot considered that landed proprietors represented the general interest and should determine the level of taxation in local assemblies. This connection between property, taxation and the citizenry would play an essential role in the course of the Revolution. This connection is also the basis upon which a general science of the social was conceived (the moral or political sciences according to the abbé Baudeau, and social science as in...
Sièyes, Condorcet or Roederer) in which political economy took its place alongside ethics, politics and jurisprudence. It was in this form that political economy was first institutionalized in the classes on moral and political sciences at the Institut (1795).

We should also take note of a specific development owed to the presence of Condorcet, a mathematician of the first rank, in Turgot's entourage. Condorcet's interest in public affairs during the Revolution gave rise to his essays on social mathematics which inserted calculus and the theory of probability into social science with respect to issues such as insurance or the rate of interest on loans. Quite remarkable is the result obtained by Condorcet in respect of the determination of truth on the part of a jury or assembly when there are several votes and more than two choices. Condorcet formulated the result which Kenneth Arrow demonstrated in 1951 as the ‘impossibility theorem’. But for the time being, this avenue remained undeveloped, apart from the work of isolated scholars like Achylle-Nicolas Isnard (Traité des richesses, 1781), Nicolas Canard (Principes d’économie politique, 1801) or Charles-François Bicquillet (Théorie élémentaire du commerce, 1804). Say rejected it quite explicitly.

1800–30: Say, the Saint-Simonians and the industrial order

Physiocracy continued to play a role during the revolutionary period. A number of followers had been shaped by this doctrine, and this remained true even of those who had distanced themselves on central points, such as the abbé Sièyes, Roederer or Condorcet. However, the diffusion of the Wealth of Nations profoundly altered the way in which the economy was conceived in France. Two authors symbolize this progression: Jean-Baptiste Say (Traité d’économie politique, 1803) and Jean-Charles Simonde de Sismondi (De la richesse commerciale, 1803). Despite their evident indebtedness to Quesnay and Turgot, many traces from these authors remaining in their writings, they founded their political economy upon the Wealth of Nations, Germain Garnier's influential translation being published in 1802. For Say and Sismondi, Smith had highlighted two salient points. The first was that the industrial producer acquired his social independence thanks to the market. He no longer depended upon a person of influence (such as a rich landed proprietor) but on a collection of purchasers. The second was that the level of economic activity did not depend on expenditures, but on the quantity of capital. In this respect the social and political dimension of political economy came to the fore in a conception of a new type of society which Say called ‘industrial society’. Say's political economy is characterized by the manner in which he orders his material by the tripartite schema of production, distribution and consumption. He did more than simply put Smith's ideas in order; he modified both Smith's ideas and those of his British interpreters. Say followed the tradition of Turgot and Condillac. His theory of value is based on utility, not labour. He thus rejected the opposition of natural to market price, in the last editions of the Traité considering only market price. Say's theory of production minimizes the role of the division of labour. He argues that the progress of wealth arises from the introduction of new machines incorporating scientific knowledge which places at the disposal of producers the free forces of nature, thereby reducing costs of production. The theory of distribution is entirely based on relations between supply and demand among different categories of the suppliers of productive services, including those of entrepreneurs.

Say's name is firmly linked to two fundamental contributions: his formulation of the law of markets and his analysis of the role of the entrepreneur. The latter played a significant part in his theory. The entrepreneur coordinates the employment of productive services within an enterprise and links different
markets (for final goods and for productive services). In this respect Say's entrepreneur, as in Cantillon, is the economic agent who confronts the uncertainties involved in market transactions. Say argues that value depends upon utility and is the measure of wealth. From 1815 Say encountered criticism on these two points from Ricardo, and never managed satisfactorily to meet the criticism that the fall in value of a good consequent upon technical progress cannot at the same time indicate that the society is richer (a given amount of utility being obtained at a lower cost) and also poorer (since value has diminished). In this debate Say had trouble in defining a theoretically founded position which was not a reformulation of the Ricardian theory, including here the theory of rent. The difference in method is certainly here more marked and on this point Say received support from Sismondi (*Nouveaux principes d'économie politique*, 2nd edition, 1826). But they were not in agreement on the implications of the law of market opportunities and on the interpretation of the English industrial crisis of 1825: for Say, it resulted from excessive credit being extended by banks, while Sismondi saw it as a crisis of overproduction originating in the growth of production exceeding that of consumption.

In France the debate on value took a distinctive course. Rossi, the successor to Say at the Collège de France, rapidly abandoned the position of his predecessor and moved nearer that of Ricardo. He also elaborated a methodological synthesis which distinguished between a pure and abstract economics in the fashion of Ricardo and an applied political economy influenced by institutional and political context. Most importantly, however, following on from Rossi, Dupuit criticized Say's position: the value of a good was not measured by its utility, instead one might measure utility by the maximum sacrifice a purchaser was prepared to make to obtain it.

Beyond these theoretical debates, the political economy of Say and his successors bore upon the nature of society. The doctrine of industrialism expressed the idea that modern society depended upon the mastery of man over nature thanks to science and technology on the one hand, and social science on the other. Industrialism endorsed and promoted industry, the social independence produced by the market and the reconfiguration of the political sphere, where the state played a diminished role, permitting agents to decide what was best for themselves while it also assigned a greater role to industrial classes in the representation of the citizenry. During the 1820s this doctrine divided into two paths: the liberal industrialism of Say, Charles Dunoyer and Charles Comte separated from the organized industrialism of Henri-Saint-Simon, Auguste Comte and the Saint-Simonians. This latter tendency argued that the market was not an institution adequate to the effective redistribution of resources, as periodic economic crises showed. It was the same with the hereditary transmission of property; in its place, industrialism envisaged a centralized and rational organization of economic activity. In addition, it asserted that industrial society could not be based simply on selfish interest and the doctrine of utility, but had need of a moral or religious dimension. Here we are already approaching socialist theses that flourished during the 1840s.

This opposition assumed particular force with the link that developed between organized industrialism and a new social category, that of the engineer. Since the 18th century France had provided itself with a corps of engineers charged with the provision and maintenance of infrastructure (bridges, roads and canals), mines and defence. These engineers were selected for their abilities in mathematics, and they employed this in a profession placed between technology and economy. ‘Engineer economists’ (Etner, 1987) created a link between political economy and mathematics in economic calculation. This is evident in the work of Dupuit, who calculated the utility of infrastructure, and expounded the principle that a tariff should be charged according to the gain that a user enjoyed. Antoine-Augustin Cournot
France, economics in (before 1870) : The New Palgrave Dictionary of Economics

(Recherches sur les principes mathématiques de la théorie des richesses, 1838) was himself a pure mathematician. While he developed an economic approach in respect of theses expounded by Rossi on the value of exchange, he remained, as a writer, isolated in his use of mathematics and also on account of his critique of free trade. His work was hardly read by his contemporaries.

1830–70: The French classical liberal school, socialism and the teaching of political economy

Say dedicated much of his life to teaching political economy: at the Athénée royal (1815–19), at the Conservatoire des arts et métiers (1819–32) and finally at the Collège de France (1830–2). The importance that Say attached to teaching political economy derived mainly from his adherence to Enlightenment philosophy, according to which human misfortune resulted from ignorance of the laws of nature and of society, and from the ascendancy of doctrines which prevented individuals from daring to think for themselves. It also followed from his own economic theory, for he maintained that scientific knowledge was among the productive services that the entrepreneur had to bring together so that he might serve the public effectively.

This perspective came to be of importance in the debate with Ricardo. Say did not neglect theory, and he sought to develop it (the law of markets, the theory of value, the theory of productive services and so on), but he considered that the essentials were already understood. Republican in outlook, Say saw in political economy the means to bring about a more efficient society, one in which there was greater justice because it was more egalitarian. The diffusion of a liberal credo favourable to commercial freedom, free trade and reduced taxation was therefore important. Agreement among economists provided a secure foundation for the production of a body of ideas appropriate for public instruction.

Ricardo's theoretical refinements, which he did not himself think had practical consequences, brought about disagreements which alienated readers from political economy and its applications, as shown by the jibes against economists of François Ferrier, a customs official and defender of the balance of trade (Du gouvernement considéré dans ses rapports avec le commerce, ou de l'administration commerciale opposée aux économistes du 19ème siècle, 1804 and 1822.) After the death of Say in 1832 this conception of political economy was epitomized in the various institutions around which liberals organized themselves. In 1832 François Guizot re-established the Académie des sciences morales et politiques that Bonaparte had suppressed; in 1842 economists founded the Society for Political Economy so that they might there discuss theory and policy; the publisher Guillaumin saw that their work was published (the Collection des principaux économistes in 1842 and then, in 1852–3, the remarkable Dictionnaire de l’économie politique). Finally, liberal economists founded a journal, the Journal des économistes, which was published from 1841 right up to the French military collapse in 1940.

The initial aim of the Journal des économistes was the diffusion of economic theory, thought to be already complete, so that it might lead to practical ends. The contemporary problem appeared to relate to the forms of association between workers and capitalists, and support for a spirit of enterprise that had not brought about all its anticipated benefits. Frédéric Bastiat led a powerful campaign on behalf of free trade, seeking to create in France a movement which was the equivalent of Cobden's Anti-Corn Law League. The struggle against socialism was not therefore a priority for liberal economists in dialogue with ‘social reformers’, notably with Pierre-Joseph Proudhon who, thanks to his relationship with Joseph Garnier, then director of the Journal, was regarded a part of the circle of economists and published his
Contradictions économique with the publisher Guillaumin. It is true that he was similar to them on one count – the defence of freedom – and which he sought to reflect in mutualism, one of the forms of association in question. Matters quickly changed in 1848; the suppression by the new authorities of the chair of political economy at the Collège de France profoundly upset economists, who set to work in support of its re-establishment; and they opposed many projects developed at this time, such as the ‘right to work’ and national workshops, which generally promoted the centralized regulation of economic activity. Besides writing in support of property and social order, the economists (especially Michel Chevalier and Joseph Garnier) opposed the ideas of Louis Blanc: remunerating work independently of its productive contribution, as in the national workshops, created a problem with incentives. Nevertheless, the Journal des économistes saw its principal adversaries as ignorance of the principles of political economy, protectionist prejudices, and socialist illusions. Bastiat developed this idea on his Sophismes économiques (1845). Socialism and protectionism were conceived as equivalent, for both involved despoliation, an involuntary transfer of resources which impoverished society to the advantage of one particular section of that society.

The creation of the Empire in 1851 opened up a cleavage among the economists. The most liberal among them, such as Gustave de Molinari, left the country, while others furthered their industrial ideas and political careers, like Chevalier, who became a Privy Councillor and personal Councillor to Napoleon III. From this position he was able to promote the central idea of liberal economics with the signature of the Cobden–Chevalier Treaty on free trade in 1860. During the Empire period there were additional measures that conformed to liberal ideas, such as restoring the right of association to workers in 1864 and furthering education in political economy. Hitherto it had been taught only in several specialized institutions (the Conservatoire, the Collège de France, and the Ponts et Chaussée), but from 1860 public education in political economy began in the provinces, and in Paris in the law faculty with a course given by Anselme Batbie. However, the development of teaching in political economy really began to develop only with the reform of the teaching of law in 1877.

Franchising typically refers to contractual relationships between legally independent firms, where one firm pays the other for the right to operate under the latter's brand, or sell its product, in a given location and time period. Franchised firms account for a large portion of commerce in the United States and around the world. The economics literature on franchising has focused mostly on why and how firms franchise, emphasizing incentive or opportunism issues on the part of franchisees and franchisors to explain various aspects of the relationships. Empirical findings have confirmed the importance of such issues in shaping these contractual relationships.

Franchising typically refers to contractual relationships between legally independent firms under which one of the firms, the franchisee, pays the other firm, the franchisor, for the right to sell the franchisor's product and/or the right to use its trademarks and business format in a given location and for a specified period of time.

According to the American Heritage Dictionary of the English Language, the word ‘franchise’ comes from the old French word franche, meaning free or exempt. In medieval times, a franchise was a right or privilege granted by a sovereign power – king, Church, or local government – to engage in activities such as building roads, holding fairs, organizing markets, or to maintain civil order and collect taxes, in a particular location and for a certain period of time. The grantee was typically required to pay a share of its product or profit to the sovereign power for this right or privilege. That payment was called a royalty,

a term we still use today.
Governments still grant franchises in certain industries, such as the cable television industry (see for example Zupan, 1989; Prager, 1990) and highway construction projects (see Engel, Fisher and Galetovic, 2001). The word ‘franchise’ is used also in the sports industry to refer to the right to operate a team in a particular locale. Most commonly, however, the term refers to the type of ongoing business relationships defined above.

In the United States, the Federal Trade Commission (FTC) has jurisdiction over federal disclosure rules for franchisors. It requires three conditions for a business relationship to be deemed a franchise and thus subject to these rules. First, the franchisor must license a trade name and trademark that the franchisee operates under, or the franchisee must sell products or services identified by this trademark. Second, the franchisor must exert significant control over the operation of the franchisee or provide significant assistance to the franchisee. Third, the franchisee must pay at least 500 dollars to the franchisor at any time before or within the first six months of operation (see Disclosure Requirements and Prohibitions concerning Franchising and Business Opportunity Ventures, CFR, Title 16, Part 436). Authorities outside the United States, including Australia, Canada, and the European Union, typically rely on similar criteria.

Franchise agreements take one of two forms: business-format franchises, where the relationship ‘includes not only the product, service, and trademark, but the entire business format itself – a marketing strategy and plan, operating manuals and standards, quality control, and continuing two way communication’ (U.S. Department of Commerce, 1988, p. 3) and product and trade name or traditional franchising, where franchised dealers ‘concentrate on one company's product line and to some extent identify their business with that company’ (1988, p. 1). The latter include car dealerships, petrol stations, and bottlers. Several countries, however, exclude these from their franchise statistics.

In 2001, the revenues of franchised chains in the United States were estimated at 1.37 trillion dollars or 13.6 per cent of GDP (Blair and Lafontaine, 2005, p. 26). In retailing, it is estimated that about one-third of each dollar of sales is achieved via franchised chains. Three-quarters of these sales occur in traditional franchise outlets. Business-format franchising, however, accounts for the majority of jobs and outlets: of the more than 750,000 franchised establishments in the United States in 2001, 620,000 were associated with the 2,500–3,000 business-format franchisors in the economy. Thus business-format franchising accounted for 4.3 times as many establishments, and employed four times as many workers, as traditional franchising did in 2001 (Price Waterhouse Coopers, 2004, p. 1).

While the United States franchising sector remains the largest in the world, franchising is increasingly a global phenomenon. Several large US-based franchisors have expanded abroad aggressively. With the development of many home-grown franchise companies, this has led to franchising sectors of many developed countries now rivalling that in the United States. According to Arthur Andersen & Co. (1995), countries such as Canada, Japan and Australia have more franchisees per capita than the United States. Still, the extent of franchising continues to vary significantly across countries.

The interest of industrial organization economists in the study of franchising emerged in the 1970s. Going back at least to Caves and Murphy (1976), Rubin (1978) and Klein (1980), economists have formulated theories about why franchising exists and why the contracts take the form they do. The economic significance of franchising in itself would easily justify this interest. However, much of the research on franchising has been carried out with a much broader goal in mind, namely to understand
how firms organize their activities generally, with franchising viewed as an exemplar of the types of long-term, contract-based organizations that stand between spot market interactions and complete vertical integration, and thus a context in which to test agency and transaction cost theory. As Caves and Murphy note (1976, p. 572), ‘The franchise relation raises fundamental questions concerning the nature of the firm and the extent of its integration.’

Caves and Murphy introduced many of the issues that have remained central themes in the literature, noting in particular the scale differential that gives rise to chain structures, the need to price franchise rights to give incentives to franchisees, and the factors that lead firms to rely to varying degrees on franchising rather than company ownership. Regarding the latter, the authors emphasized the franchisor's initial need for capital, the importance of owner operators in some industry segments, and the possibility that franchisees might, through various activities and spillover effects, damage the brand.

Mathewson and Winter (1985) formalized many of these ideas. Rubin (1978) pointed out the role that franchisors play in developing and maintaining the value of their brands, thereby noting explicitly that franchisor incentives also matter. Based on this idea, Bhattacharyya and Lafontaine (1995) developed a model to explain some remaining puzzling facts about the contracts, namely the degree of uniformity and stability of the financial terms in these contracts. Finally, a separate but complementary approach to explaining various aspects of franchise contracts, which focuses on self-enforcement, was proposed in part by Rubin but developed most explicitly by Klein (1980; 1995).

Perhaps what distinguishes franchising the most from other contractual contexts, however, is the amount of empirical work that has been conducted on the subject. This empirical literature has established several facts. First, it has shown that incentive issues on the franchisee's and the franchisor's side play a central role in franchise contracting (see Lafontaine and Slade, 2007 for a review). It has also shown that franchisees’ local profit-maximizing behaviour – or opportunism – can be a problem for franchisors. Consequently, the relationships are designed with self-enforcement in mind (see for example Brickley, Dark and Weisbach, 1991, and Kaufmann and Lafontaine, 1994, on the role of contract termination and the presence of ongoing rent respectively).

In some cases, the theories and the facts have not matched so well. For example, franchising, like sharecropping, tends to be positively associated with risk (see for example Allen and Lueck, 1995, on sharecropping). This is inconsistent with the typical agency argument that risk-averse agents should be insured more when the environment is more volatile. Lafontaine and Bhattacharyya (1995) and Prendergast (2002) explain this empirical ‘anomaly’ by noting that franchisees choose their effort level in ways that exacerbate the high and low demand signals they receive, which in turn makes the variance of outcomes – measured risk – larger for franchised than company outlets. Prendergast (2002), moreover, argues that principals will need to delegate more, and thus give higher powered incentives to agents, in uncertain environments. Ackerberg and Botticini (2002) propose instead that this anomalous effect of risk reflects an endogenous matching problem.

Finally, the literature on franchising has found that incentive requirements and mechanisms interact in important ways within a given relationship or contract (see notably Slade, 1996; Bradach, 1997; Brickley, 1999; Lafontaine and Raynaud, 2002). Moreover, competition or antitrust policy, as well as franchise-specific laws, constrain the set of contract terms franchisors can rely on. Another important – and underdeveloped – segment of the literature examines the effect of franchising on economic outcomes. The need for exogenous variation in organizational form has made this type of work difficult,
but results suggest that prices, for example, are somewhat higher under franchising (see Lafontaine and Slade, 2007, for a review). Much more work is needed, however, in both these areas.

free banking era

Arthur J. Rolnick and Warren E. Weber

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In the free banking era entry into banking was virtually unrestrained, banks could issue their own currency and governments did not insure banks; many banks closed and many noteholders reportedly suffered. An early view of this period is that free entry led to banks over-issuing notes, resulting in large losses for noteholders. More recent research has shown that this is incorrect. Although such failures and losses did occur, these were generally due to the capital losses banks suffered when the prices of the state bonds backing their notes fell, rather than to note over-issuance or fraudulent banking practices.

Imagine the US economy without Federal Reserve notes, that is, without a uniform currency. Instead, imagine that the currency consists of notes issued by privately owned banks and that are redeemable in specie on demand. And imagine that to enter the banking business is relatively easy, so that the notes of hundreds of banks exist. And imagine as you travel around the country, notes of out-of-town banks are not readily accepted as means of payment at par because the solvency of such banks is difficult to ascertain.

How well would such a banking system function? In particular, with free entry into banking, would banks not have an incentive to over-issue their notes, leaving the public holding worthless pieces of paper when the banks failed? And would trade not be difficult without the existence of a uniform currency? Indeed, a reading of historical accounts of the so-called free banking era – the 26 years from 1837 to 1863, a period when entry into banking was relatively free and banks issued their own notes – would lead to this conclusion. The prevailing view of this period, at least until the mid-1970s, was that allowing such freedom in banking was a mistake. However, a more recent examination of the era reveals that while the free banking system was not without its problems, free banks and their noteholders fared
much better than has often been portrayed.

The beginning of free banking

Prior to 1837, to establish a bank in the United States was a very cumbersome, and at times political, process. Individuals who wanted to start a bank had to obtain a charter from the legislature of the state in which they wanted to operate. Beginning in 1837, some states reformed their bank-chartering systems so that entry into the banking industry would be easier. States tempered the goal of easy entry with another goal: to provide the public with a safe bank currency. Most states attempted to reach these goals by enacting what were called free banking laws. The first free banking law was proposed in New York. Its provisions openly aimed at both easy entry and safety. The law allowed anyone to operate a bank as long as two basic requirements were met: (a) all notes the bank issued had to be backed by state bonds deposited at the state auditor's office and (b) all notes had to be redeemable on demand at par, or face, value. If the bank failed to redeem notes presented for payment, however, the auditor would close the bank, sell the bonds, and pay off the noteholders. If the bond sale did not generate enough specie to redeem the bank's notes at par, noteholders had additional protection by having first legal claim to the bank's other assets. Thus, free banking meant free entry into banking; it did not mean laissez-faire banking.

New York's proposed free banking law became the basic blueprint for the free banking laws in other states. (Michigan actually passed a free banking law modelled on the New York proposal a year before the legislation was passed there.) Table 1 shows which states passed free banking laws and when the laws passed. Note that of the states that passed such legislation, most did so in the 1850s.

aMichigan prohibited free banking after 1839 and then passed a new free banking law in 1857.
bAccording to Rockoff, very little free banking was done under the laws of these states.
cIn 1845, Ohio passed a law that provided for the establishment of ‘independent banks’ with a bond-secured note issue.

The experience

One effect of the free banking laws was to increase the number of banks. In Michigan, for example, the number of banks rose from ten before the law was passed in March 1837 to 33 one year later. In New York the number of banks rose from 97 before the law was passed in March 1838 to 162 three years later. And Indiana, Illinois, and Wisconsin, which each had only one bank in existence when their free banking laws were passed, saw 13, 41, and 15 new banks established respectively within two years. Minnesota had no banks when its free banking law was passed; it saw 16 banks established within one year. In total, of the almost 2,300 banks that existed in the United States prior to the Civil War, slightly more than three-eighths were established or operated under a free banking law (Weber, 2006).

Free banking, however, must also be judged by the laws’ second objective – by how many banks survived and provided their communities with a stable source of banking services, especially a safe currency. Measured by this criterion, free banking is generally considered a failure. Michigan's disastrous experience with free banking is probably the most famous. By the end of 1839, less than two years after its free banking law was passed, all but four of Michigan's free banks closed (Rockoff, 1975, p. 96). Although explicit loss data do not exist, it has been estimated that the total loss to Michigan's noteholders was as high as four million dollars. This would have been nearly 45 per cent of Michigan's annual income in 1840 (Rockoff, 1975, pp. 17–48). Other states’ experiences with free banking, while not as famous as Michigan's, were almost as bad. Of the 16 free banks that opened under Minnesota's 1858 law, for example, 11 closed by 1863. And many that closed left their noteholders with very little.

However, some states had positive experiences with free banking. New York had very few free bank failures and noteholder losses after 1843. Indiana had much the same record after 1854. And all the failures and losses experienced by Wisconsin free banks occurred in 1861 after the Civil War had begun and the bonds issued by Southern states had greatly depreciated in value.

Free banking was not wildcat banking

According to some historians and economists writing about this period (see, for example, Hammond, 1985, p. 618; Knox, 1903, p. 747; and Luckett, 1980, p. 242), the losses experienced under free banking
were due to fraudulent banking practices by so-called wildcat banks. These were banks that purportedly located redemption offices in remote areas, issued notes far in excess of what they planned to redeem, and then disappeared, leaving the public with notes worth considerably less than their original value. Although some wildcat banking may have occurred, this explanation is not appropriate for most free banking experience because the data do not support it. Wildcat banks supposedly stayed in business for only a few months, after which time their noteholders sustained losses. However, in New York, Indiana, Wisconsin, and Minnesota – four states that were supposed to have had many wildcats – free banks were generally not short-lived. Most losses to the holders of free bank notes were due not to fraud, but to capital losses suffered by the banks because of several substantial drops in the prices of the state bonds that were required to back the notes they issued. Moreover, while these declines in bond prices may have been induced by any number of economic developments, they were not induced by wildcat banks.

Summary and conclusion

The free banking era was a time when entry into banking was virtually unrestrained, when banks could issue their own currency and when the government did not insure banks. It was also a time when many banks closed and many noteholders reportedly suffered. An early view of this period is that free entry led to banks over-issuing notes, resulting in large losses for noteholders. More recent research has shown that this view is not correct. Although free bank failures and noteholder losses did occur, these were generally due to capital losses banks suffered when the prices of the state bonds backing their notes fell. In general, they were not due to note over-issuance or fraudulent banking practices.

Lewis Carroll, *Through the Looking-Glass*

If I dislike a commodity, you may have to pay to get me to accept it. But so long as some otherwise nonsated consumer finds this commodity to be desirable, or at least harmless, it could not have a negative price in competitive equilibrium. Likewise, if some firm can dispose of arbitrary amounts of a commodity without using any other inputs or producing any other (possibly noxious) outputs, its price in competitive equilibrium cannot be negative. Therefore competitive equilibrium analysis can be confined to the case of non-negative prices if every commodity is either harmless to someone or freely disposable. If a commodity is not freely disposable and is a ‘bad’ in the sense that everyone prefers less of it to more, it is possible to redefine the ‘commodity’ as the absence of the bad. The commodity so defined can then be treated as a good with a positive price. More generally, it might be possible to choose some alternative coordinate system in which to measure commodity bundles so that in the new coordinate system either there is free disposability or more is preferred to less. But if people are willing to pay a positive sum for a small amount of a commodity and less for a large amount, then the question of whether that commodity will have a positive or negative price in competitive equilibrium cannot be decided in advance. The sign of the equilibrium price will in general depend on supplies of this and other goods and on the detailed configuration of preferences in the economy.
Sometimes a noxious by-product of production or consumption can be transformed into a useful output if sufficient other resources are used. Then the equilibrium price for the by-product may be either positive or negative, depending on the prices of the other inputs and of the output into which it is transformed. This is particularly evident when commodities are distinguished by location. Garbage located in the centre of a city is undesirable to everyone. To bury or incinerate it is costly and generates no valuable outputs. Therefore, if garbage is disposed of in this way, its equilibrium price must be negative. But the garbage could be transported to the country, boiled and fed to pigs. Depending on the costs of this process and the price of pork, it may turn out that converting garbage to pig feed is profitable even when garbage at the city centre has a zero or positive price. Both the ultimate disposition of garbage and the sign of its price have to be determined endogenously in the competitive process.

Early proofs of the existence of competitive equilibrium (Arrow and Debreu, 1954; Gale, 1955; Debreu, 1959) assumed that all commodities are freely disposable or, equivalently, defined equilibrium so as to allow the possibility that in equilibrium some goods might be in excess supply but have zero price. Debreu (1956) shows how the assumptions of free disposal and monotonicity can be greatly relaxed. McKenzie (1959) and Debreu (1962) present general theorems on the existence of equilibrium in which free disposal is not assumed. Rader (1972), Hart and Kuhn (1975), Bergstrom (1976) and Shafer (1976) suggest further generalizations and simplifications in dealing with negative prices in equilibrium.

The formal treatment of negative prices in existence proofs presents an interesting mathematical problem. Most of the standard existence proofs apply the Kakutani fixed-point theorem to a correspondence that maps the set of possible equilibrium prices into itself in such a way that a fixed point for the mapping is a competitive equilibrium price vector. The Kakutani theorem applies to an upper hemicontinuous mapping from a closed bounded convex set to its compact, convex subsets. If the only prices to be considered are non-negative, then the domain for this correspondence can be chosen to be the unit simplex. If all price vectors, positive and negative, must be considered, then an obvious candidate for the domain of this mapping would be the unit sphere \( \{ p \in \mathbb{R}^n | p \cdot p = 1 \} \). But this is not a convex set. The closed unit ball \( \{ p \in \mathbb{R}^n | p \cdot p \leq 1 \} \) is a convex set, but it contains the vector zero, at which point the excess demand mapping is not upper hemicontinuous.

Debreu (1956) solved this problem neatly in a brief, elegant paper that has received less attention than it deserves. The existence proofs that assume free disposability of all goods had shown that there exists a non-negative price vector at which the excess demand vector is either zero or belongs to the negative orthant. Debreu generalized this result to show that if there is free disposability on any convex cone which is not a linear subspace, then a price vector can be found at which excess demand is either zero or belongs to the cone of free disposability. Furthermore, this price vector gives a non-positive value to every activity in the cone of free disposability. In particular, consider the case where one good is assumed to be freely disposable. Then, from Debreu's theorem, it follows that there exists some price vector at which excess demand for all goods other than the freely disposable good is zero, and at which there is either zero or negative excess demand for the freely disposable good. From Walras's Law and the fact that that there exists some price vector at which excess demand for all other goods is zero, it follows that the price of the freely disposable good can be positive only if excess demand is zero. Therefore this price vector is a competitive equilibrium. Thus Debreu weakened the free disposability assumption from ‘all goods are freely disposable’ to ‘at least one good is freely disposable’.

We can take Debreu's argument one step further and eliminate the assumption of even one freely
free disposal: The New Palgrave Dictionary of Economics

disposable good. Nowhere in Debreu's proof is it necessary to assume that the freely disposable good is desirable to anyone. This suggests that the existence of a freely disposable good is not likely to be essential for the existence of equilibrium. For suppose that there is an economy with no freely disposable goods. A fictional good could be introduced which is freely disposable but totally useless and totally harmless to everyone. For the augmented economy found by adding this fictional good to the original economy, by Debreu's theorem there would exist a competitive equilibrium. In this new economy it turns out that the equilibrium price of the useless, freely disposable good must be zero and the vector of equilibrium prices for the other goods can serve as a competitive equilibrium price vector for the original economy.

The approach taken by Bergstrom (1976) is equivalent to introducing a useless and harmless fictional good into Debreu's model. Taking the formal steps of this argument directly without intermediary fictions leads to an upper hemicontinuous mapping from the unit ball into itself for which there is a fixed point on the boundary of the unit ball. This fixed point turns out to be a competitive equilibrium price vector. An interesting alternative approach was taken by Rader (1972) and by Hart and Kuhn (1975). Instead of the Kakutani theorem, they use a theorem about fixed and antipodal points of a continuous mapping from the unit sphere into itself, and are thereby able to deal with all prices on the unit sphere as potential equilibrium prices.

The first and second welfare theorems and the theorems about the equivalence between the core and the set of competitive equilibria apply straightforwardly when there is not free disposal. For example, in order to prove the Pareto optimality of competitive equilibrium in an exchange economy, we simply argue along the usual lines that if any allocation is Pareto superior to a competitive equilibrium, then at the original competitive prices, the aggregate value of consumption in the proposed Pareto superior allocation must exceed the aggregate value of initial endowments. But if the proposed allocation is feasible, then the aggregate consumption vector in the proposed allocation must equal the aggregate initial endowment vector. It follows, whether prices are positive, negative or zero that if the two vectors are equal they must have the same value at the competitive price vector. Therefore there cannot be a feasible allocation which is Pareto superior to a competitive equilibrium. Similar arguments apply to the core theorem. The only matter in which a bit of care must be taken is in defining the activities available to a potential blocking coalition so as to exclude the possibility of dumping undesirable commodities. This simply amounts to the assumption that a blocking coalition must exactly equalize its total consumption of all goods to its total endowment.

Friedman, Milton (1912– 2006)

Original article by Alan Walters, updated by the editors
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Milton Friedman is widely regarded as one of the most important economists of the 20th century. He is famous for his rehabilitation of money as a major determinant of macroeconomic outcomes. For many academic economists, *A Theory of the Consumption Function* (1957) is his greatest work. Friedman showed that the Keynesian concept of household behaviour was fundamentally flawed, arguing that people adjusted their consumption to variations in their long-term expected (‘permanent’) income. As such, his theory foreshadows the approach to microfoundations that is the cornerstone of modern macroeconomics. His advocacy of economic freedom and market solutions to various socio-economic problems made him a leading policy thinker.

Article

Early years

Born on 31 July 1912 in New York City, Milton Friedman was the son of a poor immigrant dry-goods merchant, who died when Friedman was 15. Friedman was clearly outside the East Coast establishment of the United States, although he did spend a year in graduate studies at an Ivy League school,

Columbia. He graduated (BA) at Rutgers University in 1932 and completed his AM at Chicago in the following year. After a fellowship at Columbia in 1933–4, he returned to Chicago as a research assistant to Henry Schultz to work on demand analysis, until in 1935 he joined the staff of the National Resources Committee. From 1937 he started a long association with the National Bureau of Economic Research (NBER), which continued until 1981. From 1938 he began another long association – with Rose Director, his wife, which produced, *inter alia*, a son and a daughter.

In 1940 there followed a brief period as visiting professor of economics at Wisconsin. Then, after a two-year stint (1941–3) in the Treasury in the division of tax research, he became associate director of the statistical research group in the division of war research at Columbia University, which lasted until the end of the Second World War. He then spent a year as associate professor at the University of Minnesota, before returning to Chicago as professor of economics in 1946, the year in which he received a Ph.D. from Columbia. His teachers at Rutgers were Homer Jones and Arthur Burns; at Chicago, Frank Knight, Lloyd Mints and Jacob Viner; and at Columbia, Harold Hotelling, J.M. Clark and Wesley Mitchell.

Superficially this record does not seem impressive. Yet it encompasses what some scholars, particularly statisticians, would regard as Friedman's most impressive contributions. Inspired by Hotelling's work on the rank correlation coefficient, his first seminal contribution (1937) was the development of the use of rank order statistics to avoid making the assumption of normality in the analysis of variance. After 70 years this article is still regarded as one of the two or three critical papers in the development of nonparametric methods in the analysis of variance, and it was followed by a discussion of the efficiency of tests of significance of ranked data. It is not surprising that these papers have been of considerable practical use, since they were largely a development of Friedman applying his mind to the practical problems he encountered in analysing incomes and consumer expenditure at the NBER and in Washington. Even at this early stage his work bears the imprint that readily identifies all his subsequent work: it is seemingly ‘simple’, eschewing complexities and complications, concentrating on essentials, and all combined into a lucid exposition.

The detailed analysis of data on incomes and expenditures was Friedman's main occupation during these years. With the exception of Kuznets, Mitchell and Burns, it is difficult to find any eminent economist who acquired such a grounding in the basic empirical material of economics. It is characteristic of all his work that the organization of such data would suggest theoretical developments and new ways of arranging the material, and above all new insights into the economic process. His first published article (1934) was on a method of using the separability of the utility function to measure price elasticities from budgetary data. This exploration of new insights into old data was particularly evident in his book (1945; with Kuznets as joint author) on incomes from private professional practice; there one sees the first signs of the permanent income hypothesis and, indeed, the perceptive reader may guess what is likely to follow. In this book, which Friedman submitted as a doctoral thesis, he argued that the process of state licensure enabled the medical profession more effectively to limit entry into their profession and so enabled them to exploit their patients, keeping fees high and competitors out. The fact that the argument was tightly constructed and buttressed with convincing evidence generated the most vehement opposition and animosity from that proud profession, which appears unabated seven decades later.

Wartime service in the statistical research group, although an interlude in Friedman's basic work on incomes and expenditures, generated one of the most remarkable advances in statistical theory since the seminal contributions of Sir Ronald Fisher. The group was a galaxy, consisting of Abraham Wald, Allen
Wallis, Jacob Wolfowitz, Harold Hotelling and many other distinguished statisticians. The sampling inspection of wartime production of munitions and so forth was a tedious process of selecting a sample of a given size and testing to see the fraction of good ones in the batch. Friedman, together with Allen Wallis and Captain Schuyler, observed that testing a given size of sample was clearly wasteful. The process of testing itself gave information that enabled one to determine the degree of confidence achieved. Thus instead of continuing to test up to a fixed size of sample, the testing could be halted whenever a predetermined level of confidence in the decision had been reached. Friedman formulated the basic idea of what later came to be called ‘sequential sampling’ and caught the interest and imagination of Wald, who developed and proved the theorem underlying the probability ratio test and eventually produced the influential book Sequential Analysis in 1947. These ideas were adapted very rapidly, and sequential analysis became the standard method of quality control inspection. Like so many of Friedman's contributions, in retrospect it seems remarkably simple and obvious to apply basic economic ideas to quality control; that, however, is a measure of his genius.

At the end of the Second World War, Friedman could have continued his work as a statistician. He would have achieved a stature probably as great as that of his most influential teacher, Harold Hotelling. Alternatively he had all the basic qualifications to take the lead in developing the burgeoning field of econometrics, with its great emphasis on the adaptation of statistical theory to modelling economic phenomena. He chose neither. His excursions into statistics were utilitarian rather than speculative, and he could see little to be gained by the endless sharpening of statistical knives, which was the stuff of econometrics during those years following the Second World War. In this decade, his contributions to statistics were even more intimately linked with his strong belief, implanted largely by Mitchell, that economics could acquire plausibility only by being subjected to empirical verification. In spite of the predilections of many economists, Friedman believed that economics should be viewed as an empirical science.

1946–1955

This decade at Chicago, much influenced by the wisdom of Frank Knight, witnessed the rapid development of economics as a positive science with its own methodology. The prevailing view of economic theory, as developed by Lionel (later Lord) Robbins, was that the veracity of theory could be tested primarily by the correspondence between assumptions and facts. In his ‘Methodology of Positive Economics’ (in Essays in Positive Economics, 1953), Friedman argued per contra that even if one could specify empirical correlates for the assumptions (and this cannot be done in cases where the assumptions are ‘ideal types’ such as homo economicus), that is irrelevant for judging the usefulness of the theory. Only by the correspondence of the predictions and facts should theories be provisionally accepted or rejected. Results, not assumptions, should be the main focus of our scientific activity in understanding the real world. This approach applied the new philosophy of science, developed by Karl Popper, to economics and by implication to associated social sciences. To countless students, Friedman provided an agenda for what Imre Lakatos later called a progressive research programme. The simplicity of a theory in its ability to explain a lot in exchange for a little input and the degree of ‘surprise’ in the prediction were the hallmarks of the new approach to theory. But it was in the efficacy and power of the empirical tests that substantial progress was to be made.

In subsequent years the ‘Methodology’ has been the subject of enormous controversy. There is general
agreement that in applying the theory one cannot dismiss the factual basis of the assumptions in quite such a cavalier manner. Furthermore, no one would be rash enough to declare a (refutable) theory discredited if there were a single or a few counter-examples to contradict the predictions. Such absolutism has given way to more subtle interpretations depending, as Lakatos argued, on the new and surprising insights to be obtained. Most theories coexist with small subsets of anomalous results that strictly should discredit them, and yet they remain useful theories and superior to any suggested alternative. But there is no doubt that the substance of Friedman's ‘Methodology’ has not merely stood the test of time but has also had a profound and lasting effect on the profession.

The application of this methodological approach reached its apotheosis in what most academic economists would regard as Friedman's greatest work, *A Theory of the Consumption Function* (1957). The fundamental proposition that emerged from Keynes's *General Theory* (1936) was that households expanded their consumption spending by an amount less than the increase in their current income, and that this relationship was sufficiently stable to form the basis for the multiplier through which an increase in autonomous expenditure at the macro level generated a considerably larger increase in real aggregate demand. Since the regularity and predictability of the consumption function was central for the Keynesian control of the economy, it was with trepidation that many observers found that there were considerable inconsistencies between the patterns of household behaviour, particularly from the cross-section data of household surveys and the time series of the historical record. It certainly appeared that the data were quite inconsistent with the Keynesian consumption function. Friedman showed that the Keynesian concept of household behaviour was fundamentally flawed, and that the statistical results suffered from the regression fallacy. People adjusted their consumption with respect to variations in their long-term expected (or ‘permanent’) income, and paid little heed to transitory variations. This basis idea was not new – indeed it can be found in the 18th-century writings of Bernoulli – but Friedman's development showed his genius for simplicity and for the insights of thinking concretely.

But the main quality of *A Theory of the Consumption Function* was the incomparable amassing, organization and interpretation of the evidence. The relatively low propensities to consume evident in the cross-section data were shown to be entirely consistent with the much higher propensities that emerged from analyses of aggregate time series, when both sets of figures were interpreted in the form of the permanent income hypothesis. Because of the transitory component in the cross-section samples of households, the variance of measured income exceeded the variance of permanent income, and so the slope of the regression of consumer spending on income was much lower than in the aggregate time series regressions, where the transitory component was trivially small. The permanent income hypothesis adequately passed the acid test of using little to explain much.

The integrity of scholarship was demonstrated by the diligent search to find evidence that would discredit the permanent income hypothesis. It was not, and is not, normal practice to scour the literature and statistical evidence for material that might discredit a theory. But Friedman used the hypothesis in the most imaginative way to forecast, for example, the values of regression coefficients for different groups with varying fractions of transitory to permanent income. And he left instructions for other researchers to guide them in tests to be made with further analyses of different data. One of the great contributions of this book was to give a new standard for empirical economics generally. Clearly this was how it should be done. The second important effect was the introduction of the concept of permanent income into virtually every field of applied economics, such as monetary economics, housing, transport and international trade. It was a new way of thinking about chance variations and
people's decisions in the real world.

A particularly fruitful theoretical approach to the utility analysis of risk and the measurement of utility, based on the work of von Neumann and Morgenstern, appeared in two papers with L. J. Savage (1948; 1952). Using axioms that most observers would regard as acceptable and reasonable, these papers showed that choice under conditions of uncertainty could be represented as a simple process of maximizing expected utility. Thus the utilities of each of the chance outcomes were weighted by the probability of that outcome, and the sum gave an index of expected utility which, given the axioms, would be maximized by choosing from the alternative uncertain prospects. Again the basic idea was not new (it was developed originally by Bernoulli in solving the St Petersburg paradox), but Friedman and Savage discovered new insights and implications, with wide-ranging applications. Apart from rationalizing the widespread practice of simultaneously gambling and insuring, the hypothesis had a profound effect on the theory and practice of portfolio selection. For the pure economic theorist it offered the attractive proposition that, up to an arbitrary linear transformation of origin and scale, utility should be regarded as a cardinal magnitude.

Subsequent discussion (particularly by Maurice Allais) suggested that one of the axioms (the so-called ‘strong independence axiom’ which asserted that the preference order would not be affected by mixing these outcomes with equiprobable alternative outcomes) was clearly implausible and violated frequently in practical decisions. Research suggested also that in some fields, for example in air passenger insurance, the expected utility hypothesis was discredited. Nevertheless, the hypothesis still forms a cornerstone of all work – and particularly practical work – in choice among risky alternatives. With some minor exceptions, these papers mark the last contributions of Friedman to the pure theory of statistics and decision-making. Many statisticians regard the diversion of such a fertile mind from its natural field as a great shame and loss.

The gain to empirical economics – and during these years, particularly to the theory of price – was, one suspects, worth the loss. The reformulation of Marshallian demand theory as a practical instrument of analysis (1949) was an exercise in meticulous scholarship in the history of thought, but one which also argued for approaching demand analysis as a positive rather than a normative discipline, an approach which he attributed to Marshall. But the analysis of economic policy, and particularly a critique of the logical structure of the arguments and the empirical evidence adduced to support proposals on economic policy, became increasingly important. Thus the critique of the arguments showing the inferiority of excise taxes compared with alternative income taxes (1952) exposed basic methodological weaknesses in what were the standard treatments of the day.

The demonstration of the uses, as well as some abuses, of the theory of price was one of the highlights of Friedman's lectures of 1946 to 1976 (with a gap from 1963 to 1973), at the graduate school of the University of Chicago. The exploitation of demand and supply as an ‘engine of discovery’ reached out well beyond those conventionally defined limits of the subject. In these lectures Friedman gave full rein to his persistence and determination to fearlessly pursue the argument, with subtlety and imagination, wherever it led. To the students it opened up new vistas – such as the theory of human capital – and exciting ways of unravelling puzzles and resolving problems. In his hands, economics had both power and point, reality and relevance (for example, 1962). As distinct from much economic work, where complicated ideas are developed in a simple way, Friedman showed how to interpret simple ideas in a most sophisticated way.

This quality characterized his work on money, which, with the inauguration of his monetary workshop
in 1951, began to be a major interest for Friedman himself and the distinguished students and faculty that he inspired. The motivations for studying money were firmly implanted when Friedman was at the Treasury dealing with wartime inflation management, but the immediate incentive was the request from the NBER to contribute a study on money for Wesley Mitchell's project on long-term business cycles. Monetary policy as a main tool of macroeconomic management was consistent with a wide degree of free unfettered enterprise and so had an obvious appeal to the liberal (which will be used here in the 19th-century sense) Friedman. The prevailing Keynesian orthodoxy, with its emphasis on expanding the public sector, appeared to threaten liberal society. The Post Keynesian contempt for money was a tempting target that was difficult to resist. But undoubtedly Friedman's imagination had been challenged by the Chicago School's preference (particularly by Knight and Simons) for rules rather than authorities in macroeconomic as well as microeconomic policy. The uncertainties of the economic environment would be much reduced if the Federal Reserve Board followed simple rules. Friedman first suggested (1948) a countercyclical rule of financing recession-induced increases in the federal budget deficit by money creation and correspondingly by retiring money during a boom-induced surplus. The empirical evidence that he explored in subsequent years, however, led him to formulate the rule of a fixed and known expansion of the money stock, rather than indulging in countercyclical operations in vain attempts to stabilize the economy. Whatever his motives, however (and one should note that motives are quite irrelevant in judging substantive propositions), for the next 30 years Friedman's work was focused on money. At last monetary economics was to be interpreted as part of the central corpus of price theory; it was to be integrated into economics.

The monetary revolution and the rise of monetarism, 1956–1975

In the late 1950s, to anyone subjected to the Anglo-Saxon schools of economics during the previous two decades any attempt to revive monetary economics appeared to be foolhardy, like flogging a decomposing horse. The Radcliffe Committee, advised by the most eminent economists, had reported in 1959 that the quantity of money was of little or no interest since the velocity of circulation had no limits. The quantity theory of money was subject to particular scorn as a mere identity without content. As Friedman was to point out, however, all theory consists of tautologies; all that theory does is to rearrange the implications of the axioms to produce interesting, even surprising, consequences. But they remain empty and devoid of substantive as distinct from speculative content, until they have been tested against a wide body of facts.

Of course, for many years the quantity theory of money had been tested against experience and data and over several critical periods of change. The most distinguished exponents of such tests had included Irving Fisher and Keynes himself, as well as the irrepressible Clark Warburton. Yet the methodology was murky, the statistics slim, and interrelationships between data and theory obscure. In Studies in the Quantity Theory of Money (1956), Friedman and his co-authors redefined the quantity theory in terms of statements specifying a degree of stability in the demand for money. It was proposed that the demand for money by the individual household would be a stable function of its money income (later thought to be permanent income or wealth) and the cost of holding money represented by the rate of interest and the expected rate of inflation.

Friedman's presentation of the theory of the demand for money in the first essay in Studies is one of his most widely quoted papers, primarily because it is thought to show that in presenting the money demand
function as a portfolio decision with respect to alternative assets, rather than a demand related to the flow of transactions and income, Friedman was a closet Keynesian. Substantively this was a side issue; the main point was the stability of demand, particularly with respect to nominal income or wealth. Unfortunately, this first essay was not one of Friedman's better expositions. The other essays in Studies, particularly that of Cagan on hyperinflations and Selden on velocity, however, established the value of examining nominal income and inflation in the context of the demand for money. The quantity theory in its new reborn Chicago form had passed its first tests.

The unknowns, however, remained legion. The vexed question of the nature of the regime controlling the supply of money, and how to interpret the problem of identifying the demand function in the data were to persist, in the eyes of many critics, as the major weakness in such studies. Was the stock of money reacting passively to changes in nominal income (or wealth) or were prices and output responding to endogenous changes in the supply of money? The Chicago workshop averred that the answer to such questions could be obtained only by painstaking research into the history of the monetary process. Undoubtedly there were occasions when the money stock passively responded to changes in nominal income, but equally obvious were instances where the money supply changed for reasons quite independent of past or contemporaneous movements in money incomes. The role of the balance of payments and the exchange rate regime was clearly recognized, and it is not difficult to discover the genesis of the monetary theory of the balance of payments in ‘Real and Pseudo Gold Standards’ (1961) and other essays in Dollars and Deficits (1968).

Although the detailed development of the history of the money supply process and the relationships with gold and exchange rates were to appear in the monumental A Monetary History of the United States, 1867–1960 (1963), Friedman had already made it perfectly clear that a stable growth of the money supply was unlikely to be feasible under a regime of fixed exchange rates. His advocacy of flexible exchange rates (in 1953) followed logically on his views of the efficacy of free markets. Friedman was one of the very few economists (Gottfried Haberler and Egon Sohmen were among them) who clearly showed that the ambient dollar shortage was merely a consequence of fixed exchange rates and divergent monetary policies. His analysis was amply justified when by the 1960s, due to the change in monetary policies, the dollar shortage had turned into a dollar glut.

Yet in spite of the increasing attention paid to the balance of payments and the money supply process generally, the prime focus of Friedman's work remained the examination of the effects of monetary variations on nominal income, prices and output. The main questions were: (a) what was the relative importance of monetary compared with fiscal variations (the Keynes versus Monetarist debate); (b) what was the time pattern of adjustment; and (c) could expansionary financial or fiscal policies affect real output in the short or long run? The answers that evolved from Friedman's analysis were: to (a), although an increased fiscal deficit had an impact effect on nominal income this soon disappeared, whereas after a lag the increased rate of money growth permanently augmented the rate of inflation; to (b), the adjustment of nominal income to an increased rate of monetary growth involves lags that are ‘long and variable’; and to (c), in the long run additional monetary growth affects only the rate of inflation and has virtually no effect on either the level of output or its growth rate. In essence Friedman found that variations in the rate of growth of the money supply had short-run effects – sometimes, as in 1931 of a devastating magnitude – on real output as well as on prices; but in the long run (more than three years) the only substantial effect was on prices.

Over the 1960s and 1970s the results of Friedman's research for the long run were widely accepted. The
logic as well as the data were appealing: nominal variations (in money) have nominal effects (on prices) and no real effects (on output). But such agreement did not readily extend to his short-run claims of, first, the impotence of fiscal policy in countering cyclical oscillations and shocks; and, secondly, the large but unpredictable effects of monetary variation on real output and employment. The claims of Keynesian economists for the stability and size of the fiscal multipliers continued, but it is noteworthy that estimates of the size of the multipliers, except for those produced by the Cambridge (England) School, were substantially reduced in the 1980s. (One is not able to determine whether the economists or the economies have become less Keynesian and more monetarist.)

One of the abiding criticisms of Friedman's work on money (much of it in joint authorship with Anna Schwartz) is that it has no theoretical structure – or more charitably that such theoretical structure as exists is implicit rather than explicit. Processes of monetary transmissions as he describes them are alleged to be ‘black boxes’ with no precise specification of the way in which money works its magic. Friedman attempted to produce a theoretical underpinning for his approach to research in *Milton Friedman's Monetary Framework* (1974) by producing a seven-equation basic model of the (closed) economy. The critical difference between the Keynesian and the classical models was the choice of the last equation; the Keynesians chose to specify the price level as fixed by exogenous forces and the level of output as a variable determined by the level of aggregate demand, whereas the classical economists held that the level of real output was fixed by technology, skill and so on, and that the price level was determined by the model. With this simple model, Friedman was able to highlight the differences of method and approach as primarily different views about the size and stability of the coefficients of the system. In principle, at least, such issues could be resolved by appeals to the evidence. *The Framework* did not, however, make substantial progress in providing a sound analytical basis for the dynamics of the adjustment, through output, price and interest rate effects, to the new long-run equilibrium. The transmission mechanism and dynamics remain enshrouded in the gloom of a black box.

Yet in spite of what many theoretical economists considered to be drastic limitations for sound theoretical developments, in the most important and influential paper in macroeconomics in the post-war years, his presidential address to the American Economic Association, Friedman showed that the view of macroeconomic policy as a trade-off between unemployment and inflation was fundamentally flawed (1968). In the long run there was no such trade-off, while in the short run the trade-off took place only during the adjustment to the new inflationary environment, and then only because people were temporarily surprised by the new environment. The overriding objective of contractual arrangements was to fix real wages and prices. Money served as a veil, sometimes seductive but always obscuring underlying reality. The so-called Phillips curve was a short-term temptation rather than a long-term choice.

Friedman caught opinion at ebb and turned it into a flood. Throughout the 1960s the trade-off between unemployment and inflation appeared more and more illusory. Unemployment went up but inflation did not go down; it also increased. Into the 1970s and particularly during the great inflationary recession of 1974/75, when both inflation and unemployment reached new highs in most Organisation for Economic Co-operation and Development (OECD) countries, it appeared that only Friedman's view made any sense. Like Keynes's *General Theory*, it was one of the very few contributions that changed both the approach of professional economists and the policies adopted by finance ministers. Some time during the 1970s most governments recognized that the road to fuller employment did not lie over the high sierra of soaring inflation. Doctrinally, economists took into their toolbox the Friedman concept of a
‘natural rate’ of unemployment where inflation would neither accelerate nor decelerate. (The word ‘natural’, which was usually considered either normative or even desirable, was generally eschewed in favour of the term ‘non-accelerating inflation rate of unemployment’ or NAIRU.)

The natural level of unemployment was held to be determined by the nature of labour markets, such as the conventions of wage contracts, the degree of mobility, the level of unemployment benefits, the marginal utility of income, and many other ‘structural’ factors that are independent of the rate of inflation. As in the case of the permanent income hypothesis, to which it is distantly related, the concept had applications in fields far from labour markets. At the same time it provided one of the many missing links between the macroeconomics of aggregate output and inflation and the microeconomics of industrial adjustment and resource allocation. Again, in retrospect it all seems obvious; but that merely measures the magnitude of the contribution.

By any standards – even those of Keynes and the General Theory – Friedman's contribution to monetary analysis and policy must be ranked very high. Every economist, finance minister and banker felt his influence. But, as an accomplishment of the intellect, one suspects that most of Friedman's peers would still regard his work on the consumption function as the maximum maximorum of his contributions to economics. Friedman's monetary analysis did not have that sense of comprehensiveness and structural balance that are the hallmarks of his work on consumer spending. One closed A Theory of the Consumption Function, not with the feeling that nothing more need be said, but that whatever was discovered in the future must fit neatly into this superb and satisfying framework. The architecture could accommodate, and indeed so far has shaped and absorbed, all new contributions. The Monetary History and the Framework, however, although probably more influential in doctrine and policy, did not provide the commodious and harmonic form of the Consumption Function. A number of awkward corners left one wondering what to do. And since the theoretical plans were left obscure, sometimes there were questions whether the superstructure would really hold up. But this does not belittle the Monetary History so much as praise the Consumption Function.

1975–2006

The award of the Nobel Prize for Economics, long overdue in 1977, at last recorded that Friedman's great contributions had even penetrated the Swedish academies. Inevitably Friedman's rise to stardom had given many more opportunities to persuade electorates through the medium of the popular press (highlights include his columns in Newsweek from 1966 to 1984) and television (in the popular PBS and BBC series Free to Choose in 1980). His contributions to persuasive journalism delighted many, infuriated some, and made all his serious readers, if not wiser, then certainly better informed. In all these popular articles the high professional standards of integrity were maintained. But at the same time Friedman continued with his scholarly work on monetary analysis; examples include Friedman (1988; 1990; 1992). Perhaps the main output, after more than 20 years of effort, was his book with Anna J. Schwartz, Monetary Trends in the United States and the United Kingdom, Their Relation to Income, Prices and Interest Rates, 1867–1975 (1982).

The main methodological decision lying behind this study was that, since there was too much inexplicable variation in short-run variations in income and money, it was best to ignore these and concentrate on comparing the cyclical phase averages. These would screen out the short-term effect and would enable an analysis to be made of the underlying long-term money–income–interest relationships.
Even for this team of Friedman and Schwartz, the treatment of the data and the integrity of their analysis reached new heights of meticulous scholarship. Yet, considering the enormous value of the input of time and energy, the results are, as the authors confess, hardly worth the cost. For the most part the study confirms, and demonstrates with comparative data for the United States and the United Kingdom, the basic propositions on velocity, real income, prices and interest rates that had emerged in the *History*.

In his final decades, it may be claimed that Friedman had fallen prey to the same temptations that affected Alfred Marshall. For many years of his mature professional career, Marshall spent much of his time revising and refining his great *Principles*. In retrospect it seemed to be a great loss to scholarship that Marshall did not leave the *Principles* well alone and turn to his projected study of the economics of the state. The opportunity was missed. It would be, however, a travesty to draw a close parallel between Friedman and Marshall in their mature years. Perhaps with the example of Marshall in mind, Friedman had generally launched his studies on the profession and then left them largely to fend for themselves. (The only exception is the textbook *Price Theory: A Provisional Text*, 1962, which was revised in 1976.) Yet there is a sense in which Friedman, trapped by his immense success in monetary economics, had been prevented from deploying his mind in scholarly work in other fields of economics.

The possibilities are revealed in Friedman's more popular writings on issues such as public spending, price and rent control, taxation, and many issues in microeconomics. Characteristic flashes of insight and phrase, together with the innovations of approach – especially the simplifications – give the professional reader a tantalizing taste of what might have been yet another great contribution to economic science. Many economists have always believed that, in spite of his great strides in money, Friedman's relative advantage was always in the study of price theory and its manifest applications. There is the measure of the man.

**The public image of Friedman**

The conventional view of Friedman is that he is one of the most ardent and most effective advocates of free enterprise and monetarist policies over the six decades 1945 to 2006. If far short of his wishes, the success of his advocacy has by any objective standard been enormous. Opinion in Western countries, even among the clerisy, has moved decisively in its preference for those economic freedoms that he has so eloquently advocated.

It is not possible to parcel out any neat attribution of influence on these great changes in attitude and policy. Friedman himself would probably give by far the largest weight to the experience of the 1970s, particularly the disappointments over failure to restrain the growth of government spending and the great inflation from 1965 to 1981. The explanation of these events and the development of an alternative strategy, with institutions that would ensure individual economic liberty and freedom from inflation, have been, in the public perception, Friedman's great contribution to the reforms. In his appearances in the various media he was a great persuader, and he played a critical role in promoting such ideas as an all volunteer army, the voucher schemes for education and health, and indexing income tax. In effectiveness, breadth and scope, his only rival among the economists of the 20th century is Keynes.

Frisch lived a long, varied and extremely productive life. He graduated in economics at the University of Oslo in 1919 (although as a son of a goldsmith he ‘supplemented’ this by finalizing his apprenticeship as a goldsmith in 1920!). He studied in France from 1921 to 1923 and in Britain in 1923; was an associate at the University of Oslo from 1925 and received his doctorate in 1926 in mathematical statistics (Frisch, 1926a). Further studies abroad in the USA, France and Italy (1927–8) were followed by an associate professorship at the University of Oslo (1928) and a full professorship in 1931. Frisch was head of the (newly established) Institute of Economics in Oslo from 1932 to his retirement in 1965. He was also chief editor of *Econometrica* (1933–55), followed by his chairmanship of the editorial board. He was one of the founders (1930) and, in fact, the driving force behind the creation of the Econometric Society. He was a member of a number of national and international expert committees and adviser on several occasions to developing countries (India 1954–5 and Egypt several times over the years 1957–64). He received honorary doctorates from a number of universities (*inter alia* Stockholm, Copenhagen, Cambridge, Birmingham) and was – together with Jan Tinbergen – the first (1969) to receive the Alfred Nobel Memorial Prize in Economics. In addition he received (as the first recipient) the Schumpeter Prize (1955), the Feltrinelli Prize (1956) and three *Festschriften*. He was a visiting professor or guest lecturer to a number of universities – Yale, Minnesota, Paris, Pittsburgh, for example – and he was a very active participant at numerous international meetings of economists, statisticians and mathematicians. In the late 1940s there was a joke among Norwegian students that he was also a ‘visiting’ professor in Oslo. This was unfair. In particular during the 1930s he put a lot of effort into his teaching and was writing a series of lecture notes, most of them seminal, though many remained unpublished. The impressive list of his publications (Haavelmo, 1973) and activities could be continued because he was a genius, cutting
through problems like a warm knife through butter, and because his working power was extraordinary. To survey his contributions is not easy for the simple reason that there is scarcely any area of economics Frisch has not been into and left his imprint. To cooperate with him was not always easy. He was too strong, as shown by the fact that he seldom had co-authors. The list of his published and printed works comprises about 160 items. But to this should be added a long series of mimeographed contributions — many will recall the ‘Memoranda fra Socialkonomisk Institutt’ — from about 1946 onwards. They amounted altogether to 6,500 pages, and most of them are still awaiting publication (though Frisch himself argued that ‘for editing it needs a very good man, and if he is good enough, he should write himself’).

Frisch began his academic work in the theory of mathematical statistics. This profession today acknowledges his early contributions and regrets his departure from it, though admitting that in terms of the more applied theory of statistics he made noticeable contributions later on. His years in Paris, where he concentrated on mathematics, were not in vain. It is, however, in economics that Frisch made his name. He was at most of the centres and many of the corners of the subject. One may, however, also argue that his most significant contribution is in economic methodology. This comes out not only in his applications of methods but also in their general presentation. A very good example was written overnight in a hotel room at Colmar, after a day’s discussions at a meeting of the Econometric Society. The article (Frisch, 1936b) is a classic, clearing the ground about the very meaning of static versus dynamic analysis. This is by now elementary, but it is elementary because of Frisch. In his principal works on methodology, he used and unified the tools he had mastered so well: economic theory, mathematics and statistics. It is no accident that he invented the word ‘econometrics’, for in general he enriched our methodological vocabulary by a number of precise concepts: macro- versus micro-analysis, statics versus dynamics, exogenous versus endogenous variables, the concept of autonomous relations, the problem of identification of relations, confluent relations, decision models, conjectural behaviour (of firms) — a complete list would be very long.

Few would hesitate to agree that Frisch ‘created’ econometrics in the modern sense of the word. It is much more notable that he warned again and again against misuses of the new tools. In the first issue of Econometrica in 1933 he wrote: ‘The policy of Econometrica will be as heartily to denounce futile playing with mathematical symbols in economics as to encourage their constructive use.’ In Frisch (1970), he argued that ‘the econometric army has now grown to such proportions that it cannot be beaten by the silly arguments that were used against us previously. This imposes on us a social and scientific responsibility of high order in the world of today’ (p. 153). But in the very same article he also stressed (p. 163) that ‘I have insisted that econometrics must have relevance to concrete realities — otherwise it degenerates into something which is not worthy of the name econometrics, but ought rather to be called playometrics’.

Always underlying Frisch's contributions to methodology were his consistent efforts to turn economics into a precise science, quantifying the variables and the structures. This is different from the traditional ‘on the one hand and on the other’, where on balance the answer is left in the air. But this ‘aggressive’ view also presents new challenges. The economist must be prepared for the troublesome work of gathering data, to face the difficulties in estimating structures and in the end to attempt a balanced interpretation of the outcome. Frisch saw this and contributed to this debate throughout his career; illustrations might be Frisch (1933a; 1934b; 1936a; 1939). These and many other contributions had a profound influence and wide applications in pre-war as well as post-war econometrics. Again, and sadly
enough, one could also refer to a number of unpublished papers, though these were influential as contributions to scientific gatherings. A supreme example is a paper on ‘Statistical versus Theoretical Relations in Macrodynamics’, a contribution to a conference sponsored by the League of Nations in 1938 to discuss Jan Tinbergen's work for the League of Nations on the trade cycle.

One may wonder why Frisch left so many path-breaking contributions without taking the trouble to publish them. I think there is a double answer. On the one hand Frisch was an impatient man: if he had given the gist of the solution to a problem, he tended to go on to new problems. On the other hand, he was extremely careful: a publication going to the printer had to be perfect and finalized – a troublesome process which he often tended to avoid. Haavelmo (1973), reports that Frisch often argued that proofreading is one of the most difficult and important tasks of a scientist.

The general assessment above can be verified by considering Frisch's contributions in the field of demand analysis, the theory of production and the theory of macroeconomics.

In demand analysis he began as early as 1926 (Frisch, 1926b), by formulating a number of basic axioms and from these to deduce a theory of demand. Thus utility functions were not postulated but were derived from more basic axioms, all of these being formulated as being, in principle, open to testing. It may be fair to say that his work in this field culminated in Frisch (1959). It is a tribute to his work that it has in fact been used in practice, for example in Norwegian planning.

In the theory of production Frisch was a forerunner, formulating the theory in a strict mathematical form but also applying it on concrete problems. An example is Frisch (1935). However, most of his works were in the form of mimeographed lecture notes in the 1930s and remained unpublished until 1962 and later (Frisch, 1962;1963). The main results, however, were internationally known through the works of Schneider and Carlson, who at times were research associates in Oslo and very much influenced by Frisch.

Also in the theory of macroeconomics, Frisch was at the front, even, it can be argued, ahead of Keynes. Anybody reading his booklet, Frisch (1933b), and the subsequent articles in *Econometrica* (1934a), might be willing to argue that Frisch made it first. He shows convincingly how a capitalist economy may go into a deadlock when, to put it in a simple way, the tailor cannot sell to the shoemaker because the shoemaker cannot sell to the tailor:

… the cause of great depressions, such as the one we are actually in, is … fundamentally connected with the fact that modern economic life has been divided into a number of regions or groups.

Under the present system, the blind ‘economic laws’ will under certain circumstances, create a situation where these groups are forced mutually to undermine each other's position. Each group is forced to curtail the use goods produced and services rendered by the other groups, which, in turn, will cause a still further contraction of the demand for its own products, and so on. (Frisch, 1934a, pp. 259f.)

He also, in the 1934 articles, outlined (a couple of years before Leontief) an input–output analysis. His contributions in these areas were not appreciated at the time, but from a historical perspective they are path-breaking. This also holds for his contribution to the (famous) Cassel *Festschrift* (Frisch, 1933c), where a dynamic system for the economy as a whole was outlined and where he distinguished in a sharp
and fruitful way between the impulses and the propagation mechanism. In this context one may also, as an illustration of his interest in the development of economic theory, make a reference to his excellent analysis of Marshall (Frisch, 1950).

There is a direct line from here to his systems of national accounts (first published in Frisch, 1939) which had a profound influence on the planning in Norway and elsewhere after the Liberation. In the context of macroeconomics it is illustrative to mention Frisch’s discussion with J.M. Clark over the acceleration principle (Frisch, 1931, 1932). In an amazingly simple way Frisch cleared up the issue, that is, the interplay between the pure acceleration principle and the reinvestment cycle, as the following quotation shows:

Let $z$ be consumer-taking [in present day language this is simply consumption] per unit of time, $w$ capital production per unit of time, and $W$ the capital stock that exists at any moment of time. All the three magnitudes $z$, $w$, and $W$ are, of course, functions of time. In practice they would be represented by time series.

Let us, for simplicity, make the following two assumptions: A. Consumer-taking $z$ is the same as the production of the consumer good, and this again is at any time proportional to the existing capital stock $W$. In other words, we have

$$W = k z,$$

(1)

where $k$ is a constant independent of time. B. The depreciation per unit of time $u$, that is to say, the capital production that is needed for replacement purposes, is proportional to the existing capital stock. In other words, we have

$$u = h W,$$

(2)

where $h$ is a constant independent of time. Now, the rate of change with respect to time of the capital stock is equal to

$$\dot{W} = w - u$$

(3)

By virtue of (1) we have, however,
where $\dot{z}$ is the rate of change of consumer-taking. Inserting this into (3), and expressing $u$ in terms of $z$ by (2) and (1), we get

$$k\dot{z} = w - khz.$$  

So that we finally have

$$w = k(\dot{hz} + \dot{z}).$$  

The rate of change with respect to time of capital production is thus equal to

$$\dot{w} = k(\dot{hz} + \dot{z}).$$  

Formula (5) indicates the two parts of which total capital production is made up. In the first place we have the part $khz$ that represents capital production for replacement purposes. This part is (under our simplified assumption) proportional to the size of consumer-taking. In the second place, we have the part $k\dot{z}$ representing capital production for expansion purposes. This part is (under the present simplified assumption) proportional to the rate of change of consumer-taking. Thus there are two forces that act upon total capital production. If consumer-taking is increasing, but at a constantly decreasing rate, the first of these two forces tends to increase, and the second tends to slow down capital production. Which one of the two forces shall have the upper hand depends on the manner in which the increase in consumer-taking slows down, and it depends also on the rate of depreciation (Frisch, 1931, pp. 647f.).

As will be seen, it is all so simple, provided the problem is formulated clearly. And formulating problems in a fruitful way was one of his secrets.

What is a genius? It might be argued that Frisch up till now was one of the ten in our profession in the 20th century. Not that he cannot be criticized. On occasion he used his brains more or less in vain, for
example, on unimportant calculating schemes. Long after electronic calculators were on the market, he used time and effort on inventing schemes for inverting a matrix on a simple desk calculator. His various methods for the solution of programming problems – ‘the logarithmic potential method’, ‘the multiplex method’ and ‘the nonplex method’ (for example, Frisch, 1956; 1957; 1961a; 1961b) – are still disputable, taking present-day techniques into account. In other words, he might have had a weak point in not always being able to evaluate the importance of a problem; that is, he might now and then have used his immense working power on issues where his opportunity costs were too high.

Even so, his life work is impressive. And so was the man himself. His political attitude was rather to the left than to the right – while at the same time he was a devout Christian. He felt a strong social responsibility, as proved through his work on the problems of the 1930s as well as, and perhaps even more so, by his consciousness towards the less developed countries. He could at times be a bit harsh on colleagues who did not live up to his own standards for serious work. At the same time he was extremely kind and helpful to students doing their best. He never failed to encourage. And few will forget when his strong blue eyes were shining with joy.

Econometricians have developed a number of alternative methods for estimating parameters and testing hypotheses in simultaneous equations models. Some of these are limited information methods that can be applied one equation at a time and require only minimal specification of the other equations in the system. In contrast, the full information methods treat the system as a whole and require a complete specification of all the equations.

The distinction between limited and full information methods is, in part, simply one of statistical efficiency. As is generally true in inference problems, the more that is known about the phenomena being studied, the more precisely the unknown parameters can be estimated with the available data. In an interdependent system of equations, information about the variables appearing in one equation can be used to get better estimates of the coefficients in other equations. Of course, there is a trade-off: full information methods are more efficient, but they are also more sensitive to specification error and more difficult to compute.

Statistical considerations are not, however, the only reason for distinguishing between limited and full information approaches. Models of the world do not come off the shelf. In any application, the choice of which variables to view as endogenous (i.e. explained by the model) and which to view as exogenous (explained outside the model) is up to the analyst. The interpretations given to the equations of the model and the specification of the functional forms are subject to considerable discretion. The limited information and full information distinction can be viewed not simply as one of statistical efficiency but one of modelling strategy.

The simultaneous equations model can be applied to a variety of economic situations. In each case, structural equations are interpreted in light of some hypothetical experiment that is postulated. In considering the logic of econometric model building and inference, it is useful to distinguish between two general classes of applications. On the one hand, there are applications where the basic economic question involves a single hypothetical experiment and the problem is to draw inferences about the parameters of a single autonomous structural equation. Other relationships are considered only as a means for learning about the given equation. On the other hand, there are applications where the basic economic question being asked involves in an essential way an interdependent system of experiments. The goal of the analysis is to understand the interaction of a set of autonomous equations.
An example may clarify the distinction. Consider the standard competitive supply demand model where price and quantity traded are determined by the interaction of consumer and producer behaviour. One can easily imagine situations where consumers are perfectly-competitive price takers and it would be useful to know the price elasticity of market demand. One might be tempted to use time-series data and regress quantity purchased on price (including perhaps other demand determinants like income and prices of substitutes as additional explanatory variables) and to interpret the estimated equation as a demand function. If it could plausibly be assumed that the omitted demand determinants constituting the error term were uncorrelated over the sample period with each of the included regressors, this interpretation might be justified. If, however, periods where the omitted factors lead to high demand are also the periods where price is high, then there will be simultaneous equations bias. In order to decide whether or not the regression of quantity on price will produce satisfactory estimates of the demand function, the mechanism determining movements in price must be examined. Even though our interest is in the behaviour of consumers, we must consider other agents who influence price. In this case a model of producer behaviour is needed.

This example captures the essence of many econometric problems: we want to learn about a relationship defined in terms of a hypothetical isolated experiment but the data we have available were in fact generated from a more complex experiment. We are not particularly interested in studying the process that actually generated the data, except in so far it helps us to learn about the process we wish had generated the data. A simultaneous equations model is postulated simply to help us estimate a single equation of interest.

Some economic problems, however, are of a different sort. Again in the supply–demand set-up, suppose we are interested in learning how a sales tax will affect market price. If tax rates had varied over our sample period, a regression of market price on tax rate might be informative. If, however, there had been little or no tax rate variation, such a regression would be useless. But, in a correctly specified model, the effects of taxes can be deduced from knowledge of the structure of consumer and producer decision making in the absence of taxes. Under competition, for example, one needs only to know the slopes of the demand and supply curves. Thus, in order to predict the effect of a sales tax, one might wish to estimate the system of structural equations describing market equilibrium.

The distinction between these two situations can be summarized as follows: in the one case we are interested in a structural equation for its own sake; in the other case our interest is in the reduced-form of an interdependent system. If our concern is with a single equation, we might prefer to make few assumptions about the rest of the system and to estimate the needed parameters using limited information methods. If our concern is with improved reduced-form estimates, full-information approaches are natural since specification of the entire system is necessary in any case. A further discussion of these methodological issues can be found in Hood and Koopmans (1953, chs 1 and 6).

**Limited information methods**

Consider a single structural equation represented by

\[
Y = X\alpha + \epsilon
\]  

(1)
where \( y \) is a \( T \)-dimensional (column) vector of observations on an endogenous variable, \( Z \) is a \( T \times n \) matrix of observations on \( n \) explanatory variables, \( \alpha \) is an \( n \)-dimensional parameter vector, and \( u \) is a \( T \)-dimensional vector of random errors. The components of \( \alpha \) are given a causal interpretation in terms of some hypothetical experiment suggested by economic theory. For example, the first component might represent the effect on the outcome of the experiment of a unit change in one of the conditions, other things held constant. In our sample, however, other conditions varied across the \( T \) observation. The errors represent those conditions which are not accounted for by the explanatory variables and are assumed to have zero mean.

The key assumption underlying limited-information methods of inference is that we have data on \( K \) predetermined variables that are unrelated to the errors. That is, the error term for observation \( t \) is uncorrelated with each of the predetermined variables for that observation. The \( T \times K \) matrix of observations on the predetermined variables is assumed to have rank \( K \) and is denoted by \( X \). By assumption, then, \( E(X' u) \) is the zero vector. Some of the explanatory variables may be predetermined and hence some columns of \( Z \) are also columns of \( X \). The remaining explanatory variables are thought to be correlated with the error term and are considered as endogenous. Implicitly, equation (1) is viewed as part of a larger system explaining all the endogenous variables. The predetermined variables appearing in \( X \) but not in \( Z \) are assumed to be explanatory variables in some other structural equation. Exact specification of these other equations is not needed for limited information analysis.

In most approaches to estimating \( \alpha \) it is assumed that nothing is known about the degree of correlation between \( u \) and the endogenous components of \( Z \). Instead, the analysis exploits the zero correlation between \( u \) and \( X \). The simplest approach is the method of moments. Since \( X' u \) has mean zero, a natural estimate of \( \alpha \) is that vector \( a \) satisfying the vector equation \( X' (y - Za) = 0 \). This is a system of \( K \) linear equations in \( n \) unknowns. If \( K \) is less than \( n \), the estimation method fails. If \( K \) equals \( n \), the estimate is given by \((X'Z)^{-1}X'y\), as long as the inverse exists. The approach is often referred to as the method of instrumental variables and the columns of \( X \) are called instruments.

If \( K \) is greater than \( n \), any \( n \) independent linear combinations of the columns of \( X \) can be used as instruments. For example, for any \( n \times K \) matrix \( D \), \( \alpha \) can be estimated by

\[
(D'X'Z)^{-1}D'X'y
\]

as long as the inverse exists. Often \( D \) is chosen to be a selection matrix with each row containing zeros except for one unit element; that is, \( n \) out of the \( K \) predetermined variables are selected as instruments and the others are discarded. If \( Z \) contains no endogenous variables, it is a submatrix of \( X \), least squares can then be interpreted as instrumental variables using the regressors as instruments.

The estimator (2) will have good sampling properties if the instruments are not only uncorrelated with the errors but also highly correlated with the explanatory variables. To maximize that correlation, a
natural choice for $D$ is the coefficient matrix from a linear regression of $Z$ on $X$. The instruments are then the predicted values from that regression. These predicted values (or projections) can be written as $NZ$ where $N$ is the idempotent projection matrix $X(X'X)^{-1}X'$; the estimator becomes

$$(Z'NZ)^{-1}Z'NY$$

Because $N=NN$, the estimator (2) can be obtained by simply regressing $y$ on the predicted values $NZ$. Hence, this particular instrumental variables estimator is commonly called two-stage least squares. The two-stage least-squares estimator is readily seen to be the solution of the minimization problem

$$\min (y - Z\delta)'N(y - Z\delta).$$

(3)

As an alternative, it has been proposed to minimize the ratio

$$\frac{(y - Z\delta)'N(y - Z\delta)}{(y - Z\delta)'M(y - Z\delta)}$$

(4)

where $M=1-N$ is also an idempotent projection matrix. This yields the limited-information maximum-likelihood estimator. That is, if the endogenous variables are assumed to be multivariate normal and independent from observation to observation, and if no variables are excluded a priori from the other equations in the system, maximization of the likelihood function is equivalent to minimizing the ratio (4). This maximum likelihood estimate is also an instrumental variable estimate of the form (2). Indeed, the matrix $D$ turns out to be the maximum likelihood estimate of the population regression coefficients relating $Z$ and $X$. Thus the solutions of (3) and (4) are both instrumental variable estimates. They differ only in how the reduced-form regression coefficients used for $D$ are estimated.

The sampling distribution of the instrumental variable estimator depends, of course, on the choice of $D$. The endogenous variables in $Z$ are necessarily random. Hence, the estimator behaves like the ratio of random variables; its moments and exact sampling distribution are difficult to derive even under the assumption of normality. However, large-sample approximations have been developed. The two-stage least-squares estimate and the limited information maximum-likelihood estimate have, to a first order of
approximation, the same large-sample probability distribution. To that order of approximation, they are optimal in the sense that any other instrumental variable estimators based on $X$ have asymptotic variances at least as large. The asymptotic approximations tend to be reasonably good when $T$ is large compared with $K$. When $K - n$ is large, instrumental variable estimates using a subset of the columns of $X$ often outperform two-stage least squares. Further small-sample results are discussed by Fuller (1977).

**Full information methods**

Although limited-information methods like two-stage least squares can be applied to each equation of a simultaneous system, better results can usually be obtained by taking into account the other equations. Suppose the system consists of $G$ linear structural equations in $G$ endogenous variables. These equations contain $K$ distinct predetermined variables which may be exogenous or values of endogenous variables at a previous time period. The crucial assumption is that each predetermined variable is uncorrelated with each structural error for the same observation.

Let $y_1, \ldots, y_G$ be $T$-dimensional column vectors of observations on the $G$ endogenous variables. As before, the $T \times K$ matrix of observations on the predetermined variables is denoted by $X$ and assumed to have rank $K$. The system is written as

$$y_i = Z_i \alpha_i + u_i \quad (i = 1, \ldots, G) \quad (5)$$

where $Z_i$ is the $T \times n_i$ matrix of observations on the explanatory variables, $u_i$ is the error vector, and $\alpha_i$ is the parameter vector for equation $i$. Some of the columns of $Z_i$ are columns of $X$; the others are endogenous variables.

Again, estimates can be based on the method of moments. Consider the set of $GK$ equations

$$X' (y_i - Z_i \alpha_i) = 0 \quad (i = 1, \ldots, G) \quad (6)$$

If, for any $i$, $K$ is less than $n_i$, the corresponding parameter $\alpha_i$ cannot be estimated; we shall suppose that any equation for which this is true has already been deleted from the system so that $G$ is the number of equations whose parameters are estimable. If $n_i = K$ for all $i$, the solution to (6) is obtained by using limited information instrumental variables on each equation separately. If, for some $i$, $n_i < K$, the system (6) has more equations than unknowns. Again, linear combinations of the predetermined variables can be used as instruments. The optimal selection of weights, however, is more complicated than in the limited-information case and depends on the pattern of correlation among the structural errors.
If the structural errors are independent from observation to observation but are correlated across equations, we have the specification

$$E(u_i'u_j') = \sigma_{ij}(i, j = 1, \ldots, G)$$

where the $\sigma$'s are error covariances and $I$ is a $T$-dimensional identity matrix. As a generalization of (3), consider the minimization problem

$$\min \sum \sum (y_i - z_i\alpha_i)'N(y_i - z_j\alpha_j)a_{ij}$$

(7)

where the $\sigma^{ij}$ are elements of the inverse of the matrix $[\sigma_{ij}]$. For given $\sigma$'s, the first-order conditions are

$$\sum_j Z_j'N(y_i - z_j\alpha_j)a_{ij} = 0 (i = 1, \ldots, G)$$

(8)

which are linear combinations of the equations in (6). It can be demonstrated that the solution to (8) is an instrumental variables estimator with asymptotically optimal weights. In practice, the $\sigma$'s are unknown but can be estimated from the residuals of some preliminary fit. This approach to estimating the $\alpha$'s is called three-stage least squares since it involves least-squares calculations at three stages, first to obtain the projections $NZ_j$, again to obtain two-stage least-squares estimates of the $\sigma$'s, and finally to solve the minimization problem (7). For details, see Zellner and Theil (1962).

If the structural errors are assumed to be normal, the likelihood function for the complete simultaneous equations system has a relatively simple expression in terms of the reduced-form parameters. However, since the reduced form is nonlinear in the structural parameters, analytic methods for maximizing the likelihood function are not available and iterative techniques are used instead. Just as in the limited-information case, the maximum-likelihood estimator can be interpreted as an instrumental variables estimator. If in (8) the least-squares predicted values $NZ_i$ are replaced by maximum-likelihood predictions and if the $\sigma$'s are replaced by their maximum-likelihood estimates, the resulting solution is the (full-information) maximum-likelihood estimate of the $\alpha$'s. See Malinvaud (1970, ch. 19) for details.
At one time full-information methods (particularly those using maximum likelihood) were computationally very burdensome. Computer software was almost non-existent, rounding error was hard to control, and computer time was very expensive. Many econometric procedures became popular simply because they avoided these difficulties. Current computer technology is such that computational burden is no longer a practical constraint, at least for moderate-sized models. The more important constraints at the moment are the limited sample sizes compared with the number of parameters to be estimated and limited confidence we have in the orthogonality conditions that must be imposed to get any estimates at all.

John Fullarton shared at least one characteristic with his great predecessor, Ricardo: he also seemed, in the words of Lord Brougham, ‘as if he had dropped from another planet’. Although Fullarton is described in the Dictionary of National Biography as a ‘traveller and writer on the currency’, travel occupied by far the greater proportion of his life, along with a keen interest in the world of art and literature. Yet the single published work on which his considerable reputation as an economist is based had an impact comparable with that of Ricardo's intervention in the Bullion Controversy at the turn of the century.

In his early twenties, Fullarton became a surgeon in India and found time to edit a Calcutta newspaper. There he subsequently made a fortune in banking and began the first of his extensive tours through ‘our eastern possessions’, as the Dictionary of National Biography endearingly calls them. On this tour, Fullarton collected vast amounts of information and made many notes of his observations, but these were never published. In 1823, having returned to England to live, he contributed articles to the Quarterly Review on the reform crisis; however, it was not long before he resumed his travels, this time around Britain and the continent in a coach specially fitted with a library. In 1833, as a Fellow of the Royal Asiatic Society, Fullarton went again to India, and, in the following year, to China; but his zeal evaporated along with his fortune as a result of the failure of his bankers, and he moved back to London permanently.

It was in 1844, during the passage of the Bank Charter Act through the House of Commons, that Fullarton published his major work, On the Regulation of Currencies, subtitled ‘an examination of the principles on which it is proposed to restrict, within certain fixed limits, the future issues on credit of the Bank of England, and of the other banking establishments throughout the country’. It was immediately hailed as a formidable challenge to the Currency School orthodoxy, whose support for the Bank Charter Act had overwhelmed Tooke's lonely opposition in the opening round of the ‘currency-banking debate’.
Indeed, according to Gregory, Fullarton’s ‘penetrating tract’ was ‘perhaps the most subtle and able production emanating from the Banking School’ (introduction to Tooke, 1838/57, p. 81).

Fullarton’s aim was a simple one: to bolster Tooke’s case against what they both saw as ill-conceived banking legislation; in doing so, however, he not only improved its presentation, but also developed the theoretical basis of the argument in a number of important respects, taking the opportunity to lament the fact that ‘Mr. Tooke himself has been exceedingly slow in following out his original conclusions on the subject of price to all their consequences’ (1844, p. 18).

The Currency School had asserted that convertibility would not be a sufficient safeguard against the overissue of bank notes and their consequent depreciation; and that the quantity of notes in circulation would have to be regulated in accordance with the movement of bullion across the foreign exchanges. The response of Fullarton and the Banking School took three main lines. First, starting from the assumption that legal convertibility necessarily implied economic convertibility, they pointed out that any discrepancy between the note issue and a purely metallic system arose from the Currency School’s erroneous theory of metallic circulation rather than from the supposed autonomy of the notes. Second, any effect on prices attributed to bank notes could not be denied to a range of financial assets excluded by the Currency School from their definition of money. Third, bank notes were in any case not money but credit, and therefore never could be overissued, though the credit structure as a whole might be extended beyond the limits of real accumulation by speculation. It was in this context that Fullarton developed the famous ‘law of reflux’, which he called ‘the great regulating principle of the internal currency’ (1844, p. 68).

Tooke, in turn, warmly welcomed Fullarton’s analysis in the subsequent volume of his massive History of Prices, and gave some indication of the surprise he must have experienced upon its publication:

[L]est his estimate of the value of my contributions to an extension of the knowledge of this subject, should be ascribed to the bias of friendship, I think it right to state that the distinguished author was unknown to me, except by name and reputation, till after the publication of his treatise, and that I had not the slightest knowledge of such a work being in preparation. (1838/57, vol. 4, pp. x–xi)

Tooke then paid Fullarton the compliment of quoting extensively from his work, repeatedly praising the ‘wonderful clearness and vigour which distinguish his writings’ (vol. 5, p. 537). Nor was Fullarton above self-promotion: it appears that he had a hand in a Quarterly Review article, ‘The Financial Pressure’, which saw the crisis of 1847 as confirming the warnings of ‘Mr Fullarton's masterly treatise’ (see Fetter, 1965, p. 212).

It is certainly true that Fullarton’s work ‘enjoyed, in England and on the Continent, a persistent success such as few contributions to an ephemeral controversy have ever enjoyed’ (Schumpeter, 1954, p. 725). Marx, for example, included Fullarton among ‘the best writers on money’ (1867, p. 129); in his view, ‘the economic literature worth mentioning since 1830 resolves itself mainly into a literature on currency, credit, and crises’ (1894, pp. 492–3). Hilferding, too, drew heavily on Fullarton (Hilferding, 1910); and even Keynes was impressed with his ‘most interesting’ contribution to monetary thought (Keynes, 1936, p. 364 n.). Many of Fullarton’s arguments later resurfaced in the Radcliffe Report of 1959, and are still today being ‘rediscovered’. As Fullarton himself pointed out (1844, p. 5), ‘this is a subject on which
there never can be any efficient or immediate appeal to the public at large. It is a subject on which the progress of opinion always has been, and always must be, exceedingly slow.’

A branch of mathematics mainly concerned with infinite-dimensional vector spaces and their maps, functional analysis is so called because elements (points) of certain important specific spaces are functions. The necessity of considering infinite-dimensional models arises in economics in many problems, including assessment of random effects in a situation with an infinite number of natural states; study of effects arising from a ‘very large’ number of participants; problems of spatial economics; study of economic development in continuous time, in particular, with due regard for lags; economic growth on an infinite time interval; and the influence of commodity differentiation on exchange processes.

Article

Functional analysis is a branch of mathematics mainly concerned with infinite-dimensional vector spaces and their maps. Elements (points) of certain important specific spaces are functions, hence the term ‘functional analysis’.

An important role in the development of functional analysis was played by set theory, abstract algebra and axiomatic geometry. General topology, measure theory, differential equations and some other branches of mathematics evolved in close contact with functional analysis, so that it is difficult to indicate where these disciplines end and functional analysis begins.

The fundamental ideas of functional analysis appeared at the turn of the 20th century; by the 1920s it
had already evolved into an autonomous discipline. Among its founders were Banach, Fréchet, Hadamard, Hilbert, von Neumann, Riesz and Volterra.
The creation of functional analysis resulted in basic changes in the approach to many mathematical problems. The study of individual functions and equations was replaced by that of families of such objects. Abstract forms of investigation ensured a unified approach to questions which seemed distant at first glance; they were instrumental in finding more general, yet deeper and more concrete relationships. From the outset, the development of functional analysis was stimulated by the intrinsic requirements of mathematics, as well as by applications, especially to quantum mechanics. Today the language of functional analysis is actually used in all of continuous mathematics. Its methods have become the foundation of a whole series of new branches of research, both theoretical and applied, such as the theory of random processes, differential topology, dynamic systems, optimal control theory, mathematical programming, and so on. Functional methods penetrate deeper and deeper into theoretical physics and into different engineering disciplines. These methods find more and more widespread applications in mathematical economics.

Spaces studied in functional analysis usually belong to the class of linear (vector) topological spaces, that is, linear spaces supplied with a topology (a system of open sets and hence a notion of limit), for which the linear operations are continuous. A narrower class of spaces is metric vector spaces, for which distance between points is defined. The distance is given by a function (the metric, assigning a non-negative number to each pair of vectors) which possesses certain specific properties of ordinary distance. The topology in such spaces is naturally induced by the metric.

An important subclass of metric spaces is normed spaces, that is, linear spaces in which to each element \( x \) a non-negative number \( \| x \| \), called the norm of \( x \), is assigned, and the following conditions are satisfied:

1. (1) \( \| x \| = 0 \) if and only if \( x = 0 \);
2. (2) \( \| \lambda x \| = |\lambda| \| x \| \) for any scalar \( \lambda \) (homogeneity);
3. (3) \( \| x + y \| \leq \| x \| + \| y \| \) (triangle inequality).

The norm is an abstraction of the notion of ‘vector length’. The function \( d(x, y) = \| x - y \| \) is the metric in normed spaces. It is said that a sequence \( x_i \) of elements converges to the element \( x \) in the strong topology, if \( \| x_t - x \| \to 0 \) as \( t \to \infty \). A normed space is said to be a Banach space if it is complete; this means that any of its fundamental sequences (that is, such that \( \| x_t - x_s \| \to 0 \) as \( t, s \to \infty \)) has a limit.

Banach spaces often appear in applications.

A Banach space \( X \) is said to be a Hilbert space if it is supplied with a numerical function \((x, y)\), called scalar product of vectors \( x, y \in X \), related to the norm by the identity \( \| x \|^2 = (x, x) \) and satisfying the conditions:

1. (1) \((x, y)\) and \((y, x)\) are complex conjugates (in particular, for real vector spaces, \((x, y) = (y, x)\));
2. (2) \((\lambda_1 x_1 + \lambda_2 x_2, y) = \lambda_1 (x_1, y) + \lambda_2 (x_2, y)\);
3. (3) \((x, x) \geq 0 \) and \((x, x) = 0 \) only if \( x = 0 \).
The scalar product makes it possible to characterize the ‘angle between vectors’ and, in particular, to introduce the notion of orthogonal vector. As a result, the geometry of Hilbert spaces is close to Euclidean geometry.

Let us present some examples of specific spaces. The space $l_p(1 \leq p < \infty)$ of all numerical sequences $x = (\alpha_n)$ with the norm

$$
\|x\| = \left( \sum_{n=1}^{\infty} |\alpha_n|^p \right)^{1/p}
$$

is a Banach space. For $p=2$ it is a Hilbert space if the scalar product is defined by the formula

$$
(x, y) = \sum_{n=1}^{\infty} \alpha_n \overline{\beta}_n, \quad x = (\alpha_n), \quad y = (\beta_n),
$$

where $\overline{\beta}_n$ is the complex number conjugate to $\beta_n$. The space $L_2(a, b)$ of all real functions defined on the closed interval $[a, b]$, square integrable in the Lebesgue sense, is a Hilbert space (functions which differ on a set of zero measure are identified) if the scalar product is defined by the formula

$$
(x, y) = \int_a^b x(t) y(t) dt.
$$

$L_2(a, b)$ is a particular case of the Banach spaces $L_p(1 \leq p \leq \infty)$ of functions defined on so-called measure spaces. The theory of the spaces $L_p$ is part of the foundations of probability theory, where the functions from $L_p$ are interpreted as random variables. For $p \neq 2$ the spaces $l_p$ and $L_p$ are not Hilbert spaces.

Another important example is the Banach space $C(S)$ – the collection of all continuous scalar functions on the compact space $S$, with the norm

$$
\|x\| = \max_{s \in S} \|x(s)\|.
$$
All the spaces listed above are infinite dimensional, that is, contain an infinite subset of linearly independent vectors (the notion of linear independence here is the same as in linear algebra). A finite dimensional vector space may be transformed into a Banach space in many different ways by appropriate choices of norms, but the convergence in any norm will be equivalent to the coordinate one. Although many facts of classical analysis can be generalized to Banach spaces, the infinite dimensional theory is essentially different from the finite dimensional one in many ways. One of the reasons is that a bounded sequence (with respect to norm) in a Banach space does not necessarily contain any fundamental subsequences and therefore may have no limiting points; such is the sequence \( l_n, n = 1, 2, \ldots \) in \( l_2 \), whose \( n \)th element \( l_n \) is the vector all of whose coordinates are zero, except the \( n \)th, which equals 1.

A function from one space into another is often said to be an operator. Operators with scalar values are called functionals. The operators most thoroughly studied are the linear ones. An operator \( T \) from the vector space \( X \) to the vector space \( Y \) is called linear if

\[
T(\lambda_1 x_1 + \lambda_2 x_2) = \lambda_1 T(x_1) + \lambda_2 T(x_2)
\]

for all \( x_1, x_2 \in X \) and arbitrary scalars \( \lambda_1, \lambda_2 \). In particular, the derivation and integration operations determine linear operators for appropriate choices of the spaces \( X, Y \). If \( X \) and \( Y \) are finite dimensional, linear operators from \( X \) to \( Y \) are determined by matrices.

The theory of linear operators in Banach spaces is one of the most developed sections of functional analysis. It is a far-reaching generalization of linear algebra and, in particular, of matrix theory. However, the purely algebraic approach is insufficient in the infinite dimensional case. One of the reasons is the necessity of distinguishing continuous and discontinuous linear operators (continuity is not an algebraic notion), while for operators in finite dimensional space linearity implies continuity. For a linear operator from one Banach space to another to be continuous, it is necessary and sufficient that it be bounded, that is, that it map bounded sets into bounded sets.

The set \( B(x, y) \) of continuous linear operators from \( X \) to \( Y \) is a linear space with respect to the natural operations of addition and multiplication by scalars. This set becomes a Banach space if the norm \( \|T\| \) of the operator \( T \) is defined by the formula

\[
\|T\| = \sup_{\|x\| \leq 1} \|T(x)\|
\]

In the particular case when \( Y \) is the set of scalars, we get the Banach space \( X^* \) of all linear continuous functionals on \( X \), which is called adjoint to \( X \). The study of adjoint spaces is not only of intrinsic interest but is also needed to obtain deeper results about the initial space \( X \).
The adjoint space of an \( n \)-dimensional space is also \( n \)-dimensional. The space adjoint to \( l_p \) coincides, in a certain sense, with the space \( l_q \), where \( 1/q + 1/p = 1 \) (a similar statement holds for \( L_p \)). A complete description of linear continuous functionals has been obtained for many specific spaces. We only mention F. Riesz's famous theorem describing the general form of a linear continuous functional on the space \( C(S) \) of continuous functions. In the particular case when \( S \) is the closed interval \([a, b]\) on the numerical line, any element \( f \in \mathcal{C}^*(a, b) \) can be represented in the form

\[
    f(x) = \int_{a}^{b} x(t) \, d\varphi(t),
\]

where \( \varphi \) is a function of bounded variation.

The operation of taking adjoint spaces can be iterated, yielding a sequence of Banach spaces \( X, X^*, X^{**}, \ldots \) each of which is adjoint to the previous one. Each vector \( x \in X \) can be viewed as an element of the second adjoint space \( X^{**} \) by putting \( x(f) = f(x) \) for any \( f \in X^* \); the functional thus defined is linear, continuous and its norm coincides with \( \|x\| \). If all the elements of \( X^{**} \) can be represented in this way, the initial Banach space \( X \) is called reflexive.

In certain aspects reflexive spaces have more resemblance to finite dimensional ones than do non-reflexive spaces.

A sequence \( x_n \) in a Banach space \( X \) is said to converge weakly to \( x \in X \) if \( f(x_n) \to f(x) \) as \( n \to \infty \) for any functional \( f \in X^* \). This definition implicitly supplies \( X \) with the weak topology which differs, as a rule, from the original one. The consideration of different versions of convergence on the same linear space and the study of their relationships is typical of functional analysis.

Among the numerous facts of Banach space it is customary to single out three theorems which, because of their importance and manifold applications, are known as the main principles of linear analysis.

The extension principle (Hahn–Banach Theorem) states that every continuous linear functional defined on a subspace of a normed space can be extended to the entire space, preserving norm. Using this principle it is possible to prove so-called separation theorems, which claim that under appropriate conditions two non-intersecting convex sets in a Banach space may be separated by a hyperplane, that is, a set of the form \( \{x \mid f(x) = \alpha\} \), where \( f \) is a non-zero continuous linear functional and \( \alpha \) is a scalar. Separation theorems make possible the wide use of geometric ideas in the study of Banach spaces.

The uniform boundedness principle (Banach–Steinhaus Theorem) states that a sequence of linear continuous operators \( T_n \in B(X, Y) \) is pointwise convergent, that is, \( T_n(x) \to T(x) \) as \( n \to \infty \) for all \( x \in X \) if and only if the two following conditions hold:

1. (1) such a convergence takes place on a set of arguments whose linear envelope is dense in \( X \);
2. (2) the norms of all the \( T_n \) are uniformly bounded with respect to \( n \).

According to the openness principle (Banach Theorem), any continuous linear operator from one
Banach space to another sends open sets into open sets.
The development of the theory of linear operators, especially at its initial stage, was stimulated by the problem of solving linear operator equations.

\[ T(x) = y \]

(1)

where \( x, y \) are elements of infinite dimensional spaces.
The similarity between linear functionals and algebraic equations, previously noted for linear differential equations, turned out to be just as productive for integral equations, whose foundations were laid at the beginning of the century by Fredholm, Hilbert, Noether and Volterra.

An exhaustive theory has only been constructed for certain classes of equations (1). In particular, the case when \( T = I + K \) where \( I \) is the identity operator and \( K \) is compact (that is, maps bounded sets into sets with compact closure) has been conclusively studied. Compact operators often appear in applications and are very similar to finite dimensional ones.

In the study of operator equations and in many applications of operator theory a leading role is played by the notion of spectrum. The spectrum of a continuous linear operator \( T \) defined in a complex Banach space is by definition the set of all scalars \( \lambda \) for which the operator \( T - \lambda I \) has no inverse, that is, \( T - \lambda I \) is either not injective (one-to-one) or not surjective (onto). Non-zero solutions of the equation \( T(x) = \lambda x \) are called eigen-vectors of the operator \( T \), while the values of \( \lambda \) for which such solutions exist are its eigen-values. All the eigen-values are contained in the spectrum, but, unlike the finite dimensional case, the spectrum may also contain other values. A compact operator has a spectrum containing a finite or countable number of distinct numbers; in the latter case they converge to zero. Spectral analysis – the branch of functional analysis studying the properties of operator spectra – has achieved penetrating advances in the theory of Banach and operator algebras (Gelfand, von Neumann).

A linear operator \( T \) in Hilbert space is called self-adjoint if \( \langle T(x), y \rangle = \langle x, T(y) \rangle \) for all \( x, y \). A compact self-adjoint operator has properties similar to that of a symmetric matrix; for example, there exists an orthonormal basis consisting of its eigen-vectors (Hilbert–Schmidt Theorem).

Among the branches of functional analysis beyond the framework of the theory of Banach spaces, the theory of distributions (or ‘generalized functions’), initially developed (by Sobolev and Schwartz) as a rigorous foundation for formal operations with \( \delta \) -functions used in physics, should be mentioned.

In many theoretical and applied problems – in particular, in mathematical economics – it is necessary to consider semi-ordered vector spaces, characterized by the fact that some of their elements are involved in a comparison relation. The most important are those semi-ordered spaces for which every bounded (in the sense of the order relation) subset possesses a least upper bound. The foundations of the theory of such spaces were developed in the 1930s by Kantorovich and are called Kantorovich spaces (K-spaces). For example, the spaces \( l_p \) and \( L_p \) have a natural partial order relation: one sequence is greater than another, if all the coordinates of the first are greater than the corresponding coordinates of the second; the function \( x \) is greater than \( y \) if \( x(t) \) is greater than \( y(t) \) for almost all \( t \). A somewhat wider class is constituted by vector lattices, in which the existence of l.u.b. is guaranteed only for finite sets. In semi-
ordered spaces the notion of positive (not necessarily linear) operator can be introduced in a natural way; this notion has been used to generalize the theory of positive matrices. Positive operators are an important class of maps studied in non-linear functional analysis. Another important class – the monotone operators – includes operators in Hilbert space satisfying the inequality

\[(T(x) - T(y), x - y \leq 0) \text{ for all } x, y.\]

A third example is that of contraction operators, i.e. operators such that

\[\|T(x) - T(y)\| < \alpha \|x - y\| \text{ for some } \alpha < 1.\]

For those (and some other) classes of non-linear operators, conditions for the existence and uniqueness of operator equation solutions have been obtained in global terms. But, just as in classical analysis, the most universal means of studying nonlinear problems is the differential calculus. Many facts of classical differential calculus (in particular, Taylor expansions and the implicit function theorem) have been generalized to Banach spaces.

Among the main instruments of mathematical economics, convex analysis and fixed-point theorems should be noted. Both are in essence branches of functional analysis. The recent extremely rapid advances in convex analysis have been stimulated by the requirements of the theory of extremal problems in abstract spaces (mathematical programming and optimal control). A typical extremal problem is to find the maximum of the functional \(f(x)\) defined on the subset \(G\) of the space \(X\) under the constraints \(T(x) \geq 0, x \in G\) where \(T\) is an operator from \(X\) to a linear topological space \(Y\) supplied with the partial order \(\succeq\). As in the finite-dimensional situation, here the necessary and sufficient conditions for the existence of an extremum (under appropriate assumptions) may be stated in terms of saddle points of the Lagrange function

\[L(x, y^*) = f(x) + y^* (T(x)),\]

where the Lagrange multiplier \(y^*\) is an element of the space \(Y^*\) adjoint to \(Y\). In deducing this condition, separation theorems, the differential calculus and theorems on the representation of linear functionals play a fundamental role.

In order to solve functional equations and extremal problems in functional spaces, various computational procedures have been developed. In particular, generalizations of gradient methods and Newton's method have been obtained (the first results here are due to Kantorovich); the Newton–Kantorovich
method also turned out to be a powerful means of proving existence and uniqueness of solutions. Another approach to computational problems is based on the approximation of the given functional equation by a simpler one. The application of functional analysis methods leads to a general theory of such approximation methods within whose framework the rate of convergence is studied and error estimates are given for a series of computational procedures. In certain cases approximate solutions may be obtained by computer in analytic rather than numerical form (‘deductive computations’).

The necessity of considering infinite-dimensional models arises in economics in many problems, among which the following may be distinguished: (1) assessment of random effects in a situation with an infinite number of natural states; (2) study of effects arising from a ‘very large’ number of participants (competition models); (3) problems of spatial economics; (4) study of economic development in continuous time, in particular, with due regard for lags; (5) economic growth on an infinite time interval; (6) influence of commodity differentiation on exchange processes. This list is not exhaustive. As a rule, it is possible in principle to use a finite dimensional model and then pass to the limit if necessary. However, the ‘infinite dimensional’ statement of the problem is often easier to study because a more powerful analytic apparatus may be applied.

The concept of adjoint (dual) spaces mentioned above is of fundamental importance in economics. In a typical case the elements of the given space are interpreted as utilized and produced goods, while elements of the adjoint space (continuous linear functionals) are prices; the value of the functional on the given product vector determines its cost (expenditures, profits, and so on). Then semi-ordered vector spaces, expressing the ‘greater than’ relationship for certain pairs of expenditure and production vectors and taking into consideration the positivity of prices, turn out to be a natural instrument.

In the use of functional analysis methods, a very delicate question is that of choosing the functional space into which the model should be ‘embedded’; it is closely related to the chosen estimate of economic and social values.

As an example let us consider a problem of type (5). In stating dynamical optimal planning problems considerable difficulties are involved in the choice of a plan horizon and objectives for the end of a planning period. However, in many cases the initial interval of the optimal trajectory depends very weakly on these parameters and is close to the corresponding interval of the optimal (in a certain sense) infinite trajectory. This is one of the reasons growth on an infinite time interval is worth studying. For a wide class of models it is possible to show that any optimal trajectory is the result of maximizing integral profits calculated in appropriately chosen prices. An effective way of studying this question is the following. Let us embed the set of all admissible trajectories of economic growth (that is, trajectories satisfying technological and resource constraints) in an appropriate Banach space $X$ so that the adjoint space $X^*$ is interpreted as the space of prices; the value of a continuous linear functional on a vector $x \in X$ may be interpreted as the integral of the profits obtained in motion along the trajectory $x$. The set of trajectories which are better than the optimal one does not intersect the set of admissible trajectories. Under appropriate conditions these two sets may be separated by a hyperplane. The corresponding continuous linear functional will determine the required price trajectory. Using this approach, it is possible to investigate the relationship between competitive equilibrium and optimum for an infinite time interval.

Another example of productive application of functional analysis concerns the influence of commodity differentiation on market processes, a problem occupying an important place in the theory of...
monopolistic competition. In the simplest case, product differentiation is characterized by a scalar parameter assuming values in the closed interval \([a, b]\). Each consumer may choose any finite number of different goods (that is, a finite number of points \(t_i\) on the interval) and acquire them in arbitrary quantities \(x_i\) as long as he satisfies his budget restrictions for the given prices. It is natural to assume that the price \(p(t)\) depends continuously on the characteristic of the product \(t \in [a, b]\), i.e. \(p(t) \in C(a, b)\).

The result of a consumer's choice is a finite set of pairs \(x_i, t_i\) which determines a continuous linear functional in the price space \(C(a, b)\) according to the rule

\[ z(p) = \sum_i x_i p(t_i); \]

then \(z \in C^*(a, b)\). But \(C(a, b)\) can be identified with a subset of its second adjoint space (see above). Thus, as usual, price is a continuous linear functional of the space of collections of goods \(C^*(a, b)\). The fact that this space is adjoint to a certain Banach space considerably facilitates its study, since adjoint spaces possess useful topological properties. The analysis of models based on this construction yields conditions under which a market with differentiated commodities and ‘small’ participants, similar to contemporary competitive markets, ensures an optimal distribution of resources (Mas-Colell, 1975).

The proof of the existence of competitive equilibrium in the finite dimensional case is based on fixed-point theorems. Several such theorems, including the Kakutani theorem, are also valid for Banach spaces; however, in this case their application becomes more difficult because of the essential trait of infinite dimensional spaces mentioned previously – the non-compactness of the unit sphere. Another trait of infinite dimensional spaces is that special conditions are required for the separability of non-intersecting convex sets. Both of these circumstances considerably complicate the study of economic models.

In discussing the economic applications of functional analysis, two other disciplines closely related to it – measure theory and global analysis – should be mentioned. The first is widely used in the study of probabilistic models, as well as in models with a continuum of participants or products (see Hildenbrand, 1974; Mas-Colell, 1975). Global analysis, introduced into mathematical economics by Debreu and Smale, allowed us to understand the deeper structures of the sets of equilibrium states and to advance to the solution of equilibrium stability problems (see Smale, 1981).

Above we mentioned some applications of functional analysis to economics. In their turn, the problems of economics have influenced the development of mathematics. This is natural since economics is a vast field of research, differing in principle from those classical physical and mathematical disciplines on the basis of which functional analysis developed. The theory of systems of linear inequalities developed a hundred years later than the theory of linear equations, and precisely because of the needs of economics. Another interesting and important example is the transportation problem, which was first studied under the name of mass shifting problem by Kantorovich in 1942. The metric introduced in its study (interpreted as the expenditures required to shift a unit mass) has found numerous applications in functional analysis and some other fields. Many mathematical problems from functional analysis
 originating in economics still await their solution. In particular, the functional equations describing macroeconomic dynamics taking into account the differentiation of funds according to their time of creation have not been exhaustively studied (for example, see Kantorovich, Zhiyanov and Khovansky, 1978). It can be expected that further advances in the mathematical analysis of economics will become an even more powerful source in the development of mathematical methods, including functional analysis.

Abstract

Functional limit theorems are generalizations of classical central limit theorems. They allow us not only to approximate the distributions of sums of random variables, but also describe their temporal evolution. The necessary mathematical concepts as well as some sufficient conditions for convergence to a random walk are discussed.

Article

Central limit theorems guarantee that the distributions of properly normalized sums of certain random variables are approximately normal. In many cases, however, a more detailed analysis is necessary. When testing for structural constancy in models, we might be interested in the temporal evolution of our sums. So for random variables $X_i$, we are interested in analysing the behaviour of

$$\frac{1}{\sqrt{N}} \sum_{i=1}^{t} X_i$$

as a function of $t$ for $t \leq N$. It is convenient to normalize the time, too, and consider for $0 \leq z \leq 1$
Another popular application is the asymptotic behaviour of the empirical distribution function or its multivariate generalizations, though we will only briefly discuss it.

‘Functional limit thes’ are generalizations of the classical central limit theorem (CLT). Instead of analysing random variables with values in $\mathbb{R}$, I deal with random variables in more general spaces. Here I discuss only one specific example, namely the analysis of the properly normalized partial sums of random variables. In order to do so, I will first sketch the necessary concepts concerning the topology of the spaces involved. In particular, I want to demonstrate the necessity of using spaces and metrics which, at the first glance, may not look that plausible. The results are well known and can be found in many textbooks. A classical reference is Billingsley (1999). Another introduction in this field, more geared towards econometricians, is Davidson (1994).

**Foundations: metric spaces and convergence in distribution**

A common framework, allowing us to formulate more general limit theorems, assumes that our ‘random variables’ take values in so-called ‘Polish spaces’, which are just metric spaces which are separable and complete. So let us assume that we have given such a space $E$, with a metric $d(.,.)$ on it, so that there exists a countable dense subset and that the space is complete (that is, every Cauchy sequence converges). Examples are the finite-dimensional spaces with the usual distance. The space $C[0,1]$ of all continuous functions from $[0,1]$ to $\mathbb{R}$ (the set of real numbers), endowed with the metric

$$
\quad
d_M(x, y) = \max_{0 \leq t \leq 1} |x(t) - y(t)|.
$$

(3)

Let us assume that we have random variables $X_n, X$ with values in $E$: Then we define convergence in distribution of $X_n$ to $X$

$$
X_n \to^D X.
$$

(4)
We can easily see that, in the special case of the space $E$ being the set $\mathbb{R}$, our definition here is a generalization of the familiar concept of convergence in distribution. An ‘invariance principle’ is simply a statement convergence in distribution of random variables in a complex space.

If we have given a statement like (4), then for continuous $\varphi$ and large $n$ we can approximate the distribution of $\varphi(X_n)$ by the distribution of $\varphi(X)$. As an example, assume our underlying space is $C[0,1]$ (defined above), and our distance is given by (3). Suppose we have $X_n \xrightarrow{D} X$. We can easily see that the functions attaching each $z \in C[0,1]$ $\max_{0 \leq t \leq 1} z(t)$ or $\int_0^1 z(t)^2 \, dt$ are continuous with respect to our metric.

Hence we can immediately conclude that

$$\max_{0 \leq t \leq 1} X_n(t) \to \max_{0 \leq t \leq 1} X(t)$$

or

$$\int_0^1 X_n(t)^2 \, dt \to \int_0^1 X(t)^2 \, dt,$$

where ‘$\to$’ stands for the usual convergence in distribution of real-valued random variables. Sometimes it is, however, burdensome to establish continuity for some functionals, or we might even be forced to consider discontinuous functionals. In this kind of situation the following theorem is helpful. Since we only work in separable, metric spaces a function $\varphi$ defined on a general metric space $E$ is continuous at a point $x \in E$ if for all $x_n \xrightarrow{} x \varphi(x_n) \xrightarrow{} \varphi(x)$. Otherwise the $\varphi$ is called discontinuous in $x$, and let $D_\varphi$ be the set of all points where $\varphi$ is discontinuous. Now assume we have some random elements $X_n$, $X$ and
Then we have the following theorem.

**Theorem 1:** Suppose that

\[ X_n \rightarrow D X. \]

Then

\[ P(\{ X \in D_\omega \}) = 0. \]

Then

\[ \varphi(X_n) \rightarrow D \varphi(X). \]

If the discontinuities of \( \varphi \) are a null set with respect to the limiting distribution, the distributions of \( \varphi(X_n) \) can be approximated better and better by the distribution of \( \varphi(X) \).

In any case, the usefulness of functional limit theorems depends on the set of continuous functions associated with our space. On the one hand, a metric with ‘many’ continuous functions will allow us to establish many limiting relationships like (6) or (7). On the other hand, it will be harder to establish convergence, since we have to show the relation (5) for \textit{more} functions \( \varphi \). Hence we have to compromise.

**The space \( D[0,1] \)**

The first and most important application of functional limit theorems is the analysis of partial sums. When dealing with normalized sums like (1), (2) we encounter the first problem: we can easily let the time \( t \) or \( z \) be a continuous variable, but then the sum (1),(2) is a discontinuous function. Hence we have to look at spaces more general than \( C[0,1] \). One such space is the space \( D[0,1] \), defined to be the space of all bounded functions \( f \) which have only ‘jumps’ as discontinuities: at every time \( z \) the limits to the right and left of \( f(z+0) \) and \( f(z-0) \) exist).

Next we have to define a distance between the functions \( f, g \) from \( D[0,1] \). The first candidate, namely the supremum-norm (3), has the disadvantage that the corresponding space is not separable: consider for each \( a \in (0,1) \) the functions \( f_a \) defined as

\[ f_a(z) = \begin{cases} 0 & \text{if } z < a \\ 1 & \text{if } z \geq a. \end{cases} \]
Then we can easily see that in the supremum norm (3), the distance between \( f_a \) and \( f_b \) is equal to 1. Since we have more than countable real numbers in (0,1), we cannot have a countable dense subset. A distance better suited to this space is the so-called Skorohod metric. Let us first define the set \( \Lambda \) to be the set of all functions from [0,1] to [0,1] which are monotonically increasing, continuous, and map 0 and 1 into 0 and 1, respectively. Then define

\[
d_\mathcal{S}(f, g) = \inf_{\lambda \in \Lambda} \sup_{z} (|f(z) - g(\lambda(z))| + |z - \lambda(z)|).
\]

The Skorohod distance is related to the maximal distance. The main difference, however, is that we do not compare the functions \( f \) and \( g \) for the same values. The Skorohod metric allows us to ‘bend’ the argument a little. This rather small modification has enormous consequences. The corresponding space is separable: that is, there exists a countable dense subset. The metric itself is not complete (that is, there exist Cauchy sequences which do not converge). There exists, however, an equivalent metric (that is, a metric which determines the same open sets, neighbourhoods, convergent subsequences, continuous functions,…) which is complete. Moreover, we can easily see that

\[
d_\mathcal{S}(f, g) \leq d_M(x, y),
\]

so convergence in the maximum distance implies convergence in the Skorohod metric. The next question is the set of continuous functions. We can easily see that some of the usual candidates, like for example the functional mapping each \( f \) to \( \sup_{0 \leq z \leq 1} f(z) \), are continuous. The functional mapping \( f \) to \( f(z) \), however, is for \( 0 < z < 1 \) not continuous. Hence th 1 will come in handy.

The most important types of limiting processes will all have continuous trajectories. Hence, the class of functionals covered by th 1 contains all functionals which are continuous in \( C[0,1] \). For establishing this continuity, we have an interesting criterion. 

**Theorem 2:** Suppose we have \( f \in C[0,1] \), and \( f_n \in D[0,1] \) so that \( f_n \to f \) in the Skorohod metric. Then we have convergence in the supremum metric (3), too.

This result may explain the usefulness of \( D[0,1] \). On the one hand, the metric on \( D[0,1] \) is weak enough to allow for separability. This has, however, the drawback that it is hard to establish continuity of a function in the general case. If the limiting random element lies with probability 1 in \( C[0,1] \), however, it is easy to check the requirements of th 1 for a function \( \varphi: D[0,1] \to \mathbb{R} \). One only has to show that \( \varphi(f_n) \to \varphi(f) \) if \( f_n \to f \) uniformly, which is much easier to handle.
Examples for limit theorems

In this section, I want to bring some examples of functional limit theorems. Together with the discussion above, they can be used as ‘building blocks’ for the derivation of general limit theorems.

The first functional limit theorem is one of the most important, namely, the functional limit theorem for martingale differences. This theorem is of utmost importance in many statistical applications: the scores of the conditional likelihood functions are martingale differences. Furthermore, the theorem is quite general. It only assumes a Lindeberg condition (which is quite similar to the case of the classical central limit th) and some kind of normalization condition. The role of the standard normal distribution is played by the ‘standard random walk’ \( W \). \( W \) is a random element with values in \( C[0,1] \) (that is, a random function) with the following properties:

- \( W(0)=0 \).
- \( W \) is ‘Gaussian’. All finite-dimensional marginal distributions \((W(z_0),\ldots,W(z_k))\) are Gaussian with expectation 0.
- The covariance of \( W(z_1) \) and \( W(z_2) \) is \( \min(z_1, z_2) \).

A quite tedious but well known proof shows that there exists such a random element, and that its distribution (the induced probability measure on \( C[0,1] \)) is unique. Moreover, it is easy to show that \( W \) has all the properties associated with a random walk: its increments are independent from past values.

**Theorem 3:** (McLeish, 1974): Suppose we have given a triangular array of random variables \( X_{i,n} \), together with some adapted \( \mathcal{F} \)-algebras \( \mathcal{F}_i \), so that

\[
E(X_{i,n} / \mathcal{F}_{i-1,n}) = 0.
\]

Furthermore assume that the following two conditions are satisfied:

1. The ‘norming condition’ is satisfied:

\[
\sum_{i \leq n} E(X_{i,n}^2 / \mathcal{F}_{i-1,n}) \to Z
\]

uniformly in probability as \( n \to \infty \).

2. The ‘conditional Lindeberg condition’ is fulfilled: for all \( \varepsilon > 0 \)
Theorem 4: (Peligrad and Utev, 2005): Assume that we have given a stationary process $X_i$ so that

\[ \sum \frac{1}{n} \|E(S_n(1) \mid X_0, X_{-1}, \ldots)\| < \infty, \]

for all $i$

\[ \frac{1}{n} \sum X_i X_{t-1} \rightarrow E(X_i X_{t-1}) \]
and

$$\sigma^2 = \sum_{i \in \mathbb{Z}} E(X_i X_{t-i}) < \infty.$$  

Then

$$\frac{1}{\sigma} S_n$$

converges in distribution to a standard random walk $W$.

These two theorems should only act as illustrations for functional limit theorems. Especially for stationary processes, more general theorems are available. A good survey about recent results can be found in Merlevède, Peligrad and Utev (2006).

Conclusion

This short introduction article should serve only as an introduction to functional limit theorems. Over the years, a rich theory has developed unifying many aspects of the limiting behaviour of functions of random variables. In particular, I would like to mention the limiting theorems for empirical distribution functions and their generalizations (see for example van der Vaart and Wellner, 1996, for a survey, and Andrews and Pollard, 1994, for dependent random variables). These results can be used to derive ‘uniform’ central limit theorems.

The term ‘functional finance’ was created by Abba Lerner to contrast with sound finance. It involves making decisions about the deficit and the money supply with regard to their functionality, not some abstract moralistic premise. While it seems to play no role in the dynamic stochastic general equilibrium model prevalent in macroeconomics today, it does play a potential role in a more complex model where heterogeneous agents with limited information interact in a model with many different aggregate equilibria. Yet Lerner’s functional finance theoretical model is far too simple to be acceptable, even as a rough guide for policy.

Article

In the debate about how to pull economies out of the Great Depression, Abba Lerner created a steering wheel metaphor to contrast his ‘economics of control’ approach to policy with the then prevailing ‘laissez-faire’ policy. He argued that the laissez-faire approach was similar to driving a car without a steering wheel, the natural result of which was that the economy continually crashed, veering off the road first in one direction and then in another. It was time, he argued, for the government to adopt a Keynesian ‘economics of control’ approach in which the government used an explicit steering wheel – functional finance – to keep the economy running smoothly.

To complement that distinction between economics of control and laissez-faire, he contrasted the laissez-faire policy of sound finance with the economics-of-control policy of functional finance. Sound finance involved a set of rules – always balance the budget except in wartime, and do not increase the money supply.
supply at a rate greater than the growth rate of the economy. The problem, for Lerner (1944; 1951), was that these rules of sound finance were not analysed; they were simply accepted as being right. Lerner argued that, when governments understood how the macroeconomy actually operated, they would adopt an alternative ‘functional finance’ set of rules. Under the rules of functional finance, decisions about the deficit and the money supply would be made with regard to their functionality – their effect on the economy – and not with regard to some abstract moralistic premise that deficits, debt and expansionary monetary policy are inherently bad.

The rules of functional finance

Functional finance consists of the following three rules (Lerner, 1941).

1. The government shall maintain a reasonable level of demand at all times. If there is too little spending and, thus, excessive unemployment, the government shall reduce taxes or increase its own spending. If there is too much spending, the government shall prevent inflation by reducing its own expenditures or by increasing taxes.
2. By borrowing money when it wishes to raise the rate of interest, and by lending money or repaying debt when it wishes to lower the rate of interest, the government shall maintain that rate of interest that induces the optimum amount of investment.
3. If either of the first two rules conflicts with the principles of ‘sound finance’, balancing the budget, or limiting the national debt, so much the worse for these principles. The government press shall print any money that may be needed to carry out rules 1 and 2.

In proposing these rules of functional finance, Lerner's purpose was to shift thinking about government finance from principles of sound finance that make sense for individuals – such as running a balanced budget – to functional finance principles that make sense for the aggregate economy. Functional finance principles used the budget balance as a steering wheel: deficits increased economic activity, surpluses decreased economic activity. The budget balance had these effects because, in the Keynesian model, government spending and taxing decisions directly affected levels of economic activity. These effects had to be considered because, in the aggregate, the secondary effects of spending decisions and savings decisions, which Lerner and I (Colander, 1979) called macro externalities, had to be taken into account, whereas in individual decisions they did not.

Lerner's stark presentation of these rules of functional finance caused much stir in the 1940s and 1950s, when most Keynesians, including Keynes himself, were politically more circumspect about what came to be known as Keynesian ideas for government fiscal policy than they became in the 1960s (Colander and Landreth, 1996). Lerner's rules specifically ruled out worrying about the size of a country's budget deficit or national debt.

In the 1950s and 1960s, Lerner's functional finance rules became both the basis of most textbook presentations of Keynesian economics and the basis of textbook macroeconomic policy discussions. It became what was generally considered Keynesian policy. This could occur because Keynes's General Theory contained almost no discussion of policy; it did not mention fiscal policy, and yet there were strong political forces pushing for its use. Thus, when ‘Keynesian policy’ was attacked in the late 1960s
and early 1970s, it was primarily the idea of Lerner's policy of functional finance that most people were attacking (see Colander, 1984, for a discussion).

That attack on ‘Keynesian policy’ intensified through the 1970s and 1980s, and by the 1990s textbook presentations of Keynesian policies had faded away. As they did so, so too did the concept of functional finance, and by the early 2000s few economists under the age of 50 had heard of it.

While the term ‘functional finance’ has disappeared from the macroeconomic textbooks, its influence continues among macro policy economists. The rhetoric of policy-oriented macro economists and their reaction to recessions is now quite different from what it was in pre-Keynesian times. When presenting fiscal policy to voters, governments are far less likely to talk about balanced budgets. Today, the potential benefits of government deficits in a recession are recognized. Similarly, policy-oriented macroeconomists discuss fiscal policy generally in terms of debt-carrying capacity such as represented by deficits as a percentage of GDP, not the need for a balanced budget, as was the case with sound finance. Even when a policy of functional finance is not used, the functional-finance role of fiscal policy is still seen as important since the expectation that government functional-finance policy will be adopted when crises occur can reassure agents and provide stability to the economy.

Why functional finance lost favour

Functional finance lost favour for a variety of reasons. First, Lerner's discussion of functional finance did not consider the politics of government finance; it assumed that the government could change taxes and spending according to the needs of the macroeconomy. In reality, both spending and taxing are difficult political issues, and the needs of politics generally trump the needs of stabilization. Second, the lags between recognition of a problem and implementation of a policy were significant, and the policy would often go into effect long after the situation had changed. In Lerner's automobile metaphor, it was as if the steering wheel and the wheels were connected with a 30-second lag, and the windshield was opaque. Third, functional finance is built upon an assumption that the government knows what functional finance policy is best to follow – in inflationary times, increase taxes and decrease the money supply; in recessionary times, decrease taxes and increase the money supply. In the 1970s, when both inflation and recession occurred simultaneously, the functional finance rules seemed to give contradictory advice. These practical problems with implementing functional finance eliminated much, if not all, of the benefit of the steering wheel.

The reaction of Keynesian economists to the practical and informational problems was to limit the use of the deficit as a tool for fine-tuning the economy; the fiscal policy tool was a sledge, not a ball-peen hammer. The economics profession's reaction to stagflation was to accept a high rate of unemployment as the trigger for implementing an expansionary policy. Lerner did not follow the profession. His reaction to the stagflation problem was to argue that much inflation was not the result of excess demand but was instead what he called sellers’ inflation. Sellers’ inflation operated quite apart from demand pressures. Depending on how sellers’ inflation was dealt with, there could be either high full employment or low full employment (Lerner, 1972).

Lerner saw sellers’ inflation as so important that, beginning in the 1960s, he changed his research programme to centre on finding cures for sellers’ inflation. He developed a market-based incomes policy in which property rights in prices are established, and individuals have to buy the right to change prices from others who change their price in the opposite direction (Lerner and Colander, 1980). Under a
market-based incomes policy, rights in value-added prices would be tradable, so that any firm wanting to change its nominal price would have to make a trade with another firm that wanted to change its nominal price in the opposite direction. Thus, by law, the average price level would be constant, but relative prices would be free to change. With inflation controlled by such a plan, the rules of functional finance would once more become relevant (Colander, 1979). Politically, in the early 2000s such policies had little chance of even being considered by governments and had faded from economists’ radar screen.

Macro theory and functional finance

It was not only the practical problems of functional finance that led to its demise. It was also that the profession essentially dropped the theoretical model upon which the concept was based. Functional finance was based on a coordination-failure model of macroeconomics – when individuals spent or saved, they did not take into account the effect of that decision on the aggregate level of spending; thus the economy needed some mechanism to internalize the spending complementarity and thereby determine the aggregate level of spending.

Today, among theoretical macroeconomists macro policy is thought of in a dynamic stochastic general equilibrium framework, and fiscal policy is discussed within an optimal taxation framework that assumes a representative agent is optimizing over a long-term horizon. The intuition behind such models is that the effect of any government deficit is mitigated by compensatory changes in the representative agent's spending decisions. This occurs because the agent will be responsible for paying off that deficit in the future. In the now prevalent modern macroeconomic theoretical approach, the possible existence of macro externalities is essentially ruled since the representative individual is assumed to take all the indirect effects of spending into account.

Assessment of functional finance

So what should one make of functional finance? My view is that, theoretically, it remains important. The fact that much modern macroeconomic theory does not allow for the possible existence of macro externalities is, in my view, a problem of modern macro theory, not a problem with functional finance. The probability that the unique equilibrium, perfect rationality, perfect foresight, representative agent model underlying much of modern macroeconomics has much relevance to the real-world macro problems that we face is exceedingly small.

The macroeconomic theory problem seems more appropriately described as a coordination problem in which heterogeneous agents with limited information interact in a model in which many different aggregate equilibria are possible due to enormous strategic complementarities among agents. With multiple equilibria and coordination problems, there is no presumption of global optimality of the equilibrium chosen by the market. Everyone can know of the existence of a preferable equilibrium, but may not be able to achieve it by private actions. We can say something about that question only when we have a theory of equilibrium selection mechanisms. Currently we have none. Thus, in a multiple equilibrium economy with coordination failures, there should be no general presumption that the private economy, given its institutions, arrives at an equilibrium preferable to one achieved with government guidance.
That said, the functional finance theoretical model of Lerner is far too simple to be acceptable, even as a rough guide for policy. To say that individuals have limited information and do not fully take account of future effects of policy is not to say that they take no account of them. Private institutions develop which do precisely that, and any meaningful theoretical macro model must integrate such forward-looking private institutions into its structure. Doing so will involve highly complex models in which model selection by agents, agent interdependency, and social interaction by multiple agents are taken seriously. We are a long way from making such models tractable, so any formal macro model incorporating usable rules of functional finance is long in the future.

Furtado, Celso (1920–2004)

Mauro Boianovsky

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Celso Furtado (1920–2004) was one of the most influential Latin American economists of the 20th century. He was head of the development division of the United Nations Commission for Latin America in the 1950s, where he helped to formulate the structuralist approach to economics. His *Formação Económica do Brasil* (1959) is the classic interpretation of the economic history of Brazil. In 1961 he published a collection of essays about the notion of underdevelopment and development as interdependent phenomena. Furtado's last contribution was his careful discussion in the 1970s of the concept of cultural and economic dependence in underdeveloped countries.

Article

Celso Furtado was born on 26 July 1920 in Pombal (in the state of Paraiba, north-east of Brazil), and died on 20 November 2004 in Rio de Janeiro. Together with the Argentinean Raúl Prebisch, Furtado was the most widely read and influential Latin American economist of the second half of the 20th century. A prolific writer, he published more than 20 books on the economic history of Brazil and Latin America, and on the theory and policy of economic development, many of them translated into English, French and other languages.

He graduated at Universidade do Brasil (Rio) in 1944 and received his doctorate from the Sorbonne (Paris) in 1948; his thesis was about the Brazilian colonial economy. Maurice Byé was his supervisor, but it was François Perroux who impressed him most at the time. Upon his return to Brazil in that same
year, Furtado was invited to join the staff of the new United Nations Economic Commission for Latin America (ECLA) in Santiago. From 1950 to 1957 he was head of the development division of ECLA. He then left Santiago to spend an academic year at Cambridge University working with Nicholas Kaldor and Joan Robinson with a Rockefeller Foundation scholarship. In 1958 he was appointed director of the Brazilian National Development Bank, where he conceived the project that led to the creation of SUDENE (Development Agency of the Northeast of Brazil) in 1959, of which Furtado was the first director (Hirschman 1963, chapter 1). In 1962 he also became Brazil's first minister of planning, charged with drafting a national economic plan, a position he held until 1963. Deprived of his political rights following the military coup in 1964, he left Brazil to take up appointments at American and European universities. Furtado went back to Paris and became the first foreign professor to be appointed at the Sorbonne, where he taught development economics from 1965 to 1985. After Brazil returned to democracy he was appointed Minister of Culture (1986–88), and elected to the Brazilian Academy of Letters and to the Brazilian Academy of Sciences in 1997 and 2003 respectively. (Furtado's autobiography, originally published in three volumes between 1985 and 1991, was collected in 1997; the first volume, with recollections from the 1950s, his most productive period, was translated into French in 1987.)

**Structuralism and economic history**

Together with Prebisch and other economists at ECLA in the 1950s, Furtado was one of the formulators of structuralism in Latin American economics. His main contributions can be found in two books, both available in English. In his 1961 volume on economic development, which collected essays written during the 1950s, Furtado provided the most elaborate exposition of the structuralist analysis in the literature at the time. In his 1959 classic *Formação Econômica do Brasil*, written in Cambridge in 1957–8 and based on Furtado (1950; 1952; 1954), the structuralist approach was applied for the first time to the interpretation of the economic history of a Latin American country, an exercise Furtado would expand to the whole region in his 1969 book. Furtado's methodological innovation was the use of historical investigation to identify factors that are specific to each structure through time: 'bring history near to economic analysis, get from the latter precise questions and find answers in history' (1997, vol. 1, p. 205). In *Formação* he pioneered the use of modern income analysis to deal with historical phenomena by introducing macroeconomic models into the analysis of each phase of Brazilian economic development from the 16th century to the 1950s (see also Furtado, 1963, for a brief account). Furtado's role in the historiography of the industrialization process of Brazil in particular and Latin American in general may be compared to Alexander Gerschenkron's well-known interpretation (1952) of the late industrialization of Russia and other continental countries. Like Gerschenkron, Furtado examined industrialization from the point of view of history. Both rejected Walt Rostow's (1960) view that the economic development of different countries goes through a succession of phases to which a single analytical framework can be applied.

The main feature of the 1959 book is the argument that the economic history of Brazil (and other Latin American countries as well) must be based on an open growth model with international trade treated as an endogenous variable, since these countries’ economies evolved as suppliers of raw materials to the world market. Furthermore, the income-distribution profile is a main determinant of the economic
growth process through its effect on the level and structure of domestic demand in different historical phases. Furtado shows that throughout the four centuries from 1530 to 1930 the Brazilian economy depended on external demand to provide stimulus to higher productivity without previous capital accumulation, with three long-period cycles – sugar exports (1530–1650), gold mining (1700–80) and the expansion of the world market for coffee (1840–1930) – and intervening periods of relative stagnation. That phase came to an end in the economic crisis of 1929, when the collapse of export-commodity prices cut the country's import-purchasing power in half. According to Furtado, the policy adopted by the Brazilian government at the time to maintain the coffee price – that is, buying the unmarketable coffee and burning it – had the effect of an unwitting ‘Keynesian’ anti-cyclical deficit-financing policy. This contributed to maintaining domestic demand and, together with the diminished capacity to import, pushed up domestic prices of imported goods and stimulated investments in import-substituting industrial consumer goods. That process marked the beginning of a new phase in the development of Brazil, based on internal demand and import-substituting industrialization. Brazilian late industrialization – as compared with that of the United States – is explained in part by the differences between the productive structure of Brazil's export agriculture and the small agricultural properties in the English colonies of North America. The Brazilian internal market was much thinner due to the concentration of income and property, which served to maintain its stagnant colonial structure. Moreover, whereas the United States participated in the first wave of the Industrial Revolution as exporter of a key raw material (cotton), the main cause of the relative backwardness of the Brazilian economy in the first half of the 19th century, according to Furtado, was the damming up of its exports and the increase of the subsistence sector with lower productivity. Also in contrast with the late industrialization of continental European countries in the second half of the 19th century studied by Gerschenkron, the import-substitution process in Latin America did not lead to an intensive development of producer goods industries or changes in international trade (exports of manufactured goods and imports of raw materials). The evolution of trade patterns in Latin American countries during their industrialization after 1930 was quite the opposite: exports were still based on a few commodities and imports concentrated on goods whose production required huge investment and/or advanced technology.

The concept of economic underdevelopment

It was in attempting to explain the backwardness of Brazil that Furtado hit upon the idea that underdevelopment and development are two interdependent phenomena which appear simultaneously as part of the evolution of industrial capitalism. The theme was elaborated in his 1961 book, where Furtado put forward concepts of economic underdevelopment and development that have been largely accepted in the literature. An underdeveloped structure is one in which ‘full utilization of available capital is not a sufficient condition to complete absorption of the working force at a level of productivity corresponding to the technology prevailing in the dynamic sector of the economy’ (1961b, p. 141). Underdeveloped economies (as distinct from simply backward ones) are hybrid structures characterized by technological heterogeneity of the various sectors. This comes from the historical fact that the import-substituting industrialization process in those economies led entrepreneurs to adopt a technology compatible with a cost and price structure similar to that prevailing abroad. Technology becomes, therefore, an independent variable in economies where industrialization is induced from outside. Whereas
industrialization in underdeveloped economies was determined by demand, the formation process of capitalist European economies in the 18th and 19th centuries was dominated by supply factors, which led Furtado to define economic development as the introduction of new combinations of production factors which increase labour productivity. Underdevelopment is regarded as a permanent feature of the centre–periphery system, not as a stage on the road to development. Those ideas originally appeared in an essay written as the first critical comment on Ragnar Nurkse's notion of ‘balanced growth’ (advanced in Nurkse's 1950 Rio lectures), where Furtado pointed out that the dynamics of demand (internal and external) in underdeveloped economies should be studied in tandem with the process of accumulation.

According to Furtado, underdeveloped countries lack incentives to save (because of the consumer habits of higher-income groups), not to invest. The accumulation process should be examined from the point of view of changes in the process of generation, utilization and appropriation of the economic surplus, especially as affected by foreign trade. Furtado first developed these ideas in an essay originally written in Portuguese in 1955 (two years before Paul Baran made the concept of surplus a central notion of his own approach to development) and further elaborated it as part of a comment on Paul Rosenstein-Rodan's theory of ‘big push’, made at the International Economic Association conference on economic development held in Rio in 1957, and in his 1967 and 1980 textbooks.

Foreign trade and dependency

One of the main aspects of the industrialization process of Latin American countries, as discussed by Furtado in 1958 and 1960, is the persistent tendency towards balance of payment crises and inflationary pressures. Anticipating some elements of the two-gap model later developed by Chenery and Bruno (1962), Furtado showed in a two-sector model featuring a modern and a backward sector how balance of payment disequilibrium could constraint the economic growth process under the assumption that the coefficient of imports in the investment sector is larger than in the consumption sector, as is typically the case in underdeveloped countries. Such chronic disequilibrium has structural (not monetary) causes and may lead to the ‘strangulation’ of economic growth. Another obstacle to growth is that, after the end of the ‘easy’ phase of the substitution of imported consumer goods, as industrialization advances to the production of intermediate and capital goods the rate of profit falls because of the higher capital output ratio accompanied by increasing income concentration and lower aggregate demand. This was an essential element of Furtado's (1965; 1970) interpretation of the slowdown of economic growth in Latin America in the early 1960s, but, as the Brazilian economy recovered in the late 1960s and early 1970s, Furtado's stagnationist argument was criticized by economists in Brazil (see Tavares and Serra 1973).

Furtado (1972; 1974; 1978) eventually concluded that, after the two earlier periods of economic growth – determined respectively by comparative advantages and import-substitution – the Latin American economy had entered a new dynamic path in which consumption demand by high-income groups could under certain conditions become the leading factor of the system. This led him to explore in detail a theme that had often come up in his writings in the 1950s: dependency theory.

Furtado argued that underdeveloped economies feature cultural dependence, that is, consumption patterns are historically transplanted from developed countries by the upper strata of the underdeveloped areas as a result of their appropriation of the economic surplus generated through comparative advantages in foreign trade. Such modernized component of consumption brings dependence into the technological sphere by making it part of the production structure. Dependent structures are also
dualistic systems with unlimited supply of labour at a subsistence wage, as first described by Furtado (1950) in his investigation of the dynamics of the labour market in Brazilian economic history. This is close to W. Arthur Lewis's (1954) classic model, but, in contrast with Lewis, Furtado's conclusion is that industrialization within a dualist dependent structure reproduces this dualism and does not bring about a homogeneous system with real wages increasing in tandem with the average productivity of the economy. The relationship between the centre and the periphery in the world economy is defined not just by the unequal sharing of the benefits of development and technical progress (as in Prebisch's terms-of-trade argument) but by dependence involving domination and control of access to modern technology by transnational corporations. In Furtado's view, economic growth does not entail economic development in dependent and reflex economies, since it implies an aggravation of both external and internal exploitation, and thereby tends to make underdevelopment even more acute.

Futures markets provide partial income risk insurance to producers whose output is risky, but very effective insurance to commodity stockholders at remarkably low cost. Speculators absorb some of the risk but hedging appears to drive most commodity markets. The equilibrium futures price can be either below or above the (rationally) expected future price (backwardation or contango). The various effects futures markets can have on market and income stability are discussed. Rollover hedges can extend insurance from short-horizon contracts over longer periods.

Article
Futures markets for grain emerged in Chicago in the middle of the 19th century and spread rapidly to other commodities and centres. Forward contracts, in which two agents agree on the details of a transaction for delivery at a specified future date, must date back to the beginnings of commerce itself, but the distinctive feature of a futures market is that the contracts are standardized, transactions costs are minimized, and liquidity is high, so that contracts can be, and typically are, bought and sold many times during their lifetime, in contrast to most forward contracts. The standard explanation for the role of futures markets is that they help to spread and hence reduce risks, and to motivate the collection and dissemination of relevant information. Forward markets provide the same risk-sharing opportunities, but the greater transparency and liquidity of futures markets makes the latter far more potent institutions for...
The question of how well futures markets (and securities markets more generally) perform this role of collecting, aggregating and disseminating information is a large and important topic, best handled under the wider heading of ‘information’. If we assume agents have rational expectations and share common information, then the price-discovery role of futures markets can be ignored and remaining issues of risk-sharing studied in isolation. In this case there is little conceptual difference between futures and forward markets, and we can concentrate attention on the two characteristic modes of behaviour exhibited by these markets – speculation and hedging.

Speculation and hedging in commodity markets

Speculation is the purchase (or temporary sale) of goods for later resale (repurchase), rather than use, in the hope of profiting from the intervening price changes. In principle, any durable good could be the subject of speculative purchase, but, if carrying costs are high, or the good is illiquid, then the margin between the buying and selling price will be large, and speculation in that good will be normally be unattractive. Liquidity in this context means that there exists a perfect, or near-perfect, market in which the good can be sold immediately for a well-defined price, and this requirement severely limits the range of assets available for large-scale speculation. There are two types of assets – commodities traded on organized futures markets, and financial assets (bonds, shares) whose properties lend themselves particularly to speculation. Hedging, on the other hand, typically refers to a transaction on a futures markets undertaken to reduce the risks arising from some other risky activity, whether producing the commodity, storing it, or processing it for final sale.

Thus a risk-averse wheat farmer may hedge his future harvest by selling October wheat futures in January, in which case he is ‘long’ in actuals and ‘short’ in futures. A risk-averse miller who anticipates being short of wheat may hedge by buying futures now, in which case he will be a ‘long’ hedger. Speculators may be on the long or short end of any transaction, but in aggregate their position must offset any net imbalance in the long and short hedgers’ positions.

It might appear from this that hedging consists in shifting the price risk onto the speculators in return for a risk premium. This view of speculation, advanced by Keynes (1923) and Hicks (1946), has been challenged by Working (1953; 1962), who denies any fundamental difference between the motivations of hedgers and those of speculators. One danger with looking exclusively at the price risk is that it ignores the more fundamental quantity risks that give rise to the price risks. Once this is appreciated, it is possible to formulate a simple theoretical model in which all agents are alike in attempting to maximize their expected utility but differ in the risks to which they are exposed, and these differences motivate trade on futures markets. While the activities of speculators are quite well defined, those of ‘hedgers’ are in general a mixture of insurance and speculation, as we shall see.

The simplest model of speculation and hedging has just two time periods. In the first period farmers plant their wheat, and the futures market opens. In the second period the wheat is harvested, sold, and the futures contracts expire. There are only three types of agents – farmers, who produce wheat but do not consume it; speculators, who neither produce nor consume wheat; and consumers, who neither produce wheat nor trade on futures markets. All agents are assumed to have beliefs about the relevant variables, which can be described by (subjective) probability distributions, and their behaviour is described by the theory of expected utility maximization. There are \( n \) farmers, and for the moment...
suppose that they have no choice over the amount of wheat to plant, but only over the size of their sales on the futures market. In the first period farmer \( i \) believes that his second period output will be \( \tilde{q}_i \) (a random variable), and that the market clearing price will be \( \tilde{p}_i \), also a random variable. In particular, he believes that \( \tilde{q}_i \) and \( \tilde{p}_i \) are jointly normally distributed. The price of futures is \( f \), observable now, and he sells \( z_i \) futures, so that he believes his second period income will be

\[
\tilde{y}_i = \tilde{p}_i \tilde{q}_i + z_i(f - \tilde{p}_i),
\]

(1)
a random variable. The farmer's utility function exhibits constant absolute risk aversion, \( A_i \), and takes the form

\[
U^i(y) = -k_i \exp \left( -A_i \tilde{y} \right),
\]

where \( \tilde{y} \) is the random component of his income. (Any non-random components can be absorbed into the constant, \( k_i \).) This particular form has the property that maximizing expected utility is equivalent to maximizing

\[
W = E\tilde{y} - \frac{1}{2} A_i \text{Var} \tilde{y},
\]

(2)
where \( E\tilde{y} \) is the expected value of income, \( \text{Var} \tilde{y} \) is its variance, provided, as in the case here, that \( \tilde{y} \) is normally distributed. (These are the standard assumptions of the capital asset pricing model for portfolio choice, and can be viewed as second-order approximations to more general utility functions; see Newbery and Stiglitz, 1981.) If eq. (1) is substituted in (2), and if \( z_i \) can be positive (futures sales) or negative (purchases), then the value of \( z_i \) that maximizes \( W \) is

\[
\frac{\text{Cov}(\tilde{p}_i, \tilde{p}_i \tilde{q}_i)}{\text{Var} \tilde{p}_i} - \frac{E\tilde{p}_i - f}{A_i \text{Var} \tilde{p}_i}.
\]

(3)
Speculator \( j \) has no risky production, so for him \( \tilde{q}_j \) is zero, and the first terms in (1) and (3) vanish. Thus the second term in (3) can be identified as the speculative term, and is readily interpreted. The perceived
riskiness of the futures contract is measured by $\text{Var} \tilde{p}^i$, and the cost of this risk as $1/2 \text{Var} \tilde{p}^i$. The expected return to selling a futures contract is $f = E\tilde{p}^i$. In order to persuade a risk-averse speculator to buy futures and accept the risk, the return to selling must be negative, hence $f$ must be below the expected spot price, $E\tilde{p}^i$ — a situation of normal backwardation. The first term in (3) is the pure hedging term, for if the futures market appears unbiased (that is, $f = E\tilde{p}^i$) then there is no expected speculative profit, and the only motive for trade is the income insurance offered by the price insurance. The quality of income insurance depends on how well income $pq$ and price risks are correlated; that is, on the ratio of the covariance to the variance. If output is perfectly certain, then income and price are perfectly correlated, the first term will be equal to $q_i$, and the farmer would sell his entire crop on the futures market if he believed it to be unbiased. In general, though, he will not believe it to be unbiased, and he will wish to speculate in addition to hedging. His net futures trade will reflect the balance of the desire to insure and the returns to speculating.

The futures market clears, so that the sum of $z_i$ across all participants must be zero, and this condition will yield a value for the futures price. What this implies for the value of $f$ and its relation for the subsequent spot price, $p$, depends on beliefs, as well as preferences. If agents hold rational expectations, and have full information about the nature of all production and demand risks, then they will agree on the common values of the expected spot price, $E_p$, and its variance, $\text{Var}p$. In such a case the only motive for trading on the futures market is to share risk, and speculators will be willing to absorb some of the risk in return, on average, for some profit. If all farmers face perfectly correlated production risk, and if the coefficient of variation of output is $\sigma_q$, of price is $\sigma_p$, and the correlation coefficient between price and output is $r$, then market clearing on the futures market gives the bias as

$$\frac{E_p - f}{E_p} = \frac{\overline{Q} \cdot E_p \sigma_p^2 (1 + r \sigma_q / \sigma_p)}{\sum 1 / A_i}$$

(4)

and a farmer's futures sales will be

$$\frac{z_i}{Eq_i} = \beta_i (1 + r \sigma_q / \sigma_p), \beta_i \equiv 1 - \frac{\overline{Q}}{Eq_i A_i \sum 1 / A_i},$$

(5)

where $\overline{Q} = \sum Eq_i$ is average total output (see Newbery and Stiglitz, 1981, p. 186). Thus $\beta_i$ is a measure of the extent to which the farmer is more risk-averse than the average (the term in $A_i$) and more exposed to
risk \( \frac{\bar{q}_i}{\bar{q}} \). If there are \( n \) identical farmers and \( m \) identical speculators, all with the same coefficient of absolute risk aversion, \( A \), then \( \beta = m/(n + m) \). If there is no output risk, so \( \sigma q = 0 \), then, while a farmer would sell his entire crop forward on an unbiased futures market, here he would only sell a fraction \( \beta \) representing the fraction of the total risk which the speculators are willing to bear. If the only source of risk is supply variability, then \( r = -1, \sigma q / \sigma p = \varepsilon \), the elasticity of demand, and the farmer will sell a fraction of his crop \( \beta (1 - \varepsilon) \) on the futures market, possibly negative.

What lesson can be drawn from this very simplified model? First, futures markets allow speculators to bear some of the farmer's risks. The more highly correlated income and price risks, the better the market is at insuring farmers, but in general it will provide only partial insurance. It is, however, much better suited to providing insurance to stockholders who store the commodity after the harvest until needed for consumption or processing, and it is not surprising that most hedging is done by stockholders rather than farmers. Second, the greater the agreement over the expected spot price, and the less risk-averse are the speculators, the smaller will be the average perceived bias, and the larger will be the fraction of hedging to speculative sales by producers (or stockholders). Third, the greater the degree of agreement on the expected spot price, the more will speculation be a response to the demand for hedging services. The greater the disagreement on the expected spot price, the more likely it is that speculation, in the form of gambling over the expected spot price, will dominate the market. In a masterly series of studies, Holbrook Working showed that most commodity futures markets depend primarily on hedging for their existence, that the size of the open interest follows closely the demand for hedging of seasonal storage, with speculators standing ready to assume the risks offered by the hedgers (Working, 1962). The cost of these hedging services (that is, the return to the speculators) was quite remarkably small. Thus for cotton traders, the gross profit per dollar of sales over a sample of some 3,000 trades was 0.023 of one per cent with the traders making losses on 15 out of 43 trading days. (Net profits after paying commissions and expenses were substantially less; Working, 1953).

The issue of bias turns out to be more complex than the simple Keynes–Hicks risk-premium view, for even in a bilateral market of farmers and speculators the bias can go either way. Once stockholders and processors are brought into the picture, the relative demands for long and short hedges will change yet again, and in turn influence the direction of speculation (long or short) and hence of the risk premium, or bias. Hirshleifer (1988) examines the determinants of bias in a market with primary producers subject to output risk (growers) and intermediate producers (processors). He finds that processors tend to hedge long, but, if transaction costs are low, there is a downward bias in futures prices (backwardation). If transaction costs are high, growers are differentially driven from the futures market, and could reverse the bias to contango.

**Effect of speculators on stability**

Several important questions can be asked about the role of speculators. Do they tend to destabilize the spot market and/or the futures market? Do they improve efficiency? Do they have adverse macroeconomic effects? To the layman the association of speculative activity with volatile markets is often taken as proof that speculators are the cause of the instability, though the body of informed opinion is that the volatility creates a demand for hedging or insurance, which is met by the willingness of speculators to bear the risk. It is hard to test the proposition that speculation is stabilizing, for speculative
activity (notably, stockholding) can take place without futures markets. In practice, the usual question is: do futures markets, which, by lowering transaction costs, greatly facilitate speculative behaviour, improve the stability of the spot market? Even this question is not straightforward. Futures markets provide an incentive to collect information about the future market-clearing spot price, though, as often with information gathering, there are public-good problems associated with its use. Much theoretical effort has been devoted to the question of whether futures prices perfectly reveal the relevant information available to participants, and, if so, what incentives would remain for its collection. It now appears that, except in special cases, the information is only partially revealed in the market, leaving incentives for its collection, but nevertheless improving the forecasts of otherwise uninformed traders. If so, and if the spot market is intrinsically volatile (because of variations in supply caused by weather, or demand caused by the trade cycle), then better forecasts of future spot prices will tend to elicit compensating supply responses – if prices are expected to be high tomorrow, then it will pay to produce more, and to carry more stocks forward, tending to reduce, or stabilize, price fluctuations. To the extent that futures markets reduce storage risks, storage becomes cheaper, and this will tend to stabilize supplies and prices directly. On the other hand, anticipated disturbances will have a more immediate effect on current prices, and will tend to make them more responsive to news. A frost in Brazil expected to affect next year's coffee production is likely to have a more rapid effect on current coffee prices in the presence of a futures market than in its absence. Nevertheless, it improves the efficiency of the current market if it does respond to this relevant information.

The clearest example of the stabilizing effect of futures markets is provided by cobweb models, in which producers base current production decisions on last year's realized price, with consequent self-sustaining fluctuations in output without any exogenous shocks. If a futures market is set up, then producers initially planning to expand production in response to last year's high price, and selling futures, would cause the futures price to fall to the predicted spot price, and would lead them to revise their incorrect production plans, hence eliminating the cobweb and stabilizing the market.

Two other factors bear on the question of market stability. It is clear that much hinges on the nature of expectations. Speculation without hedging is a zero-sum game, and, if two speculators, each holding different views of the future price, $\bar{F}$, trade with each other, one will gain while the other will lose. If they are rational, and risk-averse, they should not be willing to engage in such swaps. On this view, speculators who are more successful at forecasting the future price will make money, and those who are less successful will lose, and be forced to leave the market, until only the good forecasters are left, and they make money only in the course of moving futures prices towards the forecast spot price. However, it is possible that a steady supply of less good speculators, who add noise to the system, lose money and exit, to be replaced by others. Their presence may worsen the predictive power of the futures price or, by increasing the returns to information gathering by the informed speculators, may actually improve the predictive power of the futures prices (Anderson, 1984a; Kyle, 1984). Depending on the direction of the net effect of uninformed speculators, the presence of a futures market (which provides them with the opportunity to gamble) may improve or worsen the efficiency of the spot market.

The other possibility is that futures markets will provide opportunities for market manipulation, by the better informed at the expense of the less well informed (corners, squeezes) or of the larger at the expense of the smaller. It is easy to show that the futures price has an effect on production decisions by extending the model of eq. (1) to allow producers to choose inputs. In the case of pure demand risk (no output uncertainty) it can be shown that the producer will base his production decisions solely on the
futures markets, hedging and speculation: The New Palgrave Dictionary of Economics

future price. Large producers (Brazil for coffee, OPEC for oil, and so on) may then find it profitable to intervene in the futures market to influence the production decisions of their competitors in the spot market, and in extreme cases may find it profitable to increase price instability, though the extent to which this is feasible will be limited by the supply of and risk tolerance of other speculators in the futures market (Newbery, 1984). This is true even if all agents hold rational expectations, and share full information (except about the actions of the large producers). If some agents use naive forecasting rules to guide their futures trading, and if these rules are known to other agents who possess market power, then it may pay the large rational agents to destabilize the price and exploit the irrationalities in the forecasting behaviour of the naive agents (Hart, 1977).

Although speculation may stabilize prices, it is quite possible for it to make prices more unstable, even if all agents have equal information and hold rational expectations. Compare two possible arrangements. In the first, futures markets are prohibited, the commodity is perishable, so there is no scope for speculative storage or speculation on the futures market. The commodity can be produced by two methods, one perfectly safe, the other risky, but on average more profitable (for example, two varieties of irrigated rice, one higher-yielding but susceptible to rust in certain weather conditions). Farmers allocate their land between the two production techniques but, in the absence of the futures market, find the risky technique relatively unattractive and so produce little. In the second arrangement, futures markets are permitted and speculators are willing to trade for a very low risk premium. Farmers are now able to sell the crop forward, and are therefore more willing to produce the risky crop, whose supply is very variable. Total supply variability increases, and hence the spot price becomes more variable.

It is quite possible that destabilizing speculation of this type yields higher potential social welfare, for yields are higher, if riskier, and the risks are borne at relatively low cost. It is also perfectly possible for speculation on a futures market to be stabilizing (by reducing the costs of storage and therefore improving arbitrage between crop years) and yet make everyone worse off (see, for example, Newbery and Stiglitz, 1981). We now know that, if the market structure is incomplete, creating additional markets can make matters worse. Speculation, which creates a market in price risks, does not thereby complete the market structure because quantity risks may remain imperfectly insured. The reason is that the market in price risks causes changes in the market equilibrium which affects the degree to which the other risks (income and quantity risks) are effectively insured. In particular, if prices are stabilized but quantities remain unstable, incomes may be less stable than if prices were free to move in response to the quantity changes.

Finally, there remains the old Keynesian question of whether speculation which succeeds in stabilizing prices will exacerbate income fluctuations. The argument, due to Kaldor (1939), is straightforward. Speculators undertake or assume the risks for storage, which then responds to mismatches in supply and demand. These stocks, or inventories of goods, will fluctuate markedly and will have the same macroeconomic effect as fluctuations in investment, tending, through the multiplier, to have a magnified effect on national income. Whether these speculative stock movements are stabilizing or destabilizing then turns on whether they offset or amplify the fluctuations in income associated with the mismatch in demand and supply that caused the stock change. Kaldor's view was that stock changes caused by supply shocks would tend to stabilize total income, while those caused by demand shocks would be destabilizing, but much will depend on the commodity price elasticities of demand and the nature of the various transmission mechanisms, particularly the lag structure. Nevertheless, the OPEC oil shocks have demonstrated that commodity supply shocks can cause significant macroeconomic disturbances, while
the increasing ease of currency speculation as restrictions are removed and transaction costs lowered has reawakened the fear that speculation may, in some cases, destabilize income and impose needless costs.

**Commodity stabilization schemes and longer-term insurance**

At various times governments and international agencies have argued that primary commodity price variability is costly to vulnerable, often poor, primary exporters, and that therefore some form of commodity stabilization scheme should be implemented. Such schemes are often poorly designed to minimize the cost of reducing risk and have a doubtful record (Newbery and Stiglitz, 1981). One might also expect that, in the presence of the kind of market failure suggested by this costly risk, alternative institutions might emerge to reduce risk, and that is indeed the case, with futures markets being the most obvious solution to commodity price risk. If primary exporting countries can hedge the export commodity price variability, then their risk will be reduced, and would seem to be eliminated if all the risk arose from price variability, with no variability in output. This would be true if there were no serial correlation in prices from year to year, but, as Deaton and Laroque (1992) found, there is considerable serial correlation for the 24 commodities they studied over the period 1900–87. Their results suggest that about one-quarter of price shocks are permanent, that three-quarters or more of the price shock will persist for at least a year, and even after two years typically 60 per cent of the price shock will persist. If countries (or producers) hedge only for the coming year, their income will still vary considerably from year to year. If they could hedge for many years ahead this problem would be reduced.

Most futures markets extend only a relatively short period ahead and, even when they extend out several years, active trading and hence liquidity is mostly confined to the near-term future, measured in months rather than years. Apart from primary exporters having to deal with serial correlation (or persistence in price shocks), producers making large, irreversible sunk investment decisions (for example, in an oil refinery, offshore oil exploitation, LNG liquefaction and regasification facilities, aluminium smelters, nuclear power stations) would make better investment decisions knowing future prices (of inputs and outputs). They would be able to borrow more cheaply if risk were reduced by contracts or hedging, reducing the cost of capital-intensive products.

Liquid futures extending out ten years would clearly help, but are lacking. In their absence, companies may prefer to vertically integrate down the supply chain to provide an implicit (if partial) hedge. Electricity and gas liberalization has been premised on separating out natural monopoly pipes and wires from potentially competitive services supplied over the networks, regulating the former and creating wholesale and retail markets for the latter. Vertical unbundling (particularly of generation and transmission) appears critical to delivering the efficiency benefits of competition (Newbery, 2005), but increases risk as wholesale electricity and fuel markets are so volatile. Forward and futures markets for electricity (and fuels such as gas) exist but basis risk (the difference between the price of the product traded and that of interest to the contractor) is high and markets are very illiquid. Vertical integration between generation and supply (or retailing) reduces spot price risk but makes the market less contestable.

Nevertheless, it is possible to use a sequence of short-term futures markets to hedge longer-term risks through a sequence of rollover hedges. Kletzer, Newbery and Wright (1992) show how to compute an $n$-year rollover hedge for a commodity with serially correlated price risk, no output risk but supply
Responsive to expected price. The way the rollover works is to sell more futures initially than needed for one-period hedging, and then use the surplus futures sales to finance the next year's futures transactions. This is not perfect, for the amount of hedging required next year will depend on production, and that will depend on the futures price prevailing next year, not as yet known. Consequently, despite the absence of production risk, future output cannot be perfectly hedged, and there remains some residual risk (as there would be if there were output risk). Nevertheless, because the costs of risk increase with the square of the deviation, reducing the risk by a given fraction reduces the cost of risk by more than that fraction and can be worthwhile. The further forward the hedge extends, the lower is the extra risk benefit provided, until the extra costs outweigh the benefit, so there is an optimal length of such a hedge.

The idea of using rollover hedging and portfolios of futures of different maturities to reduce risk has proved powerful both in theory and in hedging practice. Ross (1997) considers a world in which commodity prices are determined by many factors, and that, given enough different futures contracts and sufficiently precise knowledge of the underlying model determining prices, it would be possible to devise a perfect hedge, although in practice any such hedge would be imperfect. Neuberger (1999) develops this approach to identify an optimal hedging strategy using futures of different maturities and thus hedge long-term exposures with a combination of short-term futures. Neuberger tests his model on crude oil futures traded on NYMEX from 1986 to 1994. He asks how well one can hedge a forward commitment to deliver oil in five years’ time using two futures contracts of not more than nine months to maturity. The annualized volatility of the five-year contract is 26 per cent and that of the hedged portfolio is less than one per cent, with a hedge of short 2.89 seven-month contracts (of 1,000 barrels) and long 3.93 nine-month contracts, for each contract to deliver in five years’ time. In a model in which a trader wishes to hedge for delivery in 36 months’ time, if the portfolio is balanced monthly, 488 contracts are traded per contract delivered, although this can be cut to fewer than 60 with bimonthly rebalancing (and at lower risk).

The fact that rollover hedges allow one to reduce risk over a longer time horizon than the duration of current futures offered in the market has a number of interesting implications. It can explain why near-term futures are more popular and liquid than longer-term contracts, for they may provide a substitute for the latter at lower cost. It also explains why the volume of liquid futures can so greatly exceed the underlying physical trade, often by factors of 10 to 20. Rollovers require both a greater ratio of futures to physicals and a higher rate of trading to rebalance the portfolio over time, contributing to volume, liquidity and hence cost reduction.

Rollovers are, however, not perfect, and they may tempt traders to take imprudently large risks. One such famous case was the near-bankruptcy of Metallgesellschaft (MG), whose losses were estimated at DM 4 billion and whose survival was ensured only by a major rescue operation (Wahrenburg, 1996). At one time MG was reportedly holding short-term positions equivalent to 160 million barrels of oil or 80 times the daily output of Kuwait (Hilliard, 1999).

The case became celebrated as a test of whether MG had adopted a sound or imperfect hedging strategy. Some writers such as Culp and Miller (1995) argued that MG was following ‘a textbook hedging strategy which was not properly understood by MG's supervisory board and house banks’ (Wahrenburg, 1996, S29). Others, such as Edwards and Canter (1995), Mello and Parsons (1995), and Verleger (1999) argue that MG was excessively exposed in the wrong products. Wahrenburg argues that the MG's hedging strategy could indeed significantly reduce risk, but not completely, and that MG's equity capital
was insufficient to cover the remaining risk.

John Kenneth Galbraith was a paradox. Born in Canada in 1908, he began his professional career armed with a Ph.D. in agricultural economics from the University of California. During the Second World War he was in charge of price controls and immediately after was director of the Strategic Bombing Survey. Later he was in charge of economic affairs in the occupied countries and was awarded the Medal of Freedom for his efforts. He became a Professor of Economics at Harvard, a President of the American Economic Association, and an advisor to presidents and presidential candidates, the latter leading to his appointment as ambassador to India during the Kennedy Administration.

Yet throughout this distinguished career the economics profession moved steadily towards more formal mathematizable models and exhibited less and less interest in old-fashioned political economy, while Galbraith himself never moved an iota in either direction. In the spirit that one might expect from a former editor of Fortune magazine, his books were written always in the form of verbally persuasive economic tracts, without a hint of mathematics. His interests were always those of political economy, with political considerations ranking at least as high as, and most often higher than, those of economics. Perhaps because of his writings on the causes and consequences of the Great Depression in The Great Crash (1961) and his successful experience as a price controller during the Second World War, he was never a believer in the wisdom of the invisible hand. If there is an essential theme in his economic writings, it is that the government has a role to play in successful economies.

The Affluent Society (1955) documents the tendency of the invisible hand to promote private splendour and public squalor. Others have made that case (before and since; analytically and verbally), but no one has ever grabbed the public's attention with vivid examples as he did. There were other forces also at work, but much of the effort to improve the quality of the public sector during the 1960s can be traced to his writings. Of course, Galbraith would have wanted the government to go much farther and returned to
this theme in *The Culture of Contentment* (1992) and *The Good Society: A Humane Agenda* (1996) which describe a range of interventions to address contemporary problems.

Planning, however, was not just something for the public sector. Planning was essential to the smooth functioning of the private sector. As a result large firms had an important role to play in the private economy. They were not just actual or potential anti-trust threats. In many ways *American Capitalism* (1952b) and its doctrines of countervailing power have come to be the accepted wisdom. Big is no longer automatically bad. Major new government antitrust cases have almost disappeared. That said, *The Economics of Innocent Fraud* (1994a) emphasized Galbraith's concerns late in life about the power of corporate managers to shape society.

In the Galbraith view in *The New Industrial State* (1967a), large firms are essential since they finance much of the research and development that leads to the technical innovations that are necessary to secure a rising standard of living. Technical change had traditionally stood outside of economics as an exogenous force, although with the advent of the new growth economics this is no longer the case. Galbraith placed it where it should be at the centre of his analysis and it led to very different conclusions regarding the role of the large firm. Today it is fashionable to point to the many formerly small firms that have become technological leaders, but Galbraith would reply that most of these firms can be shown to have sprung from the laboratories of some large firm or university.

The invisible hand systematically leads to too few resources for the public sector, too few resources for research and development, and poor coordination between firms, but it also, in Galbraith's view, leads to too few resources for the poor. In *Economic Development* (1962), *The Nature of Mass Poverty* (1979a) and *The Voice of the Poor* (1983a) he has systematically argued for public actions to redress the imbalances produced by the market in the distribution of income. He was never a believer in the virtues of 'trickle down'. And as the percentage of total income going to the bottom 40 per cent of the population fell in the mid-1980s under the impact of America's current experiment with benign neglect, he could claim vindication for his earlier arguments, as he could have in the last decade of his life. The result was an economist out of the mainstream of economic thought, but in the mainstream of economic events.

Abstract

This article reviews the research of David Gale, who made lasting contributions to game theory, general equilibrium theory, and growth theory. In addition to his influence on the development of economic theory, his work has had important implications for many branches of mathematics and on mathematical education.

Article

David Gale was born in New York on 13 December 1921, and died in Berkeley, California on 7 March 2008. He received an undergraduate degree from Swarthmore and a Master's degree from the University of Michigan before earning a Ph.D. in Mathematics at Princeton. It was at Michigan, under the influence of Professor Norman Steenrod, that Gale decided to give up his study of physics and pursue a Ph.D. in mathematics. He taught at Brown University from 1950 through 1965 and then joined the faculty at the University of California, Berkeley. His principal appointment was in the Mathematics Department, but he maintained affiliations with the departments of Economics and Industrial Engineering. Gale won wide recognition for his research. His awards included a Fulbright research fellowship, two Guggenheim fellowships, elections to the American Academy of Arts and Science and the National Academy of Science, the Lester Ford Prize (for outstanding mathematical exposition), the John von Neumann Theory Prize (for fundamental contributions to operations research), and the Pirelli International Award (for the Internet Mathematics Museum ‘MathSite’).
Mukul Majumdar (1992) edited the volume *Equilibrium and Dynamics: Essays in Honour of David Gale*. The *International Journal of Game Theory*, Volume 36, Numbers 3–4, March 2008 contains a collection of papers dedicated to David Gale on the occasion of his 85th birthday. This volume was edited by Marilda Sotomayor, who had also organized a scientific day in David's honour during the 18th Summer Festival on Game Theory in Stony Brook, 12/13 July 2007. Special issues of *Games and Economic Behavior* and *The Mathematical Intelligencer* are in preparation.

Gale lived in Berkeley, California and Paris, France with his partner Sandra Gilbert, a renowned feminist literary scholar and poet. Her 2000 book of poetry *Kissing the Bread* included a section of poems she wrote for Gale called ‘When she was kissed by the mathematician’. He had three daughters and two grandsons. Julie Gale, his former wife and the mother of his daughters, died in February 2008.

**Linear inequalities**

As a graduate student at Princeton, David Gale worked with classmate Harold Kuhn on a research project supervised by Professor Albert Tucker. At the time, there was considerable excitement about the new fields of zero-sum game theory and linear programming, but the mathematics of linear inequalities had not been developed. Existing proofs of the minimax theorem of zero-sum game theory required fixed-point arguments and did not make the relationship between the theory and linear inequalities explicit. The project led to important results that identified the deep connections between the two new areas. Gale, Kuhn and Tucker (1951) contained the first complete proof of the duality theorem of linear programming, and used the theorem to prove the minimax theorem of zero-sum, two-person game theory. This paper uses convex analysis rather than fixed-point arguments to prove the minimax theorem, and implicitly provided a computational foundation for equilibrium points in zero-sum games.

Largely in recognition of their joint work, Gale, Kuhn and Tucker won the 1980 von Neumann prize for work they began in the late 1940s. Their citation stated that they ‘played a seminal role in laying the foundations of game theory, linear and non-linear programming – work that continues to be of fundamental importance to modern operations research and management science’.

**Infinite games**

Early work on non-cooperative game theory concentrated on two-player, zero-sum games. When players had finitely many pure strategies, these games were well understood. All two-player finite zero-sum games have a value, and by playing to maximize their minimum payoff, a player could guarantee this value independent of his or her opponent's strategy. Gale and Stewart (1953) studied a class of infinite zero-sum games and demonstrated that the minmax theorem need not hold in this more general setting.
The paper examines the simplest possible infinite zero-sum game. In the two-player game of perfect information, the players take turns naming binary digits, which can be thought of as the binary expansion of a number between zero and one. The first player wins if the expansion is an element of a pre-specified set. Otherwise, the second player wins. Gale and Stewart show that basic results from finite games hold if the prespecified set is closed, but that in general the game does not have a value. The class of infinite games introduced by Gale and Stewart has had broad implications for mathematics. Gale and Stewart's result led to research that identified a general set of games that do have values, culminating in a theorem of Martin (1975). The fact that some games do not have values led to developments in set theory (Mycielski, 1964).

Growth

Gale (1956a and 1960, chapter 8, section 5) generalizes and simplifies the von Neumann (1937/46) model of an expanding economy in what in now called the von Neumann–Gale model of growth. Gale made two essential additions to the original model. He substituted von Neumann's requirement that each production process involves each good in the economy (as either input or output), with a weaker, more plausible condition. Gale (1967) provides the definitive treatment of the multi-good Ramsey problem, which is a generalization of the linear von Neumann–Gale model. An agent starts with a given endowment, which must be allocated between immediate consumption and investment. What the agent invests is transformed, via a given technology, into the next period's endowment, which again may be allocated between immediate consumption and investment. The process continues indefinitely. The agent cares about the (undiscounted) sum of utility received from consumption. The problem is to find the appropriate definition for optimality and to characterize optimal consumption paths. Gale presents an appropriate optimality condition, provides conditions under which optimal paths exist, and characterizes these paths in terms of ‘turnpike’ properties. Roughly speaking, we can construct an optimal program with two phases: a bounded initial transition phase in which the state is built up to (approximate) a sustainable optimal steady state, followed by a program that approximates the best steady state consumption.

General equilibrium

Gale made several important contributions to the foundations of general equilibrium theory. Indeed, he made basic contributions to the three central issues of the theory: existence, uniqueness and stability. Gale (1955) contains a result known as the Gale–Debreu–Nikaido Lemma (Debreu, 1956; Nikaido, 1956) which contains the essential mathematical result needed to prove the existence of market equilibrium. Gale and Nikaido (1965) proves a theorem on the global univalence of differentiable mappings on $\mathbb{R}^n$. When translated into a general equilibrium context, the theorem gives sufficient conditions for equilibrium prices to be unique (see, for example, Arrow and Hahn, 1971, chapter 9). Gale (1963) provides an early robust example of global instability of the tâtonnement process in general equilibrium. Gale and Mas-Colell (1975) provides an existence theorem in an economy without ordered preferences.
College admissions and the stability of marriage

The short, deceptively simple paper is important for several reasons. The motivation for the problem comes from the real world. Gale (2001) describes how the idea for the problem came from thinking about the college application process. The translation of the practical problem into mathematics captures many important considerations but remains extraordinarily simple. The solution to the problem is not obvious, but is easy to understand. The framework lends itself to modifications that lead to insight into more complicated practical problems.

The basic problem is how to create an assignment of items from one group to items from another. The groups can be men and woman (the marriage problem), workers to jobs (labour-market matching), or students to universities (college admissions). For concreteness, consider the marriage problem, in which it is natural to impose the constraint that there are equal numbers of men and women and the desired matching is one to one. Assume everyone has preferences over potential partners (so each man can order the women from the most preferred to least preferred marriage partner, and likewise each woman can order the men). Finding a match is simple. One can order them by age and match the youngest man to the youngest woman, the second youngest man to the second youngest woman, and so on. Gale and Shapley looked for a matching in which there is no unmatched man and woman who prefer each other to their current partners. If this property failed, you would expect the matching to be unstable. Gale and Shapley show that stable matchings exist, and present a simple algorithm that constructs stable matches.

Starting in 1951, 11 years before the publication of the Gale–Shapley paper, the National Intern Matching Program used an essentially equivalent algorithm to match graduating medical students to hospital residency programmes (see Roth and Sotomayor, 1990, pp. 169–70, and Roth, 2008, appendix for a discussion of the independent development of the matching algorithm). Practical problems in a wide variety of areas (from school assignment to kidney exchange) continue to stimulate the development of matching theory.

Assignment markets and auctions

Gale's work shows sensitivity to computational issues. Knowing the connection between zero-sum, two-person game theory and the theory of linear programming combined with computational methods (like the simplex method) provides a tractable method for computing equilibria in two-player games. Demonstrating the equivalence between an equilibrium and the solution to a well-behaved optimization problem is the reason that equilibria in linear economies studied by Eisenberg and Gale (1959) can be found efficiently. Gale's work on markets with indivisible goods is another example of a situation in which Gale adds just enough structure to a general model to obtain strong results.

Shapley and Shubik (1971) introduce the assignment model, a market equilibrium model with indivisible goods. Their model has the structure of a matching game with the added feature that agents can exchange a divisible commodity, money. Demange and Gale (1985) show that this market inherits
many properties from the college admissions problem. Demange, Gale, and Sotomayor (1986) apply the framework to the study of multi-unit auctions and show how to define variations of the Vickrey auction to the multi-good setting.

Other contributions

Gale (1956b) contains a lasting contribution to the study of convex polyhedra, introducing what are now known as ‘Gale transforms’ and ‘Gale diagrams’ (see Grünbaum, 2003).

Gale (2009) describes the board games invented by Gale and his contemporaries at Princeton. Gale’s article provides an introduction to Bridg-It (or, as Martin Gardner called it, the ‘Game of Gale’) and also John Nash's game of Hex. Gale (1974) invented the game of Chomp, a simple two-player game of perfect information in which it is easy to show that one player has a winning strategy, but the winning strategy is hard to find in general.

Mathematical explorations

Gale made examples of beautiful mathematical arguments accessible to a broad audience. Between 1991 and 1996 he wrote a column entitled ‘Mathematical explorations’ for The Mathematical Intelligencer. The columns, collected in a book titled Tracking the Automatic Ant (Gale, 1998), are in the tradition of Martin Gardner's long-running ‘Mathematical games’ column in Scientific American. He also developed MathSite, a pedagogic website that uses interactive exhibits to illustrate important mathematical ideas. MathSite won the 2007 Pirelli Internationel Award for Science Communication in Mathematics.

Article

Galiani was born at Chieti, Italy, on 2 December 1728 and died in Naples on 30 October 1787. At the age of seven he was sent to Naples, where he received a classical education under the supervision of his uncle Celestino Galiani, chief almoner to the king. The young Galiani was in close touch with the cultural circles of the time and was soon introduced to the study of economics. In 1744 he translated some of Locke's writings on money. One year later he took religious orders. His extensive monetary studies culminated in the publication of *Della moneta* (1751), his main work. In 1759 he was appointed secretary of the Neapolitan embassy in Paris where he lived, almost without interruptions, for about ten years. At the end of his stay he wrote the *Dialogues sur le commerce des bléds* (1770). After his return to Naples, Galiani held several high positions in the civil service and published other essays on policy issues and in fields outside economics (Galiani, 1974; 1975).

Most of Galiani's theoretical work can be found in his *Della moneta* (1751), which appeared when he was 22. Despite the variety of topics addressed in the book, the basic contributions concern value and monetary theory. Having defined value as a relationship of subjective equivalence between a quantity of one commodity and a quantity of another, Galiani argues that value depends on utility (*utilitá*) and scarcity (*raritá*) (1751, pp. 36–56). Utility is the property of commodities to procure welfare or happiness. Man does not wish to satisfy only primary wants – like eating, drinking, and sleeping – because, once the latter have been satisfied, several others emerge so that full satisfaction is not attainable. Thus, a non-satiation postulate is assumed to hold. Scarcity refers to the quantity of goods available in the market. Although the interdependence between price and quantity in the determination of market equilibrium is clearly explained by Galiani (1751, pp. 53–4), together with the concept of
demand elasticity with respect to wealth, he states that the value of commodities is given by the quantity of labour. Galiani's stress is on value as a relative notion, not related to the intrinsic properties of commodities (1751, p. 119). This theoretical framework allows him to offer a lucid explanation of the so-called paradox of value; according to Schumpeter (1954, p. 300), he 'carried this analysis to its 18th-century peak'.

The main subject of Galiani's 1751 book, however, is money. In order to analyse the properties of a monetary economy, he inquires into the feasibility of dispensing with the use of money altogether, as in religious communities (1751, pp. 87–91). In a large society, goods could be deposited in public warehouses where each producer would be given a receipt (bullettino) stating the quantity of commodities deposited so that he would be entitled to withdraw an equivalent amount of commodities. Relative prices would be fixed by the prince. Yet these receipts are nothing but money; money is the means by which everyone's product is represented. Galiani's analysis foreshadows a basic idea shown by recent research (Ostroy, 1973), that is, that money is a mechanism to avoid inconsistent claims on commodities on the part of individuals who are motivated by self-interest (1751, p. 90). This analysis notwithstanding, Galiani vigorously rejects a fiduciary monetary system, likely under the influence of events related to John Law's experience in France. These results provide the basis for his theory of the origin of money (1751, pp. 74–81). Media of exchange were not deliberately introduced by man but emerged because some goods had properties that let them be used as means of payment. Galiani's important insight – that the commodities performing monetary functions should be of uniform quality and easily recognizable in order to bring about the reduction of transaction costs and the production of information – can be found in recent work on the subject (Jones, 1976, p. 775).

The validity of the quantity theory of money is taken for granted by Galiani. There is, however, a dynamic process through which equilibrium is attained and during this adjustment period changes in money supply affect the economy (1751, pp. 187–9). The same argument was advanced by David Hume in a celebrated passage (1752, pp. 37–8), one year after the publication of Della moneta. Although the inefficacy of expected inflation is clearly stated by Galiani (1751, p. 189), an unexpected increase in prices is thought to bring about benefits and costs. Both are discussed at length, but the analysis is rather poor and marred by inconsistencies. However, Galiani clearly understands that inflation is a concealed way of levying taxes (1751, pp. 198–9, 203–4, 208) and favours the recourse to such a policy in a critical situation when the benefits will more than offset the eventual costs (Cesarano, 1976; 1983).

As regards the international aspects of monetary economics, several passages in Della moneta show the basic principles of the theory of balance of payments adjustment, pointing out that money flows should not be tampered with by laws or regulations. Galiani views the balance of payments as an essentially monetary phenomenon and payments imbalances as a necessary event which should never be meddled with. Finally, the rate of interest is defined as the relative price of goods dated at different points in time (1751, pp. 290–1), stressing the role of different degrees of risk. In this analysis, an anticipation of the time preference theory of interest may be found.

Galiani places full trust on the laws of nature which regulate economic phenomena. These laws have universal validity and, like physical laws, can never be violated. Hence, the implementation of policy actions is constrained by the existence of natural laws (Cesarano, 1976, section 1). The economic process is guided by a ‘supreme Hand’ (1751, p. 57) which is the religiously biased counterpart (Galiani was an abbot) of Adam Smith's 'invisible hand' a quarter of a century later. This methodological
standpoint can also be found in his later book *Dialogues sur le commerce des bléds* (1770), a discussion of the 1764 French law liberalizing corn exports. The theoretical contributions of this work are not as remarkable as those of *Della moneta*. Nevertheless, the *Dialogues* are to be noted for the rather modern treatment of the principles of economic policy. The latter (1770, pp. 319–23) centres upon the fixing of a target and the choice of the means to achieve it. Galiani stresses the need to avoid abrupt changes in policy and to consider the institutional and political setting before following a specific policy. Although natural laws cannot be violated in the long run and so impose a constraint on policy actions, the latter can be effective in the short run.

Galiani's work on economics reveals a large number of contributions putting him far ahead of his time. Concerning the theory of value, Schumpeter stated:

… he [Galiani] displayed sure-footed mastery of analytical procedure and, in particular, neatness in his carefully defined conceptual constructions to a degree that would have rendered superfluous all the 19th-century squabbles – and misunderstandings – on the subject of value had the parties to these squabbles first studied his text, *Della moneta*, 1751. (1954, pp. 300–1)

His analysis of the subject of money embodies a rather coherent theoretical structure showing the basic principles upon which classical monetary theory is built.

game theory and biology

Olof Leimar

Abstract

Darwinian evolutionary dynamics and learning dynamics provide the foundation for game theory in biology. The theory is used to analyse interactions between individuals. Animal fighting behaviour, cooperative interactions and signalling interactions are examples of important areas of application. The payoffs to strategies in biological games represent Darwinian fitness, viz. survival and reproductive success. The strategies can be behaviour patterns, but also choices of phenotypic properties such as becoming a male or a female. The evolutionary analysis of allocation to male and female function is one of the most successful applications of game theory in biology.

Article

In biology, game theory is a branch of evolutionary theory that is particularly suited to the study of interactions between individuals. The evolution of animal fighting behaviour was among the first applications and it was in this context that Maynard Smith and Price (1973) developed the concept of an evolutionarily stable strategy (ESS) (see learning and evolution in games: ESS). Cooperative interactions (Trivers, 1971) and signalling interactions (Grafen, 1991), such as when males signal their quality to females, are examples of other important areas of application. There is an overlap of ideas between economics and biology, which has been quite noticeable since the 1970s and, in a few instances, earlier (Sigmund, 2005). In the early 21st century, the interchange takes the form of a joint
Strategies in games inspired by biology can represent particular behaviour patterns, including rules about which behaviour to perform in which circumstance. Other aspects of an individual's phenotype can also be viewed as the result of strategic choice. A life-history strategy specifies choices that have major impact on an individual's course of life, for instance, whether to become a male or a female or, for certain insects, whether or not to develop wings. Interactions between individuals are modelled as games where the payoffs represent Darwinian fitness. Random matching of players drawn from a large population is one common game model, which was used to study fighting behaviour (Maynard Smith and Price, 1973; Maynard Smith and Parker, 1976). ‘Playing the field’ (Maynard Smith, 1982) is a more general modelling approach, where the payoff to an individual adopting a particular strategy depends on some average property of the population (cf. population games in deterministic evolutionary dynamics). Game theory is needed for situations where payoffs to strategies depend on the state of a population, and this state in turn depends on the strategies that are present. For matching of players drawn from a population, the distribution of opposing strategies is of course given by the population distribution, but there are other reasons why the distribution of strategies influences expected payoffs. A ‘playing-the-field’ example is the choice by an individual, or by its mother, to develop into a male or a female. The two sexes occur in roughly equal proportions in many species. This observation intrigued Darwin, who was unable to provide a satisfactory explanation, writing that ‘I formerly thought that when a tendency to produce the two sexes in equal numbers was advantageous to the species, it would follow from natural selection, but I now see that the whole problem is so intricate that it is safer to leave its solution to the future’ (Darwin, 1874, p. 399). The solution to the problem was found by Düsing (1884; see also Edwards, 2000, and Fisher, 1930), and rested on the principle that, in diploid sexual organisms, the total genetic contribution to offspring by all males in a generation must equal the contribution by all females in the same generation. This gives a reproductive advantage to the rarer sex in the passing of genes to future generations. The payoffs to a mother from producing a son or a daughter must then depend on the population sex ratio, and this dependence can result in an evolutionary equilibrium at an even sex ratio (see below). The idea arose before the development of the concept of an ESS by Maynard Smith and Price (1973), but it can be regarded as the first instance of game-theoretical reasoning in biology.

**Payoffs, reproductive value, and evolutionary dynamics**

Class-structured populations in discrete time (Caswell, 2001) are often used as settings for evolutionary analysis. The classes or states are properties like female and male, and time might be measured in years. Let \( n_i(t) \) denote the number of individuals in state \( i \) at time \( t \). We can write a deterministic population dynamics as \( n(t+1) = An(t) \), where \( n \) is the vector of the \( n_i \) and \( A \) is the so-called population projection matrix. The elements \( a_{ij} \) of \( A \) can depend on \( n \) and on the strategies that are present in the population. They represent per capita genetic contributions of individuals in state \( j \) to state \( i \), in terms of offspring or individual survival. A common evolutionary analysis is to determine a stationary \( n \) for the case where all individuals use a strategy \( x \) and to examine whether rare mutants with strategy \( x' \) would increase in number in such a population.
Let us apply this scheme to the just mentioned sex ratio problem. Suppose that a mother can determine the sex of her offspring and that females in the population produce a son with probability $x$ and a daughter with probability $1 - x$. For non-overlapping generations, the dynamics $n(t + 1) = An(t)$ can be written as

$$
\begin{pmatrix}
    n_f(t+1) \\
    n_m(t+1)
\end{pmatrix}
= \begin{pmatrix}
    0.5(1-x)b & 0.5(1-x)bq \\
    0.5xb & 0.5xbq
\end{pmatrix}
\begin{pmatrix}
    n_f(t) \\
    n_m(t)
\end{pmatrix},
$$

where $b$ is the reproductive output (number of offspring) of a female, $bq$ is the reproductive output of a male, and the factor $0.5$ accounts for the genetic shares of the parents in their offspring. Because the reproductive output of all males must equal that of all females, it follows that $Q = n_f(t) / n_m(t)$ and thus that $Q = (1 - x) / x$. In a stationary population, $b=1/(1-x)$ must hold, which could come about through a dependence of $b$ on the total population size. Introducing the matrix

$$
B(x', x) = \frac{1}{2}\begin{pmatrix}
    (1-x') / (1-x) & (1-x) / x \\
    x' / (1-x) & 1
\end{pmatrix},
$$

the population projection matrix for a stationary population is $A = B(x', x)$ and the stationary $n = (n_f, n_m)$ is proportional to the leading eigenvector, $w = (1-x, x)$, of this $A$. Suppose a mutant gene causes a female to adopt the sex ratio strategy $x'$, but has no effect in a male. As long as the mutant gene is rare, only the strategy of heterozygous mutant females needs to be taken into account, and the dynamics of the mutant sub-population can be written as $n'(t+1) = A'n'(t)$ with $A' = B(x', x)$. The mutant can invade if $\lambda(x', x) > 1$ holds for the leading eigenvalue $\lambda(x', x)$ of $B(x', x)$. Direct computation of the leading eigenvalue shows that a mutant with $x' > x$ can invade if $x < 0.5$ and one with $x' < x$ can invade if $x' > 0.5$, resulting in an evolutionary equilibrium at $x=0.5$.

The reproductive value of state $i$ is defined as the $i$th component of the leading ‘left eigenvector’ $\nu$ of the stationary population projection matrix $A = B(x', x)$, that is, $\nu$ is the leading eigenvector of the transpose of $A$. It is convenient to normalize $\nu$ so that its scalar product $\nu \cdot w$ with the leading eigenvector $w$ equals $1$. For our sex ratio problem we have $\nu = \frac{1}{2}(1 / (1-x), 1 / x)$. The reproductive value of state $i$ can be interpreted as being proportional to the expected genetic contribution to future generations of an individual in state $i$. The eigenvectors $\nu$ and $w$ can be used to investigate how the leading eigenvalue depends on $x'$ near $x' = x$. It is easy to show that $\partial \lambda(x', x) / \partial x' = \partial (\nu \cdot B(x', x)w) / \partial x'$ holds at $x' = x$ (for example, Caswell, 2001), and this result can be used to identify evolutionary equilibria.
mutation has an effect in only one of the states, like the females in our example, there is further simplification in that only one column of $B(x', x)$ depends on $x'$. It follows that evolutionary change through small mutational steps in the sex ratio example can be described as if females were selected to maximize the expected reproductive value per offspring, given by

$$V(x', x) = \frac{1}{2} (1 - x') / (1 - x) + \frac{1}{2} x' / x.$$ Payoff functions having this form were introduced by Shaw and Mohler (1953), in what may have been the first worked out game-theoretical argument in biology. As we have seen, analysis of such payoff functions corresponds to an analysis of mutant invasion in a stationary population.

The concept of reproductive value was introduced by Fisher (1930) and plays an important role in the very successful field of sex ratio theory (Charnov, 1982; Pen and Weissing, 2002), as well as in evolutionary theory in general (McNamara and Houston, 1996; Houston and McNamara, 1999; Grafen, 2006). The concept is useful to represent payoffs in games played in populations in stationary environments. Reproductive value can be regarded as a Darwinian representation of the concept of utility in economics. For populations exposed to large-scale environmental fluctuations, as well as for those with limit-cycle or chaotic attractors of the population dynamics, concepts similar to reproductive value have proven less useful. In such situations, one needs the more general approach of explicitly considering evolutionary dynamics for populations of players of strategies. There are several influential approaches to the study of evolutionary dynamics in biology (Nowak and Sigmund, 2004), ranging from replicator dynamics (see deterministic evolutionary dynamics) and adaptive dynamics (Metz, Nisbet and Geritz, 1992; Metz et al., 1996; Hofbauer and Sigmund, 1998) to the traditional modelling styles of population genetics and quantitative genetics (Rice, 2004). These approaches make different assumptions about such things as the underlying genetics and the rate and distribution of mutation. Recent years have seen an increasing emphasis on explicitly dynamical treatments in evolutionary theory.

Are there mixed strategies in nature?

Biologists have wondered how individuals, as players of a game, come to play one strategy or another. For life-history strategies, involving choices between alternative phenotypes, a population containing a mixture of phenotypes could be the result of randomization at the level of an individual, which corresponds to a mixed strategy, or there could be a genetic polymorphism of pure strategies (Maynard Smith, 1982). These two possibilities can be contrasted with a third, where individuals (or their parents) use information about themselves or their local environment to make life-history choices, which could correspond to a conditional strategy in a Bayesian game. The general question is related to the issue of purification of mixed strategy equilibria in game theory (see purification). When observing populations that are mixtures of discrete phenotypes, biologists have tried to establish if one of the above three possibilities applies and, if so, what the evolutionary explanation might be. This question has been asked, for instance, about the phenomenon of alternative reproductive strategies (Gross, 1996; Shuster and Wade, 2003), like the jack and hooknose males in coho salmon (Gross, 1985) or the winged and wingless males in fig wasps (Hamilton, 1979). Since there are likely to be a number of factors that
influence the relative success of reproductive alternatives and could be known to a developing individual – for instance, its juvenile growth rate and thus its potential adult size – one might expect some form of conditional strategy to evolve. This expectation agrees with the observation that conditional determination is common (Gross, 1996). There are also instances of genetic determination of reproductive alternatives (Shuster and Wade, 2003) but, somewhat surprisingly, there is as yet no empirically confirmed case of a mixed strategy of this kind. Perhaps it has been difficult for evolution to construct a well-functioning randomization device, leaving genetic polymorphism as a more easily achieved evolutionary outcome.

Evolution of cooperation

Among the various applications of game theory in biology, the evolution of cooperation is by far the most studied issue. This great interest is based on the belief that cooperation has played a crucial role in the evolution of biological organization, from the structure of chromosomes, cells and organisms to the level of animal societies. An extreme form of cooperation is that of the genes operating in an organism. Several thousand genes coordinate and direct cellular activities that in the main serve the well-being of their organism. Kin selection (Hamilton, 1964), which predicts that agents have an evolutionary interest in assisting their genetic relatives, cannot be the main explanation for this cooperation, since the different genes in an organism are typically not closely related by descent (except for a given gene in one cell and its copies in other cells). It is instead division of labour that is the principle that unites the parts of an organism into a common interest, of sufficient strength to make it evolutionarily unprofitable for any one gene to abandon its role in the organism for its own advantage. There are of course exceptions, in the form of selfish genetic elements, but these represent a minority of cases (Burt and Trivers, 2006).

Trivers (1971) and Axelrod and Hamilton (1981) promoted the idea that many of the features of the interactions between organisms would find an explanation in the give and take of direct reciprocation. In particular, the strategy of tit for tat (Axelrod and Hamilton, 1981) for the repeated Prisoner's Dilemma game was thought to represent a general mechanism for reciprocity in cooperative interactions and received much attention from biologists. On the whole, this form of direct reciprocity has subsequently failed to be supported by empirical observation. Two reasons for this failure have been proposed (Hammerstein, 2003). One is that the structure of real biological interactions differs in important ways from the original theoretical assumptions of a repeated game. The other is that the proposed strategies, like tit for tat, are unlikely to be reached by evolutionary change in real organisms, because they correspond to unlikely behavioural mechanisms. In contrast to reciprocity, both the influence of genetic relatedness through kin selection (Hamilton, 1964) and the presence of direct fitness benefits to cooperating individuals have relatively strong empirical support. Division of labour and the direct advantages of the trading of benefits between agents are likely to be crucial ingredients in the explanation of cooperation between independent organisms. The idea of a market, where exchanges take place, is thus relevant in both biology and economics (Noe and Hammerstein, 1994).

Evolution of signalling
Signals are found in a wide variety of biological contexts, for instance in aggressive interactions, parent–offspring interactions, and in connection with mate choice. There is now a fairly well developed set of theories about biological signals (Maynard Smith and Harper, 2003). One of the most influential ideas in the field is Zahavi's handicap principle (Zahavi, 1975). It states that a signal can reliably indicate high quality of the signaller only if the signal is costly, to the extent that it does not pay low-quality individuals to display the signal. The idea can be seen as a non-mathematical version of Spence's signalling theory (Spence, 1973; 1974), but, because biologists, including Zahavi, were unaware of Spence's work in economics, Zahavi's principle remained controversial in biology until Grafen (1991) provided a game-theoretical justification. The turn of events illustrates that biologists might have benefited from being more aware of theoretical developments in economics.

An example where Zahavi's handicap principle could apply is female mate choice in stalk-eyed flies (David et al., 2000). Males of stalk-eyed flies have long eye stalks, increasing the distance between their eyes, which is likely to be an encumbrance in their day-to-day life. A high level of nutrition, but also the possession of genes for high phenotypic quality, cause males to develop longer eye stalks. Female stalk-eyed flies prefer to mate with males with eyes that are far apart, and in this way their male offspring have a greater chance of receiving genes for long eye stalks. Female choice will act to reduce genetic variation in males, but if a sufficiently broad range of genetic loci can influence eye-stalk length, because they have a general effect on the phenotypic quality of a male, processes like deleterious mutation could maintain a substantial amount of genetic variation. In this way, signalling theory can explain the evolution of elaborate male ornaments, together with a mating preference for these ornaments in females, illustrating the power of game-theoretical arguments to increase our understanding of biological phenomena.

Learning

Viewing strategies as genetically coded entities on which natural selection operates, with evolutionarily stable strategies as endpoints of evolutionary change, is not the only game-theoretical perspective that is of relevance in biology. For many categories of behaviour, learning or similar adjustment processes are important in shaping the distribution of strategies in a population. For instance, when animals search for food or locate suitable living quarters, they may have the opportunity to evaluate the relative success of different options and to adjust their behaviour accordingly. A well-studied example is the so-called producer–scrounger game, for which there are experiments with birds that forage in groups on the ground (Barnard and Sibly, 1981; Giraldeau and Caraco, 2000). The game is played by a group of foragers and consists of a number of rounds. In each round an individual can choose between two behavioural options. Producers search for and utilize new food sources, and scroungers exploit food found by producers. The game presupposes that the activities of producing and scrounging are incompatible and cannot be performed simultaneously, which is experimentally supported (Coolen, Giraldeau and Lavoie, 2001). The payoffs to the options, measured as the expected food intake per round, depend on the frequencies of the options in the group. For instance, scrounging is most profitable to an individual if no one else scrounges and yields a lower payoff with more scrounging in the group. By specifying the details of the model, one can compute an equilibrium probability of scrounging at which the payoffs to producing and scrounging are equal. This equilibrium is influenced by parameters
like expected search times and the amount of food found in a new location. It has been experimentally verified that groups of spice finches converge on such an equilibrium over a period of a few days of foraging (Mottley and Giraldeau, 2000; Giraldeau and Caraco, 2000). It is not known precisely which rules are used by individuals in these experiments to modify their behaviour, but such rules are likely to play an important role in shaping behaviour in many animals, including humans (see learning and evolution in games: adaptive heuristics). The study of these kinds of adjustments of behaviour could therefore represent an important area of overlap between biology and economics.

Johnny called me; he likes my manuscript …. I am very happy about this. After all, it wasn't easy for me to simplify his mathematical theory, and to represent it correctly. He is working continuously without a break; it is nearly eerie.

Oskar Morgenstern, Diary, 7 August 1941 (author's translation)

Thus confided Oskar Morgenstern to his wartime diary at Princeton, while working on the introductory chapter of what would become the *Theory of Games and Economic Behavior* (1944). Like other private reflections written at the time, it speaks to the distance that lay between him, the Viennese economist, and ‘Johnny’ von Neumann, the Hungarian mathematician. The two exiles had come to Princeton by quite different paths, and, in 1941, had known each other well for only two years. A product of the
Austrian school of economics, Morgenstern had strong critical faculties and epistemological interests, but limited mathematical training. Von Neumann, on the other hand, was a Hungarian mathematician of first rank, with little time for philosophical speculation but boundless confidence in the application of mathematics across the scientific domain. Yet, differences notwithstanding, they managed to forge a fruitful partnership, writing a landmark 600-page book on mathematical social science that would mark the creation of game theory and link them thereafter in the public eye.

Von Neumann (1903–1957), the privately tutored mathematical prodigy, came from a prosperous banking family of assimilated Hungarian Jews. It is not insignificant for the present subject that, during his formative years, he was witness to political upheaval, including not only the First World War but also, in Hungary, the 1919 Communist revolution of Bela Kun and its subsequent brutal suppression. Indeed, the Kun regime saw the von Neumann family temporarily flee Budapest. He also watched the growth of anti-semitism in Hungary, which would increasingly restrict the opportunities available to even well-integrated Jews such as himself. In the mid-1920s, he completed degrees in mathematics and chemical engineering at Budapest and Zurich, during that time writing several papers, mainly in the areas of axiomatic set theory and the consistency of mathematics. In 1926, he became postdoctoral fellow at the University of Göttingen, then a world centre in mathematics, whose rich environment allowed him to work close to not only its leader David Hilbert but other luminaries such as Richard Courant and Hermann Weyl. During this period, he continued working on set theory and foundations and, in particular, the mathematical theory of quantum mechanics (see von Neumann, 1932). In these works, there emerge features that would characterize von Neumann's use of mathematics in social science, including an emphasis on achieving axiomatic description of the field under study and, perhaps inherited from quantum mechanics, a belief in the inherently probabilistic nature of the world. Both of these features surfaced in another of von Neumann's Göttingen papers, one which stood apart from his main interests. This was his 1928 ‘Zur Theorie der Gesellschaftsspiele’, the theory of parlour games, first presented when von Neumann was 23 years old. Were space restrictions unimportant here, we could explore the rich background to the mathematical treatment of games. Chess held a great place in the Jewish culture of Mitteleuropa at the turn of the 20th century: from the psychological investigation of the thought processes of the grandmasters to the use of the game as source of inspiration in novelists' fiction. Legendary chess champion and mathematician, Emanuel Lasker, drew on the game for inspiration as he wrote about the workings of social life. Other mathematician contemporaries of his wondered whether so human an activity as chess could be made amenable to formal treatment. The key figures here were Ernest Zermelo in 1913 and then, in the 1920s, von Neumann's Hungarian contemporaries, Dénes König and László Kalmár. Independently, in Paris, again in the 1920s, French mathematician, Emile Borel, drew on his experience as a player of cards rather than chess to begin constructing a mathematical analysis of games involving strategy and to probe the question of equilibrium play. Von Neumann's paper may be regarded as the crowning contribution of these mathematical investigations.

His paper is a brilliant description of the generic two-person, zero-sum game, that is, in which the interests of the two players are directly opposed. He defines the game by the strategies available to both players and their associated payoffs, and, never too concerned about elegance in mathematics, gives a tortuously difficult proof of the existence of a minimax equilibrium. This is a preferred way to play, possibly requiring that strategies be chosen in a probabilistic manner, that allows each player to minimize the amount ceded to the other. The paper, which brought the discussion of the existence of
such an equilibrium to a close, finished with preliminary suggestions about how to extend the analysis to games of three or more players, in terms of coalitions and their winnings. But it went no further than that, and neither did von Neumann. Apart from some unpublished work at the time, in which he showed how the strategy of ‘bluffing’ in a simple two-person poker corresponded to the mathematically rational way to play, he essentially put the theory of games aside. Following a period as Privatdozent at the University of Berlin, he spent six months of 1930 at Princeton University's Department of Mathematics. The following year, gauging that his opportunities in Europe were limited, he moved permanently to the United States, where, along with Albert Einstein, he became one of the first members of the newly founded Institute for Advanced Study, close to Princeton University.

Morgenstern (1906–76) was part of the thriving interwar economics community in Vienna constituted by such figures as Ludwig von Mises, Hans Mayer, Friedrich Hayek, Fritz Machlup and Gottfried Haberler. Having obtained his Habilitation in 1928, he became lecturer at the University of Vienna and then director of the Rockefeller-financed Institut für Konjunkturforschung (Business Cycle Institute). Although an Austrian economist, he was not as ardent an advocate of laissez-faire liberalism as Mises and Hayek, being closer to von Wieser and Hans Mayer, both of whom were more accepting of public intervention and strong government. As Institute director, Morgenstern also had to accommodate himself to the authoritarian Christian Social government that governed Austria between 1934 and 1938. Like his fellow members of the Austrian School, not least Hayek, Morgenstern was critical of general equilibrium theory, and particularly of what the Viennese viewed as its lack of precision in treating the knowledge, beliefs and expectations of forward-looking economic actors (see Morgenstern, 1935). Unlike many of his Viennese colleagues, however, and notwithstanding his own limited training in the subject, Morgenstern learned to see the further application of mathematics as a means by which to improve the rigour of economic theory. In this, he differed from Mises and Hayek, for example, who were quite sceptical about what was to be gained by applying mathematics to the non-mechanical realm of human action. Here, Morgenstern was influenced by his contact with mathematician Karl Menger, who was son of the founder of the Austrian School of economics, was close to the Vienna Circle, and was leader of that small coterie of mathematical economists in interwar Vienna, which included Karl Schlesinger, Abraham Wald and a young Franz Alt. Menger's friendship, activities and writings, including his 1934 book on ethics and social compatibility, were of fundamental importance to Morgenstern at this time (see Menger, 1934; Leonard, 1998).

Like von Neumann, Morgenstern's career was shaped in part by social and political upheaval. In 1927, Vienna was the theatre of political violence between the Austrian Right and the Socialists. In 1934, there was a civil war in Austria, as the conservative Chancellor Dollfuss crushed the Left, and in 1938 the country was annexed by Germany. This marked the demise of one of the most intellectually and culturally active cities of interwar Europe. Although not Jewish, Morgenstern found himself ousted from his Institute and, leaving Austria in 1938, he took a position at the department of economics at Princeton University. The latter was then very much a sleepy gentlemen's college, so that, for sophisticated intellectual company, Morgenstern found himself turning towards the mathematicians and physicists at the Institute of Advanced Study.

By this time, von Neumann was already returning to game theory. Throughout the 1930s his correspondence shows him to be a very astute observer from afar of the political situation in Europe, and it was against this background of irrationality and social instability that he returned, at the close of the decade, to the development of a mathematics of alliances and coalitions. In late 1940 and 1941, quite
independent of Morgenstern, he extended his 1928 theory to the treatment of three, four and more players, culminating in an analysis of the general n-person, non-zero-sum game. These ideas on games attracted Morgenstern, who saw in them not so much a theory of the social order as a response to his Viennese concerns about how to model the interaction between economic agents. The ensuing collaboration with von Neumann in the period 1941–3 resulted in the Theory of Games and Economic Behavior, the entire technical apparatus of which was provided by von Neumann, and the introduction and general orientation by Morgenstern (see Leonard, 1995; 2008).

Contents of Theory of Games and Economic Behavior

That introductory chapter is the most accessible, and therefore most widely read and cited, part of the Theory of Games. It is at once a defence of the use of mathematics in social science and a critique of the prevailing state of mathematical economics. Von Neumann's influence, and almost religious faith in the supremacy of mathematical formalism, is clear throughout. There is nothing intrinsically different about social science, it is claimed, that renders it inaccessible to mathematical treatment. Natural phenomena, whether or not they concern human behaviour, are potential repositories of mathematics, the richness of which is likely to be correlated with the empirical prominence of the field. Social and economic activity is of such great worldly importance that it is likely to, so to speak, generate a mathematics of its own. The most prominent treatment of the area, general equilibrium theory, is merely the imitative grafting of physical science methods onto social science. This brings with it assumptions about underlying continuity of change, whereas the social domain likely requires attention to discretely separate structures, and thus the use of a different mathematics. General equilibrium theory has also failed to account for the properly interactive nature of social behaviour, particularly that which is manifest in situations involving ‘small’ numbers of agents, be they involved in the exchange of goods or in the distribution of gains through the formation of social and political groups. Throughout the book, von Neumann's preference for ‘modern’, discrete mathematics (that is, set theory and combinatorics) over the differential and integral calculus is evident. Several pages are devoted to defending the use of cardinal, or numerical, utilities, with the axiomatic proof of the existence of a cardinal utility function being included in an Appendix to the second edition, published in 1947.

Chapter 2 lays out the notion of a game, introducing the mathematical concepts of sets and partitions, and showing how the game may be described axiomatically in these terms. The whole is presented as a piece of modern, axiomatic mathematics in the spirit of Hilbert, which is to say that, although the axioms are stimulated by the common-sense features of games, the latter are soon let recede into the background and the theory pursued in a spirit of relative abstraction. While the mathematics is being followed through, the empirical is held at arm's length and everyday terms are introduced in inverted commas – hence, ‘class’, ‘discrimination’, ‘exploitation’, and so on. Only during periodic returns to the heuristics is the vocabulary of the everyday re-invoked, and the ‘common sense’ meaning of the results discussed. The minimax theorem is proved in the next chapter, using, not von Neumann's earlier proof, but a modification of the elementary 1938 proof by Borel's student Jean Ville, based on the theory of convex sets. From here on, chapter by chapter, von Neumann systematically goes through the zero-sum game for three, four and more players, exploring their combinatorial possibilities for coalition-formation and compensations (side payments). Each game is described in terms of its characteristic function, which shows the maximal payoff available to each possible coalition of the game, assuming that the
coalition plays minimax against its complement and that utility is transferable between players. In Chapter 9, the concept of strategic equivalence is introduced to show how the move from the zero-sum restriction to a constant sum retains the basic features of the game, thus allowing it to be solved by the same means. In the eleventh chapter, von Neumann drops the zero (or constant) sum restriction, moving to the ‘general game’.

The central theoretical part of the *Theory of Games* is von Neumann's solution to coalitional games, the stable set. The solution is a ‘complicated combinatorial catalogue’, indicating the minimum each participant can get if he behaves rationally. He may, of course, get more if the others behave ‘irrationally’, that is, make mistakes. Were the solution to consist of a single imputation – a vector of amounts to be received by each player – then the ‘structure of the society under consideration would be extremely simple: There would exist an absolute state of equilibrium in which the quantitative share of every participant would be precisely determined’ (1944, p. 34). However, such a unique solution does not generally exist – a given society can be organized in various ways – so the notion needs to be broadened. The solution is thus a set of possible imputations.

Any particular alliance describes only one particular consideration which enters the minds of the participants when they plan their behavior. Even if a particular alliance is ultimately formed, the division of the proceeds between the allies will be decisively influenced by the other alliances which each one might alternatively have entered … It is, indeed, this whole which is the really significant entity, more so than its constituent imputations. Even if one of these is actually applied, i.e., if one particular alliance is actually formed, the others are present in a ‘virtual’ existence: Although they have not materialized, they have contributed essentially to shaping and determining the actual reality. (1944, p. 36)

In an n-person game, therefore, a ‘solution should be a system of imputations possessing in its entirety some kind of balance and stability the nature of which we shall try to determine. We emphasize that this stability – whatever it may turn out to be – will be a property of the system as a whole and not of the single imputations of which it is composed’ (p. 36).

This stability is based on the notion of ‘domination’. One imputation, \( x \), is said to dominate another, \( y \), ‘when there exists a group of participants each one of which prefers his individual situation in \( x \) to that in \( y \), and who are convinced that they are able, as a group – i.e. as an alliance – to enforce their preferences’ (p. 38). Dominance, which is not a transitive ordering since the demurring coalition may be different in each case, forms the basis for game solutions. Von Neumann defines the solution to an n-person game as a set of imputations, \( S \), with the following characteristics:

- No imputation \( y \) contained in \( S \) is dominated by an imputation \( x \) contained in \( S \).
- Every \( y \) not contained in \( S \) is dominated by some \( x \) contained in \( S \).

A solution is thus not a single imputation but a set of possible imputations, and such a set is stable in so far as its member imputations do not dominate each other and every imputation outside the set is dominated by at least one imputation inside. Further, not only is a solution comprised of possibly many imputations, linked by these stability criteria, but a given game may have many solutions. To take a simple example, consider the zero–sum game in which a ‘pie’ of value 1 has to be divided amongst three
game theory in economics, origins of: The New Palgrave Dictionary of Economics

people. It has the following four solutions:

1. \((1/2, 1/2, 0)\) • \((1/2, 0, 1/2)\) • \((0, 1/2, 1/2)\)

2. \((x_1, x_2, c)\) where \(0 \leq c \leq 1/2\) and \(x_1 + x_2 + c = 1\)

3. \((c, x_2, x_3)\) where \(0 \leq c \leq 1/2\) and \(x_2 + x_3 + c = 1\)

4. \((x_1, c, x_3)\) where \(0 \leq c \leq 1/2\) and \(x_1 + x_3 + c = 1\)

Here, not only are there multiple solutions, but three of those actually admit an infinite number of possible imputations. Note also that the observation of a given imputation, such as \((1/2, 1/2, 0)\), says little about which solution obtains, as that imputation could occur in any of the four solutions above.

The question of which solution will obtain in a given situation, the authors say, can be broached only by considering ‘standards of behaviour’, the various rules, customs or institutions governing social organization at the time. These are extra-game considerations, not contained in the information provided by the characteristic function. To understand the analogy, von Neumann and Morgenstern advise the reader to ‘temporarily forget the analogy with games and think entirely in terms of social organization’ (p. 41, n. 1):

Let the physical basis of a social economy be given, – or to take a broader view of the matter, of a society. According to all tradition and experience human beings have a characteristic way of adjusting themselves to such a background. This consists of not setting up one rigid system of apportionment, i.e. of imputation, but rather a variety of alternatives, which will probably express some general principles but nevertheless differ among themselves in many particular respects. This system of imputations describes the ‘established order of society’ or ‘accepted standard of behavior’.

Thus, in the above game, in solution 2, player 3 is held to an amount, \(c\), that may be as small as zero, or as high as \(1/2\). The actual value of \(c\) would reflect the norms governing that player's social standing. Depending on tradition, the marginal member might or might not be completely exploited. As von Neumann and Morgenstern write: ‘A theory which is consistent at this point cannot fail to give a precise account of the entire interplay of economic interest, influence and power’ (p. 43).

When one considers the personal context in which von Neumann developed this social theory, his letters of the time dwelling on European instability, the strategic alliances involving the Germans and the Allies, the plight of the Hungarian Jews, which directly affected his family, and one then reads the Theory of Games, with its emphasis on stability and its pervasive reference to norms, discrimination and power, the book appears as his attempt, not simply to replace general equilibrium theory, but to achieve a mathematical description of social organization, broadly defined. And, to the end of his life, von Neumann spoke of it in these terms. For example, in 1955, at a Princeton conference on game theory, when mathematician John Nash raised the problem of the great multiplicity of solutions to cooperative games, von Neumann replied ‘that this result was not surprising in view of the correspondingly enormous variety of observed stable social structures; many differing conventions can endure, existing today for no better reason than that they were here yesterday’ (Wolfe, 1955, p. 25).
Role and impact of the book

The initial influence of the *Theory of Games* was felt, however, not in the area of economic or social theory per se, but in that of military strategy. During the early 1940s, while Morgenstern remained at Princeton struggling with the technical draft chapters, von Neumann was out in the world, increasingly heavily involved as mathematical advisor to various branches of the American military forces. Through his influence on the work of mathematicians at the Princeton branch of the Statistical Research Group and at the Anti-submarine Warfare Operations Research Group, game theory became an element in mathematical models of military engagements such as submarine-search and bombing strategy. Such military models involved the application of a very small part of the mathematics – usually centred on minimax theorem – to specific, confined problems. Thus, game theory qua operations research was far removed from the ambitious, abstract representation of the social order that von Neumann had pursued in the *Theory of Games*. Be that as it may, it was the perceived success of operations research during the Second World War that provided the impetus for the Army Air Corps' creation of the RAND Corporation in the late 1940s, where models of this kind continued to be developed, and for the next decade game theory was given strong institutional support. As it happens, there is little evidence that, throughout the 1950s at RAND, these game theoretic models were of anything other than very limited influence in quantitatively shaping particular strategic decisions. It is incontestable, however, that the language, terminology and ‘thought framework’ of game theory became important to the strategic mindset that dominated the Cold War period, helping shape such books as Herman Kahn's *Thinking the Unthinkable* and Thomas Schelling's *The Strategy of Conflict*.

The *Theory of Games* also set new standards for mathematical rigour in the field of economic theory. For example, before leaving France to move to the United States, economic theorist Gerard Debreu read the book in Salzburg, Austria, at a summer-school run by Harvard University. Though Debreu would never work on game theory, the book shaped his thinking greatly. His pathbreaking *Theory of Value* (1959), an axiomatic treatment of Walrasian general equilibrium theory, refers to the outstanding influence of von Neumann and Morgenstern (1944) ‘which freed mathematical economics from its traditions of differential calculus and compromises with logic’ (1959, p. x). Debreu's stance, too, on the relationship between the mathematics of general equilibrium and the empirical economic substrate is exactly that of von Neumann on games: ‘the theory, in the strict sense, is logically entirely disconnected from its interpretations’ (p. x). This austere, formal view shaped an entire generation of economic ‘high theorists’ from the 1950s till the 1980s, during which general equilibrium theory was the pinnacle of intellectual achievement in the discipline. That von Neumann's game theory should have ended up providing sustenance for Walrasian general equilibrium is one of the many historical ironies in the intellectual history of our field.

It was also in the post-war military–academic milieu that a new generation of game theorists proper came of age. Whether at Princeton or the RAND Corporation, or alternating between the two, young mathematicians such as Lloyd Shapley and John Nash took game theory and made it their own. Shapley, a towering influence in the game theory community from the 1950s onwards, produced, amongst other things, the Shapley value, which described the solution to a coalitional game in terms of the amount brought by each player to an average, randomly formed coalition. For his Ph.D. thesis, Nash sought to provide for n-person games a solution that was as well-defined as von Neumann's minimax for the two-person game. He made a conceptual division of games into cooperative, in which coalitions are
permitted, and non-cooperative, in which players act in isolation. For the latter, he proved the existence, under specific conditions, of what he called an ‘equilibrium point’, later the Nash equilibrium (see Nash, 1950a; 1950b; 1951). That von Neumann found this non-cooperative approach to be rather trivial is understandable in the light of the ambitious social theory he was pursuing, but that leaves unchanged the fact of his influence. It was also at this time that the work of Augustin Cournot was rediscovered and reinterpreted in the light of the Nash equilibrium (see Leonard, 1994; Dimand and Dimand, 1996). Subsequent work on non-cooperative game theory by Harsanyi, Selten, Aumann, Kreps and others resulted in a veritable transformation of the microeconomic canon and shaped modelling in industrial organization, international trade and a range of areas (see Dimand, 2000). The field of experimental economics, currently in rapid expansion, owes its existence in part to the appearance of game theory. Although von Neumann himself voiced scepticism as to the ability of laboratory experimentation to shed light on the stable set, game theory did provide a structured basis for empirically testing the theory of individual decision, via its utility axioms, and various solution concepts, both cooperative and non-cooperative. This experimentation, too, began at the RAND Corporation (see Kalisch et al., 1954). It should also be mentioned that, under the influence on John Maynard Smith, the theory of games has had a great impact on the field of evolutionary biology (see Maynard Smith, 1988).

In short, although it quickly attained the status of a classic, which is to say that it was cited by many but read by few, the *Theory of Games and Economic Behavior* set in motion developments that, in ways sometimes quite unintended by the its authors, gradually reshaped the warp and weft of the economics discipline. From the recasting of the economic agent as a strategic player to the reshaping of entire fields of economics; from the introduction to general equilibrium and social welfare theory of axiomatic methods and discrete mathematics to the rise of experimental economics, the direct and indirect effects of von Neumann and Morgenstern's wartime book have been profound and long-lasting.

Abstract

Game theory concerns the behaviour of decision makers whose decisions affect each other. Its analysis is from a rational rather than a psychological or sociological viewpoint. It is indeed a sort of umbrella theory for the rational side of social science, where ‘social’ is interpreted broadly, to include human as well as non-human players (computers, animals, plants). Its methodologies apply in principle to all interactive situations, especially in economics, political science, evolutionary biology, and computer science. There are also important connections with accounting, statistics, the foundations of mathematics, social psychology, law, business, and branches of philosophy such as epistemology and ethics.

Introduction

‘Interactive decision theory’ would perhaps be a more descriptive name for the discipline usually called game theory. This discipline concerns the behaviour of decision makers (players) whose decisions affect each other. As in non-interactive (one-person) decision theory, the analysis is from a rational, rather than a psychological or sociological viewpoint. The term ‘game theory’ steams from the formal resemblance of interactive decision problems (games) to parlour games such as chess, bridge, poker, monopoly, diplomacy or battleship. The term also underscores the rational, ‘cold’, calculating nature of the analysis.

The major applications of game theory are to economics, political science (on both the national and international levels), tactical and strategic military problems, evolutionary biology, and, most recently, computer science. There are also important connections with accounting, statistics, the foundations of mathematics, social psychology, and branches of philosophy such as epistemology and ethics. Game theory is a sort of umbrella or ‘unified field’ theory for the rational side of social science, where ‘social’ is interpreted broadly, to
include human as well as non-human players (computers, animals, plants). Unlike other approaches to disciplines like economics or political science, game theory does not use different, ad-hoc constructs to deal with various specific issues, such as perfect competition, monopoly, oligopoly, international trade, taxation, voting, deterrence, and so on. Rather, it develops methodologies that apply in principle to all interactive situations, then sees where these methodologies lead in each specific application. Often it turns out that there are close relations between results obtained from the general game-theoretic methods and from the more ad-hoc approaches. In other cases, the game-theoretic approach leads to new insights, not suggested by other approaches.

We use a historical framework for discussing some of the basic ideas of the theory, as well as a few selected applications. But the viewpoint will be modern; the older ideas will be presented from the perspective of where they have led. Needless to say, we do not even attempt a systematic historical survey.

1910–1930

During these earliest years, game theory was preoccupied with strictly competitive games, more commonly known as two-person zero-sum games. In these games, there is no point in cooperation or joint action of any kind: if one outcome is preferred to another by one player, then the preference is necessarily reversed for the other. This is the case for most two-person parlour games, such as chess or two-sided poker; but it seems inappropriate for most economic or political applications. Nevertheless, the study of the strictly competitive case has, over the years, turned out remarkably fruitful; many of the concepts and results generated in connection with this case are in fact much more widely applicable, and have become cornerstones of the more general theory. These include the following:

(i) The extensive (or tree) form of a game, consisting of a complete formal description of how the game is played, with a specification of the sequence in which the players move, what they know at the times they must move, how chance occurrences enter the picture, and the payoff to each player at the end of play. Introduced by von Neumann (1928), the extensive form was later generalized by Kuhn (1953), and has been enormously influential far beyond zero-sum theory.

(ii) The fundamental concept of strategy (or pure strategy) of a player, defined as a complete plan for that player to play the game, as a function of what he observes during the course of play, about the play of others and about chance occurrences affecting the game. Given a strategy for each player, the rules of the game determine a unique outcome of the game and hence a payoff for each player. Introduced by von Neumann and Morgenstern (1944), the strategic form was later generalized by Kuhn (1953), and has been enormously influential far beyond zero-sum theory.

(iii) The strategic (or matrix) form of a game. Given strategies $s^1, \ldots, s^n$ for each of the $n$ players, the rules of the game determine a unique outcome, and hence a payoff $H^i(s^1, \ldots, s^n)$ for each player $i$. The strategic form is simply the function that associates to each profile $s^i = (s^1, \ldots, s^n)$ of strategies, the payoff profile

$$H(s^i) = (H^1(s^i), \ldots, H^n(s^i)).$$

For two-person games, the strategic form often appears as a matrix: the rows and columns represent pure strategies of Players 1 and 2 respectively, whereas the entries are the corresponding payoff profiles. For zero-sum games, of course, it suffices to give the payoff to Player 1. It has been said that the simple idea of thinking of a game in its matrix form is in itself one of the greatest contributions of game theory. In facing an interactive situation, there is a great temptation to think only in terms of ‘what should I do?’. When one writes down the matrix, one is led to a different viewpoint, one that explicitly takes into account that the other players are also facing a decision problem.

(iv) The concept of mixed or randomized strategy, indicating that rational play is not in general describable by specifying a single pure strategy. Rather, it is often non-deterministic, with specified probabilities associated with each one of a specified set of pure strategies. When randomized strategies are used, payoff must be replaced by expected payoff. Justifying the use of expected payoff in this context is what led to expected utility theory, whose influence extends far beyond game theory (see 1930–1950, viii).

(v) The concept of ‘individual rationality’. The security level of Player $i$ is the amount max min $H^i(s)$ that he can guarantee to himself, independent of what the other players do (here the max is over $i$’s strategies, and the min is over $(n-1)$-tuples of strategies of the players other than $i$). An outcome is called individually rational if it yields each player at least his security level. In the game tic-tac-toe, for example, the only individually rational outcome is a draw; and indeed, it does not take a reasonably bright child very long to learn that ‘correct’ play in tic-tac-toe always leads to a draw.

Individual rationality may be thought of in terms of pure strategies or, as is more usual, in terms of mixed strategies. In the latter case, what is being ‘guaranteed’ is not an actual payoff, but an expectation; the word ‘guarantee’ means that this level of payoff can be attained in the mean, regardless of what the other players do. This ‘mixed’ security level is always at least as high as the ‘pure’ one. In the case of tic-tac-toe, each player can guarantee a draw even in the stronger sense of pure strategies. Games like this — i.e. having only one individually rational payoff profile in the ‘pure’ sense — are called strictly determined.
Not all games are strictly determined, not even all two-person zero-sum games. One of the simplest imaginable games is the one that game theorists call ‘matching pennies’, and children call ‘choosing up’ (‘odds and evens’). Each player privately turns a penny either heads up or tails up. If the choices match, 1 gives 2 his penny; otherwise, 2 gives 1 his penny. In the pure sense, neither player can guarantee more than –1, and hence the game is not strictly determined. But in expectation, each player can guarantee 0, simply by turning the coin heads up or tails up with 1/2 – 1/2 probabilities. Thus (0, 0) is the only payoff profile that is individually rational in the mixed sense. Games like this – i.e. having only one individually rational payoff profile in the ‘mixed’ sense – are called determined. In a determined game, the (mixed) security level is called the value, strategies guaranteeing it optimal.

(vi) Zermelo’s theorem. The very first theorem of Game Theory (Zermelo, 1913) asserts that chess is strictly determined. Interestingly, the proof does not construct ‘correct’ strategies explicitly; and indeed, it is not known to this day whether the ‘correct’ outcome of chess is a win for white, a win for black, or a draw. The theorem extends easily to a wide class of parlour games, including checkers, go, and chinese checkers, as well as less well-known games such as hex and gnim (Gale, 1979, 1974); the latter two are especially interesting in that one can use Zermelo’s theorem to show that Player 1 can force a win, though the proof is non-constructive, and no winning strategy is in fact known. Zermelo’s theorem does not extend to card games such as bridge and poker, nor to the variant of chess known as kriegsspiel, where the players cannot observe their opponents’ moves directly. The precise condition for the proof to work is that the game be a two-person zero-sum game of perfect information. This means that there are no simultaneous moves, and that everything is open and ‘above-board’: at any given time, all relevant information known to one player is known to all players.

The domain of Zermelo’s theorem – two-person zero-sum games of perfect information – seems at first rather limited; but the theorem has reverberated through the decades, creating one of the main strands of game theoretic thought. To explain some of the developments, we must anticipate the notion of strategic equilibrium (Nash, 1951; see 1950–1960, i). To remove the two-person zero-sum restriction, H.W. Kuhn (1953) replaced the notion of ‘correct’, individually rational play by that of equilibrium. He then proved that every n-person game of perfect information has an equilibrium in pure strategies.

In proving this theorem, Kuhn used the notion of a subgame of a game; this turned out crucial in later developments of strategic equilibrium theory, particularly in its economic applications. A subgame relates to the whole game like a subgroup to the whole group or a linear subspace to the whole space; while part of the larger game, it is self-contained, can be played in its own right. More precisely, if at any time, all the players know everything that has happened in the game up to that time, then what happens from then on constitutes a subgame.

From Kuhn’s proof it follows that every equilibrium (not necessarily pure) of a subgame can be extended to an equilibrium of the whole game. This, in turn, implies that every game has equilibria that remain equilibria when restricted to any subgame. R. Selten (1965) called such equilibria subgame perfect. In games of perfect information, the equilibria that the Zermelo–Kuhn proof yields are all subgame perfect.

But not all equilibria are subgame perfect, even in games of perfect information. Subgame perfection implies that when making choices, a player looks forward and assumes that the choices that will subsequently be made, by himself and by others, will be rational; i.e. in equilibrium. Threats which it would be irrational to carry through are ruled out. And it is precisely this kind of forward-looking rationality that is most suited to economic applications.

Interestingly, it turns out that subgame perfection is not enough to capture the idea of forward-looking rationality. More subtle concepts are needed. We return to this subject below, when we discuss the great flowering of strategic equilibrium theory that has taken place since 1975, and that coincides with an increased preoccupation with its economic applications. The point we wished to make here is that these developments have their roots in Zermelo’s theorem.

A second circle of ideas to which Zermelo’s theorem led has to do with the foundations of mathematics. The starting point is the idea of a game of perfect information with an infinite sequence of stages. Infinitely long games are important models for interactive situations with an indefinite time horizon – i.e. in which the players act as if there will always be a tomorrow. To fix ideas, let A be any subset of the unit interval (the set of real numbers between 0 and 1). Suppose two players move alternately, each choosing a digit between 1 and 9 at each stage. The resulting infinite sequence of digits is the decimal expansion of a number in the unit interval. Let \( G_A \) be the game in which 1 wins if this number is in A, and 2 wins otherwise. Using Set Theory’s ‘Axiom of Choice’, Gale and Stewart (1953) showed that Zermelo’s theorem is false in this situation. One can choose A so that \( G_A \) is not strictly determined; that is, against each pure strategy of 1, Player 2 has a winning pure strategy, and against each pure strategy of 2, Player 1 has a winning pure strategy. They also showed that if A is open or closed, then \( G_A \) is strictly determined.

Both of these results led to significant developments in foundational mathematics. The axiom of choice had long been suspect in the eyes of mathematicians; the extremely anti-intuitive nature of the Gale–Stewart non-determinateness example was an additional nail in its coffin, and led to an alternative axiom, which asserts that \( G_A \) is strictly determined for every set A. This axiom, which contradicts the axiom of choice, has been used to provide an alternative axiomatization for set theory (Myckielski and Steinhaus, 1964), and this in turn has spawned a large literature (see Moschovakis, 1980, 1983). On the other hand, the positive result of Gale and Stewart was successively generalized to wider and wider families of sets A that are ‘constructible’ in the appropriate sense (Wolfe, 1955; Davis, 1964), culminating in the theorem of Martin (1975), according to which \( G_A \) is strictly determined whenever A is a Borel set.

Another kind of perfect information game with infinitely many stages is the differential game. Here time is continuous but usually of finite duration; a decision must be made at each instant, so to speak. Typical examples are games of pursuit. The theory of differential games was first developed during the 1950s by Rufus Isaacs at the Rand Corporation; his book...
on the subject was published in 1965, and since then the theory has proliferated greatly. A differential game need not necessarily be of perfect information, but very little is known about those that are not. Some economic examples may be found in Case (1979).

(vii) The minimax theorem. The minimax theorem of von Neumann (1928) asserts that every two-person zero-sum game with finitely many pure strategies for each player is determined; that is, when mixed strategies are admitted, it has precisely one individually rational payoff vector. This had previously been verified by E. Borel (e.g. 1924) for several special cases, but Borel was unable to obtain a general proof. The theorem lies a good deal deeper than Zermelo’s, both conceptually and technically. For many years, minimax was considered the elegant centrepiece of game theory. Books about game theory concentrated on two-person zero-sum games in strategic form, often paying only desultory attention to the non-zero sum theory. Outside references to game theory often gave the impression that non-zero sum games do not exist, or at least play no role in the theory. The reaction eventually set in, as it was bound to. Game theory came under heavy fire for its allegedly exclusive concern with a special case that has little interest in the applications. Game theorists responded by belittling the importance of the minimax theorem. During the fall semester of 1964, the writer of these lines gave a beginning course in Game Theory at Yale University, without once even mentioning the minimax theorem. All this is totally unjustified. Except for the period up to 1928 and a short period in the late Forties, game theory was never exclusively or even mainly concerned with the strictly competitive case. The forefront of research was always in n-person or non-zero sum games. The false impression given of the discipline was due to the strictly competitive theory being easier to present in books, more ‘elegant’ and complete. But for more than half a century, that is not where most of the action has been. Nevertheless, it is a great mistake to belittle minimax. While not the centrepiece of game theory, it is a vital cornerstone. We have already seen how the most fundamental concepts of the general theory – extensive form, pure strategies, strategic form, randomization, utility theory – were spawned in connection with the minimax theorem. But its importance goes considerably beyond this.

The fundamental concept of non-cooperative n-person game theory – the strategic equilibrium of Nash (1951) – is an outgrowth of minimax, and the proof of its existence is modelled on a previously known proof of the minimax theorem. In cooperative n-person theory, individual rationality is used to define the set of imputations, on which much of the cooperative theory is based. In the theory of repeated games, individual rationality also plays a fundamental role. In many areas of interest – stochastic games, repeated games of incomplete information, continuous games (i.e. with a continuum of pure strategies), differential games, games played by automata, games with vector payoffs – the strictly competitive case already presents a good many of the conceptual and technical difficulties that are present in general. In these areas, the two-person zero-sum theory has become an indispensable spawning and proving ground, where ideas are developed and tested in a relatively familiar, ‘friendly’ environment. These theories could certainly not have developed as they did without minimax. Finally, minimax has had considerable influence on several disciplines outside of game theory proper. Two of these are statistical decision theory and the design of distributed computing systems, where minimax is used for ‘worst case’ analysis. Another is mathematical programming; the minimax theorem is equivalent to the duality theorem of linear programming, which in turn is closely related to the idea of shadow pricing in economics. This circle of ideas has fed back into game theory proper; in its guise as a theorem about linear inequalities, the minimax theorem is used to establish the condition of Bondareva (1963) and Shapley (1967) for the non-emptiness of the core of an n-person game, and the Hart-Schmeidler (1988) elementary proof for the existence of correlated equilibria.

(viii) Empirics. The correspondence between theory and observation was discussed already by von Neumann (1928), who observed that the need to randomize arises endogenously out of the theory. Thus the phenomenon of bluffing in poker may be considered a confirmation of the theory. This kind of connection between theory and observation is typical of game theory and indeed of economic theory in general. The ‘observations’ are often qualitative rather than quantitative; in practice, we do observe bluffing, though not necessarily in the proportions predicted by theory. As for experimentation, strictly competitive games constitute one of the few areas in game theory, and indeed in social science, where a fairly sharp, unique ‘prediction’ is made (though even this prediction is in general probabilistic). It thus invites experimental testing. Early experiments failed miserably to confirm the theory; even in strictly determined games, subjects consistently reached individually irrational outcomes. But experimentation in rational social science is subject to peculiar pitfalls, of which early experimenters appeared unaware, and which indeed mar many modern experiments as well. These have to do with the motivation of the subjects, and with their understanding of the situation. A determined effort to design an experimental test of minimax that would avoid these pitfalls was recently made by B. O’Neill (1987); in these experiments, the predictions of theory were confirmed to within less than one per cent.

1930–1950

The outstanding event of this period was the publication, in 1944, of the Theory of Games and Economic Behavior by John von Neumann and Oskar Morgenstern. Morgenstern was the first economist clearly and explicitly to recognize that economic agents must take the interactive nature of economics into account when making their decisions. He and von Neumann met at Princeton in the late Thirties, and started the collaboration that culminated in the Theory of Games. With the publication of this book, game theory came into its own as a scientific discipline.
In addition to expounding the strictly competitive theory described above, the book broke fundamental new ground in several directions. These include the notion of a cooperative game, its coalitional form, and its von Neumann–Morgenstern stable sets. Though axiomatic expected utility theory had been developed earlier by Ramsey (1931), the account of it given in this book is what made it ‘catch on’. Perhaps most important, the book made the first extensive applications of game theory, many to economics.

To put these developments into their modern context, we discuss here certain additional ideas that actually did not emerge until later, such as the core, and the general idea of a solution concept. At the end of this section we also describe some developments of this period not directly related to the book, including games with a continuum of strategies, the computation of minimax strategies, and mathematical advances that were instrumental in later work.

(i) Cooperative games. A game is called cooperative if commitments—agreements, promises, threats—are fully binding and enforceable (Harsanyi 1966, p. 616). It is called non-cooperative if commitments are not enforceable, even if pre-play communication between the players is possible. (For motivation, see 1950–1960, iv.)

Formally, cooperative games may be considered a special case of non-cooperative games, in the sense that one may build the negotiation and enforcement procedures explicitly into the extensive form of the game. Historically, however, this has not been the mainstream approach. Rather, cooperative theory starts out with a formalization of games (the coalitional form) that abstracts away altogether from procedures and from the question of how each player can best manipulate them for his own benefit; it concentrates, instead, on the possibilities for agreement. The emphasis in the non-cooperative theory is on the individual, on what strategy he should use. In the cooperative theory it is on the group: What coalitions will form? How will they divide the available payoff between their members?

There are several reasons that cooperative games came to be treated separately. One is that when one does build negotiation and enforcement procedures explicitly into the model, then the results of a non-cooperative analysis depend very strongly on the precise form of the procedures, on the order of making offers and counter-offers, and so on. This may be appropriate in voting situations in which precise rules of parliamentary order prevail, where a good strategist can indeed carry the day. But problems of negotiation are usually more amorphous; it is difficult to pin down just what the procedures are. More fundamentally, there is a feeling that procedures are not really all that relevant; that it is the possibilities for coalition forming, promising and threatening that are decisive, rather than whose turn it is to speak.

Another reason is that even when the procedures are specified, non-cooperative analyses of a cooperative game often lead to highly non-unique results, so that they are often quite inconclusive.

Finally, detail distracts attention from essentials. Some things are seen better from a distance; the Roman camps around Metzada are indiscernible when one is in them, but easily visible from the top of the mountain. The coalitional form of a game, by abstracting away from details, yields valuable perspective.

The idea of building non-cooperative models of cooperative games has come to be known as the Nash program since it was first proposed by John Nash (1951). In spite of the difficulties just outlined, the programme has had some recent successes (Harsanyi, 1982; Harsanyi and Selten, 1972; Rubinstein, 1982). For the time being, though, these are isolated; there is as yet nothing remotely approaching a general theory of cooperative games based on non-cooperative methodology.

(ii) A game in coalitional form, or simply coalitional game is a function $v$ associating a real number $v(S)$ with each subset $S$ of a fixed finite set $I$, and satisfying $v(\emptyset) = 0$ (denotes the empty set). The members of $I$ are called players, the subsets $S$ of $I$ coalitions and $v(S)$ is the worth of $S$.

Some notation and terminology: The number of elements in a set $S$ is denoted $|S|$. A profile of strategies, numbers, etc.) is a function on $I$ (whose values are strategies, numbers, etc.). If $x$ is a profile of numbers and $S$ a coalition, we write $x(S) = \sum_{i \in S} x^i$. An example of a coalitional game is the three-person voting game; here $I = 3$, and $v(S) = 1$ or 0 according as to whether $\emptyset \subset S \subset 2$ or not. A coalition $S$ is called winning if $v(S) = 1$, losing if $v(S) = 0$. More generally, if $w$ is a profile of non-negative numbers (weights) and $q$ (the quota) is positive, define the weighted voting game $v$ by $v(S) = 1$ if $w(S) \geq q$ and $v(S) = 0$ otherwise. An example is a parliament with several parties. The players are the parties, rather than the individual members of parliament, $w$ is the number of seats held by party $i$, and $q$ is the number of votes necessary to form a government (usually a simple majority of the parliament). The weighted voting game with quota $q$ and weights $w$ is denoted $[q; w]$; e.g., the three-person voting game is $[2; 1, 1, 1]$.

Another example of a coalitional game is a market game. Suppose there are $l$ natural resources, and a single consumer product, say ‘bread’, that may be manufactured from these resources. Let each player $i$ have an endowment $e_i$ of resources (an $l$-vector with non-negative coordinates), and a concave production function $u_i$ that enables him to produce the amount $u_i(x_i)$ of bread given the vector $x = (x_1, \ldots, x_l)$ of resources. Let $v(S)$ be the maximum amount of bread that the coalition $S$ can produce; it obtains this by redistributing its resources among its members in a manner that is most efficient for production, i.e.

$$v(S) = \max \left\{ \sum_{i \in S} u_i(x^i); \sum_{i \in S} x^i - \sum_{i \in S} e^i \right\}$$

where the $x^i$ are restricted to have non-negative coordinates.
These examples illustrate different interpretations of coalitional games. In one interpretation, the payoff is in terms of some single desirable physical commodity, such as bread; \( v(S) \) represents the maximum total amount of this commodity that the coalition \( S \) can procure for its members, and it may be distributed among the members in any desired way. This is illustrated by the above description of the market game.

Underlying this interpretation are two assumptions. First, that of transferable utility (TU): that the payoff is in a form that is freely transferable among the players. Second, that of fixed threats: that \( S \) can obtain a maximum of \( v(S) \) no matter what the players outside of \( S \) do. Another interpretation is that \( v(S) \) represents some appropriate index of \( S \)'s strength (if it forms). This requires neither transferable utility nor fixed threats. In voting games, for example, it is natural to define \( v(S) = 1 \) if \( S \) is a winning coalition (e.g. can form a government or ensure passage of a bill), 0 if not. Of course, in most situations represented by voting games, utility is not transferable.

Another example is a market game in which the \( x^i \) are consumption goods rather than resources. Rather than bread, \( \sum_{i \in S} u^i(x^i) \) may represent a social welfare function such as is often used in growth or taxation theory. While \( v(S) \) cannot then be divided in an arbitrary way among the members of \( S \), it still represents a reasonable index of \( S \)'s strength. This is a situation with fixed threats but without TU.

Von Neumann and Morgenstern considered strategic games with transferable payoffs, which is a situation with TU but without fixed threats. If the profile \( s \) of strategies is played, the coalition \( S \) may divide the amount \( \sum_{i \in S} u^i(S) \) among its members in any way it pleases. However, what \( S \) gets depends on what players outside \( S \) do. Von Neumann and Morgenstern defined \( v(S) \) as the maximal payoff of \( S \) in the two-person zero-sum game in which the players are \( S \) and \( 1 \setminus S \), and the payoff to \( S \) is \( \sum_{i \in S} u^i(\delta) \); i.e., as the expected payoff that \( S \) can assure itself (in mixed strategies), no matter what the others do. Again, this is a reasonable index of \( S \)'s strength, but certainly not the only possible one.

We will use the term TU coalitional game when referring to coalitional games with the TU interpretation. In summary, the coalitional form of a game associates with each coalition \( S \) a single number \( v(S) \), which in some sense represents the total payoff that that coalition can get or may expect. In some contexts, \( v(S) \) fully characterizes the possibilities open to \( S \); in others, it is an index that is indicative of \( S \)'s strength.

(iii) Solution concepts. Given a game, what outcome may be expected? Most of game theory is, in one way or another, directed at this question. In the case of two-person zero-sum games, a clear answer is provided: the unique individually rational outcome. But in almost all other cases, there is no unique answer. There are different criteria, approaches, points of view, and they yield different answers.

A solution concept is a function (or correspondence) that associates outcomes, or sets of outcomes, with games. Usually an ‘outcome’ may be identified with the profile of payoffs that outcome yields to the players, though sometimes we may wish to think of it as a strategy profile.

Of course a solution concept is not just any such function or correspondence, but one with a specific rationale; for example, the strategic equilibrium and its variants for strategic form games, and the core, the von Neumann–Morgenstern stable sets, the Shapley value and the nucleolus for coalitional games. Each represents a different approach or point of view. What will ‘really’ happen? Which solution concept is ‘right’? None of them; they are indicators, not predictions. Different solution concepts are like different indicators of an economy; different methods for calculating a price index; different maps (road, topo, political, geologic, etc., not to speak of scale, projection, etc.); different stock indices (Dow Jones, Standard and Poor's NYSE, etc., composite, industrials, utilities, etc.); different batting statistics (batting average, slugging average, RBI, hits, etc.); different kinds of information about rock climbs (arabic and roman difficulty ratings, route maps, verbal descriptions of the climb, etc.); accounts of the same event by different people or different media; different projections of the same three-dimensional object (as in architecture or engineering). They depict or illuminate the situation from different angles; each one stresses certain aspects at the expense of others.

Moreover, solution concepts necessarily leave out altogether some of the most vital information, namely that not entering the formal description of the game. When applied to a voting game, for example, no solution concept can take into account matters of custom, political ideology, or personal relations, since they don't enter the coalitional form. That does not make the solution useless. When planning a rock climb, you certainly want to take into account a whole lot of factors other than the physical characteristics of the rock, such as the season, the weather, your ability and condition, and with whom you are going. But you also do want to know about the ratings.

A good analogy is to distributions (probability, frequency, population, etc.). Like a game, a distribution contains a lot of information; one is overwhelmed by all the numbers. The median and the mean summarize the information in different ways; though other than by simply stating the definitions, it is not easy to say how. The definitions themselves do have a certain fairly clear intuitive content; more important, we gain a feeling for the relation between a distribution and its median and mean from experience, from working with various specific examples and classes of examples over the course of time.

The relationship of solution concepts to games is similar. Like the median and the mean, they in some sense summarize the large amount of information present in the formal description of a game. The definitions themselves have a certain fairly clear intuitive content, though they are not predictions of what will happen. Finally, the relations between a game and its core, value, stable sets, nucleolus, and so on is best revealed by seeing where these solution concepts lead in specific games and classes of games.

(iv) Domination, the core and imputations. Continuing to identify ‘outcome’ with ‘payoff profile’, we call an outcome \( y \) of a game feasible if the all-player set \( I \) can achieve it. An outcome \( x \) dominates \( y \) if there exists a coalition \( S \) that can achieve at least its part of \( x \), and each of whose members prefers \( x \) to \( y \); in that case we also say that \( S \) can improve upon \( y \).

The core of a game is the set of all feasible outcomes that are not dominated.
In a TU coalitional game \( v \), feasibility of \( x \) means \( x(i) \not\in v(i) \), and \( x \) dominating \( y \) via \( S \) means that \( x(S) \not\in v(S) \) and \( x^i > y^i \) for all \( i \in S \). The core of \( v \) is the set of all feasible \( y \) with \( y(S) \not\in v(S) \) for all \( S \).

At first, the core sounds quite compelling; why should the players be satisfied with an outcome that some coalition can improve upon? It becomes rather less compelling when one realizes that many perfectly ordinary games have empty cores, i.e. every feasible outcome can be improved upon. Indeed, this is so even in as simple a game as the 3-person voting game.

For a coalition \( S \) to improve upon an outcome, players in \( S \) must trust each other; they must have faith that their comrades inside \( S \) will not desert them to make a coalition with other players outside \( S \). In a TU 3-person voting game, \( v^* = (1/3, 1/3, 1/3) \) is dominated via \( \{1, 2\} \) by \( x^* = (1/2, 1/2, 0) \). But 1 and 2 would be wise to view a suggested move from \( y \) to \( x \) with caution. What guarantee does 1 have that 2 will really stick with him and not accept offers from 3 to improve upon \( x \) with \( y \), say, \((0, 2/3, 1/3)\)? For this he must depend on 2's good faith, and similarly 2 must depend on 1's.

There are two exceptions to this argument, two cases in which domination does not require mutual trust. One is when \( S \) consists of a single player. The other is when \( S = 1 \), so that there is no one outside \( S \) to lure one's partners away.

The requirement that a feasible outcome \( y \) be undominated via one-person coalitions (individual rationality) and via the all-person coalition (efficiency or Pareto optimality) is thus quite compelling, much more so than that it be in the core. Such outcomes are called imputations. For TU coalitional games, individual rationality means that \( \forall i \) (we do not distinguish between \( i \) and \( \{i\} \)), and efficiency means that \( v(\emptyset) = v(1) \). The outcomes associated with most cooperative solution concepts are imputations; the imputations constitute the stage on which most of cooperative game theory is played out.

The notion of core does not appear explicitly in von Neumann and Morgenstern, but it is implicit in some of the discussions of stable sets there. In specific economic contexts, it is implicit in the work of Edgeworth (1881) and Ransmeier (1942). As a general solution concept in its own right, it was developed by Shapley and Gillies in the early Fifties. Early references include Luce and Raiffa (1957) and Gillies (1959).

(v) Stable sets. The discomfort with the definition of core expressed above may be stated more sharply as follows. Suppose we think of an outcome in the core as ‘stable’. Then we should not exclude an outcome \( y \) just because it is dominated by some other outcome \( x \); we should demand that \( x \) itself be stable. If \( x \) is not itself stable, then the argument for excluding \( y \) is rather weak; proponents of \( y \) can argue with justice that replacing it with \( x \) would not lead to a more stable situation, so we may as well stay where we are. If the core were the set of all outcomes not dominated by any element of the core, there would be no difficulty; but this is not so.

Von Neumann and Morgenstern were thus led to the following definition: A set \( K \) of imputations is called stable if it is the set of all imputations not dominated by any element of \( K \). This definition guarantees neither existence nor uniqueness. On the face of it, a game may have many stable sets, or it may have none. Most games do, in fact, have many stable sets; but the problem of existence was open for many years. It was solved by Lucas (1969), who constructed a ten-person, TU coalitional game without any stable set. Later, Lucas and Rabie (1982) constructed a fourteen-person TU coalitional game without any stable set and with an empty core to boot.

Much of the Theory of Games is devoted to exploring the stable sets of various classes of TU coalitional games, such as 3- and 4-person games, voting games, market games, compositions of games, and so on. (If \( v \) and \( w \) have disjoint player sets \( I \) and \( J \), their composition \( u \) is given by \( u(S) = v(S \cap I) + w(S \cap J) \).) During the 1950s many researchers carried forward with great vigour the work of investigating various classes of games and describing their stable sets. Since then work on stable sets has continued unabated, though it is no longer as much in the forefront of game-theoretic research as it was then. All in all, more than 200 articles have been published on stable sets, some 80 per cent of them since 1960. Much of the recent activity in this area has taken place in the Soviet Union.

It is impossible here even to begin to review this large and varied literature. But we do note one characteristic qualitative feature. By definition, a stable set is simply a set of imputations; there is nothing explicit in it about social structure. Yet the mathematical description of a given stable set can often best be understood in terms of an implicit social structure or form of organization of the players. Cartels, systematic discrimination, groups within groups, all kinds of subtle organizational forms spring to one's attention. These forms are endogenous, they are not imposed by definition, they emerge from the analysis. It is a mystery that just the stable set concept, and it only, is so closely allied with endogenous notions of social structure.

We adduce just one, comparatively simple example. The TU three-person voting game has a stable set consisting of the three imputations \((1/2, 1/2, 0), (1/2, 0, 1/2), (0, 1/2, 1/2)\). The social structure implicit in this is that all three players will not compromise by dividing the payoff equally. Rather, one of the three 2-person coalitions will form and divide the payoff equally, with the remaining player being left ‘in the cold’. Because any of these three coalitions can form, competition drives them to divide the payoff equally, so that no player will prefer any one coalition to any other.

Another stable set is the interval \((\alpha, 1 - \alpha, 0)\), where \( \alpha \) ranges from 0 to 1. Here Player 3 is permanently excluded from all negotiations; he is ‘discriminated against’. Players 1 and 2 divide the payoff in some arbitrary way, not necessarily equally; this is because a coalition with 3 is out of the question, and so competition no longer constrains 1 and 2 in bargaining with each other.

(vi) Transferable utility. Though it no longer enjoys the centrality that it did up to about 1960, the assumption of transferable utility has played and continues to play a major role in the development of cooperative game theory. Some economists have questioned the appropriateness of the TU assumption, especially in connection with market models; it has been...
castigated as excessively strong and unrealistic.
This situation is somewhat analogous to that of strictly competitive games, which as we pointed out above (1930–1950, vii), constitute a proving ground for developing and testing ideas that apply also to more general, non-strictly competitive games. The theory of NTU (non-transferable utility) coalitional games is now highly developed (see 1960–1970, i), but it is an order of magnitude more complex than that of TU games. The TU theory is an excellent laboratory or model for working out ideas that are later applied to the more general NTU case.

Moreover, TU games are both conceptually and technically much closer to NTU games than strictly competitive games are to non-strictly competitive games. A very large part of the important issues arising in connection with non-strictly competitive games do not have any counterpart at all in strictly competitive games, and so simply cannot be addressed in that context. But by far the largest part of the issues and questions arising in the NTU theory do have counterparts in the TU theory; they can at least be addressed and dealt with there. Almost every major advance in the NTU theory – and many a minor advance as well – has had its way paved by a corresponding advance in the TU theory. Stable sets, core, value, and bargaining set were all defined first for TU games, then for NTU. The enormous literature on the core of a market and the equivalence between it and competitive equilibrium (c.e.) in large markets was started by Martin Shubik (1959a) in an article on TU markets. The relation between the value and c.e. in large markets was also explored first for the TU case (Shapley, 1964; Shapley and Shubik, 1969b; Aumann and Shapley, 1974; Hart, 1977a), then for NTU (Champsaur, 1975, but written and circulated circa 1970; Aumann, 1975; Mas-Colell, 1977; Hart, 1977b). The same holds for the bargaining set; first TU (Shapley, 1984), then NTU (Mas-Colell, 1988). The connection between balanced collections of coalitions and the non-emptiness of the core (1960–1970, viii) was studied first for TU (Bondareva, 1963; Shapley, 1967), then for NTU (Scarf, 1967; Billera, 1970b; Shapley 1973a); this development led to the whole subject of Scarf’s algorithm for finding points in the core, which he and others later extended to algorithms for finding market equilibria and fixed points of mappings in general. Games arising from markets were first abstractly characterized in the TU case (Shapley and Shubik, 1969a), then in the NTU case (Billera and Bixby, 1973; Mas-Colell, 1975). Games with a continuum of players were conceived first in a TU application (Milnor and Shapley, 1979, but written and circulated in 1960), then NTU (Aumann, 1964). Strategic models of bargaining where time is of the essence were first treated for TU (Rubinstein, 1982), then NTU (Binmore, 1982). One could go on and on.

In each of these cases, the TU development led organically to the NTU development; it isn’t just that the one came before the other. TU is to cooperative game theory what Drosophila is to genetics. Even if it had no direct economic interest at all, the study of TU coalitional games would be justified solely by their role as an outstandingly suggestive research tool.

(vii) Single play. Von Neumann and Morgenstern emphasize that their analysis refers to ‘one-shot’ games, games that are played just once, after which the players disperse, never to interact again. When this is not the case, one must view the whole situation – including expected future interactions of the same players – as a single larger game, and it, too, is to be played just once. To some extent this doctrine appears unreasonable. If one were to take it literally, there would be only one game to analyse, namely the one whose players include all persons ever born and to be born. Every human being is linked to every other through some chain of interactions; no person or group is isolated from any other.

Savage (1954) has discussed this in the context of one-person decisions. In principle, he writes, one should ‘envisage every conceivable policy for the government of his whole life in its most minute details, and decide here and now on one policy. This is utterly ridiculous …’ (p. 16). He goes on to discuss the small worlds doctrine, ‘the practical necessity of confining attention to, or isolating, relatively simple situations …’ (p. 82).

To a large extent, this doctrine applies to interactive decisions too. But one must be careful, because here ‘large worlds’ have qualitative features totally absent from ‘small worlds’. We return to this below (1950–1960, ii, iii).

(viii) Expected utility. When randomized strategies are used in a strategic game, payoff must be replaced by expected payoff (1910–1930, iv). Since the game is played only once, the law of large numbers does not apply, so it is not clear why a player would be interested specifically in the mathematical expectation of his payoff.

There is no problem when for each player there are just two possible outcomes, which we may call ‘winning’ and ‘losing’, and discriminate 1 and 0 respectively. (This involves no zero-sum assumption; e.g. all players could win simultaneously.) In that case the expected payoff is simply the probability of winning. Of course each player wants to maximize this probability, so in that case use of the expectation is justified.

Suppose now that the values of i’s payoff function Hi are numbers between 0 and 1, representing win probabilities. Thus, for the ‘final’ outcome there are still only two possibilities; each pure strategy profile s induces a random process that generates a win for i with probability Hi(s). Then the payoff expectation when randomized strategies are used still represents i’s overall win probability.

Now in any game, each player has a most preferred and a least preferred outcome, which we take as a win and a loss. For each payoff h, there is some probability p such that i would as soon get h with certainty as winning with probability p and losing with probability 1 − p. If we replace all the h’s by the corresponding p’s in the payoff matrix, then we are in the case of the previous paragraph, so use of the expected payoff is justified.

The probability p is a function of h, denoted ui(h), and called i’s von Neumann–Morgenstern utility. Thus, to justify the use of expectations, each player’s payoff must be replaced by its utility.

The key property of the function ui is that if h and g are random payoffs, then i prefers h to g iff Eui(h) > Eui(g), where E denotes expectation. This property continues to hold when
we replace \( u^i \) by a linear transform of the form \( \alpha u^i + \beta \), where \( \alpha \) and \( \beta \) are constants with \( \alpha > 0 \). All these transforms are also called utility functions for \( i \), and any one of them may be used rather than \( u^i \) in the payoff matrix.

Recall that a strictly competitive game is defined as a two-person game in which if one outcome is preferred to another by one player, the preference is reversed for the other. Since randomized strategies are admitted, this condition applies also to ‘mixed outcomes’ (probability mixtures of pure outcomes). From this it may be seen that a two-person game is strictly competitive if and only if, for an appropriate choice of utility functions, the utility payoffs of the players sum to zero in each square of the matrix.

The case of TU coalitional games deserves particular attention. There is no problem if we assume fixed threats and continue to denominate the payoff in bread (see ii). But without fixed threats, the total amount of bread obtainable by a coalition \( S \) is a random variable depending on what players outside \( S \) do; since this is not denominated in utility, there is no justification for replacing it by its expectation. But if we do denominate payoffs in utility terms, then they cannot be directly transferred. The only way out of this quandary is to assume that the utility of bread is linear in the amount of bread (Aumann, 1960). We stress again that no such assumption is required in the fixed threat case.

Applications

The very name of the book, *Theory of Games and Economic Behavior*, indicates its underlying preoccupation with the applications. Von Neumann had already mentioned *Homo Economicus* in his 1928 paper, but there were no specific economic applications there.

The method of von Neumann and Morgenstern has become the archetype of later applications of game theory. One takes an economic problem, formulates it as a game, finds the game-theoretic solution, then translates the solution back into economic terms. This is to be distinguished from the more usual methodology of economics and other social sciences, where the building of a formal model and a solution concept, and the application of the solution concept to the model, are all rolled into one.

Among the applications extensively treated in the book is voting. A qualitative feature that emerges is that many different weight-quotient configurations have the same coalitional form; \([5; 2, 3, 4]\) is the same as \([2; 1, 1, 1]\). Though obvious to the sophisticated observer when pointed out, this is not widely recognized; most people think that the player with weight 4 is considerably stronger than the others (Vinacke and Arkoff, 1957). The Board of Supervisors of Nassau County operates by weighted voting; in 1964 there were six members, with weights of 31, 31, 28, 21, 2, 2, and a simple majority quota of 58 (Lucas, 1983, p. 188). Nobody realized that three members were totally without influence, that \([58; 31, 31, 28, 21, 2, 2] = [2; 1, 1, 1, 0, 0, 0]\).

In a voting game, a winning coalition with no proper winning subsets is called minimal winning (mw). The game \([q; w]\) is homogeneous if \( w(S) = q \) for all minimal winning \( S \); thus \([3; 2, 1, 1, 1]\) is homogeneous, but \([5; 2, 2, 2, 1, 1, 1]\) is not. A decisive voting game is one in which a coalition wins if and only if its complement loses; both the above games are decisive, but \([3; 2, 1, 1, 1]\) is not. TU decisive homogeneous voting games have a stable set in which some mw coalition forms and divides the payoff in proportion to the weights of its members, leaving nothing for those outside. This is reminiscent of some parliamentary democracies, where parties in a coalition government get cabinet seats roughly in proportion to the seats they hold in parliament. But this fails to take into account that the actual number of seats held by a party may well be quite disproportional to its weight in a homogeneous representation of the game (when there is such a representation).

The book also considers issues of monopoly (or monopsony) and oligopoly. We have already pointed out that stable set theory concerns the endogenous emergence of social structure. In a market with one buyer (monopsonist) and two sellers (duopolists) where supply exceeds demand, the theory predicts that the duopolists will form a cartel to bargain with the monopsonist. The core, on the other hand, predicts cut-throat competition; the duopolists end up by selling their goods for nothing, with the entire consumer surplus going to the buyer.

This is a good place to point out a fundamental difference between the game-theoretic and other approaches to social science. The more conventional approaches take institutions and their assumptions as given, and ask where they lead. The game theoretic approach asks how the institutions came about, what led to them? Thus general equilibrium theory takes the idea of market prices for granted; it concerns itself with their existence and properties, calculating them, and so on. Game Theory asks, why are there market prices? How did they come about? Under what conditions will all traders trade at given prices?

Conventional economic theory has several approaches to oligopoly, including competition and cartelization. Starting with any particular one of these, it calculates what is implied in specific applications. Game theory proceeds differently. It starts with the physical description of the situation only, making no institutional or doctrinal assumptions, then applies a solution concept and sees where it leads.

In a sense, of course, the doctrine is built into the solution concept; as we have seen, the core implies competition, the stable set cartelization. It is not that game theory makes no assumptions, but that the assumptions are of a more general, fundamental nature. The difference is like that between deriving the motion of the planets from Kepler's laws or from Newton's laws. Like Kepler's laws, which apply to the planets only, oligopoly theory applies to oligopolistic markets only. Newton's laws apply to the planets and also to apples falling from trees; stable sets apply to markets and also to voting.

To be sure, conventional economics is also concerned with the genesis of institutions, but on an informal, verbal, ad-hoc level. In game theory, institutions like prices or cartels are outcomes of the formal analysis.

(x) Games with a continuum of pure strategies were first considered by Ville (1938), who proved the minimax theorem for them, using an appropriate continuity condition. To guarantee the minimax (security) level, one may need to use a continuum of pure strategies, each with probability zero. An example due to Kuhn (1952) shows that in general one cannot guarantee anything even close to minimax using strategies with finite support. Ville's theorem was extended in the fifties to strategic equilibrium in non-strictly competitive games.
(xi) Computing security levels, and strategies that will guarantee them, is highly non-trivial. The problem is equivalent to that of linear programming, and thus succumbed to the simplex method of George Dantzig (1951a, 1951b).

(xii) The major advance in relevant mathematical methods during this period was Kakutani’s fixed point theorem (1941). An abstract expression of the existence of equilibrium, it is the vital active ingredient of countless proofs in economics and game theory. Also instrumental in later work were Lyapounov’s theorem on the range of a vector measure (1940) and von Neumann’s selection theorem (1949).

1950- 1960

The 1950s were a period of excitement in game theory. The discipline had broken out of its cocoon, and was testing its wings. Giants walked the earth. At Princeton, John Nash laid the groundwork for the general non-cooperative theory, and for cooperative bargaining theory; Lloyd Shapley defined the value for coalitional games, initiated the theory of stochastic games, co-invented the core with D.B. Gillies, and, together with John Milnor, developed the first game models with continua of players; Harold Kuhn worked on behaviour strategies and perfect recall; Al Tucker discovered the prisoner’s dilemma; the Office of Naval Research was unstinting in its support. Three Game Theory conferences were held at Princeton, with the active participation of von Neumann and Morgenstern themselves. Princeton University Press published the four classic volumes of Contributions to the Theory of Games. The Rand Corporation, for many years to be a major centre of game theoretic research, had just opened its doors in Santa Monica. R. Luce and H. Raiffa (1957) published their enormously influential Games and Decisions. Near the end of the decade came the first studies of repeated games.

The major applications at the beginning of the decade were to tactical military problems: defense from missiles, Colonel Blotto, fighter-fighter duels, etc. Later the emphasis shifted to deterrence and cold war strategy, with contributions by political scientists like Kahn, Kissinger, and Schelling. In 1954, Shapley and Shubik published their seminal paper on the value of a voting game as an index of power. And in 1959 came Shubik’s spectacular rediscovery of the core of a market in the writings of F.Y. Edgeworth (1881). From that time on, economics has remained by far the largest area of application of game theory.

(i) An equilibrium (Nash, 1951) of a strategic game is a (pure or mixed) strategy profile in which each player’s strategy maximizes his payoff given that the others are using their strategies. See the entry on Nash equilibrium, refinements of.

Strategic equilibrium is without doubt the single game theoretic solution concept that is most frequently applied in economics. Economic applications include oligopoly, entry and exit, market equilibrium, search, location, bargaining, product quality, auctions, insurance, principal-agent, higher education, discrimination, public goods, what have you. On the political front, applications include voting, arms control, and inspection, as well as most international political models (deterrence, etc.) Biological applications of game theory all deal with forms of strategic equilibrium; they suggest a simple interpretation of equilibrium quite different from the usual overt rationalism (see 1970–1986, i). We cannot even begin to survey all this literature here.

(ii) Stochastic and other dynamic games. Games played in stages, with some kind of stationary time structure, are called dynamic. They include stochastic games, repeated games with or without complete information, games of survival (Milnor and Shapley, 1957; Luce and Raiffa, 1957; Shubik, 1959) or ruin (Rosenthal and Rubinstein, 1984), recursive games (Everett, 1957), games with varying opponents (Rosenthal, 1979), and similar models.

This kind of model addresses the concerns we expressed above (1930–1950, vii) about the single play assumption. The present can only be understood in the context of the past and the future: ‘Know whence you came and where you are going’ (Ethics of the Fathers III:1). Physically, current actions affect not only current payoff but also opportunities and payoffs in the future. Psychologically, too, we learn: past experience affects our current expectations of what others will do, and therefore our own actions. We also teach: our current actions affect others’ future expectations, and therefore their future actions.

Two dynamic models – stochastic and repeated games – have been especially ‘successful’. Stochastic games address the physical point, that current actions affect future opportunities. A strategic game is played at each stage: the profile of strategies determines both the payoff at that stage and the game to be played at the next stage (or a probability distribution over such games). In the strictly competitive case, with future payoff discounted at a fixed rate, Shapley (1953a) showed that stochastic games are determined; also, that they have optimal strategies that are stationary, in the sense that they depend only on the game being played (not on the history or even on the date). Bewley and Kohlberg (1976) showed that as the discount rate tends to 0 the value tends to a limit; this limit is the same as the limit, as \( k \to \infty \), of the values of the \( k \)-stage games, in each of which the payoff is the mean payoff for the \( k \) stages. Mertens and Neyman (1981) showed that the value exists also in the undiscounted infinite stage game, when payoff is defined by the Cesaro limit (limit, as \( k \to \infty \), of the average payoff in the first \( k \) stages). For an understanding of some of the intuitive issues in this work, see Blackwell and Ferguson (1968), which was extremely influential in the modern development of stochastic games.

The methods of Shapley, and of Bewley and Kohlberg, can be used to show that non-strictly competitive stochastic games with fixed discounts have equilibria in stationary strategies, and that when the discount tends to 0, these equilibria converge to a limit (Mertens, 1982). But unlike in the strictly competitive case, the payoff to this limit need not correspond to an equilibrium of the undiscounted game (Sorin, 1986b). It is not known whether undiscounted non-strictly competitive stochastic games need at all have strategic equilibria.

(iii) Repeated games model the psychological, informational side of ongoing relationships. Phenomena like cooperation, altruism, trust, punishment, and revenge are predicted by the
theory. These may be called ‘subjective informational’ phenomena, since what is at issue is information about the behaviour of the players. Repeated games of incomplete
information (1960–1970, ii) also predict ‘objective informational’ phenomena such as secrecy, and signalling of substantive information. Both kinds of informational issue are quite
different from the ‘physical’ issues addressed by stochastic games.

Given a strategic game $G$, consider the game $G^\infty$ each play of which consists of an infinite sequence of repetitions of $G$. At each stage, all players know the actions taken by all
players at all previous stages. The payoff in $G^\infty$ is some kind of average of the stage payoffs; we will not worry about exact definitions here.

The reader is referred to the entry on repeated games. Here we state only one basic result, known as the Folk Theorem. Call an outcome (payoff profile) $x$ feasible in $G$ if it is
achievable by the all-player set when using a correlated randomizing device; i.e. is in the convex hull of the ‘pure’ outcomes. Call it strongly individually rational if no player $i$ can be
prevented from achieving $x_i$ by the other players, when they are randomizing independently; i.e. if $x' \square \min \max H(s)$, where the max is over $i$'s strategies, and the min is over $(n - 1)$-
tuples of mixed strategies of the others. The Folk Theorem then says that the equilibrium outcomes in the repetition $G^\infty$ coincide with the feasible and strongly individually rational
outcomes in the one-shot game $G$.

The authorship of the Folk Theorem, which surfaced in the late Fifties, is obscure. Intuitively, the feasible and strongly individually rational outcomes are the outcomes that could
arise in cooperative play. Thus the Folk Theorem points to a strong relationship between repeated and cooperative games. Repetition is a kind of enforcement mechanism; agreements
are enforced by ‘punishing’ deviators in subsequent stages.

(iv) The Prisoner's Dilemma is a two-person non-zero sum strategic game with payoff matrix as depicted in Figure 1. Attributed to A.W. Tucker, it has deservedly attracted enormous
attention; it is said that in the social psychology literature alone, over a thousand papers have been devoted to it.

Figure 1
One may think of the game as follows: Each player decides whether he will receive $1000 or the other will receive $3000. The decisions are simultaneous and independent, though the players may consult with each other before deciding.

The point is that ordinary rationality leads each player to choose the $1000 for himself, since he is thereby better off no matter what the other player does. But the two players thereby get only $1000 each, whereas they could have gotten $3000 each if both had been 'friendly' rather than 'greedy'.

The universal fascination with this game is due to its representing, in very stark and transparent form, the bitter fact that when individuals act for their own benefit, the result may well be disaster for all. This principle has dozens of applications, great and small, in everyday life. People who fail to cooperate for their own mutual benefit are not necessarily foolish or irrational; they may be acting perfectly rationally. The sooner we accept this, the sooner we can take steps to design the terms of social intercourse so as to encourage cooperation.

One such step, of very wide applicability, is to make available a mechanism for the enforcement of voluntary agreements. 'Pray for the welfare of government, without whose authority, man would swallow man alive' (Ethics of the Fathers III:2). The availability of the mechanism is itself sufficient; once it is there, the players are naturally motivated to use it. If they can make an enforceable agreement yielding (3, 3), they would indeed be foolish to end up with (1, 1). It is this that motivates the definition of a cooperative game (1930–1950).

The above discussion implies that (g, g) is the unique strategic equilibrium of the prisoner's dilemma. It may also be shown that in any finite repetition of the game, all strategic equilibria lead to a constant stream of 'friendly' choices by each player; but this is a subtler matter than the simple domination argument used for the one-shot case. In the infinite repetition, the Folk Theorem (iii) shows that (3, 3) is an equilibrium outcome; and indeed, there are equilibria that lead to a constant stream of 'friendly' choices by each player. The same holds if we discount future payoff in the repeated game, as long as the discount rate is not too large (Sorin, 1986a).

R. Axelrod (1984) has carried out an experimental study of the repeated prisoner's dilemma. Experts were asked to write computer programmes for playing the game, which were matched against each other in a 'tournament'. At each stage, the game ended with a fixed (small) probability; this is like discounting. The most successful program in the tournament turned out to be a 'cooperative' one: Matched against itself, it yields a constant stream of 'friendly' choices; matched against others, it 'punishes' greedy choices. The results of this experiment thus fit in well with received theoretical doctrine.

The design of this experiment is noteworthy because it avoids the pitfalls so often found in game experiments: lack of sufficient motivation and understanding. The experts chosen by Axelrod understood the game as well as anybody. Motivation was provided by the investment of their time, which was much more considerable than that of the average subject, and by the glory of a possible win over distinguished colleagues. Using computer programmes for strategies presages important later developments (1970–1986, iv).

Much that is fallacious has been written on the one-shot prisoner's dilemma. It has been said that for the reasoning to work, pre-play communication between the players must be forbidden. This is incorrect. The players can communicate before they are blue in the face, and agree solemnly on (f, f); when faced with the actual decision, rational players will still choose g. It has been said that the argument depends on the notion of strategic equilibrium, which is open to discussion. This too is incorrect; the argument depends only on strong domination, i.e. on the simple proposition that people always prefer to get another $1000. 'Resolutions' of the 'paradox' have been put forward, suggesting that rational players will play f after all: that my choosing f has some kind of 'mirror' effect that makes you choose it also. Worse than just nonsense, this is actually vicious, since it suggests that the prisoner's dilemma does not represent a real social problem that must be dealt with.

Finally, it has been said that the experimental evidence – Axelrod's and that of others – contradicts theory. This too is incorrect, since most of the experimental evidence relates to repeated games, where the friendly outcome is perfectly consonant with theory; and what evidence there is in one-shot games does point to a preponderance of 'greedy' choices. It is true that in long finite repetitions, where the only equilibria are greedy, most experiments nevertheless point to the friendly outcome; but fixed finite repetitions are somewhat artificial, and besides, this finding, too, can be explained by theory (Neyman, 1985; see 1970–1986, iv).

(v) We turn now to cooperative issues. A model of fundamental importance is the bargaining problem of Nash (1950). Formally, it is defined as a convex set C in the Euclidean plane, containing the origin in its interior. Intuitively, two players bargain; they may reach any agreement whose payoff profile is in C; if they disagree, they get nothing. Nash listed four axioms – conditions that a reasonable compromise solution might be expected to satisfy – such as symmetry and efficiency. He then showed that there is one and only one solution satisfying them, namely the point x in the non-negative part of C that maximizes the product x1x2. An appealing economic interpretation of this solution was given by Harsanyi (1956).

By varying the axioms, other authors have obtained different solutions to the bargaining problem, notably Kalai-Smorodinski (1975) and Maschler-Perles (1981). Like Nash's solution, each of these is characterized by a formula with an intuitively appealing interpretation.

Following work of A. Rubinstein (1982), K. Binmore (1982) constructed an explicit bargaining model which, when analyzed as a non-cooperative strategic game, leads to Nash’s solution of the bargaining problem. This is an instance of a successful application of the ‘Nash program’ (see 1930–1950, vi). Similar constructions have been made for other solutions of the bargaining problem.

An interesting qualitative feature of the Nash solution is that it is very sensitive to risk aversion. A risk loving or risk neutral bargainer will get a better deal than a risk averse one; this is so even when there are no overt elements of risk in the situation, nothing random. The very willingness to take risks confers an advantage, though in the end no risks are actually taken.

Suppose, for example, that two people may divide $600 in any way they wish; if they fail to agree, neither gets anything. Let their utility functions be $u^1(x) = x$ and $u^2(x) = \sqrt{x}$ so that 1 is risk neutral, 2 risk averse. Denominating the payoffs in utilities rather than dollars, we find that the Nash solution corresponds to a dollar split of $400$-$200$ in favour of the risk neutral bargainer.

This corresponds well with our intuitions. A fearful, risk averse person will not bargain well. Though there are no overt elements of risk, no random elements in the problem description, the bargaining itself constitutes a risk. A risk averse person is willing to pay, in terms of a less favourable settlement, to avoid the risk of the other side’s being adamant, walking away, and so on.

(vi) The *value* (Shapley, 1953b) is a solution concept that associates with each coalitional game $v$ a unique outcome $\phi_v(v)$. Fully characterized by a set of axioms, it may be thought of as a reasonable compromise or arbitrated outcome, given the power of the players. Best, perhaps, is to think of it simply as an index of power, or what comes to the same thing, of social productivity (see Shapley value).

It may be shown that Player $i$’s value is given by

$$\phi_i(v) = (1/n! \sum \psi(S^i_R)), $$

where $\sum$ ranges over all $n!$ orders on the set $I$ of all players, $S^i_R$ is the set of players up to and including $i$ in the order $R$, and $\psi(S)$ is the *contribution* $\psi(S) - \psi(S \setminus i)$ of $i$ to the coalition $S$; note that this implies linearity of $\phi_v$ in $v$. In words, $\phi_i(v)$ is $i$’s mean contribution when the players are ordered at random; this suggests the social productivity interpretation, an interpretation that is reinforced by the following remarkable theorem (Young 1985): Let $\psi$ be a mapping from games $v$ to efficient outcomes $\psi(v)$, that is symmetric among the players in the appropriate sense. Suppose $\psi$ $\phi_v$ depends only on the $2^{n-1}$ contributions $\psi(S)$, and monotonically so. Then $\psi$ must be the value $\phi$. In brief, if it depends on the contributions only, it’s got to be the value, even though we don’t assume linearity to start with.

An intuitive feel for the value may be gained from examples. The value of the 3-person voting game is $(1/3, 1/3, 1/3)$, as is suggested by symmetry. This is not in the core, because $(1, 2)$ can improve upon it. But so can $(1, 3)$ and $(2, 3)$; starting from $(1/3, 1/3, 1/3)$, the players might be well advised to leave things as they are (see 1930–1950, iv). Differently viewed, the symmetric stable set predicts one of the three outcomes $(1/2, 1/2, 0)$, $(1/2, 0, 1/2)$, $(0, 1/2, 1/2)$. Before the beginning of bargaining, each player may figure that his chances of getting into a ruling coalition are $1/2$ and conditional on this, his payoff is $1/2$. Thus his ‘expected outcome’ is the value, though in itself, this outcome has no stability.

In the homogenous weighted voting game $[3; 2, 1, 1, 1]$, the value is $(1/2, 1/6, 1/6, 1/6)$; the large player gets a disproportionate share, which accords with intuition: ‘l’union fait la force.’

Turning to games of economic interest, we model the market with two sellers and one buyer discussed above (1930–1950, ix) by the TU weighted voting game $[3; 2, 1, 1]$. The core consists of the unique point $(1, 0, 0)$, which means that the sellers must give their merchandise, for nothing, to the buyer. While this has clear economic meaning—cutthroat competition—it does not seem very reasonable as a compromise or an index of power. After all, the sellers do contribute something; without them, the buyer could get nothing. If one could be sure that the sellers will form a cartel to bargain with the buyer, a reasonable compromise would be $(1/2, 1/4, 1/4)$. In fact, the value is $(2/3, 1/6, 1/6)$, representing something between the cartel solution and the competitive one; a cartel is possible, but is not a certainty.

Consider next a market in two perfectly divisible and completely complementary goods, which we may call right and left gloves. There are four players; initially 1 and 2 hold one and two left gloves respectively, 3 and 4 hold one right glove each. In coalitional form, $\nu(1234) = \nu(234) = 2$, $\nu(14) = \nu(12) = \nu(13) = 1$, $\nu(5) = 0$ otherwise, where $i = 1, 2$, and $j = 3, 4$. The core consists of $(0, 0, 1, 1)$ only; that is, the owners of the left gloves must simply give away their merchandise, for nothing. This in itself seems strange enough. It becomes even stranger when one realizes that Player 2 could make the situation entirely symmetric (as between 1, 2 and 3, 4) simply by burning one glove, an action that he can take alone, without consulting anybody.

The value can never suffer from this kind of pathological breakdown in monotonicity. Here $\phi(v) = (1/4, 7/12, 7/12, 7/12)$, which nicely reflects the features of the situation. There is an oversupply of left gloves, and 3 and 4 do benefit from it. Also 2 benefits from it; he always has the option of nullifying it, but he can also use it (when he has an
opportunity to strike a deal with both 3 and 4). The brunt of the oversupply is thus born by 1 who, unlike 2, cannot take measures to correct it. Finally, consider a market with 2,000,001 players, 1,000,000 holding one right glove each, and 1,000,001 holding one left glove each. Again, the core stipulates that the holders of the left gloves must all give away their merchandise, for nothing. True, there is a slight oversupply of left gloves; but one would hardly have imagined so drastic an effect from one single glove out of millions. The value, too, takes the oversupply into account, but not in such an extreme form; altogether, the left-glove holders get about 499,557 pairs, the right about 500,443 (Shapley and Shubik, 1969b). This is much more reasonable, though the effect is still surprisingly large: The short side gains an advantage that amounts to almost a thousand pairs.

The value has many different characterizations, all of them intuitively meaningful and interesting. We have already mentioned Shapley's original axioms, the value formula, and Young's characterization. To them must be added Harsanyi's (1959) dividend characterization, Owen's (1972) fuzzy coalition formula, Myerson's (1977) graph approach, Dubey's (1980) diagonal formula, the potential of Hart and Mas-Colell (1986), the reduced game axiomatization by the same authors, and Roth's (1977) formalization of Shapley's (1953b) idea that the value represents the utility to the players of playing a game. Moreover, because of its mathematical tractability, the value lends itself to a far greater range of applications than any other cooperative solution concept. And in terms of general theorems and characterizations for wide classes of games and economies, the value has a greater range than any other solution concept, bar none.

Previously (1930–1950, iii), we compared solution concepts of games to indicators of distributions, like mean and median. In fact the value is in many ways analogous to the mean, whereas the median corresponds to something like the core, or to core-like concepts such as the nucleolus (1960–1970, iv). Like the core, the median has an intuitively transparent and compelling definition (the point that cuts the distribution exactly in half), but lacks an algebraically neat formula; and like the value, the mean has a neat formula whose intuitive significance is not entirely transparent (thought through much experience from childhood on, many people have acquired an intuitive feel for it). Like the value, the mean is linear in its data; the core, nucleolus, and median are not. Both the mean and the value are very sensitive to their data: change one datum by a little, and the mean (or value) will respond in the appropriate direction; neither the median nor the core is sensitive in this way: one can change the data in wide ranges without affecting the median (or core) at all. On the other hand, the median can suddenly jump because of a moderate change in just one datum; thus the median of 1,000,001 zeros and 1,000,001 ones is 0, but jumps to 1 if we change just one datum from 0 to 1. We have already seen that the core may behave similarly, but the mean and the value cannot. Both the mean and the value are mathematically very tractable, resulting in a wide range of applications, both theoretical and practical; the median and core are less tractable, resulting in a narrower (though still considerable) range of applications.

The first extensive applications of the value were to various voting games (Shapley and Shubik, 1954). The key observation in this seminal paper was that the value of a player equals his probability of pivoting — turning a coalition from losing to winning — when the players are ordered at random. From this there has grown a very large literature on voting games. Other important classes of applications are to market games (1960–1970, v) and political-economic games (e.g. Aumann and Kurz, 1977; Neyman, 1985b).

(vii) Axiomatics. The Shapley value and Nash's solution to the bargaining problem are examples of the axiomatic approach. Rather than defining a solution concept directly, one writes down a set of conditions for it to satisfy, then sees where they lead. In many contexts, even a relatively small set of fairly reasonable conditions turn out to be self-contradictory; there is no concept satisfying all of them. The most famous instance of this is Arrow's (1951) impossibility theorem for social welfare functions, which is one of the earliest applications of axiomatics in the social sciences.

It is not easy to pin down precisely what is meant by 'the axiomatic method'. Sometimes the term is used for any formal deductive system, with undefined terms, assumptions, and conclusions. As understood today, all of game theory and mathematical economics fits that definition. More narrowly construed, an axiom system is a small set of individually transparent conditions, set in a fairly general and abstract framework, which when taken together have far-reaching implications. Examples are Euclid's axioms for geometry, the Zermelo–Fraenkel axioms for set theory, the conditions on multiplication that define a group, the conditions on open sets that define a topological space, and the conditions on preferences that define utility and/or subjective probability.

Game theoretic solution concepts often have both direct and axiomatic characterizations. The direct definition applies to each game separately, whereas most axioms deal with relationships between games. Thus the formula for the Shapley value $\varphi v$ enables one to calculate it without referring to any game other than $v$. But the axioms for $\varphi$ concern relationships between games; they say that if the values of certain games are so and so, then the values of certain other, related games must be such and such. For example, the additivity axiom is $\varphi (v + w) = \varphi v + \varphi w$. This is analogous to direct vs. axiomatic approaches to integration. Direct approaches such as limit of sum work on a single function; axiomatic approaches characterize the integral as a linear operator on a space of functions. (Harking back to the discussion at (vi), we note that the axioms for the value are quite similar to those for the integral, which in turn is closely related to the mean of a distribution.)

Shapley's value and the solutions to the bargaining problem due to Nash (1950), Kalai and Smorodinsky (1975) and Maschler and Perles (1981) were originally conceived axiomatically, with the direct characterization coming afterwards. In other cases the process was reversed; for example, the nucleolus, NTU Shapley value, and NTU Harsanyi value were all axiomatized only years after their original direct definition (see 1960–1970). Recently the core, too, has been axiomatized (Peleg, 1985, 1986).

Since axiomatizations concern relations between different games, one may ask why the players of a given game should be concerned with other games, which they are not playing. This has several answers. Viewed as an indicator, a solution of a game doesn't tell us much unless it stands in some kind of coherent relationship to the solutions of other games. The ratings for a rock climb tell you something if you have climbed other rocks whose ratings you know; topographic maps enable you to take in a situation at a glance if you have used them before. If we view a solution as an arbitrated or imposed outcome, it is natural to expect some measure of consistency from an arbitrator or judge. Indeed,
much of the law is based on precedent, which means relating the solution of the given ‘game’ to those of others with known solutions. Even when viewing a solution concept as a norm of actual behaviour, the very word ‘norm’ implies that we are thinking of a function on classes of games rather than of a single game; outcomes are largely based on mutual expectations, which are determined by previous experience with other games, by ‘norms’.

Axiomatizes serve a number of useful purposes. First, like any other alternative characterization, they shed additional light on a concept, enable us to ‘understand’ it better. Second, they underscore and clarify important similarities between concepts, as well as differences between them. One example of this is the remarkable ‘reduced game property’ or ‘consistency principle’, which is associated in various different forms with just about every solution concept, and plays a key role in many of the axiomatizations (see 1970–1986, vii). Another example consists of the axiomatizations of the Shapley and Harsanyi NTU values. Here the axioms are exact analogues, except that in the Shapley case they refer to payoff profiles, and in the Harsanyi case to 2^n-tuples of payoff profiles, one for each of the 2^n coalitions (Hart, 1985a). This underscores the basic difference in outlook between those two concepts: The Shapley value assumes that the all-player coalition eventually forms, the intermediate coalitions being important only for bargaining chips and threats, whereas the Harsanyi value takes into account a real possibility of the intermediate coalitions actually forming.

Last, an important function of axiomatics relates to ‘counter-intuitive examples’, in which a solution concept yields outcomes that seem bizarre; e.g. the cores of some of the games discussed above in (vi). Most axioms appearing in axiomatizations do seem reasonable on the face of it, and many of them are in fact quite compelling. The fact that a relatively small selection of such axioms is often categoric (determines a unique solution concept), and that different such selections yield different answers, implies that all together, these reasonable-sounding axioms are contradictory. This, in turn, implies that any one solution concept will necessarily violate at least some of the axioms that are associated with other solution concepts; thus if the axioms are meant to represent intuition, counter-intuitive examples are inevitable.

In brief, axiomatics underscores the fact that a ‘perfect’ solution concept is an unattainable goal, a fata morgana; there is something ‘wrong’, some quirk with every one. Any given kind of counterintuitive example can be eliminated by an appropriate choice of solution concept, but only at the cost of another quirk turning up. Different solution concepts can therefore be thought of as results of choosing not only which properties one likes, but also which examples one wishes to avoid.

1960–1970

The Sixties were a decade of growth. Extensions such as games of incomplete information and NTU coalitional games made the theory much more widely applicable. The fundamental underlying concept of common knowledge was formulated and clarified. Core theory was extensively developed and applied to market economies; the bargaining set and related concepts such as the nucleolus were defined and investigated; games with many players were studied in depth. The discipline expanded geographically, outgrowing the confines of Princeton and Rand; important centres of research were established in Israel, Germany, Belgium and the Soviet Union. Perhaps most important was the forging of a strong, lasting relationship with mathematical economics and economic theory.

(i) **NTU coalitional games and NTU value.** Properly interpreted, the coalitional form (1930–1950, ii) applies both to TU and to NTU games; nevertheless, for many NTU applications one would like to describe the opportunities available to each coalition more faithfully than can be done with a single number. Accordingly, define a game in **NTU coalitional form** as a function that associates with each coalition S a set V(S) of S-tuples of real numbers (functions from S to ℜ). Intuitively, V(S) represents the set of payoff S-tuples that S can achieve. For example, in an exchange economy, V(S) is the set of utility S-tuples that S can achieve when its members trade among themselves only, without recourse to agents outside of S. Another example of an NTU coalitional game is Nash’s bargaining problem (1950–1960, iii), where one can take V(1, 2) = C, V(1) = (0), V(2) = (0).

The definitions of stable set and core extend straightforwardly to NTU coalitional games, and these solution concepts were among the first to be investigated in that context (Aumann and Peleg, 1960; Peleg, 1963a; Aumann, 1961). The first definitions of NTU value were proposed by Harsanyi (1959, 1963), but they proved difficult to apply. Building on Harsanyi’s work, Shapley (1969) defined a value for NTU games that has proved widely applicable and intuitively appealing.

For each profile λ of non-negative numbers and each outcome x, define the *weighted outcome* λ x by \(\langle \lambda x \rangle^i = \lambda^i x^i\). Let \(v_\lambda(S)\) be the maximum total weight that the coalition S can achieve,

\[
v_\lambda(S) = \max \left\{ \sum_{i \in S} \lambda^i x^i | x \in V(S) \right\}.
\]

Call an outcome x an **NTU value** of V if \(x \in V(N)\) and there exists a weight profile \(\lambda\) with \(\lambda x = \phi v\lambda\); in words, if x is feasible and corresponds to the value of one of the coalitional games \(v_\lambda\).
Intuitively, $v_\lambda(S)$ is a numerical measure of S's total worth and hence $\varphi_i v_\lambda$ measures i's social productivity. The weights $\lambda^i$ are chosen so that the resulting value is feasible; an infeasible result would indicate that some people are overrated (or underrated), much like an imbalance between supply and demand indicates that some goods are overpriced (or underpriced).

The NTU value of a game need not be unique. This may at first sound strange, since unlike stability concepts such as the core, one might expect an 'index of social productivity' to be unique. But perhaps it is not so strange when one reflects that even a person's net worth depends on the prevailing (equilibrium) prices, which are not uniquely determined by the exogenous description of the economy.

The Shapley NTU value has been used in a very wide variety of economic and political-economic applications. To cite just one example, the Nash bargaining problem has a unique NTU value, which coincides with Nash's solution. For a partial bibliography of applications, see the references of Aumann (1985).

We have discussed the historical importance of TU as pointing the way for NTU results (1930–1950, vi). There is one piquant case in the reverse direction. Just as positive results are easier to obtain for TU, negative results are easier for NTU. Non-existence of stable sets was first discovered in NTU games (Stearns 1967), and this eventually led to Lucas's famous example (1969) of non-existence for TU.

(ii) Incomplete information. In 1957, Luce and Raiffa wrote that a fundamental assumption of game theory is that 'each player ... is fully aware of the rules of the game and the utility functions of each of the players ... this is a serious idealization which only rarely is met in actual situations' (p. 49). To deal with this problem, John Harsanyi (1967) constructed the theory of games of incomplete information (sometimes called differential or asymmetric information). This major conceptual breakthrough laid the theoretical groundwork for the great blooming of information economics that got under way soon thereafter, and that has become one of the major themes of modern economics and game theory.

For simplicity, we confine attention to strategic form games in which each player has a fixed, known set of strategies, and the only uncertainty is about the utility functions of the other players; these assumptions are removable. Bayesian rationality in the tradition of Savage (1954) dictates that all uncertainty can be made explicit; in particular, each player has a personal probability distribution on the possible utility (payoff) functions of the other player. But these distributions are not sufficient to describe the situation. It is not enough to specify what each player thinks about the other's payoffs; one must also know what he thinks they think about his (and each others') payoffs, what he thinks they think he thinks about their payoffs, and so on. This complicated infinite regress would appear to make useful analysis very difficult.

To cut this Gordian knot, Harsanyi postulated that each player may be one of several types, where a type determines both a player's own utility function and his personal probability distribution on the types of the other players. Each player is postulated to know his own type only. This enables him to calculate what he thinks the other players' types – and therefore their utilities – are. Moreover, his personal distribution on their types also enables him to calculate what he thinks they think about his type, and therefore about his utility. The reasoning extends indefinitely, and yields the infinite regress discussed above as an outcome.

Intuitively, one may think of a player's type as a possible state of mind, which would determine his utility as well as his distribution over others' states of mind. One need not assume that the number of states of mind (types) is finite; the theory works as well for, say, a continuum of types. But even with just two players and two types for each player, one gets a non-trivial infinite string of beliefs about utilities, beliefs about beliefs, and so on.

A model of this kind – with players, strategies, types, utilities, and personal probability distributions – is called an I-game (incomplete information game). A strategic equilibrium in an I-game consists of a strategy for each type of each player, which maximizes that type's expected payoff given the strategies of the other players' types.

Harsanyi's formulation of I-games is primarily a device for thinking about incomplete information in an orderly fashion, bringing that wild, bucking infinite regress under conceptual control. An (incomplete) analogy is to the strategic form of a game, a conceptual simplification without which it is unlikely that game theory would have gotten very far. Practically speaking, the strategic form of a particular game such as chess is totally unmanageable, one can't even begin to write it down. The advantage of the strategic form is that it is a comparatively simple formulation, mathematically much simpler than the extensive form; it enables one to formulate and calculate examples, which suggest principles that can be formulated and proved as general theorems. All this would be much more difficult – probably unachievable – with the extensive form; one would be unable to see the forest for the trees. A similar relationship holds between Harsanyi's I-game formulation and direct formulations in terms of beliefs about beliefs. (Compare the discussion of perspective made in connection with the coalitional form (1930–1950, i).) That situation is somewhat different, though, since in going to the coalitional form, substantive information is lost. Harsanyi's formulation of I-games loses no information; it is a more abstract and simple – and hence transparent and workable – formulation of the same data as would be contained in an explicit description of the infinite regress.

Harsanyi called an I-game consistent if all the personal probability distributions of all the types are derivable as posteriors from a single prior distribution $p$ on all n-tuples of types. Most applications of the theory have assumed consistency. A consistent I-game is closely related to the ordinary strategic game ($C$-game) obtained from it by allowing 'nature' to choose an n-tuple of types at random according to the distribution $p$, then informing each player of his type, and then playing the I-game as before. In particular, the strategic equilibria of a consistent I-game are essentially the same as the strategic equilibria of the related $C$-game. In the cooperative theory, however, an I-game is rather different from the consistent $H$-game if all the personal probability distributions of all the types are derivable as posteriors from a single prior distribution $p$.

In a repeated game of incomplete information, the same game is played again and again, but the players do not have full information about it; for example, they may not know the others' utility functions. The actions of the players may implicitly reveal private information, e.g. about preferences; this may or may not be advantageous for them. We have seen
That repetition may be viewed as a paradigm for cooperation. Strategic equilibria of repeated games of incomplete information may be interpreted as a subtle bargaining process, in which the players gradually reach wider and wider agreement, developing trust for each other while slowly revealing more and more information (Hart, 1985b).

Common knowledge. Luce and Raiffa, in the statement quoted at the beginning of (ii), missed a subtle but important point. It is not enough that each player be fully aware of the rules of the game and the utility functions of the players. Each player must also be aware of this fact, i.e. of the awareness of all the players; moreover, each player must be aware that each player is aware that each player is aware, and so on ad infinitum. In brief, the awareness of the description of the game by all players must be a part of the description itself.

There is evidence that game theorists had been vaguely cognizant of the need for some such requirement ever since the late Fifties or early Sixties; but the first to give a clear, sharp formulation was the philosopher D.K. Lewis (1969). Lewis defined an event as common knowledge among a set of agents if all know it, all know that all know it, and so on ad infinitum.

The common knowledge assumption underlies all of game theory and much of economic theory. Whatever be the model under discussion, whether complete or incomplete information, consistent or inconsistent, repeated or one-shot, cooperative or non-cooperative, the model itself must be assumed common knowledge; otherwise the model is insufficiently specified, and the analysis incoherent.

Bargaining set, kernel, nucleolus. The core excludes the unique symmetric outcome $(1/3, 1/3, 1/3)$ of the three-person voting game, because any two-person coalition can improve upon it. Stable sets $(1950–1950, v)$ may be seen as a way of expressing our intuitive discomfort with this exclusion. Another way is the bargaining set (Davis and Maschler, 1965). If, say, I suggests $(1/2, 1/2)$ to replace $(1/3, 1/3, 1/3)$, then 3 can suggest to 2 that he is as good a partner as 1; indeed, 3 can even offer 2/3 to 2, still leaving himself with the $1/3 he was originally assigned. Formally, if we call $(1/2, 1/2, 0)$ an objection to $(1/3, 1/3, 1/3)$, then $(0, 2/3, 1/3)$ is a counter objection, since it yields to 3 at least as much as he was originally assigned, and yields to 3’s partners in the counter objection at least as much as they were assigned either originally or in the objection. In brief, the counter-objecting player tells the objecting one, ‘I can maintain my level of payoff and that of my partners, while matching your offers to players we both need.’ An imputation is in the core if there is no objection to it. It is in the bargaining set if there is no justified objection to it, i.e. one that has no counter-objectition.

Like the stable sets, the bargaining set includes the core (dominating and objecting are essentially the same). Unlike the core and the set of stable sets, the bargaining set is for TU games never empty (Peleg, 1967). For NTU it may be empty (Peleg, 1963b); but Asscher (1976) has defined a non-empty variant; see also Billera (1970a).

Crucial parameters in calculating whether an imputation $x$ is in the bargaining set of $v$ are the excesses $\nabla(S) - \chi(S)$ of coalitions $S$ w.r.t. $x$, which measure the ability of members of $S$ to use $x$ in an objection (or counter-objection). Not, as is often wrongly assumed, because the initiator of an objection can assign the excess to himself while keeping his partners at their original level, but for precisely the opposite reason: because he can parcel out the excess to his partners, which makes counterobjecting more difficult.

These excesses are ubiquitous in bargaining set calculations that it eventually took on intuitive significance on its own. This led to the formulation of two additional solution concepts: the kernel (Davis and Maschler, 1965), which is always included in the bargaining set but is often much smaller, and the nucleolus (Schmeidler, 1969), which always consists of a single point in the kernel.

To define the nucleolus, choose first all those imputations $x$ whose maximum excess (among the $2^n$ excesses $\nabla(S) - \chi(S)$) is minimum (among all imputations). Among the resulting imputations, choose next those second largest excess is minimum, and so on. Schmeidler’s theorem asserts that by the time we have gone through this procedure $2^n$ times, there is just one imputation left.

We have seen that the excess is a measure of a coalition’s ‘manoeuvring ability’; in these terms the greatest measure of stability, as expressed by the nucleolus, is reached when all coalitions have manoeuvring ability as nearly alike as possible. An alternative interpretation of the excess is as a measure of $S$’s total dissatisfaction with $x$, the volume of the cry that $S$ might raise against $x$. In these terms, the nucleolus suggests that the final accommodation is determined by the loudest cry against it. Note that the total cry is determining, not the average cry; a large number of moderately unhappy citizens can be as potent a force for change as a moderate number of very unhappy ones. Variants of the nucleolus that use the average excess miss this point.

When the core is non-empty, the nucleolus is always in it. The nucleolus has been given several alternative characterizations, direct (Kohlberg, 1971, 1972) as well as axiomatic (Sobolev, 1975). The kernel was axiomatically characterized by Peleg (1986), and many interesting relationships have been found between the bargaining set, core, kernel, and nucleolus (e.g. Maschler, Peleg and Shapley, 1979). There is a large body of applications, of which we here cite just one: In a decisive weighted voting game, the nucleolus constitutes a set of weights (Peleg 1968). Thus the nucleolus may be thought of as a natural generalization of ‘voting weights’ to arbitrary games. (We have already seen that value and weights are quite different: see 1950–1960, vi.)

The equivalence principle. Perhaps the most remarkable single phenomenon in game and economic theory is the relationship between the price equilibria of a competitive market economy, and all but one of the major solution concepts for the corresponding game (the one exception is the stable set, about which more below). By a ‘market economy’ we here mean a pure exchange economy, or a production economy with constant returns.

We call an economy ‘competitive’ if it has many agents, each individual one of whom has too small an endowment to have a significant effect. This has been modelled by three approaches. In the asymptotic approach, one lets the number of agents tend to infinity, and shows that in an appropriate sense, the solution concept in question – core, value, bargaining set, or strategic equilibrium – tends to the set of competitive allocations (those corresponding to price equilibria). In the continuum approach, the agents constitute a (non-
In the non-standard approach, the agents constitute a non-standard model of the integers in the sense of Robinson (1974), and again one gets equality. Both the continuum and the non-standard approaches require extensions of the theory to games with infinitely many players; see vi.

Intuitively, the equivalence principle says that the institution of market prices arises naturally from the basic forces at work in a market, (almost) no matter what we assume about the way in which these forces work. Compare (1930–1950, ix).

For simplicity in this section, unless otherwise indicated, the terms ‘core’, ‘value’, etc., refer to the limiting case. Thus ‘core’ means the limit of the cores of the finite economies, or the core of the continuum economy, or of the non-standard economy.

For the core, the asymptotic approach was pioneered by Edgeworth (1881), Shubik (1959) and Debreu and Scarf (1963). Anderson (1986) is an excellent survey of the large literature that ensued. Early writers on the continuum approach included Aumann (1964) and Vind (1965); the non-standard approach was developed by Brown and Robinson (1975). Except for Shubik's, all these contributions were NTU. See the entry on CORE. After a 20-year courtship, this was the honeymoon of game theory and mathematical economics, and it is difficult to convey the palpable excitement of those early years of intimacy between the two disciplines.

Some early references for the value equivalence principle, covering both the asymptotic and continuum approaches, were listed above (1930–1950, vi). For the non-standard approach, see Brown and Loeb (1976). Whereas the core of a competitive economy equals the set of all competitive allocations, this holds for the value only when preferences are smooth (Shapley, 1964; Aumann and Shapley, 1974; Aumann 1975; Mas-Colell, 1977). Without smoothness, every value allocation is competitive, but not every competitive allocation need be a value allocation. When preferences are kinky (non-differentiable utilities), the core is often quite large, and then the value is usually a very small subset of the core; it gives much more information. In the TU case, for example, the value is always a single point, even when the core is very large. Moreover, it occupies a central position in the core (Hart, 1980; Tauman, 1981; Mertens, 1988); in particular, when the core has a centre of symmetry, the value is that centre of symmetry (Hart, 1977a).

For example, suppose that in a glove market (1950–1960, vi), the number (or measure) of left-glove holders equals that of right-glove holders. Then at a price equilibrium, the price ratio between left and right gloves may be anything between 0 and ∞ (inclusive!). Thus the left-glove holders may end up giving away their merchandise for nothing to the right-glove holders, or the other way around, or anything in between. The same, of course, holds for the core. But the value prescribes precisely equal prices for right and left gloves. It should be noted that in a finite market, the core contains the competitive allocations, but usually also much more. As the number of agents increases, the core ‘shrinks’, in the limit leaving only the competitive allocations. This is not so for the value; in finite markets, the value allocations may be disjoint from the core, and a fortiori from the competitive allocations (1950–1960, vi).

We have seen (1930–1950, iv) that the core represents a very strong and indeed not quite reasonable notion of stability. It might therefore seem perhaps not so terribly surprising that it shrinks to the competitive allocations. What happens, one may ask, when one considers one of the more reasonable stability concepts that are based on domination, such as the bargaining set or the stable sets?

For the bargaining set of TU markets, an asymptotic equivalence theorem was established by Shapley and Shubik in the mid-Seventies, though it was not published until 1984. Extending this result to NTU, to the continuum, or to both seemed difficult. The problems were conceptual as well as mathematical; it was difficult to give a coherent formulation. In 1986, Shapley presented the TU proof at a conference on the equivalence principle that took place at Stony Brook. A. Mas-Colell, who was in the audience, recognized the relevance of several results that he had obtained in other connections; within a day or two he was able to formulate and prove the equivalence principle for the bargaining set in NTU continuum economies (Mas-Colell, 1988). In particular, this implies the core equivalence principle; but it is a much stronger and more satisfying result.

For the strategic equilibrium the situation had long been less satisfactory, though there were results (Shubik, 1973; Dubey and Shapley, 1980). The difficulty was in constructing a satisfactory strategic (or extensive) model of exchange. Very recently Douglas Gale (1986) provided such a model and used it to prove a remarkable equivalence theorem for strategic equilibria in the continuum mode.

The one notable exception to the equivalence principle is the case of stable sets, which predict the formation of cartels even in fully competitive economies (Hart, 1974). For example, suppose half the agents in a continuum initially hold 2 units of bread each, half initially hold 2 units of cheese, and the utility functions are concave, differentiable, and symmetric (e.g., \( u(x, y) = \sqrt{x} + \sqrt{y} \)). There is then a unique price equilibrium, with equal prices for bread and cheese. Thus each agent ends up with one piece of bread and one piece of cheese; this is also the unique point in the core and in the bargaining set, and the unique NTU value. But stable set theory predicts that the cheese holders will form a cartel, the bread holders will form a cartel, and these two cartels will bargain with each other as if they were individuals. The upshot will depend on the bargaining, and may yield an outcome that is much better for one side than for the other. Thus at each point of the unique stable set with the full symmetry of the game, each agent on each side gets as much as each other agent on that side; but these two amounts depend on the bargaining, and may be quite different from each other.

In a sense, the failure of stable set theory to fall into line makes the other results even more impressive. It shows that there isn't some implicit tautology lurking in the background, that the equivalence principle makes a substantive assertion.

In the  *Theory of Games*, von Neumann and Morgenstern (1944) wrote that
One may take the theorems constituting the equivalence principle as embodying precisely this kind of ‘result’. Yet it is interesting that Morgenstern himself, who died in 1977, never became convinced of the validity of the equivalence principle; he thought of it as mathematically correct but economically wrongheaded. It was his firm opinion that economic agents organize themselves into coalitions, that perfect competition is a fiction, and that stable sets explain it all. The greatness of the man is attested to by the fact that though scientifically opposed to the equivalence principle, he gave generous support, both financial and moral, to workers in this area.

(vi) Many players. The preface to Contributions to the Theory of Games I (Kuhn and Tucker, 1950) contains an agenda for future research that is remarkable in that so many of its items -- computation of minimax, existence of stable sets, \( n \)-person value, NTU games, dynamic games -- did in fact become central in subsequent work. Item 11 in this agenda reads, ‘establish significant asymptotic properties of \( n \)-person games, for large \( n \).’ We have seen (v) how this was realized in the equivalence principle for large economies. But actually, political game models with many players are at least as old as economic ones, and may be older. During the early Sixties, L.S. Shapley, working alone and with various collaborators, wrote a series of seven memoranda at the Rand Corporation under the generic title ‘Values of Large Games’, several of which explored models of large elections, using the asymptotic and the continuum approaches. Among these were models which had both ‘atoms’ -- players who are significant as individuals -- and an ‘ocean’ of individually insignificant players. On example of this is a corporation with many small stockholders and a few large stockholders; see also Milnor and Shapley (1978). ‘Mixed’ models of this kind -- i.e. with an ocean as well as atoms -- have been explored in economic as well as political contexts using various solution notions, and a large literature has developed. The core of mixed markets has been studied by Drèze, Gabszewicz and Gepts (1969), Gabszewicz and Mertens (1971), Shitovitz (1973) and many others. For the nucleolus of ‘mixed’ voting games, see Galil (1974). Among the studies of values of mixed games are Hart (1973), Fegelman and Quinzii (1980), and Neyman (1987).

Large games in which all the players are individually insignificant -- non-atomic games -- have also been studied extensively. Among the early contributions to value theory in this connection are Kannai (1966), Riker and Shapley (1968), and Aumann and Shapley (1974). The subject has proliferated greatly, with well over a hundred contributions since 1974, including theoretical contributions as well as economic and political applications.

There are also games with infinitely many players in which all the players are atoms, namely games with a denumerable infinity of players. Again, values and voting games loom large in this literature. See, e.g., Shapley (1962), Artstein (1972) and Berbee (1981).

(vii) Cores of finite games and markets. Though the core was defined as an independent solution concept by Gillies and Shapley already in the early Fifties, it was not until the Sixties that a significant body of theory was developed around it. The major developments centre around conditions for the core to be non-empty; gradually it came to be realized that such conditions hold most naturally and fully when the game has an ‘economic’ rather than a ‘political’ flavour, when it may be thought of as arising from a market economy.

The landmark contributions in this area were the following: the Gale--Shapley 1962 paper on the core of a marriage market; the work of Bondareva (1963) and Shapley (1967) on the balancedness condition for the non-emptiness of the core of a TU game; Scarf’s 1967 work on balancedness in NTU games; the work of Shapley and Shubik (1969a) characterizing TU market games in terms of non-emptiness of the core; and subsequent work, mainly associated with the names of Billera and Bixby (1973), that extended the Shapley–Shubik condition to NTU games. Each of these contributions was truly seminal, in that it inspired a large body of subsequent work.

Gale and Shapley (1962) asked whether it is possible to match \( m \) women with \( m \) men so that there is no pair consisting of an unmatched woman and man who prefer each other to the partners with whom they were matched. The corresponding question for homosexuals has a negative answer; the preferences of four homosexuals may be such that no matter how they are paired off, there is always an unmatched pair of people who prefer each other to the person with whom they were matched. This is so, for example, if the preferences of \( a, b, \) and \( c \) are cyclic, whereas \( d \) is lowest in all the others’ scales. But for the heterosexual problem, Gale and Shapley showed that the answer is positive.

This may be stated by saying that the appropriately defined NTU coalitional game has a non-empty core. Gale and Shapley proved not only the non-emptiness but also provided a simple algorithm for finding a point in it.

This work has spawned a large literature on the cores of discrete market games. One fairly general recent result is Kaneko and Wooders (1982), but there are many others. A fascinating application to the assignment of interns to hospitals has been documented by Roth (1984). It turns out that American hospitals, after fifty years of turmoil, finally developed in 1950 a method of assignment that is precisely a point in the core.

We come now to general conditions for the core to be non-empty. Call a TU game \( v \) superadditive at a coalition \( U \) if \( \forall (U) \supset \sum_j v(S_j) \) for any partition of \( U \) into disjoint coalition \( S_j \).

This may be strengthened by allowing partitions of \( U \) into disjoint ‘part-time’ coalitions \( \Theta S \), interpreted as coalitions \( S \) operating during a proportion \( \Theta \) of the time \( 0 \supset \Theta \supset 1 \). Such a partition is therefore a family \( \{ \Theta_j S_j \} \), where the total amount of time that each player in \( U \) is employed is exactly 1; i.e., where \( \sum_j \Theta_j \chi S_j = \chi U \), where \( \chi S \) is the indicator function of \( S \). If we think of \( v(S) \) as the revenue that \( S \) can generate when operating full-time, then the part-time coalition \( \Theta S \) generates \( \Theta v(S) \). Superadditivity at \( U \) for part-time coalitions thus means that
\[ \sum_{j} \theta_{j} \delta_{j} = x_{U} \text{ implies } \nu(U) \geq \sum_{j} \theta_{j} \nu(S_{j}) \]

A TU game \( \nu \) obeying this condition for \( U = I \) is called balanced; for all \( U \), totally balanced.

Intuitively, it is obvious that a game with a non-empty core must be superadditive at \( I \); and once we have the notion of part-time coalitions, it is only slightly less obvious that it must be balanced. The converse was established (independently) by Bondareva (1963) and Shapley (1967). Thus a TU game has a non-empty core if and only if it is balanced.

The connection between the core and balancedness (generalized superadditivity) led to several lines of research. Scarf (1967) extended the notion of balancedness to NTU games, then showed that every balanced NTU game has a non-empty core. Unlike the Bondareva–Shapley proof, which is based on linear programming methods, Scarf’s proof was more closely related to fixed-point ideas. Eventually, Scarf realized that his methods could be used actually to prove Brouwer’s fixed-point theorem, and moreover, to develop effective algorithms for approximating fixed points.

For the NTU case, characterizations of market games have been obtained by Billera and Bixby (1973), Mas-Colell (1975), and others.

Though the subject of this section is finite markets, it is nevertheless worthwhile to relate the results to non-atomic games (where the players constitute a non-atomic continuum, an ‘ocean’). The total balancedness condition then takes on a particularly simple form. Suppose, for simplicity, that \( \nu \) is a function of finitely many measures, i.e., \( \nu(S) = f(\mu(S)) \), where \( \mu = (\mu_{1}, \ldots, \mu_{n}) \), and the \( \mu_{j} \) are non-atomic measures. Then \( \nu \) is a market game iff \( f \) is concave and 1-homogeneous \( (f(\theta x) = \theta f(x)) \) when \( \theta \geq 0 \). This is equivalent to saying that \( \nu \) is superadditive (at all coalitions), and \( f \) is 1-homogeneous (Aumann and Shapley, 1974).

Perhaps the most remarkable expression of the connection between superadditivity and the core has been obtained by Wooders (1983). Consider coalitional games with a fixed finite number \( k \) of ‘types’ of players, the coalitional form being given by \( \nu(S) = f(\mu(S)) \), where \( \mu \) is the profile of type sizes in \( S \), i.e. it is a vector whose \( k \)-th coordinate represents the number of type \( i \) players in \( S \). (To specify the game, \( \mu(I) \) must also be specified.) Assume that \( f \) is superadditive, i.e. \( f(x + y) \geq f(x) + f(y) \) for all \( x \) and \( y \) with non-negative integer coordinates; this assures the superadditivity of \( \nu \). Moreover, assume that \( f \) obeys a ‘Lipschitz’ condition, namely that \( \| f(x) - f(y) \| / \| x - y \| \) is uniformly bounded for all \( x \neq y \), where \( \| x \| = \max_{i} |x_{i}| \). Then for each \( \varepsilon > 0 \), when the number of players is sufficiently large, the \( \varepsilon \)-core is non-empty. (The \( \varepsilon \)-core is defined as the set of all outcomes \( x \) such that \( x(S) \geq \nu(S) - \varepsilon \| S \| \) for all \( S \).) Roughly, the result says that the core is ‘almost’ non-empty for sufficiently large games that are superadditive and obey the Lipschitz condition.

Intuitively, the superadditivity together with the Lipschitz condition yield ‘approximate’ 1-homogeneity, and in the presence of 1-homogeneity, superadditivity is equivalent to concavity. Thus \( f \) is approximately a 1-homogeneous concave function, so that we are back in a situation similar to that treated in the previous paragraph. What makes this result so remarkable is that other than the Lipschitz condition, the only substantive assumption is superadditivity.

Wooders (1983) also obtained a similar theorem for NTU; Wooders and Zame (1984) obtained a formulation that does away with the finite type assumption.

1970 - 1986

We do not yet have sufficient distance to see the developments of this period in proper perspective. Political and political economic models were studied in depth. Non-cooperative game theory was applied to a large variety of particular economic models, and this led to the study of important variants on the refinements of the equilibrium concept. Great strides were made in almost all the areas that had been initiated in previous decades, such as repeated games (both of complete and of incomplete information), stochastic games, value, core, nucleolus, bargaining theory, games with many players, and so on (many of these developments have been mentioned above). Game Theory was applied to biology, computer science, moral philosophy, cost allocation. New light was shed on old concepts such as randomized strategies.

Sociologically, the discipline proliferated greatly. Some 16 or 17 people participated in the first international workshop on game theory held in Jerusalem in 1965; the fourth one, held...
in Cornell in 1978, attracted close to 100, and the discipline is now too large to make such workshops useful. An international workshop in the relatively restricted area of repeated games, held in Jerusalem in 1985, attracted over 50 participants. The *International Journal of Game Theory* was founded in 1972; *Mathematics of Operations Research*, founded in 1975, was organized into three major ‘areas’, one of them Game Theory. Economic theory journals, such as the *Journal of Mathematical Economics*, the *Journal of Economic Theory*, *Econometrica*, and others devoted increasing proportions of their space to game theory. Important centres of research, in addition to the existing ones, sprang up in France, Holland, Japan, England, and India, and at many Universities in the United States.

Gradually, game theory also became less personal, less the exclusive concern of a small ‘in’ group whose members all know each other. For years, it had been a tradition in game theory to publish only a fraction of what one had found, and then only after great delays, and not always what is most important. Many results were passed on by word of mouth, or remained hidden in ill-circulated research memoranda. The ‘Folk Theorem’ to which we alluded above (1950–1960, iii) is an example. This tradition had both beneficial and deleterious effects. On the one hand, people did not rush into print with trivia, and the slow cooking of results improved their flavour. As a result, phenomena were sometimes rediscovered several times, which is perhaps not entirely bad, since you understand something best when you discover it yourself. On the other hand, it was difficult for outsiders to break in; non-publication caused less interest to be generated than would otherwise have been, and significantly impeded progress.

Be that as it may, those days are over. There are now hundreds of practitioners, they do not all know each other, and sometimes have never even heard of one another. It is no longer possible to communicate in the old way, and as a result, people are publishing more quickly. As in other disciplines, it is becoming difficult to keep abreast of the important developments. Game theory has matured.

(i) Applications to biology. A development of outstanding importance, whose implications are not yet fully appreciated, is the application of game theory to evolutionary biology. The high priest of this subject is John Maynard Smith (1982), a biologist whose concept of *evolutionarily stable strategy*, a variant of strategic equilibrium, caught the imagination both of biologists and of game theorists. On the game theoretic side, the theme was taken up by Reinhard Selten (1980, 1983) and his school; a conference on ‘Evolutionary theory in biology and economics’, organized by Selten in Bielefeld in 1985, was enormously successful in bringing field biologists together with theorists of games to discuss these issues. A typical paper was tit for tat in the great tit (Regelmann and Curio, 1986); using actual field observations, complete with photographs, it describes how the celebrated ‘tit for tat’ strategy in the repeated prisoners’ dilemma (Axelrod, 1984) accurately describes the behaviour of males and females of a rather common species of bird called the great tit, when protecting their young from predators.

It turns out that ordinary, utility maximizing rationality is much more easily observed in animals and even plants than it is in human beings. There are even situations where rats do significantly better than human beings. Consider, for example, the famous probability matching experiment, where the subject must predict the values of a sequence of i.i.d. random variables taking the values L and R with probabilities 3/4 and 1/4 respectively; each correct prediction is rewarded. It is of course optimal always to predict L; but human subjects tend to match the probabilities, i.e. to predict L about 3/4 of the time. On the other hand, while rats are not perfect (i.e. do not predict L all the time), they do predict L significantly better than human beings. Consider, for example, the famous probability matching experiment, where the subject must predict the values of a sequence of i.i.d. random variables taking the values L and R with probabilities 3/4 and 1/4 respectively; each correct prediction is rewarded. It is of course optimal always to predict L; but human subjects tend to match the probabilities, i.e. to predict L about 3/4 of the time. On the other hand, while rats are not perfect (i.e. do not predict L all the time), they do predict L significantly better than human beings.

Several explanations have been suggested. One is that in human experimentation, the subjects try subconsciously to ‘guess right’, i.e. to guess what the experimenter ‘wants’ them to do, rather than maximizing utility. Another is simply that the rats are more highly motivated. They are brought down to 80 per cent of their normal body weight, are literally starving; it is much more important for them to behave optimally than it is for human subjects.

Returning to theory, though the notion of strategic equilibrium seems on the face of it simple and natural enough, a careful examination of the definition leads to some doubts and questions as to why and under what conditions the players in a game might be expected to play a strategic equilibrium. See the entry on Nash equilibrium, refinements of.

Evolutionary theory suggests a simple rationale for strategic equilibrium, in which there is no conscious or overt decision making at all. For definiteness, we confine attention to two-person games, though the same ideas apply to the general case. We think of each of the two players as a whole species rather than an individual; reproduction is assumed asexual. The set of pure strategies of each player is interpreted as the locus of some gene (examples of a locus are eye colour, degree of aggressiveness, etc.); individual pure strategies are interpreted as alleles (blue or green or brown eyes, aggressive or timid behaviour, etc.). A given individual of each species possesses just one allele at the given locus; he interacts with precisely one individual in the other species, who also has just one allele at the locus of interest. The result of the interaction is a definite increment or decrement in the fitness of each of the two individuals, i.e. the number (or expected number) of his offspring; thus the payoff in the game is denominated in terms of fitness.

In these terms, a mixed strategy is a distribution of alleles throughout the population of the species (e.g., 40% aggressive, 60% timid). If each individual of each species is just as likely to meet any one individual of the other species as any other one, then the probability distribution of alleles that each individual faces is precisely given by the original mixed strategy. It then follows that a given pair of mixed strategies is a strategic equilibrium if and only if it represents a population equilibrium, i.e. a pair of distributions of characteristics (alleles) that does not tend to change.

Unfortunately, sexual reproduction screws up this story, and indeed the entire Maynard Smith approach has been criticized for this reason. But to be useful, the story does not have to be taken entirely literally. For example, it applies to evolution that is cultural rather than biological. In this approach, a ‘game’ is interpreted as a kind of confrontational situation (like shopping for a car) rather than a specific instance of such a situation; a ‘player’ is a role (‘buyer’ or ‘salesman’), not an individual human being; a pure strategy is a possible kind of behaviour in this role (‘hard sell’ or ‘soft sell’). Up to now this is indeed not very different from traditional game theoretic usage. What is different in the evolutionary interpretation is that pure or mixed strategic equilibria do not represent conscious rational choices of the players, but rather a population equilibrium which evolves as the result of how successful
(ii) Randomization as ignorance. In the traditional view of strategy randomization, the players use a randomizing device, such as a coin flip, to decide on their actions. This view has always had difficulties. Practically speaking, the idea that serious people would base important decisions on the flip of a coin is difficult to swallow. Conceptually, too, there are problems. The reason a player must randomize in equilibrium is only to keep others from deviating. For himself, randomizing is unnecessary; he will do as well by choosing any pure strategy that appears with positive probability in his equilibrium mixed strategy.

Of course, there is no problem if we adopt the evolutionary model described above in (i); mixed strategies appear as population distributions, and there is no explicit randomization at all. But what is one to make of randomization within the more usual paradigm of conscious, rational choice?

According to Savage (1954), randomness is not physical, but represents the ignorance of the decision maker. You associate a probability with every event about which you are ignorant, whether this event is a coin flip or a strategic choice by another player. The important thing in strategy randomization is that the other players be ignorant of what you are doing, and that they ascribe the appropriate probabilities to each of your pure strategies. It is not necessary for you actually to flip a coin.

The first to break away from the idea of explicit randomization was J. Harsanyi (1973). He showed that if the payoffs to each player in a game are subjected to small independent random perturbations, known to i but not to the other players, then the resulting game of incomplete information has pure strategy equilibria that correspond to the mixed strategy equilibria of the original game. In plain words, nobody really randomizes. The appearance of randomization is due to the payoffs not being exactly known to all; each player, who does know his own payoff exactly, has a unique optimal action against his estimate of what the others will do.

This reasoning may be taken one step further. Even without perturbed payoffs, the players simply do not know which strategies will be chosen by the other players. At an equilibrium of ‘matching pennies’, each player knows very well what he himself will do, but ascribes 1/2 – 1/2 probabilities to the other’s actions; he also knows that the other ascribes those probabilities to his own actions, though it is admittedly not quite obvious that this is necessarily the case. In the case of a general n-person game, the situation is essentially similar; the mixed strategies of i can always be understood as describing the uncertainty of players other than i about what i will do (Aumann, 1987).

(iii) Refinements of strategic equilibrium. In analysing specific economic models using the strategic equilibrium – an activity carried forward with great vigour since about 1975 – it was found that Nash's definition does not provide adequately for rational choices given one's information at each stage of an extensive game. Very roughly, the reason is that Nash’s definition ignores contingencies ‘off the equilibrium path’. To remedy this, various ‘refinements’ of strategic equilibrium have been defined, starting with Selten’s (1975) ‘trembling hand’ equilibrium. Please refer to our discussion of Zermelo's theorem (1930–1950, vi), and to Section IV of the entry on nash equilibrium, refinements of.

The interesting aspect of these refinements is that they use irrationality to arrive at a strong form of rationality. In one way or another, all of them work by assuming that irrationality cannot be ruled out, that the players ascribe irrationality to each other with a small probability. True rationality requires ‘noise’; it cannot grow in sterile ground, it cannot feed on itself only.

(iv) Bounded rationality. For a long time it has been felt that both game and economic theory assume too much rationality. For example the hundred-times repeated prisoner's dilemma has some $2^{2^{100}}$ pure strategies; all the books in the world are not large enough to write this number even once in decimal notation. There is no practical way in which all these strategies can be considered truly available to the players. On the face of it, this would seem to render statements about the equilibrium points of such games (1950–1960, iv) less compelling, since it is quite possible that if the sets of strategies were suitably restricted, the equilibria would change drastically.

For many years, little on the formal level was done about these problems. Recently the theory of automata has been used for formulations of bounded rationality in repeated games. Neyman (1985a) assumes that only strategies that are programmable on an automaton of exogenously fixed size can be considered ‘available’ to the players. He then shows that even when the size is very large, one obtains results that are qualitatively different from those when all strategies are permitted. Thus in the n-times repeated prisoner's dilemma, only the greedy-greedy outcome can occur in equilibrium; but if one restricts the players to using automata with as many as $e^{(n)}$ states, then for sufficiently large $n$, one can approximate in equilibrium any feasible individually rational outcome, and in particular the friendly–friendly outcome. For example, this is the case if the number of states is bounded by any fixed polynomial in $n$. In unpublished work, Neyman has generalized this result from the prisoner's dilemma to arbitrary games; specifically, he shows that a result similar to the Folk Theorem holds in any long finitely repeated game, when the automaton size is limited as above to subexponential.

Another approach has been used by Rubinstein (1986), with dramatically different results. In this work, the automaton itself is endogenous; all states of the automaton must actually be used on the equilibrium path. Applied to the prisoner's dilemma, this assumption leads to the conclusion that in equilibrium, one cannot get anywhere near the friendly–friendly outcome. Intuitively, the requirement that all states be used in equilibrium rules out strategies that punish deviations from equilibrium, and these are essential to the implicit enforcement mechanism that underlies the folk theorem. See the discussion at (1950–1960, iii) above.

(v) Distributed computing. In the previous subsection (iv) we discussed applications of computer science to game theory. There are also applications in the opposite direction; with the advent of distributed computing, game theory has become of interest in computer science. Different units of a distributed computing system are viewed as different players, who must communicate and coordinate. Breakdowns and failures of one unit are often modelled as malevolent, so as to get an idea as to how bad the worst case can be. From the point of view of computer tampering and crime, the model of the malevolent player is not merely a fiction; similar remarks hold for cryptography, where the system must be made proof against purposeful attempts to ‘break in’. Finally, multi-user systems come close to being games in the ordinary sense of the word.
(vi) Consistency is a remarkable property which, in one form or another, is common to just about all game-theoretic solution concepts. Let us be given a game, which for definiteness we denote $v$, though it may be NTU or even non-cooperative. Let $x$ be an outcome that 'solves' the game in some sense, like the value or nucleolus or a point in the core. Suppose now that some coalition $S$ wishes to view the situation as if the players outside $S$ get their components of $x$ so to speak exogenously, without participating in the play. That means that the players in $S$ are playing the 'reduced game' $v^S$, whose all-player set is $S$. It is not always easy to say just how $v^S$ should be defined, but let's leave that aside for the moment. Suppose we apply to $v^S$ the same solution concept that when applied to $v$ yields $x$. Then the consistency property is that $x|S$ (x restricted to $S$) is the resulting solution. For example, if $x$ is the nucleolus of $v$, then for each $v$, the restriction $x|S$ is the nucleolus of $v^S$.

Consistency implies that it is not too important how the player set is chosen. One can confine attention to a 'small world', and the outcome for the denizens of this world will be the same as if we had looked at them in a 'big world'. In a game theoretic context, consistency was first noticed by J. Harsanyi (1959) for the Nash solution to the $n$-person bargaining game. This is simply an NTU game $V$ in which the only significant coalitions are the single players and the all-player coalition, and the single players are normalized to get 0. The Nash solution, axiomatized by Harsanyi (1959), is the outcome $x$ that maximizes the product $x_1 x_2 \cdots x_n$. To explain the consistency condition, let us look at the case $n = 3$, in which case $V(\{1, 2, 3\})$ is a subset of 3-space. If we let $S = \{1, 2\}$, and if $x_0$ is the Nash solution, then 3 should get $x_0^3$. That means that 1 and 2 are confined to bargaining within that slice of $V(\{1, 2, 3\})$ that is determined by the plane $x^3 = x_0^3$. According to the Nash solution for the two-person case, they should maximize $x_1 x_2$ over this slice; it is not difficult to see that this maximum is attained at $(x_0^1, x_0^2)$, which is exactly what consistency requires.

Davis and Maschler (1965) proved that the kernel satisfies a consistency condition; so do the bargaining set, core, stable set, and nucleolus, using the same definition of the reduced game $v^S$ as for the kernel (Aumann and Drèze, 1974). Using a somewhat different definition of $v^S$, consistency can be established for the value (Hart and Mas-Colell, 1986). Note that strategic equilibria, too, are consistent; if the players outside $S$ play their equilibrium strategies, an equilibrium of the resulting game on $S$ is given by having the players in $S$ play the same strategies that they were playing in the equilibrium of the large game.

Consistency often plays a key role in axiomatizations. Strategic equilibrium is axiomatized by consistency, together with the requirement that in one-person maximization problems, the maximum be chosen. A remarkable axiomatization of the Nash solution to the bargaining problem (including the 2-person case discussed at 1950–1960, $v$), in which the key role is played by consistency, has been provided by T. Lensberg (1981). Axiomatizations in which consistency plays the key role have been provided for the nucleolus (Sobolev, 1975), core (Peleg, 1985, 1986), kernel (Peleg, 1986), and value (Hart and Mas-Colell, 1986). Consistency-like conditions have also been used in contexts that are not strictly game-theoretic, e.g. by Balinski and Young (1982), W. Thomson, J. Roemer, H. Moulin, H.P. Young and others.

In law, the consistency criterion goes back at least to the 2000-year old Babylonian Talmud (Aumann and Maschler, 1985). Though it is indeed a very natural condition, its huge scope is still somewhat startling.

(vii) The fascination of cost allocation is that it retains the formal structure of cooperative game theory in a totally different interpretation. The question is how to allocate joint costs among users. For example, the cost of a water supply or sewage disposal system serving several municipalities (e.g. Bogardi and Szidarovsky, 1976); the cost of telephone calls in an organization such as a university or corporation (Billera, Heath and Raanen, 1978); or the cost of an airport (Littlechild and Owen, 1973, 1976). In the airport case, for example, each 'player' is one landing of one airplane, and $v(S)$ is the cost of building and running an airport large enough to accommodate the set $S$ of landings. Note that $v(S)$ depends not only on the number of landings in $S$ but also on its composition; one would not charge the same for a landing of a 747 as for a Piper, for example because the 747 requires a longer runway. The allocation of cost would depend on the solution concept; for example, if we are using the Shapley value $\phi$, then the fee for each landing $i$ would be $\phi^i v$.

The axiomatic method is particularly attractive here, since in this application the axioms often have rather transparent meaning. Most frequently used has been the Shapley value, whose axiomatic characterization (see Shapley value) is particularly transparent (Billera and Heath, 1982).

The literature on the game theoretic approach to cost allocation is quite large, probably several hundred items, many of them in the accounting literature (e.g. Roth and Verrecchia, 1979).

Concluding remarks

(i) Ethics. While game theory does have intellectual ties to ethics, it is important to realize that in itself, it has no moral content, makes no moral recommendations, is ethically neutral. Strategic equilibrium does not tell us to maximize utility, it explores what happens when we do. The Shapley value does not recommend dividing payoff according to power, it simply measures the power. Game Theory is a tool for telling us where incentives will lead. History and experience teach us that if we want to achieve certain goals, including moral and ethical ones, we had better see to the incentive effects of what we are doing; and if we do not want people to usurp power for themselves, we had better build institutions that spread power as thinly and evenly as possible. Blaming game theory – or, for that matter, economic theory – for selfishness is like blaming bacteriology for disease. Game theory studies
(ii) **Mathematical methods.** We have had very little to say about mathematical methods in the foregoing, because we wished to stress the conceptual side. Worth noting, though, is that, mathematically, game theoretic results developed in one context often have important implications in completely different contexts. We have already mentioned the implications of two-person zero-sum theory for the theory of the core and for correlated equilibria (*1910–1930*, vii). The first proofs of the existence of competitive equilibrium (Arrow and Debreu, 1954) used the existence of strategic equilibrium in a generalized game (Debreu, 1952). Blackwell's 1956 theory of two-person zero-sum games with vector payoffs is of fundamental importance for n-person repeated games of complete information (Aumann, 1961) and for repeated games of incomplete information (e.g. Mertens, 1982; Hart, 1985b). The Lemke–Howson algorithm (1962) for finding equilibria of two-person non-zero sum non-cooperative games was seminal in the development of the algorithms of Scarf (1967, 1973) for finding points in the core and finding economic equilibria.

(iii) **Terminology.** Game theory has sometimes been plagued by haphazard, inappropriate terminology. Some workers, notably L.S. Shapley (1973b), have tried to introduce more appropriate terminology, and we have here followed their lead. What follows is a brief glossary to aid the reader in making the proper associations.

How should a coalition of cooperating players allocate payoffs to its members? This question arises in a broad range of situations and evokes an equally broad range of issues. For example, it raises technical issues in accounting, if the players are divisions of a corporation, but involves issues of social justice when the context is how people behave in society. Despite the breadth of possible applications, coalitional game theory offers a unified framework and solutions for addressing such quests. This article presents some of its major models and proposed solutions.

Geary was born on 11 April 1896 in Dublin, and died on 8 February 1983, also in Dublin. He was educated at University College, Dublin, from 1913 to 1918, and at the Sorbonne from 1919 to 1921. In 1922 he became assistant lecturer in mathematics at University College, Southampton. He held the post of statistician in the Department of Industry and Commerce in Dublin from 1923 to 1949. From 1946 to 1947 he was a Senior Research Fellow in the Department of Applied Economics in Cambridge. He held the position of First Director in the Central Statistical Office of Eire from 1949 to 1957. In 1957 he was appointed Head of the National Accounts Branch of the United Nations Statistical Office, which post he held until 1960. From 1960 to 1966 he was director of the newly founded Economic (and Social) Research Institute in Dublin, remaining attached to it as consultant from 1966 until his death. Geary was a mathematical statistician of international standing. His statistical writings cover a wide range of topics, among them testing for normality, the distribution of ratios, parameter estimation, and so on, some of which are relevant to econometric methodology. Indeed, much of his work has an explicitly economic content: he was probably responsible for the excellent report prepared by the Department of Industry and Commerce containing the first national accounts of Eire (Eire, Minister for Finance, 1946); he wrote many papers on the determination of relationships between variables, notably Geary (1948; 1949), in the second of which he uses instrumental variables; he derived the form of the utility function underlying the linear expenditure system (Geary, 1950–51); he was part-author of a monograph on linear programming applied to economics (Geary and McCarthy, 1964); and he built a model of the Irish economy based on an accounting framework (Geary, 1963–4). His published output numbers 112 titles, more than half of which appeared after his 65th birthday. A full bibliography is appended to Spencer (1976; 1983).

Joshua Gee's place in the history of economics rests on his contributions to the protectionist literature during the early decades of the 18th century. He collaborated with Henry Martin among others in publishing the *British Merchant* that argued the protectionist case in 1713 and 1714 against the Treaty of Commerce proposed at Utrecht, and he published an extensive discussion of England's foreign trade, together with strong protectionist sentiments, in *The Trade and Navigation of Great Britain Considered* in 1729. Addressing the current decline in the English export trades, the high level of imports of certain commodities, the demand for which, particularly in the case of French fashion goods, could be met by home produced import substitutes, the declining health of the woollen industry, and the currently widespread unemployment, Gee made a number of proposals for government regulation of trade and manufacturing. These proposals were directed principally to the need for ‘finding effectual ways for employing the poor’, thereby aligning his work with the widespread employment argument of the time. To the same end he advocated also a wider development of workhouses. Following Josiah Child, Gee proposed that trade with the colonial plantations should be regulated in such a way as not only to encourage their production of the materials needed for English manufacturing industries, thereby ‘employing all the poor’, but also to facilitate ‘supplying our plantations with everything they want and all manufactured within ourselves’.

Gee's descriptive essays exhibited an understanding of the interdependence of economic activities and processes, ‘one employment depending on another’, and of ‘the circulation of commerce that must infuse riches into every part’. He argued that higher domestic commodity prices would induce workers to increase their supply of labour, leading to higher incomes and also higher discretionary consumption expenditures. But such potentially important notions were not accorded any systematic or analytical
development.

gender differences (experimental evidence)

Catherine C. Eckel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Laboratory experiments find differences between women and men in three main areas: altruism, risk aversion and competition. The types of experiments and findings are described, and findings summarized. These results parallel similar findings in other social sciences, and are consistent with observed differences in the field.

Article

Henry Higgins famously enquires, ‘Why can't a woman be more like a man?’ While others might phrase it differently, the question of how and why women and men differ is the subject of hundreds of books and articles every year. Experimental economists have investigated gender differences in at least three areas: cooperation and altruism, attitudes toward risk, and preferences for engaging in competitive activities. While this research has proceeded largely independently of other social sciences, the results across fields are parallel.

Most experimental research on gender differences is motivated by an interest in the persistent gender gap in earnings, with women earning significantly less than men even after adjusting for productivity related differences in education, experience, choice of employment, and so on (Weichselbaumer and Winter-Ebmer, 2005). While this gender gap has diminished since the 1970s it has not disappeared. Attention is also directed at the fact that women are underrepresented in leadership positions. Within economics, the Committee on the Status of Women in the Economics Profession of the American Economic Association keeps tabs on the progress of women. Their most recent survey shows that
women continue to lag behind men in their progress towards higher academic ranks. While women earned 20 per cent of Ph.D.s in economics in the 1980s and 25 per cent in the 1990s, only 8.3 per cent of full professors in Ph.D. granting departments are women (see Committee on the Status of Women, 2007).

Differences in the behaviour of women and men are extensively documented in research in psychology and sociology. An overview of this work, which covers differences in ability, personality, leadership styles, aggression, competitiveness and so on, can be found in Rhoads (2004) and Maccoby (1998) among many others. Experiments have examined gender differences in situations involving salient monetary incentives since Rapoport and Chammah (1965), who explored variations of the Prisoner's Dilemma (PD) game. Early experimental work in psychology and sociology tended to involve this game, or related social dilemma (SD) games, with mixed results. In games with this incentive structure – where each player has a dominant strategy to free ride, but group payoffs are maximized by choosing a cooperative strategy – many studies have found that women are more cooperative, and many that they are less so.

Experimental research in economics focuses on examining the types of preferences that might be related to the gender gap: those that relate to cooperating, taking risks and competing. Compared to the stereotypical male person, the stereotypical female person is more altruistic and cooperative, and more averse to risk and competition. Partial surveys of research in experimental economics on gender differences are provided by Eckel and Grossman (2008a), which focuses on altruism and cooperation, and (2008b), which surveys studies of risk aversion, and a more comprehensive review is contained in Croson and Gneezy (2007).

Cooperation

If there is no systematic difference between the sexes in their play of PD and SD games, can we abandon this element of the stereotype and conclude that women are no more cooperative than men when money is at stake? Eckel and Grossman (1998) were the first to point out that these games confound two possible differences in the preferences of women and men. Suppose that, true to stereotype, women are both more altruistic and more risk averse. Altruistic preferences imply that women will be more likely to choose a cooperative strategy in PD and SD games. However, risk aversion implies just the opposite. The cooperative strategy is also the risky strategy; a cooperator risks being exploited, with corresponding low earnings. The best choice for an altruistic, risk-averse person would depend on the parameters of the game, that is, the trade-off between the gain to cooperation and the penalty if one is betrayed. Thus the games that have been most commonly used to measure cooperation may be confounded by risk aversion.

Eckel and Grossman's (1998) strategy was to separate altruism from risk aversion. In a double-anonymous dictator game, where there is no financial (or social) risk, they report that women give about twice as much to an anonymous partner. This result has not always been replicated by subsequent studies, and behaviour can vary with the characteristics of the recipients when they are known, but overall it is rare to find a situation where men are more altruistic. In more complex experiments (Andreoni and Vesterlund, 2001; Dickinson and Tiefenthaler, 2002), subjects make a series of dictator decisions in tokens, where the tokens have different exchange rates for each of the players. In these games men tend to maximize efficiency, allocating more to the partner with the better exchange rate,
while women tend to try to equalize earnings. Thus men appear more altruistic at exchange rates that benefit the recipient. At equal exchange rates, women give more than men. Moreover, in studies where subjects can give to a charitable organization, Eckel and Grossman consistently find that women give more than men (for example, Eckel and Grossman, 2003).

Another experimental environment that has received a great deal of attention is the ultimatum game, which suffers from a similar problem. In that game, a person might make a generous offer because of altruism or because of risk aversion; similarly, a person might accept a low offer for multiple reasons. The greater altruism and risk aversion attributed to women implies more generous ultimatum offers by women. However, results in this game are mixed (Eckel and Grossman, 2001; Solnick, 2001). Women and men make similar offers on average, but, more importantly, both make lower offers to women than to men, suggesting a commonly held belief that women will accept lower offers (because they are more altruistic?). On the respondent side, the results of these two studies are contradictory. In general, however, results indicate that women are more likely to accept an offer of a given size than the reverse. A higher degree of altruism is consistent with lower wages, with more altruistic persons both requesting and accepting lower wage offers. It is worth pointing out that (to my knowledge) no studies have tested the external validity of these measures of altruism; that is, economists have little or no knowledge of how well laboratory-elicited preferences ‘predict’ how people behave as they go about their daily lives. While lab decisions are real in the sense that there are resource consequences to decisions, the context is very different from field decisions. However, there are several studies that explicitly examine cultural context, and find a positive relationship between how groups play a public goods game and how they harvest natural resources (Carpenter and Seki, 2006). There is also some evidence that the gender gap in earnings is smaller in the nonprofit sector, where altruistic preferences might be especially valuable (Leete, 2000).

Risk aversion

Like cooperation, gender differences in risk aversion have been much studied in fields outside economics. In most situations, greater risk taking by men is well documented (Byrnes, Miller and Schafer, 1999). Economists have a rather narrow way of thinking about risk aversion compared with other social scientists; we view preferences as represented by a utility function that evaluates alternatives across all decision-making domains. Diminishing marginal utility of income or wealth produces risk aversion: the expected value of a gamble always has higher utility than the gamble itself. (Of course constant marginal utility implies risk neutrality, and increasing marginal utility risk seeking.) This view of risk aversion implies that any task that measures the curvature of the utility function in money should give a good measure of risk attitudes that is then applicable across all situations. Experimental economists have developed different games that do just that.

Like their counterparts in the other social sciences, economists tend to find women more risk averse than men, though both are surprisingly risk averse considering the level of stakes in our games. Though the difference is not always statistically significant, it is rare that it goes the other way. However, there is a potential problem with commonly used measures that might distort the gender difference. The experiments tend to be complicated, requiring a relatively high level of mathematical ability to be clearly understood. This is not a big problem if any resulting ‘noise’ does not bias the measure.
Unfortunately, there is some indication that difficult tasks cause low-ability subjects to make systematically different choices. To the extent that mathematical ability is correlated with gender, this could bias inferences about differences in risk aversion.

A popular initial experiment used a risky version of the Becker, DeGroot and Marschak (1964) (BDM) preference elicitation procedure. This mechanism elicits subjects' valuations for gambles with various probabilities of winning a particular prize. To make it incentive compatible, this mechanism requires two stages. In the first the subject writes down a minimum selling price for a gamble that pays off X dollars with probability p. In the second a random price is drawn from a uniform distribution between 0 and X dollars. If the drawn price is above the elicited price, the subject sells the gamble, and if not the subject plays the gamble. This mechanism has been criticized for its complexity, and for the low incentive for accuracy with low-probability gambles. Subjects with low maths ability may be more likely to overvalue these low probability gambles because they are confused by the second stage of the game. For example, consider a 0.05 probability of winning 10 dollars; any value drawn in the second stage is likely to be far above the expected value of the gamble, so it may not be worthwhile for the subject to bother calculating his reservation value, and he is likely to err on the high side. This would tend to make subjects look less risk averse. Indeed, BDM studies tend to find fewer risk-averse and more risk-seeking subjects.

A cleverly designed game developed by Holt and Laury (2002) has subjects choose between pairs of lotteries that are constructed so as to easily ‘back out’ a coefficient of relative risk aversion for a specified utility functional form. This game is easily comprehended by college students, and produces intuitively appealing results in educated populations (Andersen et al., 2006). However, there is some evidence it is less successful for less literate populations, limiting its usefulness in the field (Dave et al., 2007). Like the BDM procedure, failure to account for differences in mathematical ability may distort estimates of gender differences.

A third type of game involves fewer choices among simpler, 50/50 gambles (Binswanger, 1980; Eckel and Grossman, 2002). A subject chooses her favourite from among a set of 50–50 gambles that vary in risk and expected return. The experiment allows categorization of subjects into ordered categories, from most to least risk averse. There is some evidence that this experiment is easier to comprehend for populations with low mathematical literacy, although the trade-off is that the measure is coarser than the others described above. One troubling result even for educated groups is that different measures of risk aversion completed by the same set of people tend to exhibit low correlations across measures, suggesting that our underlying construct may need some work.

The experiments above all involve individual decisions. Additional indirect evidence of risk aversion can be found in a market environment. Women are more likely than men to overbid in first-price auctions, behaviour that can be caused by risk aversion. Chen, Katuscak and Ozdenoren (2005) find that women tend to overbid, but women's bids are most like men's when oestrogen levels are lowest, suggesting a biological mechanism driving greater risk aversion.

Gender differences are typically, but not always, found across all experiments designed to measure risk aversion. Women are more risk averse across environments. Several studies have begun to examine external validity of the measures. In general, lab measures of risk attitudes have low (though sometimes statistically significant) correlations with decisions in other lab experiments, and low correlations with risky field behaviours, such as buying an extended warranty for an automobile or computer (Moore, 2002). Risk attitudes also are related to a person's willingness to borrow to finance higher education
gender differences (experimental evidence) : The New Palgrave Dictionary of Economics

expenditure (Eckel et al., 2007). Many current studies will further examine external validity of experimental preference measures. As with altruism, to my knowledge, no study has related experimental risk measures to employment earnings. However, field studies tend to confirm gender stereotypes, with women investing in more conservative portfolios (Sunden and Surette, 1998), more likely to buy warranties (Moore, 2002), and more likely to negotiate contracts with larger salary components and smaller performance-related components (Chauvin and Ash, 1994). The outstanding question is whether experimentalists can measure risk attitudes in experimental games in a way that meaningfully predicts risky choices in field and, in particular, employment settings.

Competition

Women do not like competition. Psychologists have long known that girls are less competitive than boys, that they play different games and avoid competitive situations. For example, Maccoby (1998) quotes many such studies, including one showing that, in same-sex groups of fourth and sixth graders, boys spontaneously engaged in competitive activities 50 per cent of the time, while girls engaged in such play only one per cent of the time (1998, p. 39). Men do not merely like competition, they also do better when a situation is more competitive. Rhoads (2004) surveys work in this area and gives dozens of examples. Some authors have used these differences to argue that women are inherently ill-suited to the workplace (Browne, 2002), and others that women have an advantage because competition does not get in the way of making the best decisions (Helgesen, 1990). The taste for competition is no doubt related to men's higher levels of confidence; overconfidence can also interfere with profit-maximization, as Barber and Odean (2001) show in a study of online stock trading.

Experimental economists have discovered this, too: Gneezy, Niederle and Ructichini (2003) show in a lab experiment that introducing competition makes men, but not women, more productive in solving mazes. The study compares work performance under two types of compensation: piece rates, where workers are paid by the maze, and winner-take all, tournament rate, where only the highest producer is paid. Women work about the same under the two schemes, while men work significantly harder for the tournament payment. This result spurred two additional studies where women and men choose their preferred compensation rate. In the first, Gupta, Poulsen and Villeval (2005) again use mazes and find that 60 per cent of men and 34 per cent of women choose the tournament rate. Niederle and Vesterlund (2007) are careful to choose a task where women and men perform the same under piece and tournament rates – solving easy maths problems. Here again, men are more likely to choose the tournament (73 per cent compared to 35 per cent). This effect remains after controlling for subjects' measured ability as well as their own perceptions of their abilities; thus the result is not due to overconfidence. Men sacrifice earnings in this game because low-ability men choose the tournament, but women lose more and so earn less than men because high-ability women shy away from the tournament.

If women avoid competition, this, too, may have consequences for earnings. If a preference to avoid competition transfers from the lab to the field, then it is likely to affect the earnings of women. As with cooperation and risk, more study is needed to verify the external validity of the lab-based measures of aversion to competition.
Conclusion

Laboratory experiments show a collection of preferences that differ, on average, between the sexes. Women tend to be more altruistic, risk averse, and competition averse. This pattern of preferences could lead to patterns of behaviour that result in lower wages for women, such as accepting low offers or avoiding competitive situations. For example, Babcock and Laschever (2003) find that lower average starting salaries for women public policy graduates are the result of differences in the way men and women treat job offers. Women tend to accept the best offer they receive from potential employers; men, by contrast, respond to an offer by asking for more. This behaviour seems very much like that observed in the lab, and suggests that altruism, risk aversion, and competition aversion may play a role in explaining this.

The results of economics lab experiments are largely consistent with research from the other social sciences, and psychology in particular. Economics experiments are conducted in settings where payoffs are salient, and where there is no deception. This work has not only confirmed but also legitimized research on gender differences for economists. The importance of the work is to show that individual differences in preferences, whether by nature or nurture, can be substantial, and are correlated with observable characteristics of individuals. Decision-making in the workplace occurs in a much more complex environment, making it difficult or impossible to sort out the effects of the various dimensions of preferences. However, lab experiments allow a much higher degree of control over the environment so that variability in specific aspects of preferences can be isolated.

gender roles and division of labour

Joyce P. Jacobsen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

All human societies exhibit some degree of division of labour by gender. These divisions continue to exist as participation in paid work has increased over time. Gender divisions occur between household tasks, between unpaid and paid work, and within paid work. Economists have explained these divisions through reliance on essentialist arguments and/or the fundamental economic concepts of efficiency of specialization and division of labour, and investment in human capital. However, gender discrimination can also cause division of labour, and the feedback effects of such discrimination make it difficult to untangle the causes of the gender division of labour.

Article

All human societies have a gender-related division of labour, although the particulars of division vary across time and culture. It is generally agreed to be a pre-capitalist phenomenon, based on anthropological and historical information, and related to the widespread existence of patriarchy, that is, male-controlled and male-favouring social systems. Let us start by considering the arguments for why there would be gender-related task specialization in a non-market setting, that is, in a pre-capitalist society.

Gender roles and task specialization
Most of the arguments posited for why a gender-related division of labour exists have been essentialist. The general analytical approach has been to posit a specific biological sex-related difference and then show that it leads to gender task specialization. The factor can be a sex difference in ability, including in some models the ability to develop or learn particular types of skills – and thus specialization leads to efficiency in production. Or the determining factor can be a sex difference in preference or taste – and thus specialization leads directly to utility maximization. In the first category, analysts have posited differences in childbirth and child-raising abilities, fecundity, physical strength, aggression/dominance/coalition-building/risk-taking, or cognitive differences (Fausto-Sterling, 1985; Duley, Sinclair and Edwards, 1986; Becker, 1991; Siow, 1998). Gender differences in ability need not imply unbiased gains for both sexes. Indeed, if patriarchy arises because of one or more of these differences, then it is also plausible that the gender division of labour favours men, or at least some men. In the second category, analysts have posited such factors as sex differences in preferences for spouse's age (Elul, Silva-Reus and Volij, 2002), differences in caring for children and others (Folbre, 1995), and different preferences for meaningful work and other job characteristics over money (Brown and Corcoran, 1997).

A smaller set of analysts has presented non-essentialist arguments, where the general approach has been to posit that a division of labour is efficient and that some specialized human capital must be acquired initially in order to improve efficiency further; in addition, human capital in the form of specialized experience can be developed through continued application to the specific task. Therefore, in order to maximize output, societies should train some people to do one type of task, and others to do something different, and leave them in those roles for extended periods of time. Formal models of this type then link the labour market with the marriage market to consider the coordination problem and societal output maximization in arguing why it is important that people of one type, for example, sex, be assigned to one sort of task (Hadfield, 1999; Engineer and Welling, 1999; Baker and Jacobsen, 2006). If some types of output can be produced and traded only with the household, then it is important to match people of different types within marriages. Thus men should do one type of task and women another to reduce the coordination problem. The dilemma for these models is to explain why particular tasks are assigned to men and others assigned to women, particularly if some tasks are preferable on some dimension (for example, they have higher prestige or portability) and also tend empirically to be assigned to men. Thus these models often have to fall back on an essentialist starting point in order to determine initial assignment. They can then argue that societal dynamics in determining future gender assignments are affected by the initial assignment and by technological change.

The non-essentialist arguments do a better job than the essentialist arguments of explaining why societies have prescribed gender roles rather than allowing for flexibility of task assignment based on actual individual abilities. A strong essentialist argument would broach no conflict between biological sex and gender roles, yet we see deviations from gender roles by individuals, weakening the essentialist argument. Thus essentialists need a more nuanced approach in which biological sex (whether chromosomal or hormonal) leads to different probabilities of particular outcomes, or different distributions of traits. Then an argument based on efficiency of division of labour, along with the need to make specialized human capital investments early on in children's lives (Becker, 1991), leads society to assign gender roles based on average or modal outcomes by sex.

The question then arises of how to deal with deviations from gender roles. People can generally articulate gender norms, that is, roles that are considered sex-appropriate, and know when they or others...
are violating them. Gender roles can relate also to age, and also may have caste or class or racial/ethnic aspects, so tasks may be assigned differentially based on these other dimensions, too. Societies deal with deviations in different ways, including complete proscription; allowing people to change later on at an efficiency loss; allowing for exceptions only if people show particular deviant traits early on; and laissez-faire. Akerlof and Kranton (2000) posit that gender identity appears in the utility function and that deviations from sex-appropriate gender identity cause utility loss for individuals. Badgett and Folbre (2003) discuss the potential penalty that one may face in the marriage market for being in a gender-non-conforming occupation. Changes in social norms regarding the social construction of sexuality may have had some effect in reducing these losses (Matthaei, 1995). Deviation tends to appear only within a dualist system; indeed, the prominence of gender duality in most, but not all, cultures is notable. In cultures with a third gender role, such persons either are assigned to specific reserved occupations or must conform to the cross-gender role if sex is not aligned with gender (Jacobsen, 2006).

Gender division of labour between non-market and market work

With the development of markets for paid labour, division additionally occurs between unpaid (non-market) and paid (market) work. It is a general observation across societies that women are more likely to specialize in non-market work and men in market work, or women to divide time between non-market and market work, and men to specialize in market work. As a first step in explaining this pattern, the neoclassical approach posits that division of labour is efficient. The household is considered the nexus for production and consumption of non-market commodities. Thus division of labour within the household occurs, with some members specializing in market work, others in non-market work. In models of the modern household, children are generally treated as consumption goods, or sometimes as investments, when previously they were thought of as additional suppliers of market or non-market labour. In order to motivate the particular gender division of labour, writers fall back generally on one or more essentialist arguments for why women do non-market work, in particular the relation to bearing and raising children. If the division of labour between non-market and market falls along gender lines, the marriage market may then be conceptualized as the market for non-market, or spousal, labour (Grossbard-Shechtman, 1993).

While the argument that specialization and division of labour is more efficient might hold in a static framework, it is not obvious that this is necessarily optimal in a dynamic framework, at least not for both parties. Specialization in non-market labour is the less desirable specialty as it limits the market for one's services by definition; indeed, if there is no marriage, there is no market for one's services at all. Thus models have explicitly linked the household division of labour to the operation of the marriage market, whether these concerns are taken into account in settling on a division of output before entering into marriage (Lundberg and Pollak, 1994) or within marriages through ongoing negotiation over distribution of the household's product.

It is also problematic to argue that specialization decisions are made solely on the basis of relative productivity. If there is discrimination in the labour market such that women are paid below their actual marginal product, then women's comparative advantage is more likely to lie in household work. Lower wages can also lead to intermittent labour force attachment, which leads back to lower wages (Gronau, 1988). Becker (1991) argues that effort as well as time must be allocated across types of labour; if
women expend more effort on household work, then they have less effort to exert on market work, thus receiving lower wages. Also, if women train to do household work, whether or not they have a greater aptitude for it, then they are more likely to have comparative advantage in household work (and the opposite for men and market work). Thus the efficiency arguments can be self-fulfilling.

One way to attempt to untangle these feedback mechanisms is to see what happens when society experiences changes through technology, political upheaval, or other factors. But the processes of political and economic change have had mixed effects on the gender division of labour, even as they have had large effects in changing the nature of work and the mix between household and market work. Some hold the view that capitalism accentuates the gender division of labour through accentuating the division between household and market work, while others think capitalism is useful in reducing the gender division of labour. Some argue that patriarchy and capitalism are mutually reinforcing (Hartmann, 1976; Humphries, 1991) and that socialism needs to include the overturning of both systems (Engels, 1884) including reassignment or eradication of patriarchy-enforcing property rights (Braunstein and Folbre, 2001). Cases of transition from capitalism to socialism – and for some countries back again – have provided mixed evidence; in practice, socialism appears to have increased women's total work time, increasing their paid work without decreasing their unpaid work (Jacobsen, 2006).

In practice, most people in modern societies do both paid and unpaid work, whether in a given time period or across the life cycle. Technological change affects gender work assignments over time whenever it is non-neutral with respect to initially gendered task assignments. It appears that the particular form in which technological change has occurred has made capital complementary to women's market work (Galor and Weil, 1996) and substitutable for women's non-market work (Greenwood, Seshadri and Yorukoglu, 2005). Real wages have been rising for women over the past century. The net effect has been to reduce women's time spent in non-market work and to increase their time spent in market work.

**Gender segregation in market work**

Even as paid labour has become more extensive and women have increasingly participated in paid work, extensive gender segregation persists across time and space in labour markets (Anker, 1998; Jacobsen, 2006). Market work for women often still emulates their areas of traditional female-dominated non-market work, such as child care and teaching of young children, nursing and eldercare, and food preparation and service. Men still dominate the occupations that have required more physical strength, and in industrialized societies are more likely to work in outdoor occupations. What is harder to explain along essentialist or traditionalist lines is why there would be gender segregation for other types of occupations that have arisen later in economic development, such as various types of professions. Economists have advanced various explanations for occupational gender segregation. Again, many rely on essentialist arguments regarding differences in abilities and/or preferences to explain why women and men would choose different paid work. One approach is to argue that some jobs are more compatible with non-market duties. Thus, if women are doing most of the non-market work (which begs the question of why they are doing it), they must choose jobs that allow for this balance, including those that allow for part-time work. A dynamic version of this argument is that women know they will be balancing paid work with non-market work, particularly during their childbearing years, and thus choose
occupations that are potentially more compatible with this lower level of attachment to paid work. Notably, even in occupations where women have increased their representation substantially, there is within-occupation gender segregation along various lines, including sub-specialties, firm size, employer type (for-profit, non-profit, government), and so on. These patterns appear in many cases to be consistent with an argument that women prefer more flexible employment, that is, jobs that require less travel and less overtime work, and allow for part-time and/or flexible hours.

To switch from a supply-side to a demand-side focus, other economists have argued that gender segregation is driven by employers' choosing whom to hire, not by employees' choosing where to work. Re Becker (1971), employers may get utility directly from discriminating or simply from maintaining social norms. Employer discrimination can occur if there is insufficient competition from non-discriminating employers to drive out discriminating employers. Segregation can occur without loss of profits in Becker's employee and customer discrimination models. Male-dominated unions and other professional organizations can keep women out of particular occupations by denying them training (Fawcett, 1892). Statistical discrimination is another potential explanation of gender segregation, with the usual chicken-and-egg problem: employers don't see women doing the non-traditional task, so cannot tell whether women are good at it (Lundberg and Startz, 1983). Some have also called into question the implicit assumption of exogeneity of gender-linked preferences if pre-labour market treatment of girls and boys is different (Corcoran and Courant, 1987).

There is interesting evidence regarding the instability of gender integration from studying workers like clerks, bank tellers, and schoolteachers, whose occupations have tipped from being male-dominated to female-dominated, thus re-segregating quite rapidly (Reskin and Roos, 1990). In addition, jobs can vary in their gender assignment from society to society (Jacobsen, 2006). Thus the maintenance of gender segregation in and of itself appears to be even more fundamental than essentialist arguments regarding differential ability and/or job preferences can explain.

A notable pattern is that female-dominated jobs tend to pay less, even to the men in them, than do ‘comparable’ male-dominated jobs. Thus occupational segregation is linked with lower pay for women. This relationship could arise through various mechanisms. If women are crowded into a smaller set of occupations through hiring discrimination, crowding will lead to lower pay for women if labour demand does not adjust across occupations. If women are willing to trade off pay for working conditions, crowding into the more desirable occupations means lower pay by choice. However, reducing occupational segregation is neither necessary nor sufficient to raise pay for women; some countries (such as Sweden and Australia) with higher relative earnings for women also exhibit greater occupational segregation than countries with lower relative earnings for women (such as Japan and the United States) (Jacobsen, 2006).

Policies affecting the gender division of labour

In post-industrial societies, many public and business policies affect the gender division of labour and occupational segregation. Any policy affecting the net wage rate, including taxes on earnings, the deducibility of childcare expenses, or means-tested government benefits, affects the market work-non-market work–leisure trade-off. In general, the asymmetry between taxable income and non-taxable household production produces a bias towards household production. The net effect on behaviour of the
large number of relevant policies is unclear. Few policies have directly aimed at reducing occupational segregation. Affirmative action has had much more notable effects on racial employment than on gender employment patterns. Educational access policies, such as the opening of college and postgraduate programmes to women, have been more important, particularly for increasing women's participation in the professions. However, the focus on access to formal education has not encouraged women to enter those jobs traditionally learned through apprenticeships, such as the crafts and trades; these areas continue to be among the most male-dominated of occupations. Meanwhile, few policies have encouraged men to enter female-dominated occupations such as nursing and childcare, even as shortages of caring labour appear.

Lack of explicit gender-desegregation public policy reflects the continued ambivalence in society regarding the desirability of gender desegregation. This stands in notable contrast to stated beliefs regarding racial desegregation, where separatism has become increasingly spurned. Gender segregation occurs in other social spaces such as sports and schooling. Most amateur sports teams continue to be gender-segregated even as US Title IX legislation and similar actions in other countries increases access to sports for high school and college women. Single-sex schooling persists in a wide range of societies and is even encouraged up through high school, although colleges are mainly co-educational except in the most gender-segregated societies such as Saudi Arabia. This segregation is often couched in terms of improving women's (and sometimes men's) outcomes (that is, through arguing that women perform better in single-sex systems), yet still constitutes an argument for separate spheres. In addition, ambivalence continues towards men raising children, the desirability of outsourced childcare, and thus the desirability of mothers working full-time. Economists and other social scientists have performed a useful service in documenting the extent and nature of gender segregation, but have not yet led a full public debate as to its desirability.

general equilibrium (new developments)

Abstract

General equilibrium theory is the theory of mass markets. The foundations of general equilibrium theory were laid in the late 19th and early 20th centuries by Walras and Edgeworth. The modern formulation was conceived in the 1950s by Arrow, Debreu and McKenzie, who also established the fundamental results: existence of competitive equilibrium, Pareto optimality of equilibrium allocations (the First Welfare Theorem), and supportability of Pareto optimal allocations as equilibria with transfers (the Second Welfare Theorem). The ideas of general equilibrium theory are widely used in models of markets of all kinds, including in finance, international trade and macroeconomics.

Article

The fundamental ideas, results and applications of general equilibrium theory are well described in general equilibrium, which was originally written for the first (1987) edition of The New Palgrave. However, there has been a great deal of notable work since – too much to adequately survey in the limited space available here. The discussion addresses only a few topics on which research has been
especially active:

- determinacy of equilibrium
- perfect competition and justification of the assumption of price-taking
- equilibration
- infinitely many commodities
- incomplete markets
- hidden information and hidden actions.

Determinacy

For many purposes, it is not enough to know simply that competitive equilibrium exists; we would like to know how equilibrium varies when the underlying parameters of the model vary. Such comparative statics analysis is simplest and most convincing when equilibrium is unique and depends nicely on the underlying parameters. However, it has been known for a long time that even some very simple economies admit multiple equilibria and that conditions on the primitives of an economy that guarantee uniqueness of equilibrium must necessarily be unpleasantly strong. For many purposes, however, it is enough to know that equilibria are locally unique, and locally depend nicely on underlying parameters.

Competitive equilibrium prices are the solutions of the system of equations asserting, for each good, that demand equals supply (equivalently, that aggregate excess demand is zero). In an economy with $L$ consumption goods, this is a system of $L$ equations with $L$ unknowns; taking account of the price normalization and Walras's Law (aggregate expenditure equals aggregate income), this reduces to a system of $L-1$ equations in $L-1$ unknowns. Because the number of equations equals the number of unknowns, heuristic considerations (linear approximations, for example) suggest that local uniqueness might not be too much to hope for. However, local uniqueness does not always obtain: it is easy to exhibit simple Edgeworth box (two persons, two goods) exchange economies for which the set of equilibrium prices is a continuum.

Debreu (1970; 1972) showed that, if preferences are sufficiently smooth and indifference surfaces are not flat and do not intersect the boundary (for example, if preferences arise from utility functions that are twice continuously differentiable and differentiably strictly concave, and exhibit infinite marginal utility for consumption at zero levels of consumption), then almost all specifications of initial endowments lead to a finite number of equilibria, and those equilibria depend locally smoothly on endowments. Debreu's method was to first use the assumptions on preferences to show that the aggregate excess demand mapping is continuously differentiable, then to rely on Sard's theorem (which guarantees that for almost every $y \in Y$ every point in the inverse image $f^{-1}(y)$ is regular), and finally to appeal to the implicit function theorem.

Two limitations of Debreu's analysis are of particular note. The first is the assumption that indifference surfaces do not intersect the boundary. An implication of this assumption is that, at equilibrium, every agent consumes every commodity. This certainly seems false-to-fact, and this assumption would be objectionable in many applied models. Boundary consumptions create problems because they lead (almost necessarily) to an aggregate excess demand function that is not differentiable. Shannon (1994) extends Debreu's results, obtaining generic determinacy while accommodating boundary consumptions,
by showing that the aggregate excess demand function, although not differentiable, is Lipschitz (that is, \( |f(x) - f(y)| \leq C |x - y| \) for some constant \( C \)) and that the required implications of smooth analysis remain valid for Lipschitz functions. Blume and Zame (1993) follow a different approach, based on real algebraic geometry and particularly useful for applied models, treating only utility functions that are sufficiently smooth (roughly, piecewise real-analytic), but accommodating both boundary consumptions and utility functions that are not strictly concave.

A second, more subtle, limitation of Debreu's analysis is that the set of boundary endowments is of measure zero. Hence, saying that 'almost all specifications of initial endowments lead to a finite number of equilibria' says nothing at all about an environment in which some agents are not endowed with strictly positive amounts of all commodities. If it is true that most economic agents do not consume all goods, it is even more true that most economic agents are endowed with only a few goods – perhaps even with their own labour and nothing else. A more satisfactory specification would allow for the possibility that some agents' endowments of some goods are constrained to be zero, and to ask for determinacy for generic specifications of other goods. Surprisingly, Minehart (1997) finds that such specifications are compatible with robust indeterminacy. Mas-Colell (1985) and Anderson and Zame (2001) show that generic determinacy is restored if we interpret genericity in the sense of preferences (or utility functions) as well as endowments.

For economies with an infinite dimensional space of commodities, Debreu's arguments are typically inapplicable because the commodity space and the price space are different and demand functions are almost never continuously differentiable (Araujo, 1987). However, the same outline can be applied, not to the aggregate excess demand mapping, but to the aggregate excess spending mapping. (Given a vector \( \lambda = (\lambda_i) \) of utility weights for the agents, find the (unique) allocation \( (x_i) \) that maximizes the weighted sum \( \sum \lambda_i u_i(x_i) \) of agent utilities and the price \( p \) that supports this allocation. The value of the excess spending map \( S \) at weights \( \lambda \) is the vector \( S(\lambda) = (p \cdot x_i - p \cdot e_i) \). The price \( p \) and allocation \( (x_i) \) constitute a competitive equilibrium if \( S(\lambda) = 0 \).) Under the assumptions that utility is separable (across time or across states of the world) and that the underlying felicity functions satisfy Debreu's assumptions (at each date or in each state of the world), Kehoe and Levine (1985) show that the excess spending map is smooth and hence that equilibria are generically finite in number and depend nicely on parameters. In the general case, Shannon (1999) and Shannon and Zame (2002) identify conditions on utility functions implying that the excess spending map is Lipschitz; an application of Lipschitz analysis again yields generic determinacy.

**Perfect competition and price-taking**

The definition of competitive equilibrium rests on the assumption of perfect competition; that is, that agents are price-takers. This assumption is clearly untenable if some agents are large, in the sense of controlling resources that are a significant fraction of the social total (although competitive equilibrium may serve as a useful benchmark even in such environments). A large and important literature attempts to understand when the assumption of price-taking behaviour is sensible.

One of the central themes in this literature seeks to justify price-taking behaviour by showing that cooperative outcomes are competitive – or almost competitive – when the population is large and agents...
are small. The largest portion of this literature is inspired by Edgeworth, who gave an informal argument that, for economies with two commodities and two consumers, replication shrinks the core of the economy (the set of feasible allocations on which no coalition can improve using only its own resources) to the set of competitive allocations. Debreu and Scarf (1963) give a formal statement of Edgeworth's assertion and show that it holds for economies with any (finite) number of commodities and consumers (assuming that consumers have strictly convex preferences). Formally: as the number of consumers grows the core coincides to the set of competitive allocations. Aumann (1964; 1966) constructs a formal limit model (with a continuum of consumers) and establishes (under quite general assumptions on preferences) that the core coincides with the set of competitive allocations.

Although these results are exceedingly elegant, the ‘real’ economy is finite and that replication and strict convexity of preferences are strong assumptions; hence neither Aumann's core equivalence theorem nor Debreu and Scarf's core convergence theorem applies directly to the ‘real’ economy. The results of Keiding (1974), Dierker (1975) and Anderson (1978) go a long way to removing this objection, showing that for every finite economy every core allocation can be approximately decentralized by some price, and that the deviation from exact decentralization (by some measures) is small provided the number of consumers is large and that no consumer is endowed with more than a small fraction of the social total of any good. For an excellent survey of the state of the art in the late 1980s, see Anderson (1993).

Although these (and related) results are usually accepted as cooperative justification for price-taking, more recent work reveals surprising subtleties.

1. Aumann's core equivalence theorem for continuum economies assumes only that preferences are locally non-satiated (not necessarily monotone). It had been widely assumed that convergence theorems for finite economies should obtain under the same assumption. (The results of Debreu and Scarf, Keiding, Dierker, and Anderson assume that preferences are strictly monotone.) However, Manelli (1991a; 1991b) shows that core convergence may fail if preferences are not monotone, and Hara (2005) shows that further problems may arise if some commodities are bads.

2. Most of the work on core convergence treats only exchange economies. Xiong and Zheng (2005) show that the validity of core convergence for production economies depends in a subtle way on smoothness of preferences, the presence or absence of boundary allocations, and especially on the interpretation of firm shares as control rights.

3. The core is a cooperative solution notion based on blocking; the various bargaining sets use core logic, but impose more stringent requirements for blocking. (An allocation fails to be in the core there is a coalition \( C \) and an allocation \( g \) for \( C \) such that all members of \( C \) prefer \( g \) to \( f \); we might say the coalition \( C \) has an objection to \( f \). An allocation \( f \) fails to be in the classical bargaining set if there is a coalition \( C \) and an allocation \( g \) for \( C \) such that all members of \( C \) prefer \( g \) to \( f \) – so \( C \) has an objection to \( f \) – and in addition there is no coalition \( D \) and allocation \( h \) for \( D \) such that all members of \( D \) prefer \( h \) to \( f \) and all members of \( C \cap D \) prefer \( h \) to \( g \) – so no coalition has a counter objection to \( g \).) The bargaining sets are larger than the core, so convergence of bargaining sets to the set of competitive allocations is a more stringent test of competition than is convergence of the core. Anderson (1998) establishes a convergence result for the classical bargaining set and a variant, but Anderson, Trockel and Zhou (1997) show that core convergence can fail for other bargaining sets. Convergence of the core is sometimes interpreted as the
inability of groups to manipulate the outcome; non-convergence of (some) bargaining sets casts doubt on this interpretation.

4. If the number of commodities is fixed and finite and the number of traders is large, then there are many potential buyers and sellers of each good; markets are thick. Recent work on the core in economies with a continuum of agents and an infinite number of commodities highlight the importance of thick markets for perfect competition. If the commodity space is separable, then there are ‘many more agents than commodities’, and Aumann's core equivalence theorem obtains (Rustichini and Yannelis, 1991), but if the commodity space is sufficiently large then there can be ‘more commodities than agents’, and Aumann's theorem can fail (Tourky and Yannelis, 2001). Ostroy and Zame (1994) focuses on the extent to which commodities are good substitutes, which can be interpreted as ‘economic thickness’. If markets are economically thick then again Aumann's theorem obtains, but if markets are economically thin then Aumann's theorem can fail.

5. When the commodity space is infinite dimensional and the number of traders is finite, the situation is even subtler. The Debreu–Scarf core convergence theorem holds (Aliprantis, Brown and Burkinshaw, 1985), but most of the obvious analogues of the general core convergence theorems of Keiding, Dierker and Anderson fail (Anderson and Zame, 1997). Thus there is a substantial difference between replica economies and general large finite economies; there can also be a substantial difference between large finite economies and continuum economies. Anderson and Zame (1997) identify two reasons for these differences: the first is that the integrability assumptions inherent in the continuum model, usually viewed as economically innocuous in the finite dimensional setting, impose economically serious restrictions in the infinite dimensional setting; the second is that various compactness properties that are inherent in the finite dimensional setting no longer obtain in the infinite dimensional setting. A different consequence of the latter fact is that there are well-behaved continuum economies for which the core is empty and no competitive equilibrium exists (Zame, 1986).

The work discussed above seeks to give cooperative justifications for price-taking behaviour; a different literature seeks to give non-cooperative justifications. For exchange economies, Rubinstein and Wolinsky (1985) propose a search model in which agents enter the market, meet and trade at random, leave the market to consume, and are replaced. They argue that the steady-state outcome of the bargaining game may differ from the competitive outcome. Rubinstein and Wolinsky focus on a setting in which the number of potential buyers is different from the number of potential sellers, but posit a replacement process in which agents who match and leave the market are replaced with exact duplicates. As a result, agents on the short side of the market are unable to exercise their market power. Gale (1986a; 1986b; 1987; 2000) offers different models, using different replacement processes, and shows that outcomes of the search/bargaining game (both in the steady state and not) do coincide with competitive outcomes.

For production economies, Allen and Hellwig (1986a; 1986b) argue that Bertrand price competition leads to approximately competitive prices and outcomes if there is a large number of firms supplying a competitive consumption sector. Cheng (2002) argues that, if firms are risk averse and costs are uncertain, then Cournot quantity competition leads to approximately competitive prices and outcomes.
but Bertrand price competition may not.

Ostroy (1980; 1981) suggests a different approach to perfect competition, based more directly on the ability of individuals to influence prices or to favourably manipulate outcomes. Favourable manipulation will certainly be impossible from any outcome for which each individual already extracts his or her marginal product. A formal definition is easiest for finite economies with transferable utility. For each sub-coalition $S$ of the set $N$ of all agents, let $v(S)$ be the maximal total utility obtainable by redistribution of the total endowment of $S$. (The assumption of transferable utility guarantees that this is economically sensible.) The marginal contribution of agent $i$ to society is thus $v(N) - v(N \setminus i)$. If $x$ is the vector of utilities of a feasible allocation, then agent $i$ extracts his/her marginal product if $x_i = v(N) - v(N \setminus i)$; an allocation at which each agent extracts his or her marginal product is said to satisfy the no-surplus property. The appropriate extensions of these definitions to continuum economies use limits of small coalitions as proxies for individuals and derivatives as proxies for individual marginal products. For continuum economies with a finite number of goods, no-surplus is generic – but not universal. No-surplus is closely related to perfect elasticity of demand and supply (Ostroy, 1984) and to the inability of agents to manipulate; for some environments, these notions are coincident (Gretsky, Ostroy and Zame, 1999). Makowski and Ostroy (2001) provide an overview, bibliography and applications to innovation and mechanism design; Makowski (2004) gives a striking application to non-contractible investment and the ‘hold-up’ problem. See also perfect competition; Shapley value.

**Equilibration**

The definition of competitive equilibrium identifies a particular state of the economy but provides no clue as to the process by which the economy is to reach this state. Without such a process, competitive equilibrium may retain its usefulness as a benchmark (normative solution), but is in doubt as a description of reality (positive solution). Unfortunately, no such process has been described.

Walras suggested a simple and appealing process that he called tâtonnement: from any given price system $p$, adjust prices in proportion to excess demands. However, for some economies, the tâtonnement process does not converge (Scarf, 1960). Indeed, in view of the fact that, aside from the necessity of satisfying Walras's law, the excess demand function of an economy is essentially arbitrary (Sonnenschein, 1973; Mantel, 1974; Debreu, 1974), the tâtonnement process may follow an essentially arbitrary dynamic: converge from some initial prices, diverge from others, and cycle from still others. Although more complicated adjustment processes have been proposed, none seems economically sensible. Moreover, any adjustment process that is universally convergent must of necessity use an enormous amount of information: not just the excess demand of each good at each price, but the derivatives of excess demand of each good with respect to own price and the prices of other goods as well (Saari and Simon, 1978; Saari, 1985). An additional difficulty with tâtonnement is that, because prices adjust without trade, it does not seem to describe any process we see in the real world. (Walras imagined a fictitious ‘auctioneer’ who sets a tentative price, receives tentative demands, adjusts the tentative price, and so on, with the process continuing until excess demand for all goods is zero, at which point trade takes place.)

Keisler (1996) offers a suggestive model of price adjustment with trade. Consider a large finite
general equilibrium (new developments) : The New Palgrave Dictionary of Economics

population of traders and a single warehouse. The warehouse manager announces an initial price $p_0$. At each time $t$ thereafter, a single consumer, chosen at random, comes to the warehouse, trades at the current price $p_t$, and leaves the economy. (Thus, the trader has no incentive to misrepresent or to wait.) The warehouse manager adjusts prices in a direction proportional to the net trade of the most recent consumer, leading to a new price $p_{t+1}$, and the process continues. Keisler shows that, if the population is large, the price adjustments (the constant of proportionality) are small, and the initial price $p_0$ is in the basin of attraction of some price $p^*$ that is a stable equilibrium for the Walrasian tâtonnement process, then with probability close to 1 the price path will reach, and eventually stay in, a small neighbourhood of $p^*$ and most trades will take place at prices near $p^*$. (Because the warehouse manager adjusts prices following every trade, prices do not converge – but they do not leave a small neighbourhood of $p^*$.)

Given that the Walrasian tâtonnement process need have no stable equilibria, one might ask why Keisler’s result is of interest. It should be kept in mind, however, that the Debreu–Mantel–Sonnenschein theorem describes only the theoretical possibilities for the aggregate excess demand function of an economy; it does not describe the aggregate excess demand function of any real economy. If the aggregate excess demand function of the real economy is – always or frequently – well-behaved, then Keisler’s result provides hope for a sensible process that converges to equilibrium.

Of course it is not possible to observe the aggregate excess demand function of the real economy. Failing that, it seems natural to ask whether there are reasonable conditions on preferences and endowments – and especially on the distribution of preferences and endowments – that are compatible with empirical observation and also guarantee that the aggregate excess demand function is well-behaved (stable or locally stable for Walrasian tâtonnement or some other natural adjustment process). A sufficient condition for this to be true is that the economy admit a representative consumer, in the sense that the demand function of the economy is the demand function of a one-agent economy. (The tâtonnement process follows the differential equation $dp/dt=K[w−D(p)]$, where $w$ is the aggregate endowment and $D(p)$ is aggregate demand at the price $p$, given endowment $w$. Fix any equilibrium price $p^*$; by definition, $D(p^*)=0$. At any non-equilibrium price $p$, $w$ is affordable but not chosen, so $w$ is dis-preferred to $D(p)$. By assumption, $D$ is the demand function of a single agent, so revealed preference applies; hence $D(p)$ cannot be affordable at the equilibrium price $p^*$; that is, $p^*·D(p)>0$. Walras’s Law guarantees that $p·D(p)=p·w$ for all prices $p$. Taken together, these are enough to guarantee that the tâtonnement process converges from any initial price to the equilibrium price $p^*$.)

One promising approach focuses on the distribution of preferences and endowments and shows that aggregate market demand $D$ obeys the law of demand; that is, $(p−p’)(D(p)−D(p’))<0$. (Existence of a representative consumer is not enough to not guarantee the law of demand in the aggregate.) For example, if all agents have the same demand function, income is independent of price, the income density is decreasing and the smallest incomes are sufficiently small, then the law of demand will hold in the aggregate (Hildenbrand, 1983). These assumptions are strong but can be significantly weakened (Chiappori, 1985; Quah, 1997). Alternatively, if all agents have the same income, then sufficient heterogeneity of demand functions will also imply the law of demand in the aggregate (Grandmont, 1987); again, these assumptions are strong, but can be significantly weakened (Grandmont, 1992; Quah, 2002). See also aggregation (theory).
Incomplete markets

The standard Arrow–Debreu–McKenzie general equilibrium model posits a market for every commodity. Since the description of a commodity includes the date and state of nature in which it will be delivered, this entails markets for all claims to all goods in all future dates and states of the world. Radner (1972), building on an earlier model of Arrow (1953), offers an alternative model in which at each date and state of the world there are spot markets for commodities available at that date and state of the world and for assets or securities (state-contingent claims to wealth at future dates), but not for commodities at other dates and states. In this model, the transfer of wealth across time or across states of nature can be accomplished only by trading available assets. If all state- and time-dependent wealth transfers can be accomplished by trading available assets, then asset markets are complete, and the model reduces to the Arrow–Debreu–McKenzie model; in the alternative case, asset markets are incomplete.

In principle, asset payoffs (or dividends) in a given date-event may depend arbitrarily on commodity spot prices in that date-event, and even on the prices of other assets. Two particular kinds of securities are of special interest. Financial assets or nominal assets are those whose dividends are independent of prices; such assets are abstractions of real-world instruments such as treasury bills. Real assets are those whose dividends in a given date-event are the value at commodity spot prices of a specified bundle of commodities; such assets are abstractions of real-world instruments such as commodity forward contracts. (Most real-world forward contracts are marked-to-market; that is, they promise to deliver the value of a particular bundle of commodities rather than the physical bundle itself. In a perfectly competitive market, the distinction is unimportant, but in a real-world market the distinction can be significant if, as sometimes happens, the physical good promised is in sufficiently short supply that the promised quantity cannot be delivered.)
