De Finetti assigned a fundamental role in Bayesian analysis to exchangeability. A finite sequence of random quantities is exchangeable if the joint probability of the sequence, or any subsequence, is invariant under permutations of the subscripts. An infinite sequence is exchangeable if any finite subsequence is exchangeable. Exchangeability involves recognizing symmetry in beliefs concerning observables, and presumably this is something about which a researcher may have intuition. It provides an operational meaning to the weakest possible notion of a sequence of 'similar' random quantities. It is operational because it requires only probability assignments of observable quantities, although admittedly this becomes problematic in the case of infinite exchangeability.

The links between exchangeable beliefs over uncertain observables and the parameters in statistical models are provided by various generalizations of Bruno de Finetti's celebrated representation theorem for infinite sequences of exchangeable Bernoulli random variables (see Bernardo and Smith, 1994, ch. 4). These theorems provide conditions under which exchangeability, and other symmetries, give rise to an isomorphic world consisting of i.i.d. observations with a given sampling distribution, conditional on a mathematical construct (a parameter), and guarantee the existence of a prior distribution for it. De Finetti put parameters in their proper perspective: they are mathematical constructs that provide a convenient index for a family of probability distributions, and they induce conditional independence in sequences of observables.

Bayesian inference involves updating prior beliefs into posterior beliefs conditional on observed data. Appealingly, Bayesian analysis requires only a few general principles that are applied over and over again in different settings. Bayesians begin by specifying a joint distribution for all quantities (denoted in bold italics) under consideration except known constants. The Bayesian paradigm reduces statistical inference to applied probability. Quantities that become known under sampling (data) are denoted by the T-dimensional vector $y \in Y$, and the remaining unknown (and unobserved) quantities (parameters) by the m-dimensional vector $\theta \in \Theta \subseteq \mathbb{R}^m$. Unless noted otherwise, $y$ and $\theta$ are treated as continuous random variables. Working in terms of densities, consider

$$f(y, \theta) = f(\theta)f(y|\theta) = f(y|\theta)f(\theta), \quad y, \theta \in Y \times \Theta,$$

(1)

where $f(\theta)$ is the prior density, $f(y|\theta)$ viewed as a function of $\theta$ for known $y$ is the likelihood function [denoted $L(\theta; y)$], $f(\theta | y)$ is the posterior density, and

$$f(y) = \int_\Theta f(\theta)L(\theta; y) \, d\theta = E_{\theta}[L(\theta; y)], \quad y \in Y,$$

(2)

is the marginal density of the data $y$. From (1), Bayes’ theorem for densities follows:

$$f(\theta | y) \propto f(\theta)L(\theta; y) \propto f(\theta)L(\theta; y), \quad \theta \in \Theta.$$

(3)

Hereafter, (3) is adopted as the way to update prior beliefs when $y=y$ is observed.
Fortunately, sometimes the integration in (2) can be performed analytically and so the updating of prior beliefs in light of the data to obtain the posterior beliefs is straightforward. These situations correspond mostly to cases where $L(\theta, y)$ belongs to the exponential family of densities. In this case the prior density can be chosen so that the posterior density falls within the same elementary family of distributions as the prior. These prior families are called conjugate families. Conjugate priors are more flexible than they may appear at first since mixtures of conjugate priors are themselves conjugate, although they may be daunting to elicit.

The denominator in (3) serves as an integrating constant. Hence, when one considers experiments employing the same prior, and which yield proportional likelihoods for the observed data, identical posteriors will emerge, consistent with the likelihood principle (Berger and Wolpert, 1988). Unlike the inherent ex ante perspective of frequentist statistics, which seeks properties of procedures in repeated sampling, posterior density (3) is ex post – it conditions on the observed data $y=y$, and dispenses with the part of the sample space $Y$ that could have been observed but was not.

In most practical situations not all elements of $\theta$ are of direct interest. Let $\theta = [\beta', \delta'] \in \mathcal{B} \times \Delta$ be partitioned into parameters of interest $\beta$ and nuisance parameters $\delta$. Nuisance parameters are well-named for frequentists, because dealing with them in a general setting is one of the major problems non-Bayesian researchers face. In contrast, Bayesians adopt a universal approach to eliminating nuisance parameters from the problem: integrate them out of the joint posterior to obtain the marginal posterior density for $\beta$:

\[ f(\beta | y) = \int_{\Delta} f(\beta, \delta | y) d\delta, \beta \in \mathcal{B}. \]

(4)

Point estimation

Consider a loss (cost) function $C(\hat{\beta}, \beta)$ for the parameters of interest $\beta$, that is, a nonnegative function satisfying $C(b, b) = 0$ and which measures the consequences of using the estimate $\hat{\beta}$ when the parameter of interest is $\beta$. Both frequentists and Bayesians seek to ‘minimize’ (in some sense) $C(\hat{\beta}, \beta)$, but first its randomness must be eliminated.

From the frequentist point of view, $\beta$ is a degenerate random variable equal to $\beta$, but $C(\hat{\beta}, \beta)$ is stochastic because $\hat{\beta}$ is viewed ex ante as the estimator $\hat{\beta} = \hat{\beta}(y)$ depending on the data $y$ which are random viewed ex ante. One way to circumscribe the randomness of $C(\hat{\beta}, \beta)$ is to focus on its expected value, assuming it exists. Frequentists consider the risk function

\[ R(\hat{\beta}|\beta, \delta) = E_{y|\beta=\beta, \delta=\delta}[C(\hat{\beta}(y), \beta)], \]

(5)

where the expectation is taken with respect to the sampling density $f(y|\beta, \delta), y \in Y$.

In contrast, the Bayesian perspective is entirely ex post, and it seeks a function $\hat{\beta} = \hat{\beta}(y)$ of the observed data $y=y$ to serve as a point estimate of the parameter of interest $\beta$. Unlike the frequentist approach, no role is provided for data that could have been observed, but were not. Since $\hat{\beta}$ is unknown, the Bayesian perspective suggests formulation of subjective beliefs about it, given all the information at hand. Such information is fully contained in marginal posterior density (4). In contrast to (5), Bayesians focus on expected posterior loss:

\[ c(\hat{\beta}|y) = E_{\beta|y=y}[C(\hat{\beta}, \beta)] = \int_{\mathcal{B}} C(\hat{\beta}, \beta) f(\beta | y) d\beta. \]

(6)
The second Bayesian commandment (after Bayes’ theorem) is: act so as to minimize expected posterior loss, that is, find
\[ \hat{\beta}^* \equiv \text{argmin}_{\hat{\beta}} \mathbb{E}_{\hat{y}} \left[ C(\hat{\beta}, b) \right] \].

Frequentists emphasize the sampling distribution \( y | \beta = \hat{\beta}, \delta = \delta \) and Bayesians emphasize the posterior distribution \( f(\hat{\beta} | y) \). The debate is about the desired conditioning – as are most debates in statistics. Posterior expectation (8) removes \( \beta \) from yielding a criterion \( C(\hat{\beta} | y) \), unlike risk function (5), involving only known quantities.

For simplicity, consider univariate \( \beta \) and the following three loss functions in which \( c, c_1, c_2, \) and \( d \) are known constants: the quadratic loss function \( C(\hat{\beta}, b) = (\hat{\beta} - b)^2 \), the asymmetric linear loss function \( C(\hat{\beta}, b) = c_1|\hat{\beta} - b| \) if \( \hat{\beta} \leq b \), and \( C(\hat{\beta}, b) = c_2|\hat{\beta} - b| \) if \( \hat{\beta} > b \), and the all-or-nothing loss function \( C(\hat{\beta}, b) = c \), if \( |\hat{\beta} - b| > d \), and \( C(\hat{\beta}, b) = 0 \), if \( |\hat{\beta} - b| \leq d \). The resulting Bayesian point estimates are the posterior mean, the \( q \)th posterior quantile where \( Q = \frac{c_1}{c_1 + c_2} \), and the centre of an interval of width \( 2d \) having maximum posterior probability (yielding the posterior mode as \( d \to 0 \)), respectively. When \( \beta \) is a vector, the most popular loss functions are the weighted squared error generalization of quadratic loss, \( C(\hat{\beta}, b) = (\hat{\beta} - b)' Q (\hat{\beta} - b) \), where \( Q \) is a positive definite matrix, or the all-or-nothing loss function. In these cases the Bayesian point estimates are again the posterior mean and mode (as \( d \to 0 \)), respectively.

Minimum risk estimators do not exist in general because (5) depends on \( \beta \) and \( \delta \), and so an estimator that minimizes (5) will also depend on \( \beta \) and \( \delta \). Often extraneous side conditions are imposed (for example, unbiasedness) to sidestep the problem. In contrast, Bayesian point estimates are optimal by construction from the ex post standpoint. In general they also have good ex ante risk properties. Consider the minimizer of (6) viewed from the ex ante standpoint before the data are realized, that is, the Bayesian point estimator \( \hat{\beta}^* = \text{Bayesian point estimator} \). Provided the prior distribution is proper (it integrates to unity), then \( \hat{\beta}^* \) satisfies the minimal frequentist requirement of admissibility (its risk cannot be dominated by another estimator everywhere in the parameter space). Furthermore, in most interesting settings, all admissible estimators are either Bayes or limits thereof known as generalized Bayes estimators based on an improper prior whose integral diverges.

Interval estimation

Bayesian interval estimation follows directly from the posterior density \( f(\beta | y) \). Because opinions about the unknown parameter are treated in a probabilistic manner, there is no need to introduce the additional concept of ‘confidence’. For example, given a region \( B^\dagger \subset B \), it is meaningful to ask: given the data, what is the probability that \( \beta \) lies in \( B^\dagger \)? The answer is direct:

\[ \text{Prob}(b \in B^\dagger | y) = \int_{B^\dagger} f(\beta | y) \, db. \]  

(7)

Alternatively, given a desired probability content of \( 1 - \alpha \), it is possible to reverse this procedure and find a corresponding region \( B^\dagger \). The ‘smallest’ region \( B^\dagger \) satisfying (9), known as the highest posterior density (HPD) region of content \( (1 - \alpha) \) for \( \beta \) corresponds to imposing the added condition that for all \( \beta_1 \in B^\dagger \) and \( \beta_2 \not\in B^\dagger \), \( f(\beta_1 | y) \geq f(\beta_2 | y) \).

Hypothesis testing

Consider a partition of the parameter space \( B \) for the parameter of interest \( \beta \) according to \( B = B_1 \cup B_2 \), where \( B_1 \cap B_2 = \emptyset \). Suppose interest lies in testing \( H_1: \beta \in B_1 \) versus \( H_2: \beta \in B_2 \) based on a sample \( y \) yielding the likelihood \( L(\beta, \delta; y) \). The relevant decision space is \( D = \{d_1, d_2\} \), where \( d_j \equiv \text{choose hypothesis } H_j \) (j=1, 2). Extensions to cases involving more than two hypotheses are straightforward. Let \( C(d; b) \geq 0 \) denote the relevant loss function. Without loss of generality, assume that correct decisions yield zero loss.

From the Bayesian perspective a hypothesis is of interest only if the prior distribution assigns it positive probability. Therefore, assume \( \pi_j = \text{Prob}(H_j) = \text{Prob}(b \in B_j) > 0 \) (j=1,2) with \( \pi_1 + \pi_2 = 1 \). Let \( f_j(\beta, \delta | H_j) \) be the prior density under \( H_j \) (j=1, 2).
Under $H_j$, the marginal data density (expected likelihood) is

$$f(y|H_j) = \int F_j(\cdot) \, dF_j(\beta, \delta; y) = E_{\beta, \delta|H_j}[\mathcal{L}(\beta, \delta; y)] (j = 1, 2),$$

where $F_j(\cdot)$ denotes the c.d.f. corresponding to the distribution $\beta, \delta | H_j$. From Bayes' theorem it follows that the posterior probability of $H_j$ is

$$p_j = \frac{nf_j(y|H_j)}{f(y)} (j = 1, 2),$$

where the marginal density of the data is $f(y) = n_1f(y|H_1) + n_2f(y|H_2)$. Under $H_j$, the posterior density of $\beta$ and $\delta$ is (according to Bayes' theorem):

$$f(\beta, \delta|y, H_j) = \frac{f_j(\beta, \delta|H_j)\mathcal{L}(\beta, \delta; y)}{f(y|H_j)} , \beta \in B_j \delta \in \Delta (j = 1, 2).$$

As in the case of estimation, the optimal Bayesian decision $d_*$ in the hypothesis testing context minimizes expected posterior loss, that is,

$$d_* = \text{argmin} c(d|y),$$

where

$$c(d|y) = \tilde{n}_1c(d|y, H_1) + \tilde{n}_2c(d|y, H_2),$$

and $c(d|y, H_j) = E_{\theta|y, H_j}[C(d; \theta)] (j = 1, 2)$. Specifically, $c(d_1|y) = \tilde{n}_2c(d_1|y, H_2)$, and $c(d_2|y) = \tilde{n}_1c(d_2|y, H_1)$. Therefore, it is optimal to choose $H_2$ [that is, $c(d_2|y) < c(d_1|y)$] iff

$$d_* = d_2 \text{ iff } \frac{\tilde{n}_2}{\tilde{n}_1} > \frac{c(d_2|y, H_1)}{c(d_1|y, H_2)} (12a)$$

The quantities $\frac{\tilde{n}_2}{\tilde{n}_1}$ and $\frac{\tilde{n}_2}{\tilde{n}_1}$ are the prior odds and posterior odds, respectively, of $H_2$ versus $H_1$. From (9) it follows immediately that these two odds are related by $\frac{\tilde{n}_2}{\tilde{n}_1} = B_{21}\left(\frac{\tilde{n}_2}{\tilde{n}_1}\right)$, where $B_{21} = \frac{f(y|H_2)}{f(y|H_1)}$ is the Bayes factor for $H_2$ versus $H_1$. See Kass and
Raftery (1995) for an excellent review. In terms of the Bayes factor $B_{21}$, (12a) can also be written

$$d_\ast = d_{2\text{iff}}B_{21} \geq \left[ \frac{c(d_2|y, H_1)}{c(d_2|y, H_2)} \right] \left[ \frac{n_1}{n_2} \right].$$

(12b)

In general, expected posterior loss $c(d|y, H_j)$ depends on the data $y$, and hence, Bayes factor $B_{21}$ does not serve as complete data summary because the right-hand side of the inequality in (12b) also depends on the data. One exception is when both hypotheses are simple. Another is when an all-or-nothing loss is used such that the loss $C(d_i, b) = C_1$ resulting from decision $d_i$ when $\beta \in B_j$, $i \neq j$, is constant for all $\beta \in B_j$. In this case, for $i \neq j$, $c(d_i|y, H_j) = c(d_j|y, H_j) = C_1$, and decision rule (12b) reduces to

$$d_\ast = d_{2\text{iff}}B_{21} > \frac{n_1C_2}{n_2C_1}.$$

(12c)

The right-hand side of the inequality in (12c) is a known constant Bayesian critical value.

Prediction

The sampling distribution of an out-of-sample $\hat{Y}$ given $y = y$ and $\theta$, would be an acceptable predictive distribution if $\theta$ was known, but without knowledge of $\theta$ it cannot be used. In its place is the Bayesian predictive density

$$f(\hat{Y}|y) = \frac{f(\hat{Y}, y)}{f(y)} = \int_{\Theta} \frac{f(\hat{Y}, y, \theta)}{f(y)} d\theta = \int_{\Theta} f(\hat{Y}|y, \theta) \left[ \frac{f(\theta)f(y|\theta)}{f(y)} \right] d\theta = \int_{\Theta} f(\hat{Y}|y, \theta) f(y|\theta)d\theta = E_{\theta|y}[f(\hat{Y}|y, \theta)], \hat{Y} \in \tilde{Y}$$

(13)

If the past and future are independent conditional on $\theta$ (as in random sampling), then $f(\hat{Y}|y, \theta) = f(\hat{Y}|\theta)$ Letting $\tilde{C}(\hat{Y}_P, \hat{Y})$ denote a predictive loss function measuring the performance of a predictor $\hat{Y}_P$ of $\hat{Y}$, the optimal point predictor $\hat{Y}_\ast$ is defined to be

$$\hat{Y}_\ast = \text{argmin}_{\hat{Y}_P} E_{\hat{Y}|y}[\tilde{C}(\hat{Y}_P, \hat{Y})].$$

For example, if $\hat{Y}$ is a scalar and predictive loss is quadratic, then the optimal point estimate is the predictive mean $\hat{Y}_\ast = E(\hat{Y}|y)$. Predictive density (13) can also be used to generate forecast intervals analogous to HPD intervals. Predictive density (13) treats all parameters as nuisance parameters and integrates them out of the predictive problem. A similar strategy is used when adding parametric hypotheses to the analysis. Consider the hypothesis $H_j$ and associated prior $f_j(\beta, \delta|H_j)$ ($j=1, 2$). Given data $y$ leading to the posterior $f_j(\beta, \delta|y, H_j)$, the predictive density of $\hat{Y}$ conditional on $H_j$ is

$$f(\hat{Y}|y, H_j) = \int_{\Theta} f(\hat{Y}|\theta, y, H_j) f(\theta|y, H_j)d\theta \hat{Y} \in \tilde{Y}.$$  

(14)
Using the posterior probabilities (9), the marginal predictive density of \( \tilde{y} \) is the mixture density

\[
\pi(\tilde{y}|y) = \pi_1 \pi(\tilde{y}|y, H_1) + \pi_2 \pi(\tilde{y}|y, H_2), \quad \tilde{y} \in \tilde{Y}
\]  

(15)

and it is the basis for interval and point prediction. For example, under quadratic loss the optimal Bayesian point prediction is the predictive mean

\[
E(\tilde{y}|y) = \pi_1 E(\tilde{y}|y, H_1) + \pi_2 E(\tilde{y}|y, H_2),
\]  

(16)

which is a weighted average of the optimal point forecasts \( E(\tilde{y}|y, H_1) \) under each hypothesis. The weights \( \pi_j (j = 1, 2) \) in (16) have an intuitive appeal: the forecast of the more probable hypothesis a posteriori receives more weight.

**Choice of prior**

Critics of Bayesianism find the choice of prior is the major stumbling block in adopting the Bayesian approach. In contrast, proponents see the required effort to be manageable and well worth it. Usually the likelihood is parameterized to facilitate thinking in terms of \( \theta \), and so subject matter considerations should suggest 'plausible' values of \( \theta \). Even when such direct thinking about \( \theta \) is possible, it is also useful to think predictively (for example, see Kadane and Wolfson, 1998) about the observable \( y \) and use (2) to back out a parametric prior \( f(\theta | \lambda) \) for a specific value of some hyperparameter \( \lambda \in \Lambda \) in some space \( \Lambda \). Usually such analyses restrict attention to conjugate priors. This ideal, however, is difficult to achieve.

Public research involving only a single prior is likely to draw few readers. Entertaining various professional positions in terms of \( \theta \) can lead to different choices of \( \lambda \). Rather than thinking of eliciting the prior, it is more useful to think in terms of a family \( \mathcal{A} = \{ f(\theta | \lambda), \lambda \in \Lambda \} \) of parametric priors. If a prior \( f(\lambda) \) is available for \( \lambda \), then we are back in the single prior case with the prior \( f(\theta) = \int_{\mathcal{A}} f(\theta | \lambda) f(\lambda) d\lambda \). In most practical problems, however, there will be no agreed upon \( f(\lambda) \), and the researcher is left with investigating the sensitivity of the analyses to different elements in \( \mathcal{A} \). This is easier said than done, but in principle it can be done. For large dimensional \( \theta \), this can be difficult because the effects of the prior can be subtle: it may have little posterior influence on some functions of the data and have an overwhelming influence on other functions. Often a quantity of interest like the posterior mean \( E(\theta | y) \) can be analytically restricted to a fairly small set of possible values for any given \( \lambda \in \Lambda \). The extreme bounds analysis developed by Leamer (1982) is a leading example. In contrast, empirical Bayes analysis proceeds by using the data to estimate \( \lambda \).

Kass and Wasserman (1996) survey formal rules that have been suggested for choosing a prior. Many of these rules reflect the desire to let the 'data speak for themselves'. This has led to variety of non-subjective priors intended to capture the elusive notion of non-informativeness. These priors are intended to lead to proper posteriors dominated by the data. They also serve as benchmarks for posteriors derived from ideal subjective considerations. At first many of these priors were also motivated on simplicity grounds. But as problems were discovered, and other features were seen to be relevant, derivation of such priors became more complicated, possibly even more so than a legitimate attempt to elicit an actual subjective prior.

One interpretation of letting the data speak for themselves is to use classical techniques. Maximum likelihood estimates are rationalizable in a Bayesian framework by appropriate choice of prior distribution and loss function, specifically a uniform prior and an all-or-nothing loss function. But in what parameterization should one be uniform?

In order to overcome the re-parameterization problem, Jeffreys sought a general rule for choosing a prior so that the same posterior inferences were obtained regardless of the parameterization chosen. Jeffreys (1961) made a general (but not dogmatic) argument in favor of choosing a prior proportional to the square root of the information matrix, that is, \( f(\theta) \propto |J(\theta)|^{1/2} \), where \( J(\theta) = E_y \left[ -\partial^2 L(\theta ; y) / \partial \theta \partial \theta' \right] \) is the information matrix of the sample. This prior has the desirable feature that if the model is reparameterized by a one-to-one transformation, say \( \psi = h(\theta) \), then choosing the prior \( f(\psi) \propto |E_{y|\alpha} \left[ -\partial^2 L(\psi ; y) / \partial \psi \partial \psi' \right] |^{1/2} \)}
will lead to identical posterior inferences as using $f(\theta)$. Such priors are said to follow Jeffreys’ rule.

Not all of Jeffreys’ recommendations always followed Jeffreys rule: When $\Theta$ is a bounded interval, Jeffreys assumed a constant proper prior. When $\Theta = \mathbb{R}$, Jeffreys assumed a constant improper prior. When $\Theta = [0, \infty)$, Jeffreys chose $f(\theta) = \frac{1}{\theta}$ because it is invariant under power transformations. When $\Theta = [\theta_1, \theta_2]$, where $\theta_1$ is a location parameter and $\theta_2$ is a non-location parameter, Jeffreys chose $f(\theta) \propto J(\theta)^{1/2}$, where $J(\theta)$ is calculated holding $\theta_1$ fixed. In the case of mixture models, Jeffreys argued that the mixing parameters should be treated independently from the other parameters. There is a fair amount of agreement that such priors may be reasonable in one-parameter problems, but substantially less agreement (including Jeffreys) in multiple parameter problems.

Usually, Jeffreys’ rule and other formal rules surveyed by Kass and Wasserman (1996), lead to improper priors, that is, priors which integrate to infinity rather than unity (a proper prior). When blindly plugged into Bayes’ theorem as a prior they lead to proper posterior densities, but not always. They also produce proper predictive densities (13), but not proper marginal data densities (8). Furthermore, improper priors, in contrast to proper priors, are not guaranteed to lead to admissible Bayesian point estimators, and marginalization paradoxes can occur.

Bernardo (1979) suggested a method for constructing reference priors offering two innovations. First, he defined a notion of missing information in terms of the Kullback-Leibler distance between the posterior and the prior density. Second, he developed a stepwise procedure for handling nuisance parameters. If there are no nuisance parameters, then his method usually leads to Jeffreys’ rule. Subsequently, numerous refinements have been made in joint work with James O. Berger.

There are many candidates for non-subjective priors, and they often have properties that seem rather non-Bayesian. Most non-subjective priors depend on some or all of the following: (a) the form of the likelihood, (b) the sample size, (c) an expectation with respect to the sampling distribution, (d) the parameters of interest, and (e) whether the researcher is engaging in estimation, testing or predicting. The dependency in (c) of Jeffreys’ prior on a sampling theory expectation makes it sensitive to a host of problems related to the likelihood principle. In light of (d), a non-subjective prior can depend on subjective choices such as which are the parameters of interest and which are nuisance parameters. Different quantities of interest require different non-subjective priors which cannot be combined in a coherent manner. My advice is use a non-subjective prior only with great care, and never alone. I include non-subjective priors in the class of priors over which I perform a sensitivity analysis.

One reaction to choice of prior is to not make one and proceed with an asymptotic analysis. The same way sampling distributions of the maximum likelihood estimator $\hat{\theta}_{\text{ML}}$ in regular situations is asymptotically normal, posterior density (5) can be approximated as $T \rightarrow \infty$ by the multivariate normal density

$$
\mathcal{N}_{\infty}(\hat{\theta}_{\text{ML}}, J_T(\hat{\theta}_{\text{ML}})) = \sqrt{2\pi}^{-m/2} |J_T(\hat{\theta}_{\text{ML}})|^{1/2} \exp \left[ -\frac{1}{2} (\theta - \hat{\theta}_{\text{ML}})' J_T(\hat{\theta}_{\text{ML}}) (\theta - \hat{\theta}_{\text{ML}}) \right],
$$

where $J_T(\cdot)$ is the information matrix. This approximation does not depend on the prior. As an approximation to the posterior density of $\theta$, the approximation usually improves by replacing the information matrix by the observed Hessian of the log-likelihood evaluated at $\hat{\theta}_{\text{ML}}$. The quality of this approximation can usually be improved by incorporating some information on the prior. For example, by using

$$
\mathcal{N}(\hat{\theta}, \hat{\theta}_{\text{ML}}, \hat{J}_T(\hat{\theta}))^{-1},
$$

where $\hat{\theta}$ is the posterior mode and $\hat{J}_T(\hat{\theta})$ is the Hessian of the log posterior evaluated at $\hat{\theta}$. Further asymptotic analysis using Laplace approximations (see Tierney and Kadane, 1986) often given remarkably accurate results.

### Model building

A ‘true model’ is an oxymoron. An economic model is an abstract representation of reality that highlights what a researcher deems relevant to a particular economic issue. By definition an economic model is literally false, and so questions regarding its literal truth are trivial. Whether the model is useful is another matter.

A subjectivist’s econometric model expresses probabilistically the researcher’s beliefs concerning future observables of interest to economists. It has two components: a likelihood for viewing observables in the world, and a prior reflecting a professional position of interest. Poirier (1988) introduced the metaphor window for a likelihood function because it captures its essential role in de Finetti representation theorems: a parametric medium for viewing the observable world. Both model components are subjective, and both involve mathematical constructs called parameters. Parameters simply index distributions; any correspondence to physical reality is a rare side bonus.

In choosing the window $\mathcal{L}(\theta; \gamma)$ the researcher is torn in two directions: choosing the dimensionality of $\theta$ to be large increases the chances of getting a bevy of researchers to agree to disagree in terms of the appropriate priors for $\theta$, but a large dimensional $\theta$ necessitate increasingly more informative priors if anything useful is to be learned from a finite sample. In one sense this dichotomy between prior and likelihood is tautological: if there is no agreement, then presumably the likelihood can always be expanded until agreement is obtained. The resulting window, however, may be hopelessly complex. The ‘bite’ in the statement comes from the

http://www.dictionaryofeconomics.com.proxy.library.csi....edu/article?id=pde2008_8000222&goto=a&result_number=112(第 8/12 页)2008-12-30 0:39:54
assertion that a researcher believes agreement is compelling in the case of a particular window. Despite the many arguments in the literature over the wisdom of ‘general to specific’ as opposed to ‘specific to general modelling’, observed behaviour suggests researchers start with a finite parameterization of the problem that can be both simplified and expanded. The arguments are really over a matter of emphasis rather than kind.

Diagnostic checking of the maintained initial window can help achieve agreement on it. If the diagnostic checks indicate window expansion, then rethinking is required, a new window must be introduced, and the diagnostic checking process repeated. The extent of diagnostic testing depends in part on the size of the initial window. Everything else being equal, small windows require more checking to convince others of their value than large windows. Reporting that the initial window passes diagnostic checks is intended to soothe the concerns of members of the research community. For good discussions of diagnostic checking, see Gelman et al. (2003) and Lancaster (2004). Such checking can be as much an art as a science.

Conscientious empirical researchers provide their readers with a variety of ways of looking at the data. This amounts to checking how the observed data fit marginal density (2), how out-of-sample observables fit predictive densities (13) or (15), and how posterior densities (3) or (10) are summarized and interpreted. This task is complicated when \( m \) is large or when many hypotheses are entertained. Furthermore, the question arises: ‘How should we bring together the results?’ Is one hypothesis is to be chosen after an ‘enlightened’ search of the data? If so, then the question is how to properly express uncertainty that reflects both sampling uncertainty from estimating the unknown parameters under a hypothesis and uncertainty over the hypothesis itself. The common practice of choosing a single hypothesis and then proceeding conditionally on it, is difficult to rationalize because the researcher’s uncertainty is understated unless that hypothesis has a posterior probability near unity. Readers are interested in a clear articulation of the researcher’s uncertainty because it can serve as a useful gauge or reference point for their own uncertainty.

When considering two hypotheses \( H_1 \) and \( H_2 \) it is possible to assign only \( \pi_1 + \pi_2 = 1 - \varepsilon \) prior probability to them, and to reserve \( \varepsilon \) (0<\( \varepsilon \)<1) probability for an unspecified \( H_3 \) representing ‘something else’. Then interpreting \( \pi_j \)relatively as \( \text{Prob}(H_j|H_1 \text{ or } H_2) \) \((j=1, 2)\), posterior probabilities (11) can be computed and also interpreted relatively as \( \text{Prob}(H_j|y, H_1 \text{ or } H_2) \) without specifying \( \varepsilon \). If in the process the researcher’s creative mind has a new insight leading to specification of ‘something else’, then some fraction \( \pi_3 \) of \( 1 - \varepsilon \) can be allocated to \( H_3 \) and the process repeated with the remaining portion allocated to a another unspecified \( H_4 \). The catch here is that \( H_3 \) is data-instigated (that is, created after looking at the data), and the researcher faces choice of a ‘post-data prior’ involving both \( \pi_3 \) and any parameters unrestricted under \( H_3 \). However, the need for sensitivity analysis in public research implies the researcher is simply left with the usual task of presenting a variety of mappings from ‘interesting’ priors to posteriors. It is left to the reader to decide whether the priors are sufficiently plausible to warrant serious consideration of the data instigated hypothesis. Priors that have been contaminated by data can be presented as such – as always it remains for the reader to assess their plausibility.

Regression

To illustrate the preceding discussion, consider the standard normal linear regression model with fixed regressors \( X \) yielding likelihood function \( \mathcal{L}(\theta, \gamma) = \varphi(\gamma; X\beta, \sigma^2 I_N) \), where \( \theta = [\beta', \sigma^{-2}]' \) and \( \beta \) is \( K \times 1 \) parameter of interest. Working in terms of the precision \( \sigma^{-2} \), the conjugate normal-gamma prior is

\[
\ell(\beta, \sigma^{-2}) = \Phi_K(\beta; b, \sigma^2 Q)\varphi(\sigma^{-2}; \underline{s}^2, \nu),
\]

the straightforward to show that (5) implies the normal-gamma posterior distribution

\[
\ell(\beta, \sigma^{-2}|y) = \Phi_K(\beta; b, \sigma^2 Q)\varphi(\sigma^{-2}; \underline{s}^2, \nu),
\]
where \( \tilde{\beta} = \tilde{Q}(Q^{-1}b + X'b) \), \( \tilde{Q} = (Q^{-1} + X'X)^{-1} \), \( \tilde{\nu} = \nu + T \) and
\[
\tilde{s}^2 = \nu s^2 + (y - X\beta)'(y - X\beta) + (b - \tilde{b})'Q + (X'X)^{-1}(b - \tilde{b}).
\]
The marginal posterior distribution of \( \beta \) is the multivariate-
t density
\[
f(\beta|y) = \left[ \frac{\pi^{K/2} \Gamma(\nu/2)}{\bar{\nu}^{K/2} \Gamma(\nu+K)/2} \right]^{-1} \left[ \frac{\nu}{\nu - 1} \right]^{-1/2} \left[ \frac{\nu}{\nu + K} \right]^{-1/2} \left[ \frac{\nu}{\nu + K} \right]^{-1/2} \left[ \frac{\nu + K}{\nu + K} \right]^{-1/2}.
\]
Furthermore, the predictive density of an out-of-sample observation \( \tilde{y} \) corresponding to the regressors \( \tilde{x} \) is the university t
density
\[
f(\bar{y}|y) = \pi^{-T/2} \frac{1}{\Gamma(\nu/2)} \left[ \frac{\nu}{\nu - 1} \right]^{1/2} \left[ \frac{\nu}{\nu + 1} \right]^{1/2} \left[ \nu + \tilde{s}^2 \tilde{X}' \tilde{X}^{-1} \tilde{y} \right]^{-\nu/2}.
\]
where \( \tilde{s}^2 = s^2 (1 + \tilde{X}'\tilde{Q}^{-1}\tilde{X}) \).

Note that no full column rank assumption for \( X \) is required for the preceding analysis. This reflects a general result that
unidentifiability of a parameter, such as \( \beta \), when \( \text{rank}(X) < K \), is not much of a problem for a Bayesian with a proper prior, because
the posterior is guaranteed to be proper. There is no ‘free lunch’, however, because there will exist some quantity \( \eta \) about which no
learning occurs, that is, \( f(\eta|y) = f(\eta) \). For example, if \( Xc = 0 \) for some nonzero \( K \times 1 \) vector \( c \), then the prior and posterior
distributions for \( \eta = c'Q^{-1}b \) given \( \sigma^2 \) is univariate normal with mean \( c'Q^{-1}b \) and variance \( \sigma^2 c'Q^{-1}c \). Whether lack of updating
is a problem depends on whether \( \eta \) is a quantity of interest. Note that \( \eta \) depends on both the nature of the collinearity (through \( c \))
and the prior (through \( Q \)).

Under weighted squared error loss, the Bayesian point estimate of \( \beta \) is the posterior mean \( \tilde{b} \). The matrix weighted average of \( b \) and
is \( \tilde{b} \) is precisely the way a classicist combines two samples from the same distribution: a fictitious sample yielding an OLS estimate
\( \tilde{b} \) with \( \text{Var}(b|\sigma^2) = \sigma^2 \tilde{Q} \), and an actual sample yielding the OLS estimate \( b \) with \( \text{Var}(b|\sigma^2) = \sigma^2 (X'X)^{-1} \). Elliptical HPD regions
for \( \beta \) can be formed using (21). Bayes factors for hypothesis tests involving restrictions on \( \beta \) can be formed from versions of
marginal likelihood (22). Finally, under quadratic loss the Bayesian point prediction of \( \tilde{y} \) is \( \tilde{y} = \tilde{x}'\tilde{b} \) and forecast intervals can be
Bayesian econometrics: The New Palgrave Dictionary of Economics

obtained directly from the predictive distribution (23). The standard ‘noninformative’ prior is \( f(\beta, \sigma^{-2}) \propto \sigma^{-2} \), which, unlike the conjugate case, is predicated on the independence of prior beliefs concerning \( \beta \) and \( \sigma^{-2} \). For this prior, under weighted squared error loss, the Bayesian point estimate of \( \beta \) is the OLS estimate \( \hat{b} \). HPD regions are numerically identical to frequentist confidence regions of the same level. Under quadratic loss the Bayesian point prediction of \( \hat{Y} \) is \( \hat{Y}^* = \hat{X} \hat{\beta} \) and forecast intervals are numerically identical to frequentist forecast intervals of the same level. Bayes factors, however, are not well defined in this case since the prior is improper, and as a result the Bayes factor involves a ratio of arbitrary constants. One class of alternatives in this case are the **intrinsic Bayes factors**, proposed by Berger and Pericchi (1996), which sometimes correspond to actual Bayes factors for particular proper priors known as **intrinsic priors**.

**Conclusion**

The coherence of the Bayesian approach contrasts sharply with the conventional statistical methods which sometimes advocate negative estimators of positive quantities to ensure unbiasedness, and confidence intervals which may be null or consist of the whole parameter space. Furthermore, Bayesian methods are completely general and do not require usual regularity conditions, asymptotics, sufficient statistics of finite dimension, or pivotal quantities.

There are now a number of textbook sources for Bayesian econometrics. Bayesian econometrics textbooks started with the major contribution of Zellner (1971). While not a textbook as such, Leamer (1978) remains a transparent introduction to Bayesian thinking. Poirier (1995) provides an intermediate level comparison of Bayesian and frequentist reasoning. More recently, Bauwens, Lubrano and Richard (1999), Koop (2003), Koop et al. (2007), Lancaster (2004), and Geweke (2005) have covered extensively the statistical models of direct interest to economists. These four texts also serve as excellent introductions to modern computational techniques. Finally, Koop, Poirier and Tobias (2006) provides extensive solved Bayesian exercises.

Bayesian methods in macroeconometrics

Frank Schorfheide
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses how Bayesian methods can be used to cope with challenges that arise in the econometric analysis of dynamic stochastic general equilibrium models and vector autoregressions.

Keywords

Bayes’ theorem; Bayesian methods in macroeconometrics; business cycles; calibration; Cowles Commission; dynamic macroeconomics; dynamic stochastic general equilibrium (DSGE) models; economic growth; estimation; expectations; identification; statistical inference; intertemporal optimization problems; joint probability distributions; likelihood functions; macroeconometrics; misspecification; monetary policy shocks; neoclassical growth model; probability; rational expectations; structural change; system-of-equations models; technology shocks; vector autoregressions; linear models; Markov chain Monte Carlo methods; stochastic growth models; habit formation; maximum likelihood; posterior probability; regime-switching models; latent state variables; state-space models

Article

Macroeconometrics encompasses a large variety of probability models for macroeconomic time series as well as estimation and inference procedures to study the determinants of economic growth, to examine the sources of business cycle fluctuations, to understand the propagation of shocks, to generate forecasts, and to predict the effects of economic policy changes. Bayesian methods are a collection of inference procedures that permit researchers to combine initial information about models and their parameters with sample information in a logically coherent manner by use of Bayes’ theorem. Both prior and post-data information is represented by probability distributions.

Unfortunately, the term ‘macroeconometrics’ is often narrowly associated with large-scale system-of-equations models in the Cowles Commission tradition that were developed from the 1950s to the 1970s. These models came under attack on academic grounds in the mid 1970s. Lucas (1976) argued that the
models are unreliable tools for policy analysis because they are unable to predict the effects of policy regime changes on the expectation formation of economic agents in a coherent manner. Sims (1980) criticized the fact that many of the restrictions that are used to identify behavioural equations in these models are inconsistent with dynamic macroeconomic theories and proposed the use of vector autoregressions (VARs) as an alternative. Academic research on econometric models in the Cowles tradition reached a trough in the early 1980s and never recovered. The state-of-the-art is summarized in a monograph by Fair (1994).

I am adopting a modern view of macroeconometrics in this article and will portray an active research area that is tied to modern dynamic macroeconomic theory. Reviewing Bayesian methods in macroeconometrics in a short essay is a difficult task. My review is selective and not representative of Bayesian time-series analysis in general. I have chosen some topics that I believe are important, but the list is by no means exhaustive. I focus on the question how Bayesian methods are used to address some of the challenges that arise in the econometric analysis of dynamic stochastic general equilibrium (DSGE) models and VARs. A more extensive treatment can be found in the survey article by An and Schorfheide (2007).

DSGE models

The term ‘DSGE model’ is often used to refer to a broad class of dynamic macroeconomic models that spans the standard neoclassical growth model discussed in King, Plosser and Rebelo (1988) as well as the monetary model with numerous real and nominal frictions developed by Christiano, Eichenbaum and Evans (2005).

A common feature of these models is that decision rules of economic agents are derived from assumptions about preferences and technologies by solving intertemporal optimization problems. Moreover, agents potentially face uncertainty with respect to, for instance, total factor productivity or the nominal interest rate set by a central bank. This uncertainty is generated by exogenous stochastic processes or shocks that shift technology or generate unanticipated deviations from a central bank's interest-rate feedback rule. Conditional on distributional assumptions for the exogenous shocks, the DSGE model generates a joint probability distribution for the endogenous model variables such as output, consumption, investment, and inflation.

What are the goals?

While macroeconometric methods are used to address many different questions, several issues stand out. Business cycle analysts are interested in identifying the sources of fluctuations; for instance, how important are monetary policy shocks for movements in aggregate output? We would like to understand the propagation of shocks; for example, what happens to aggregate hours worked in response to a technology shock? Moreover, researchers ask questions about structural changes in the economy: has monetary policy changed in the early 1980s? Why did the volatility of many macroeconomic time series drop in the mid 1980s? Macroeconometricians are also interested in forecasting the future: how will inflation and output growth rates evolve over the next eight quarters? Finally, an important aspect of macroeconometrics is to predict the effect of policy changes: how will output and inflation respond to an
What are the challenges?

In principle one could proceed as follows: specify a DSGE model that is sufficiently rich to address the substantive economic question of interest; derive its likelihood function and fit the model to historical data; answer the questions based on the estimated DSGE model. Unfortunately, this is easier said than done. A trade-off between theoretical coherence and empirical fit poses the first challenge to macroeconomic analysis.

Under certain regularity conditions DSGE models can be well approximated by VARs that satisfy particular cross-coefficient restrictions. The DSGE model is misspecified if these restrictions are at odds with the data and the model has difficulties in tracking and forecasting historical time series. Misspecification was quite apparent for the first generation of DSGE models and has led Kydland, Prescott, and their followers since the early 1980s to abandon formal econometric procedures and advocate a calibration approach, outlined for instance in Kydland and Prescott (1996). Recent Bayesian and non-Bayesian research, however, has resulted in formal econometric tools that are general enough to explicitly account for misspecification problems that arise in the context of DSGE models. Examples of Bayesian approaches are Canova (1994), Dejong, Ingram, and Whiteman (1996), Geweke (1999), Schorfheide (2000), Del Negro and Schorfheide (2004), and Del Negro et al. (2006).

The presence of misspecification might suggest that we should simply ignore the cross-coefficient restrictions implied by dynamic economic theories in the empirical work and try to answer the questions posed above directly by VARs. Unfortunately, there is no free lunch. VARs have many free parameters, and without restrictions on their coefficients tend to generate poor forecasts. VARs do not provide a tight economic interpretation of economic dynamics in terms of the behaviour of rational, optimizing agents. Moreover, it is difficult to predict the effects of rare policy regime changes on the expectation formation and the behaviour of economic agents since these are not explicitly modelled. While the most recent generation of DSGE models comes much closer to matching the empirical fit of VARs, as documented in Smets and Wouters (2003), a trade-off between theoretical coherence and empirical fit remains.

A second challenge is identification. The parameters of a model are identifiable if no two parameterizations of that model generate the same probability distribution for the observables. In VARs the mapping between the one-step-ahead forecast errors of the endogenous variables and the underlying structural shocks is not unique, and additional restrictions are necessary to identify, say, a monetary policy or a technology shock. Many of the popular identification schemes and the controversies surrounding them are surveyed in Cochrane (1994), Christiano and Eichenbaum (1999) and Stock and Watson (2001).

DSGE models can be locally approximated by linear rational expectations (LRE) models. While tightly parameterized compared to VARs, LRE models can generate delicate identification problems. Suppose a model implies that \( y_t = \theta e_t [y_{t-1}] + u_t \), where \( u_t \) is an independently distributed random variable with mean zero. If \( 0 \leq \theta < 1 \), then the only stable law of motion for \( y_t \) that satisfies the rational expectations restrictions is \( y_t = u_t \), which means that \( \theta \) is not identifiable. More elaborate examples are discussed in Beyer and Farmer (2004), Lubik and Schorfheide (2004; 2006), and Canova and Sala (2006).
Unfortunately, it is in many cases difficult to detect identification problems in DSGE models, since the mapping from the structural parameters into the autoregressive law of motion for $y_t$ is highly nonlinear and typically can be evaluated only numerically.

Many regularities of macroeconomic time series are indicative of nonlinearities, for instance, the rise and fall of inflation in the 1970s and early 1980s and time-varying volatility of many macroeconomic time series; see, for example, Cogley and Sargent (2005), Sargent, Williams, and Zha (2006), and Sims and Zha (2006). In VARs nonlinear dynamics are typically generated with time-varying coefficients, whereas most DSGE models are nonlinear and only for convenience approximated by linear rational expectations models. Conceptually the analysis of nonlinear models is very similar to the analysis of linear models, but the implementation of the computations is often more cumbersome and poses a third challenge.

**How can Bayesian analysis help?**

Bayesian analysis is conceptually straightforward. Pre-sample information about parameters is summarized by a prior distribution $p(\theta)$. We can also assign discrete probabilities to distinct models although the distinction between models and parameters is somewhat artificial. The prior is combined with the conditional distribution of the data given the parameters (likelihood function) $p(Y|\theta)$. The application of Bayes’ theorem yields the posterior model probabilities and parameter distributions $p(\theta|Y)$. Markov chain Monte Carlo methods can be used to generate $\theta$ draws from the posterior. Based on these draws one can numerically approximate the relevant moments of the posterior and make inference about taste and technology parameters as well as the relative importance and the propagation of the various shocks.

Since DSGE models are to some extent micro-founded, macroeconomists require their parameterization to be consistent with microeconometric evidence on, for instance, labour supply elasticities and the frequency with which firms adjust their prices. If information in the estimation sample were abundant and model misspecification were not a concern, then there would be little need for a prior distribution that summarizes information contained in other data-sets. However, in the estimation of DSGE model this additional information plays an important role.

The prior is used to down-weigh the likelihood function in regions of the parameter space that are inconsistent with out-of-sample information and in which the structural model becomes uninterpretable. The shift from prior to posterior can be an indicator of tensions between different sources of information. If the likelihood function peaks at a value that is at odds with, say, the micro-level information that has been used to construct the prior distribution then marginal data density $\int p(Y|\theta) p(\theta) d\theta$ will be low. If two models have equal prior probabilities, then the ratio of their marginal data densities determine the posterior model odds. Hence, in a posterior odds comparison a DSGE model
Bayesian methods in macroeconometrics: The New Palgrave Dictionary of Economics will automatically be penalized for not being able to reconcile two sources of information with a single set of parameters.

Identification problems manifest themselves through ridges and multiple peaks of equal height in the likelihood function. While Bayesian inference is based on the same likelihood function as classical maximum likelihood estimation, it can bring to bear additional information that may help to discriminate between different parameterizations of a model. If, for instance, the likelihood function is invariant to a subvector $\theta_1$ of $\theta$ then the posterior distribution of $\theta_1$ conditional on the remaining parameters will simply equal to the prior distribution. Hence, a comparison of priors and posteriors can provide important insights about the extent to which the data provide information about the parameters of interest. Regardless, the posterior provides a coherent summary of pre-sample and sample information and can be used for inference and decision making. This insight has been used, for instance, by Lubik and Schorfheide (2004) to assess whether monetary policy in the 1970s was conducted in a way that would allow expectations to be self-fulfilling and cause business cycle fluctuations unrelated to fundamental shocks.

Bayesian inference is well suited for model comparisons. Under a loss function that is zero if the correct model is chosen and 1 otherwise, it is optimal to select the model that has the highest posterior probability. However, in many applications, in particular related to the comparison of two possibly misspecified DSGE models, this zero–1 loss function is not very attractive because it does provide little insight into the dimensions along which the structural models should be improved. Schorfheide (2000) provides a framework for the comparison of two or more potentially misspecified DSGE models. A VAR plays the role of a reference model. If the DSGE models are indeed misspecified the VAR will attain the highest posterior probability and the model comparison is based on the question: given a particular loss function, which DSGE model best mimics the dynamics captured by the VAR?

VARs typically have many more parameters than DSGE models and the role of prior distributions is mainly to reduce the effective dimensionality of this parameter space to avoid over-fitting. More interestingly, if one interprets the DSGE model as a set of restrictions on the VAR, then the DSGE model induces a degenerate prior for the VAR coefficients. If the researcher is concerned about potential misspecification of the DSGE model, a natural approach is to relax the DSGE model restrictions and construct a non-degenerate prior distribution that concentrates most of its mass near the restrictions. This approach was originally proposed by Ingram and Whiteman (1994) and has been further developed by Del Negro and Schorfheide (2004), who provide a framework for the joint estimation of VAR and DSGE model parameters. The framework generates a continuum of intermediate specifications that differ according to the degree by which the restrictions are relaxed. This degree is measured by a hyperparameter and the posterior distribution of the hyperparameter can be interpreted as a measure of fit.

Incorporating model and parameter uncertainty into a decision is straightforward in a Bayesian set-up. Levin et al. (2006), for instance, study the effect of optimal monetary policy under parameter uncertainty in the context of an estimated DSGE model. Let $\delta$ denote a decision, such as the choice of a monetary policy rule or a tax rate, and $L(\delta, \theta)$ be a loss function that is used to evaluate the decision. The optimal choice minimizes the posterior risk $\int L(\delta, \theta) p(\theta | Y) d\theta$. The calculation of the risk is facilitated by Markov chain Monte Carlo methods that enable a numerical evaluation of expected losses. If the parameter $\theta$ in the loss function is replaced by a future observation $y'$ and $p(\theta | Y)$ is replaced by the
predictive distribution \( p(y' | Y) \), the decision-theoretic framework can also be used to generate forecasts from the Bayes model.

Finally, with respect to the analysis of nonlinear models, Bayesian methods are in some instances very helpful. Data-augmentation techniques let researchers efficiently deal with numerical complications that arise in models with latent state variables, such as regime-switching models or VARs with time-varying coefficients as in Cogley and Sargent (2005) and Sims and Zha (2006). On the other hand, the need to compute a likelihood function can create serious obstacles. For instance, the computation of the likelihood function for a DSGE model solved with a nonlinear solution method requires a computational-intensive particle filter as in Fernández-Villaverde and Rubio-Ramírez (2006).

**Conclusion**

The Bayesian paradigm provides a rich framework for inference and decision making with modern macroeconometric models such as DSGE models and VARs. The econometric methods can be tailored to cope with the challenges in this literature: potential model misspecification and a trade-off between theoretical coherence and empirical fit, identification problems, and estimation of models with many parameters based on relatively few observations. Advances in Bayesian computations let the researcher efficiently deal with numerical complications that arise in models with latent state variables, such as regime-switching models, or nonlinear state-space models.

Schorfheide, Frank. "Bayesian methods in macroeconometrics.” The New Palgrave Dictionary of
Bayesian nonparametrics

Stephen Graham Walker
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses Bayesian nonparametric models, arguing that all Bayesians are constructing probability distributions (the prior) on spaces of density functions. The parametric Bayesian can be seen to be making restrictive assumptions about the choice of density for modelling data. In contrast, the nonparametric Bayesian constructs a probability distribution on as many densities as possible. The model is infinite dimensional, yet inference is possible, including density estimation and the implementation of decision rules, such as the maximization of expected utility. An example of a nonparametric model is given and a means by which to make inference provided by simulation techniques.

Keywords

Bayesian nonparametrics; density functions; expected utility; latent variables; likelihood; Markov chain Monte Carlo methods; parametric models; probability distribution; statistical inference; uncertainty

Article

Bayesian nonparametrics, and more generally the Bayesian approach to statistical inference, finds a theoretical justification via a set of axioms of rational behaviour in the presence of uncertainty. Bayesian decision theory establishes how decisions must be made if one desires to avoid irrational behaviour. Thus, coherence is a fundamental concept and is often used as the main argument against competing statistical approaches, such as those based on sampling or fiducial methods. See Lindley (1978) and Bernardo and Smith (1994, ch. 2), who provide a comprehensive discussion on the axiomatic approach to Bayesian inference.
Bayesian statistics is now commonplace among statistical procedures, and is routinely employed in many areas of science, including economics, medicine, biology and others. The use of a prior distribution is the distinguishing feature; the prior distribution updates to the posterior distribution when
the data are observed. The prior distribution is assumed to represent subjective beliefs about an unknown parameter; the data then provide further information about the parameter, and the revised beliefs are then to be found in the posterior distribution. The updating mechanism from prior to posterior is formalized through the procedure of multiplying the likelihood function by the prior density function. This idea was apparently first written down by Thomas Bayes in the 18th century.

The uncertainty which frustrates the choice of decision is to be assessed via the use of a probability distribution, and the coherent way to make progress with the inclusion of data is via Bayes’s theorem.

To elaborate, suppose $\Theta$ is a parameter to be investigated, which if known would provide a decision, and that $\Theta$ belongs to the parameter space $\Theta$, which is a finite dimensional space. For example, $\Theta$ could represent the real line. Data arise from the density $f(x_1, \theta)$ in the form of independent and identically distributed observations, say $x_1, \ldots, x_n$, that is, a sample of size $n$. The likelihood function is any function of $\theta$ which is proportional to

$$l(\theta) = \prod_{i=1}^{n} f(x_i, \theta).$$

Let $\pi(\theta)$ denote the prior density function. Then the posterior density function is given by

$$\pi(\theta|x_1, \ldots, x_n) = \frac{l(\theta) \pi(\theta)}{\int_{\Theta} l(\theta) \pi(\theta) d\theta}. $$

Inference about $\theta$ is then performed using the posterior distribution. For example, an estimate of $\theta$ could be the posterior mean, which is

$$\hat{\theta} = \int_{\Theta} \theta \pi(\theta|x_1, \ldots, x_n).$$

Alternatively, interest might be in the estimate of the density function $f(x_1, \theta)$ itself. In the Bayesian approach this would be provided by the predictive density function, which is given by

$$\hat{f}(x_1, \ldots, x_n) = \int_{\Theta} f(x_1, \theta) \pi(\theta|x_1, \ldots, x_n).$$
Making decisions under uncertainty can be undertaken via the maximization of expected utility approach, see Hirshleifer and Riley (1992), which for the Bayesian would amount to maximizing, over the decision space,

\[
\bar{u}(d) = \int_{\Theta} u(d, \theta) \pi(d|\theta, x_1, \ldots, x_n),
\]

where \(u(d, \theta)\) is the utility (reward) of selecting decision \(d\) from a set of possible decisions when the true parameter state is \(\theta\).

The key to the understanding of Bayesian nonparametrics is to think about the family of densities from which the data arose, which in the parametric case is represented as \(f(x, \theta)\). Such a family may be known, or assumed to be known, for the data \(\{x_1, \ldots, x_n\}\) and the family can be represented by a finite dimensional parameter \(\theta\). On the other hand, it may not be known, making assumptions about the family of densities problematic. In this case what is actually unknown is the density function which generated the data: not a parameter, but the entire density function itself. As a Bayesian it is incumbent on the experimenter to construct a prior distribution on the unknown, which is the entire density, and so a probability distribution, the prior, must be placed on the space of density functions. Let such a space be denoted by \(F\), so a prior distribution \(\Pi\) must be constructed on \(F\). In fact, any parametric Bayesian model defines a probability measure on \(F\). With a parametric model indexed by \(\theta \in \Theta\), with family of densities \(f(x, \theta)\) and prior \(\pi(\theta)\), yields

\[
P(f \in A) = \int_{\{\theta: f(\cdot; \theta) \in A\}} \pi(d\theta),
\]

for suitable sets of densities \(A \subset F\). If we let \(\Pi(A) = P(f \in A)\), then \(\Pi\) is the prior distribution on \(F\), and the pair \(\{f(x, \theta), \pi(\theta)\}\) are a useful way to construct a probability on \(F\). However, this approach of using the parametric model restricts the choice, the \(A\)'s for which \(\Pi(A)>0\) form a very small set, and so, while it can be seen that all Bayesians are constructing probability measures on \(F\), it is the parametric Bayesian who is making restrictive assumptions.

A consequence of the restrictive choice can be seen by considering \(\Omega \subset F\), which we define to be the smallest set of densities which are allocated probability 1, that is, \(\Pi(\Omega) = 1\). A parametric family is typically checked off with the data once it has been observed, to see if the model and the data are compatible. Yet this practice is clearly in contradiction (that is, incoherent) with the allocation of probability 1. See Lindsey (1999) for more on this aspect of Bayesian inference. It is the responsibility of the Bayesian to select \(\Omega\) large enough to make any such checks redundant. This may mean having \(\Omega\) to be the set of all densities, or at least having the set of \(A\)'s for which \(\Pi(A)>0\) to be as large as can be
Bayesian nonparametrics: The New Palgrave Dictionary of Economics

achieved.

In the Bayesian nonparametric approach, the prior distribution is placed on \( F \) directly and there is no finite-dimensional parameter characterizing the random density functions chosen from the prior. The model is infinite-dimensional. The prior is now written as \( \Pi(\text{d}f) \) to reflect the fact that there is no parametric \( \theta \) generating the density \( f \). The likelihood function simply becomes

\[
\ell(f) = \prod_{i=1}^{n} f(x_i)
\]

and so the posterior is given by

\[
\Pi(\text{d}f|x_1, \ldots, x_n) = \frac{\prod_{i=1}^{n} f(x_i)\Pi(\text{d}f)}{\int_F \prod_{i=1}^{n} f(x_i)\Pi(\text{d}f)}.
\]

Now, for example, the estimate of the density generating the data can be the predictive density, which is

\[
\hat{f}(x|x_1, \ldots, x_n) = \int_F f(x)\Pi(\text{d}f|x_1, \ldots, x_n).
\]

For decision theory, if \( u(d, f) \) is the utility of decision \( d \) when \( f \) is the true density, that is, the true density function generating observations, then the maximization of the expected utility rule yields the decision \( d \) maximizing

\[
\tilde{u}(d) = \int_F u(d, f)\Pi(\text{d}f|x_1, \ldots, x_n).
\]

So what has happened is that we have replaced the finite-dimensional \( \theta \) with the infinite-dimensional \( f \). Obviously, the important feature in Bayesian nonparametrics is to be able construct a probability distribution \( \Pi \) on \( F \) such that \( \Omega \) is large. Suppose \( F \) is the space of density functions defined on the real line. Then, for example, we could choose \( \Pi \) by restricting attention to the normal family of density functions. That is, a random normal density function chosen from \( \Pi \) has the mean \( \mu \) chosen from the

Bayesian nonparametrics: The New Palgrave Dictionary of Economics

probability density \( \pi (\mu) \) and the variance \( \sigma^2 \) chosen from the probability density \( \pi (\sigma^2) \).

However, the shape of densities constructed this way is restricted to the normal shape and \( \Omega \) will not be large. To generate more shapes of density function, one needs to increase the number of parameters from two to a large number, even an infinite, but countable, number. This can be achieved by a mixture model, taking the normal distribution and mixing it over the parameters by using a random distribution function. If we let \( \theta = (\mu, \sigma^2) \) and let \( N \) denote the normal density function, then a random density function can be obtained via

\[
f_\theta(x) = \int_\Theta N(x|\theta) \, dP(\theta),
\]

where \( P \) is a random distribution function defined on \((-\infty, +\infty) \times (0, +\infty)\). The variety of shapes for \( f_\theta \) as \( P \) varies over distribution functions is enlarged significantly.

The choice for the random distribution function \( P \) needs to be discussed. A common choice is the Dirichlet process model, introduced by Ferguson (1973). The model generates random distribution functions which are discrete. Essentially, a random path (stochastic process) is generated which behaves as a distribution function. That is, it starts at zero and moves to 1 in a non-decreasing way. It is possible to sample a Dirichlet process via the strategy of taking \( \{\theta_j\}_{j=1}^{\infty} \) to be independent and identically distributed from some fixed distribution \( P_0 \) and \( \{v_j\}_{j=1}^{\infty} \) to be independent and identically distributed from beta \((1, c)\) for some \( c > 0 \). Then

\[
P = \sum_{j=1}^{\infty} w_j \delta_{\theta_j},
\]

where \( w_1 = v_1 \) and for \( j > 1, \)

\[
w_j = v_j \prod_{i=1}^{j-1} (1 - v_i).
\]

It is straightforward to show that the sum of the \( w_j \)'s is one. It is that \( E(P) = P_0 \) and for suitable sets \( B, \)
Using the Dirichlet process itself for modelling independent and identically distributed observations, say \( \{y_1, \ldots, y_n\} \), can be done and the posterior is also a Dirichlet process with updated parameters \( c \to c+n \) and

\[
P_0 \to \frac{cP_0 + nP_n}{c+n},
\]

where \( P_n \) is the empirical distribution function of \( \{y_1, \ldots, y_n\} \). Hence, the Bayes estimate is a nice mixture of the prior choice and the empirical distribution.

However, the Dirichlet process is better placed to construct random density functions via mixtures, and we can write the random density function based on the mixture as

\[
f_{\mathbf{w}, \Theta}(x) = \sum_{j=1}^{\infty} w_j N(x|\theta_j).
\]

This is an infinite-dimensional model and is known as the mixture of Dirichlet process model. It was first studied by Lo (1984) and can really be estimated only by using recent advances in posterior simulation techniques based on Gibbs samplers and more generally Markov chain Monte Carlo methods (Smith and Roberts, 1993; Tierney, 1994). The original simulation technique was introduced by Escobar (1988), and since then a number of algorithms have been described. A nice approach, as is becoming usual with Bayesian nonparametric models, is to use latent variables. A slice variable can work well with the mixture of Dirichlet process model by introducing the latent variable \( u \), which has joint density with \( x \) given by

\[
f_{\mathbf{w}, \Theta}(x, u) = \sum_{j=1}^{\infty} 1(u < w_j) N(x|\theta_j).
\]

Integrating over \( u \) returns us to the original model, and the usefulness of the latent variable is apparent in...
that it makes the infinite sum finite. That is, there is only a finite number of the \( w_j \) which are greater than \( u \), for each \( u > 0 \). A Gibbs sampler can now be employed on the model exactly. Typically one is interested in prediction, and at each iteration of the Markov chain it is possible to sample from the predictive density.

There is nowadays a wide range of Bayesian nonparametric models from which to select for any kind of statistical context. See, for example, Walker et al. (1999) for details. Analysis, in the way of inference or decision making, is then typically undertaken using simulation techniques such as Markov chain Monte Carlo methods.

Most Bayesian nonparametric priors are based on stochastic processes. The probability measure for the process acts as the prior distribution. One such example employed in survival models is based on independent increment processes; one has

\[
S(t) = e^{-Z(t)},
\]

where, with probability 1, \( Z \) is a non-decreasing process with \( Z(0) = 0 \) and \( \lim_{t \to +\infty} Z(t) = +\infty \). Here \( S \) is a random survival distribution, the law governing the path is the prior. The posterior is also based on an independent increment process (conjugate), and a limiting version of the Bayes estimate turns out to be the Kaplan–Meier nonparametric estimator for a survival function.

Bayesian nonparametric models support more outcomes than parametric models. Prior distributions are constructed on function spaces, such as density functions, survival distribution functions or even hazard functions. The prior distributions are the laws governing stochastic processes whose sample paths behave like these types of functions. Inference is typically reliant on Markov chain Monte Carlo methods, often following the introduction of latent variables.

Bayesian statistics

José M. Bernardo
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Statistics is primarily concerned with analysing data, either to assist in appreciating some underlying mechanism or to reach effective decisions. All uncertainties should be described by probabilities, since probability is the only appropriate language for a logic that deals with all degrees of uncertainty, not just absolute truth and falsity. This is the essence of Bayesian statistics. Decision-making is embraced by introducing a utility function and then maximizing expected utility. Bayesian statistics is designed to handle all situations where uncertainty is found. Since some uncertainty is present in most aspects of life, Bayesian statistics arguably should be universally appreciated and used.

Article

Bayesian statistics is a comprehensive approach to both statistical inference and decision analysis which derives from the fact that, for rational behaviour, all uncertainties in a problem must necessarily be described by probability distributions. Unlike most other branches of mathematics, conventional methods of statistical inference do not have an axiomatic basis; as a consequence, their proposed desiderata are often mutually incompatible, and the analysis of the same data may well lead to incompatible results when different, apparently intuitive, procedures are tried. In marked contrast, the Bayesian approach to statistical inference is firmly based on axiomatic foundations which provide a unifying logical structure and guarantee the mutual consistency of the methods proposed. Bayesian methods constitute a complete paradigm for statistical inference, a scientific revolution in Kuhn’s sense. Bayesian statistics require only the mathematics of probability theory and the interpretation of probability which most closely corresponds to the standard use of this word in everyday language: a conditional measure of uncertainty. The main consequence of these axiomatic foundations is precisely the requirement to describe with probability distributions all uncertainties present in the problem. Hence, parameters are treated as random variables; this is not a description of their variability (parameters are typically fixed unknown quantities) but a description of the uncertainty about their true values.

The Bayesian paradigm is easily summarized. Thus, if available data $D$ are assumed to have been generated from a probability distribution $P(D|\omega)$ characterized by an unknown parameter vector $\omega$, the uncertainty about the value of $\omega$ before the data have been observed must be described by a prior probability distribution $P(\omega)$. After data $D$ have been observed, the uncertainty about the value of $\omega$ is described by its posterior distribution $P(\omega|D)$, which is obtained via Bayes’s theorem; hence the adjective Bayesian for this form of inference. Point and region estimates for $\omega$ may be derived from $P(\omega|D)$ as useful summaries of its contents. Measures of the compatibility of the posterior with a particular set $\Theta_0$ of parameter values may be used to test the hypothesis $H_0 = \{\omega \in \Theta_0\}$. If data consist of a random sample $D = \{x_1, \ldots, x_n\}$ from a probability distribution $P(x|\omega)$, inferences about the value of a future observation $x$ from the same process are derived from the (posterior) predictive distribution $P(x|D) = \int_{\Theta} P(x|\omega) P(\omega|D) d\omega$.

An important particular case arises when either no relevant prior information is readily available, or that information is subjective and an ‘objective’ analysis is desired, one that is
exclusively based on accepted model assumptions and well-documented data. This is addressed by reference analysis which uses information-theoretic concepts to derive the appropriate reference posterior distribution \( \mathcal{H}(\omega | D) \), defined to encapsulate inferential conclusions about the value of \( \omega \) solely based on the assumed probability model \( \mathcal{P}(D | \omega) \) and the observed data \( D \).

**Foundations**

The central element of the Bayesian paradigm is the use of probabilities to describe all relevant uncertainties, interpreting \( \mathcal{P}(\mathcal{A} | H) \), the probability of \( \mathcal{A} \) given \( H \), as a conditional measure of uncertainty, on a \([0,1]\) scale, about the occurrence of the event \( \mathcal{A} \) in conditions \( H \). There are two different independent arguments which prove the mathematical inevitability of the use of probabilities to describe uncertainties.

**Exchangeability and representation theorems**

Available data often consist of a finite set \( \{x_1, \ldots, x_n\} \) of ‘homogeneous’ observations, in the sense that only their values matter, not the order in which they appear. Formally, this is captured by the notion of exchangeability. The set of random vectors \( \{x_1, \ldots, x_n\}, x_j \in \mathbf{X}, \) is exchangeable if their joint distribution is invariant under permutations. An infinite sequence of random vectors is exchangeable if all its finite subsequences are exchangeable. Notice that, in particular, any random sample from any model is exchangeable. The general representation theorem implies that, if a set of observations is assumed to be a subset of an exchangeable sequence, then it constitutes a random sample from a probability model ( \( \mathcal{P}(\mathcal{X}) \), \( \omega \in \Omega \)), described in terms of some parameter vector \( \omega \); furthermore, this parameter \( \omega \) is defined as the limit (as \( n \to \infty \)) of some function of the observations, and available information about the value of \( \omega \) must necessarily be described by some probability distribution \( \mathcal{P}(\omega) \). This formulation includes ‘nonparametric’ (distribution free) modelling, where \( \omega \) may index, for instance, all continuous probability distributions on \( \mathbf{X} \). Notice that \( \mathcal{P}(\omega) \) does not model a possible variability of \( \omega \) (since \( \omega \) will typically be a fixed unknown vector), but models the uncertainty associated with its actual value. Under exchangeability (and therefore under any assumption of random sampling), the general representation theorem provides an existence theorem for a probability distribution \( \mathcal{P}(\omega) \) on the parameter space \( \Omega \), and this is an argument which depends only on mathematical probability theory.

**Statistical inference and decision theory**

Statistical decision theory provides a precise methodology to deal with decision problems under uncertainty, but it also provides a powerful axiomatic basis for the Bayesian approach to statistical inference. A decision problem exists whenever there are two or more possible courses of action. Let \( \mathcal{A} \) be the class of possible actions, let \( \Theta \) be the set of relevant events which may affect the result of choosing an action, and let \( \mathcal{C}(\mathcal{A}, \Theta) \in C \), be the consequence of having chosen action \( a \) when event \( \Theta \) takes place. The triplet \( \{\mathcal{A}, \Theta, C\} \) describes the structure of the decision problem. Different sets of principles have been proposed to capture a minimum collection of logical rules that could sensibly be required for rational decision-making. These all consist of axioms with a strong intuitive appeal; examples include the transitivity of preferences (if \( a_1 \succ a_2 \) and \( a_2 \succ a_3 \), then \( a_1 \succ a_3 \)), and the sure thing principle (if \( a_1 \succ a_2 \) given \( E \), and \( a_1 \succ a_2 \) given \( \overline{E} \), then \( a_1 \succ a_2 \)). Notice that these rules are not intended as a description of actual human decision-making, but as a normative set of principles to be followed by someone who aspires to achieve coherent decision-making. There are naturally different options for the set of acceptable principles, but they all lead to the same basic conclusions:

- Preferences among possible consequences should be measured with a utility function \( u(C) = u(a, q) \) which specifies, on some numerical scale, their desirability.
- The uncertainty about the relevant events should be measured with a probability distribution \( \mathcal{P}(q|D) \) describing their plausibility given the conditions under which the decision must be taken (assumptions made and available data \( D \)).
- The best strategy is to take that action \( a^* \) with maximizes the corresponding expected utility, \( \int \mathcal{P}(q|\mathcal{A}) \mathcal{P}(\mathcal{A}|D) dq \).

Notice that the argument described above establishes (from another perspective) the need to quantify the uncertainty about all relevant unknown quantities (the actual value of the
vector $\theta$), and specifies that this must have the mathematical structure of a probability distribution. It has been argued that the development described above (which is not qualified when decisions have to be made) does not apply to problems of statistical inference, where no specific decision making is envisaged. Notice, however, that (a) a problem of statistical inference is typically considered worth analysing because it may eventually help make sensible decisions (as Ramsey put it in the 1930s, a lump of arsenic is poisonous because it may kill someone, not because it has actually killed someone), and (b) statistical inference on $\theta$ has the mathematical structure of a decision problem, where the class of alternatives is the functional space of all possible conditional probability distributions of $\theta$ given the data, and the utility function is a measure of the amount of information about $\theta$ which the data may be expected to provide.

In statistical inference it is often convenient to work in terms of the non-negative loss function $\ell(a, q) = \sup_{a \in A} (u(a, q) - u(a, q))$, which directly measures, as a function of $\theta$, the penalty for choosing a wrong action. The undesirability of each possible action $a \in A$ is then measured by its expected loss, $l(a|D) = \int_A \ell(a, q) \cdot p(q|D) \; dq$, and the best action $a^*$ is that with the minimum expected loss.

The Bayesian paradigm

The statistical analysis of some observed data set $D \in \mathcal{D}$ typically begins with some informal descriptive evaluation, which is used to suggest a tentative, formal probability model $\{ p(D|\omega, H), \; \omega \in \Omega \}$ which, given some assumptions $H$, is supposed to represent, for some (unknown) value of $\omega$, the probabilistic mechanism which has generated the observed data $D$. The arguments outlined above establish the logical need to assess a prior probability distribution $p(\omega|H)$ over the parameter space $\Omega$, describing the available knowledge about the value of $\omega$ under the accepted assumptions $H$, prior to the data being observed. It then follows from Bayes's theorem that, if the probability model is correct, all available information about the value of $\omega$ after the data $D$ have been observed is contained in the corresponding posterior distribution,

$$p(\omega|D, H) = \frac{p(D|\omega, H) \cdot p(\omega|H)}{\int_\Omega p(D|\omega, H) \cdot p(\omega|H) \; d\omega}, \; \omega \in \Omega$$

(1)

It is this systematic use of Bayes's theorem to incorporate the information provided by the data that justifies the adjective ‘Bayesian’ by which the paradigm is usually known. It is obvious from Bayes's theorem that any value of $\omega$ with zero prior density will have zero posterior density. Thus, it is typically assumed (by appropriate restriction, if necessary, of the parameter space $\Omega$) that prior distributions are strictly positive. To simplify the presentation, the assumptions $H$ are often omitted from the notation, but the fact that all statements about $\omega$ given $D$ are also conditional to $H$ should always be kept in mind.

Computation of posterior densities is often facilitated by noting that Bayes's theorem may be simply expressed as $p(\omega|D) \propto p(D|\omega) \cdot p(\omega)$ (where $\propto$ stands for ‘proportional to’ and where, for simplicity, the assumptions $H$ have been omitted from the notation), since the missing proportionality constant $[\int_\Omega p(D|\omega) \cdot p(\omega) \; d\omega]^{-1}$ may always be deduced from the fact that $p(D|\omega)$, a probability density, must integrate to 1.

Improper priors

An improper prior function is defined as non-negative function $\pi(\omega)$ such that $\int_\Omega \pi(\omega) \; d\omega$ is not finite. The formal expression of Bayes's theorem remains, however technically valid if $p(\omega)$ is replaced by an improper prior function $\pi(\omega)$, provided the proportionality constant exists, thus leading to a well-defined proper posterior density $\pi(\omega|D) \propto p(D|\omega) \cdot \pi(\omega)$, which does integrate to 1.

Likelihood principle

Considered as a function of $\omega$ for fixed data $D$, $p(D|\omega)$ is often referred to as the likelihood function. Thus, Bayes's theorem is simply expressed in words by the statement that the posterior is proportional to the likelihood times the prior. It follows from (1) that, provided the same prior $p(\omega)$ is used, two different data sets $D_1$ and $D_2$, with possibly different probability models $p_1(D_1|\omega)$ and $p_2(D_2|\omega)$ which yield proportional likelihood functions, will produce identical posterior distributions for $\omega$. This immediate consequence of Bayes's theorem has been proposed as a principle on its own, the likelihood principle, and it is seen by many as an obvious requirement for reasonable statistical inference.
Bayesian statistics: The New Palgrave Dictionary of Economics

particular, for any given prior \( P(\omega) \), the posterior distribution does not depend on the set \( D \) of possible data values (the outcome space). Notice, however, that the likelihood principle applies only to inferences about the parameter vector \( \omega \) once the data have been obtained. Consideration of the outcome space is essential, for instance, in model criticism, in the design of experiments, in the derivation of predictive distributions, and in the construction of objective Bayesian procedures.

Sequential learning

Naturally, the terms ‘prior’ and ‘posterior’ are only relative to a particular set of data. As one would expect, if exchangeable data \( D = \{x_1, \ldots, x_n\} \) are sequentially presented, the final result will be the same whether data are globally or sequentially processed. Indeed, \( P(\omega|x_1, \ldots, x_{i+1}) \propto P(x_{i+1}|\omega) P(\omega|x_1, \ldots, x_i) \), for \( i = 1, \ldots, n-1 \), so that the ‘posterior’ at a given stage becomes the ‘prior’ at the next.

Sufficiency

For a given probability model, one may find that some particular function of the data \( t = t(D) \in T \) is a sufficient statistic in the sense that, given the model, \( t(D) \) contains all information about \( \omega \) which is available in \( D \). Formally, \( t \) is sufficient if (and only if) there exist non-negative functions \( f \) and \( g \) such that the likelihood function may be factorized in the form

\[
P(D|\omega) = f(\omega, t) g(D).
\]

A sufficient statistic always exists, for \( t(D) = D \) is obviously sufficient; however, a much simpler sufficient statistic, with a fixed dimensionality which is independent of the sample size, often exists. In fact this is known to be the case whenever the probability model belongs to the generalized exponential family, which includes many of the more frequently used probability models. It is easily established that if \( t \) is sufficient, then the posterior distribution of \( \omega \) depends only on the data \( D \) through \( t(D) \), and

\[
P(\omega|D) = P(\omega|t) \propto P(t|\omega) P(\omega).
\]

Robustness

As one would expect, for fixed data and model assumptions, different priors generally lead to different posteriors. Indeed, Bayes’ theorem may be described as a data-driven probability transformation machine which maps prior distributions (describing prior knowledge) into posterior distributions (representing combined prior and data knowledge). It is important to analyse the robustness of the posterior to changes in the prior. Objective posterior distributions based on reference priors (see below) play a central role in this context. Investigation of the sensitivity of the posterior to changes in the prior is an important ingredient of the comprehensive analysis of the sensitivity of the final results to all accepted assumptions, which any responsible statistical study should contain.

Nuisance parameters

Typically, the quantity of interest is not the whole parameter vector \( \omega \), but some function \( q = q(\omega) \) of possibly lower dimension than \( \omega \). Any valid conclusion on the value of \( \theta \) will be contained in its posterior probability distribution \( P(q|D) \), which may be derived from \( P(\omega|D) \) by standard use of probability calculus. Indeed, if \( \lambda = \lambda(\omega) \in \Lambda \) is some other function of \( \omega \) such that \( \Psi = (\theta, \lambda) \) is a one-to-one transformation of \( \omega \), and \( J(\omega) = (\partial \Psi / \partial \omega) \) is the corresponding Jacobian matrix, one may change variables to obtain

\[
P(\Psi|D) = P(q, \lambda|D) = P(\omega|D) J(\omega),
\]

and the required posterior of \( \theta \) is

\[
P(\theta|D) = \int_{\Lambda} P(q, \lambda|D) d\lambda,
\]

the marginal density obtained by integrating out the nuisance parameter \( \lambda \). Naturally, introduction of \( \lambda \) is not necessary if \( \theta (\omega) \) is a one-to-one transformation of \( \omega \). Notice that elimination of unwanted nuisance parameters, a simple integration within the Bayesian paradigm, is a difficult (often polemic) problem for conventional statistics.

Restricted parameter space

Sometimes, the range of possible values of \( \omega \) is effectively restricted by contextual considerations. If \( \omega \) is known to belong to \( \Omega_c \subseteq \Omega \), the prior distribution is positive only in \( \Omega_c \) and, if one uses Bayes’s theorem, it is immediately found that the restricted posterior is

\[
P(\omega|D, \omega \in \Omega_c) = P(\omega|D) \int_{\Omega_c} P(\omega|D) d\omega,
\]
Bayesian statistics: The New Palgrave Dictionary of Economics

for \( \omega \in \Omega \), and obviously vanishes if \( \omega \notin \Omega \). Thus, to incorporate a restriction on the possible values of the parameters, it suffices to renormalize the unrestricted posterior distribution to the set \( \Omega \subset \Omega \) of parameter values which satisfy the required condition. Incorporation of known constraints on the parameter values, a simple renormalization within the Bayesian paradigm, is another very difficult problem for conventional statistics.

Asymptotic behaviour

The behaviour of posterior distributions when the sample size is large is important, for at least two different reasons: (a) asymptotic results provide useful first-order approximations when actual samples are relatively large, and (b) objective Bayesian methods typically depend on the asymptotic properties of the assumed model. Let \( D = \{ x_1, \ldots, x_n \} \), \( x_j \in \mathcal{X} \), be a random sample of size \( n \) from \( \{ p(\omega | x), \omega \in \Omega \} \). It may be shown that, as \( n \to \infty \), the posterior distribution \( p(\omega | D) \) of a discrete parameter \( \omega \) typically converges to a degenerate distribution which gives probability one to the true value of \( \omega \), and that the posterior distribution of a continuous parameter \( \omega \) typically converges to a normal distribution centred at its maximum likelihood estimate (MLE) \( \hat{\omega} \), with a covariance matrix \( F^{-1}(\hat{\omega}) / n \), where \( F(\omega) \) is Fisher information matrix, of general element

\[
F_{ij}(\omega) = -E_{X|\omega} \left[ -\frac{\partial^2}{\partial \omega_i \partial \omega_j} \log p(x|\omega) \right].
\]

Prediction

When data consist of a set \( D = \{ x_1, \ldots, x_n \} \) of homogeneous observations, one is often interested in predicting the value of a future observation \( x \) generated by the same random mechanism that has generated the observations in \( D \). It follows from the foundations arguments discussed above that the solution to this prediction problem must be a probability distribution \( p(x|D) \) which describes the uncertainty about the value that \( x \) will take, given the information provided by \( D \), and any other available knowledge. In particular, if contextual information suggests that data \( D \) may be considered to be a random sample from a distribution in the family \( \{ p(\omega | x), \omega \in \Omega \} \), and \( p(\omega) \) is a probability distribution which encapsulates all available prior information on the value of \( \omega \), the corresponding posterior will be (by Bayes's theorem)

\[
p(\omega | D) \propto \prod_{j=1}^{n} p(x_j | \omega) p(\omega).
\]

Since \( p(x, \omega, D) = p(x | \omega) \), the total probability theorem may then be used to obtain the desired posterior predictive distribution

\[
p(x | D) = \int_{\Omega} p(x | \omega) p(\omega | D) d\omega
\]

which has the form of a weighted average: the average of all possible probability distributions of \( x \), weighted with their corresponding posterior densities. Notice that the conventional practice of plugging in some point estimate \( \hat{\omega} = \hat{\omega}(D) \) and using \( p(x | \hat{\omega}) \) to predict \( x \) may be seriously misleading, for this totally ignores the uncertainty about the true value of \( \omega \). If the assumptions on the probability model are correct, the posterior predictive distribution \( p(x | D) \) will converge, as the sample size increases, to the distribution \( p(x | \omega) \) which has generated the data. Indeed, a good technique to assess the quality of the inferences about \( \omega \) encapsulated in \( p(\omega | D) \) is to check against the observed data the predictive distribution \( p(x | D) \) generated from \( p(\omega | D) \). The argument used to derive \( p(x | D) \) may be extended to obtain the predictive distribution of any function \( y \) of future observations generated by the same process, namely, \( p(y | D) = \int_{\Omega} p(y | \omega) p(\omega | D) \).

Reference analysis

The posterior distribution combines the information provided by the data with relevant available prior information. In many situations, however, either the available prior information

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_B000314&goto=a&result_number=115[] 14[] 2008-12-30 0:46:03
is too vague to warrant the effort required to have it formalized in the form of a probability distribution, or it is too subjective to be useful in scientific communication or public decision making. It is therefore important to identify the mathematical form of a reference prior, a prior that would have a minimal effect, relative to the data, on the posterior inference. Much work has been done to formulate priors which would make this idea mathematically precise. This section summarizes an approach, based on information theory, which may be argued to provide the most advanced general procedure available. In this formulation, the reference prior is that which maximizes the missing information about the quantity of interest.

Reference distributions

Consider data $D$, generated by a random mechanism $P(D|\theta)$ which depends only on a real-valued parameter $\theta \in \Theta \subset \mathbb{R}$, and let $T = t(D) \in T$ be any sufficient statistic (which may well be the complete data set $D$). In Shannon's general information theory, the amount of information $I(T, P(\theta))$ which may be expected to be provided by $D$, about the value of $\theta$ is

$$I(T, P(\theta)) = \int_T \int_{\Theta} P(t|\theta) \log \frac{P(t|\theta)}{P(t)} d\theta dt = E_{\theta} \left[ \int_\Theta P(\theta|t) \log \frac{P(\theta|t)}{P(\theta)} d\theta \right]$$

the expected logarithmic divergence of the prior from the posterior. This is a functional of the prior distribution $P(\theta)$: the larger the prior information, the smaller the information which the data may be expected to provide. The functional $I(T, P(\theta))$ is concave, non-negative, and invariant under one-to-one transformations of $\theta$. Consider now the amount of information $I(T^k, P(\theta))$ about $\theta$ which may be expected from the experiment which consists of $k$ conditionally independent replications $(t_1, \ldots, t_k)$ of the original experiment. As $k \to \infty$, such an experiment would provide any missing information about $\theta$ which could possibly be obtained within this framework; thus, as $k \to \infty$, the functional $I(T^k, P(\theta))$ will approach the missing information about $\theta$ associated with the prior $P(\theta)$. Intuitively, the reference prior for $\theta$ is that which maximizes the missing information about $\theta$. If $p_k(\theta|P)$ denotes the prior density which maximizes $I(T^k, P(\theta))$ in the class $P$ of strictly positive prior distributions which are compatible with accepted assumptions on the value of $\theta$ (which may well be the class of all strictly positive proper priors), then the $\theta$-reference prior is the limit of the sequence of priors $\{p_k(\theta|P)\}_{k=1}^\infty$. The limit is taken in the precise sense that, for any value of the sufficient statistic $t$, the reference posterior, the pointwise limit $p(\theta|t)$ of the corresponding sequence of posteriors $\{p_k(\theta|t, P)\}_{k=1}^\infty$, where $p_k(\theta|t, P) \propto P(t|\theta) p_k(\theta|P)$, may be obtained from $p(\theta|t)$ by formal use of Bayes' theorem, so that $p(\theta|t) \propto P(t|\theta) p(\theta|P)$. The limiting procedure in the definition of a reference prior is not some kind of asymptotic approximation, but an essential element of the definition, required to capture the basic concept of missing information. Notice that, by definition, reference distributions depend only on the asymptotic behaviour of the assumed probability model, a feature which greatly simplifies their actual derivation.

Reference prior functions are often simply called reference priors, even though they are usually improper. They should not be considered as expressions of belief, but technical devices to obtain (proper) posterior distributions, which are a limiting form of the posteriors that would have been obtained from prior beliefs which, when compared with the information which data could provide, are relatively uninformative with respect to the quantity of interest.

If $\theta$ may take only a finite number $m$ of different values, the missing information about $\theta$ associated to the prior $P(\theta)$ is its entropy, $H\{P(\theta)\} = - \sum_{j=1}^m p(\theta_j) \log p(\theta_j)$. Hence the reference prior $p(\theta|P)$ is in this case the prior with maximum entropy within $P$. In particular, if $P$ contains all priors over $\{\theta_1, \ldots, \theta_m\}$, then the reference prior when $\theta$ is the quantity of interest is the uniform prior $p(\theta) = \{1/m, \ldots, 1/m\}$.

If the sufficient statistic $t$ is a consistent, asymptotically sufficient estimator $\tilde{\theta}$ of a continuous parameter $\theta$, and the class of priors is the set $P_0$ of all strictly positive priors, then the reference prior is simply

$$p(\theta|P_0) \propto P(\theta|\tilde{\theta})|_{\tilde{\theta} = \theta} \propto P(\theta|\hat{\theta})|_{\hat{\theta} = \theta}$$

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_800034&type=article&result_number=115
where $\rho(\tilde{y}|\theta)$ is any asymptotic approximation to the posterior distribution of $\theta$, and $p(\tilde{y}|\theta)$ is the sampling distribution of $\tilde{y}$. Under conditions which guarantee asymptotic posterior normality, this reduces to Jeffreys prior, $n(\theta|\theta) \approx F(\theta)^{1/2}$, where $F(\theta)$ is Fisher information function. One-parameter reference priors are consistent under re-parametrization; thus, if $\psi = \psi(\theta)$ is a piecewise one-to-one function of $\theta$, then the $\psi$-reference prior is simply the appropriate probability transformation of the $\theta$-reference prior.

**Example 1.** Exponential data. If $x = \{x_1, \ldots, x_n\}$ is a random sample from $\theta e^{-\theta x}$, the reference prior is Jeffreys prior $n(\theta) = \theta^{-1}$, and the reference posterior is a gamma distribution $n(\theta|\theta) = \mathcal{Ga}(t, n)$, where $t = \sum_{j=1}^{n} x_j$. With a random sample of size $n = 5$ (simulated from an exponential distribution with $\theta = 2$), which yielded a sufficient statistic $t = \sum_{j=1}^{n} x_j = 2.949$, the result is represented in the upper panel of Figure 1. Inferences about the value of a future observation from the same process may are described by the reference predictive posterior

$$
n(x|\theta) = \int_{0}^{\infty} \theta e^{-\theta x} \mathcal{Ga}(\theta|n, t) \, d\theta = nt^n (x + t)^{-(n+1)}.
$$

**Figure 1**

Bayesian reference analysis of the parameter $\theta$ of an exponential distribution $p(x|\theta) = \theta e^{-\theta x}$, given a sample of size $n = 5$ with $t = \sum_{j=1}^{n} x_j = 2.949$. 

\[\pi(\theta|f, n)\]

Nuisance parameters

The extension of the reference prior algorithm to the case of two parameters follows the usual mathematical procedure of reducing the problem to a sequential application of the established procedure for the single parameter case. Thus, if one drops explicit mention to the class \( r \) of priors compatible with accepted assumptions to simplify notation, if the probability model is \( \{ p(\theta, \lambda), \theta \in \Theta, \lambda \in \Lambda \} \) and a \( \theta \) -reference prior \( \pi(\theta, \lambda) \) is required, the reference algorithm proceeds in two steps:

1. Conditional on \( \theta \), \( p(\theta, \lambda) \) depends only on the nuisance parameter \( \lambda \) and, hence, the one-parameter algorithm may be used to obtain the conditional reference prior \( \pi(\theta, \lambda) \).
2. If \( \pi(\lambda|\theta) \) is proper, this may be used to integrate out the nuisance parameter, thus obtaining the one-parameter integrated model

\[
p(\theta) = \int_{\Lambda} p(\theta, \lambda) \pi(\lambda|\theta) \, d\lambda
\]

to which the one-parameter algorithm may be applied again to obtain \( \pi(\theta) \). The \( \theta \) -reference prior is then \( \pi(\theta, \lambda) = \pi(\lambda|\theta) \pi(\theta) \), and the required reference posterior is \( \pi(\theta|\xi) \propto p(\theta|\xi) \pi(\theta) \).

If the conditional reference prior \( \pi(\lambda|\theta) \) is not proper, then the procedure is performed within an increasing sequence \( \{ \Lambda_i \} \) of subsets converging to \( \Lambda \) over which \( \pi(\lambda|\theta) \) is integrable. This makes it possible to obtain a corresponding sequence of \( \theta \) -reference posteriors \( \{ \pi_i(\theta|\xi) \} \) for the quantity of interest \( \theta \), and the required reference posterior is the corresponding pointwise limit \( \pi(\theta|\xi) = \lim_{i} \pi_i(\theta|\xi) \).

The \( \theta \) -reference prior does not depend on the choice of the nuisance parameter \( \lambda \). Notice, however, that the reference prior may depend on the parameter of interest; thus, the \( \theta \) -reference prior may differ from the \( \phi \) -reference prior unless either \( \phi \) is a piecewise one-to-one transformation of \( \theta \) or \( \phi \) is asymptotically independent of \( \theta \). This is an expected consequence of the fact that the conditions under which the missing information about \( \theta \) is maximized may be different from the conditions under which the missing information about some function \( \phi = \phi(\theta, \lambda) \) is maximized.

The preceding algorithm may be generalized to any number of parameters. Thus, if the model is \( p(\theta_1, \ldots, \theta_m) \), a reference prior \( \pi(\theta_1, \theta_2|\theta_{m-1}, \ldots, \theta_1) \times \cdots \times \pi(\theta_2|\theta_1) \times \pi(\theta_1) \) may sequentially be obtained for each ordered parametrization \( \{ \theta_1(\omega), \ldots, \theta_m(\omega) \} \) of interest, and these are invariant under re-parametrization of any of the \( \theta_j(\omega) \)'s. The choice of the ordered parametrization \( \{ \theta_1, \ldots, \theta_m \} \) precisely describes the particular prior required.

Flat priors

Mathematical convenience often leads to the use of ‘flat’ priors, typically some limiting form of a convenient family of priors; this may, however, have devastating consequences. Consider, for instance, that in a normal setting \( p(\mu|m) = N_k(\mu|m, n^{-1}) \), inferences are desired on \( \theta = \Sigma_{j=1}^{k} \mu_j^2 \), the squared distance of the unknown mean \( \mu \) to the origin. It is easily verified that the posterior distribution of \( \theta \) based on a uniform prior on \( \mu \) (or in any ‘flat’ proper approximation) is strongly inconsistent (Stein’s paradox). This is due to the fact that a uniform (or nearly uniform) prior on \( \mu \) is highly informative about \( \theta \), introducing a severe bias on its marginal posterior. The reference prior which corresponds to a parametrization of the form \( \{ \theta, \lambda \} \) produces, however, for any choice of the nuisance parameter \( \lambda \), a reference posterior \( \pi(\theta, \lambda) \propto \theta^{-1/2} \chi^2(\nu, \mu, n\theta) \), where \( \Sigma_{j=1}^{k} \mu_j^2 \), with appropriate consistency properties. Far from being specific to Stein’s example, the inappropriate behaviour in problems with many parameters of specific marginal posterior
distributions derived from multivariate ‘flat’ priors (proper or improper) is indeed very frequent. Hence, sloppy, uncontrolled use of ‘flat’ priors (rather than the relevant reference priors) should be very strongly discouraged.

Inference summaries

From a Bayesian perspective, the final outcome of a problem of inference about any unknown quantity is the corresponding posterior distribution. Thus, given some data $D$ and conditions $H$, all that can be said about any function $q = q(\omega)$ of the parameters which govern the model is contained in the posterior distribution $p(q|D, H)$, and all that can be said about some function $y$ of future observations from the same model is contained in its posterior predictive distribution $p(y|D, H)$. However, to make it easier for the user to assimilate the appropriate conclusions, it is often convenient to summarize the information contained in the posterior distribution by (a) providing values of the quantity of interest which, in the light of the data, are likely to be a good proxy for its true (unknown) value, and by (b) measuring the compatibility of the results with hypothetical values of the quantity of interest which might have been suggested in the context of the investigation. The Bayesian counterparts of those of traditional problems of estimation and hypothesis testing are now briefly considered.

Point estimation

Let $D$ be the available data, which are assumed to have been generated by a probability model $\{ p(D|\omega), \omega \in \Omega \}$, and let $q = q(\omega) \in \Theta$ be the quantity of interest. A point estimator of $\theta$ is some function of the data $\hat{q} = \hat{q}(D)$ which could be regarded as an appropriate proxy for the actual, unknown value of $\theta$. Formally, to choose a point estimate for $\theta$ is a decision problem, where the action space is the class $\Theta$ of possible $\theta$ values. As dictated by the foundations of decision theory, to solve this decision problem it is necessary to specify a loss function $\ell(\hat{q}, q)$ measuring the consequences of acting as if the true value of the quantity of interest were $\hat{q}$ when it is actually $\theta$. The expected posterior loss if $\hat{q}$ were used is

$$
I(\hat{q}|D) = \int_{\Theta} \ell(\hat{q}, q) \ p(q|D) \ dq,
$$

and the corresponding Bayes estimator is that function of the data, $q^* = q^* (D)$, which minimizes $I(\hat{q}|D)$.

For any given model, data and prior, the Bayes estimator obviously depends on the loss function which has been chosen. The loss function is context specific, and should be selected in terms of the anticipated uses of the estimate; however, a number of conventional loss functions have been suggested for scientific communication. These loss functions produce estimates which may often be regarded as simple descriptions of the location of the posterior distribution. If the loss function is quadratic, so that $\ell(\hat{q}, q) = (\hat{q} - q)^2$, the corresponding Bayes estimator is the posterior mean $E[q|D]$ (on the assumption that the mean exists). Similarly, if the loss function is a zero-one function, so that $\ell(\hat{q}, q) = 0$ if $\hat{q}$ belongs to a ball or radius $\varepsilon$ centred in $\theta$, and $\ell(\hat{q}, q) = 1$ otherwise, the corresponding Bayes estimator converges to the posterior mode as the ball radius $\varepsilon$ tends to zero (on the assumption that a unique mode exists). If $\theta$ is univariate and the loss function is linear, so that $\ell(\hat{q}, \theta) = c_1 (\hat{q} - \theta)$ if $\hat{q} \geq \theta$, and $\ell(\hat{q}, \theta) = c_2 (\theta - \hat{q})$ otherwise, the Bayes estimator is the posterior quantile of order $c_2 / (c_1 + c_2)$, so that $P(\theta < \hat{q}^*) = c_2 / (c_1 + c_2)$. In particular, if $c_1 = c_2$, the corresponding Bayes estimator is the posterior median. The results quoted for linear loss functions clearly illustrate the fact that any possible parameter value may turn out to be a Bayes estimator: it all depends on the loss function characterizing the consequences of the anticipated uses of the estimate.

Conventional loss functions are typically non-invariant under re-parametrization, so that the Bayes estimator $\phi^*$ of a one-to-one transformation $\phi = \phi(q)$ of the original parameter $\theta$ is not necessarily $\phi^* (\theta^*)$ (the univariate posterior median, which is invariant, is an interesting exception). Moreover, conventional loss functions focus on the discrepancy between the estimate $\hat{q}$ and the true value $\theta$, rather than on the more relevant discrepancy between the probability models which they label. Intrinsic losses directly focus on the discrepancy between the probability distributions $p(D|q)$ and $p(D|\hat{q})$, and typically produce invariant solutions. An attractive example is the intrinsic discrepancy $\ell(\hat{q}, q)$, defined as the minimum logarithmic divergence between a probability model labelled by $\theta$ and a probability model labelled by $\hat{q}$. When there are no nuisance parameters, this is
Bayesian statistics: The New Palgrave Dictionary of Economics

where \( t = t(D) \in T \) is any sufficient statistic (which may well be the whole data set \( D \)). The definition is easily extended to problems with nuisance parameters. The Bayes estimator is obtained by minimizing the corresponding posterior expected loss. An objective estimator, the intrinsic estimator \( \hat{\theta}_{\text{intr}} = \hat{\theta}_{\text{intr}}(D) \), is obtained by minimizing the expected intrinsic discrepancy with respect to the reference posterior distribution,

\[
\delta(\hat{\theta}, \theta) = \min \left\{ \kappa(\hat{\theta}|\theta), \kappa(q|\theta) \right\}, \kappa(q|\theta) = \int_T \frac{p(\theta|q)}{p(\theta|q)} d\tau
\]

(6)

Since the intrinsic discrepancy is invariant under re-parametrization, minimizing its posterior expectation produces invariant estimators. Thus, the intrinsic estimator of say, the log of the speed of a galaxy is simply log of the intrinsic estimator of the speed of the galaxy.

Region estimation

To describe the inferential content of the posterior distribution of the quantity of interest \( p(q|D) \) it is often convenient to quote credible regions, defined as subsets of the parameter space \( \Theta \) of given posterior probability. For example, the identification of regions containing 50, 90, 95, or 99 per cent of the probability under the posterior may be sufficient to convey the general quantitative messages implicit in \( p(q|D) \). Indeed, this is the intuitive basis of graphical representations of univariate distributions like those provided by boxplots. A posterior q-credible region for \( \theta \) is any region \( C \subset \Theta \) such that \( \int_C p(q|D) dq = q \). Notice that this provides immediately a direct intuitive statement about the unknown quantity of interest \( \theta \) in probability terms, in marked contrast to the circumspectatory statements provided by conventional confidence intervals. A credible region is invariant under re-parametrization; thus, for any q-credible region \( C \) for \( \theta \), \( \phi(C) \) is a q-credible region for \( \phi = \phi(q) \).

Clearly, for any given \( q \) there are generally infinitely many credible regions. Credible regions are often selected to have minimum size (length, area, volume), resulting in highest probability density (HPD) regions, where all points in the region have larger probability density than all points outside. However, HPD regions are not invariant under re-parametrization: the image \( \phi(C) \) of an HPD region \( C \) will be a credible region for \( \phi \), but will not generally be HPD; indeed, there is no compelling reason to restrict attention to HPD credible regions. In one-dimensional problems, posterior quantiles are often used to derive credible regions. Thus, if \( \theta_q = \theta_q(D) \) is the 100q per cent posterior quantile of \( \theta \in \Theta \subset \mathbb{R} \), then \( C = \{ \theta; \theta \leq \theta_q \} \) is a one-sided, typically unique q-credible region, and it is invariant under re-parametrization; the similarly invariant probability centred q-credible regions of the form \( C = \{ \theta; \theta(1 - q)/2 \leq \theta \leq \theta(1 + q)/2 \} \) are easier to compute than HPD regions; this notion, however, does not extend to multivariate problems.

Choosing a p-credible region may be seen as a decision problem where the action space is the class of all p-credible regions. Foundations then dictate that a loss function \( \ell(q, q) \) must be specified, and that the region chosen should consist of those \( \theta \) values with the lowest expected posterior loss \( \ell(\hat{\theta}|D) = \int \ell(\hat{\theta}|q) p(q|D) dq \). By definition, lowest posterior loss (LPL) regions are credible regions where all points in the region have smaller expected posterior loss than all points outside. If the loss function is quadratic, so that \( \ell(q, q) = (q - \hat{q})' (q - \hat{q}) \), the LPL p-credible region is a Euclidean sphere centred at the posterior mean \( E[\theta|D] \). Like HPD regions, LDL quadratic credible regions are not invariant under re-parametrization; however, LDL intrinsic regions, which minimize the posterior expectation of the invariant intrinsic discrepancy loss (6) are obviously invariant. Intrinsic p-credible regions are LDL intrinsic regions which minimize the expected intrinsic discrepancy with respect to the reference posterior distribution. These provide a general, invariant, objective solution to multivariate region estimation. The notions of point and region parameter estimation described above may easily extended to prediction problems by using the posterior predictive rather than the posterior of the parameter.

Hypothesis testing

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_B0003346&goto=a&result_number=115
The posterior distribution \( P(q|D) \) of the quantity of interest \( \theta \) conveys immediate intuitive information on those values of \( \theta \) which, given the assumed model, may be taken to be \( \text{compatible with} \) the observed data \( D \), namely, those with a relatively high probability density. Sometimes, a restriction \( q \in \Theta_0 \subset \Theta \) of the possible values of the quantity of interest (where \( \Theta_0 \) may possibly consist of a single value \( \theta_0 \)) is suggested in the course of the investigation as deserving special consideration, either because restricting \( \theta \) to \( \Theta_0 \) would greatly simplify the model or because there are additional, context-specific arguments suggesting that \( q \in \Theta_0 \). Intuitively, the hypothesis \( H_0 = \{ q \in \Theta_0 \} \) should be judged to be \( \text{compatible with} \) the observed data \( D \) if there are elements in \( \Theta_0 \) with a relatively high posterior density; however, a more precise conclusion is often required and, once again, this is possible with a decision-oriented approach. Formally, testing the hypothesis \( H_0 = \{ q \in \Theta_0 \} \) is a \( \text{decision problem} \) where the action space has only two elements, namely, to accept (\( a_0 \)) or to reject (\( a_1 \)) the proposed restriction. To solve this decision problem, it is necessary to specify an appropriate loss function, \( \ell(\theta, q) \), measuring the consequences of accepting or rejecting \( H_0 \) as a function of the actual value \( \theta \) of the vector of interest. The optimal action will be to reject \( H_0 \) if (and only if) the expected posterior loss of accepting, \( \int_{\Theta} \ell(\theta_0, q) P(q|D) \, dq \), is larger than the expected posterior loss of rejecting, \( \int_{\Theta} \Delta \ell(\theta, q) P(q|D) \, dq > 0 \).

\[
\int_{\Theta} \left[ \ell(\theta_0, q) - \ell(\theta_1, q) \right] P(q|D) \, dq = \int_{\Theta} \Delta \ell(\theta, q) P(q|D) \, dq > 0 \quad (8)
\]

Therefore, only the loss difference \( \Delta \ell(q) = \ell(\theta_0, q) - \ell(\theta_1, q) \), which measures the \( \text{advantage} \) of rejecting \( H_0 \) as a function of \( \theta \), has to be specified: the hypothesis \( H_0 \) should be rejected whenever the expected advantage of rejecting \( H_0 \) is positive.

The simplest loss structure has the zero-one form given by \( \{ \ell(\theta_0, q) = 0, \ell(\theta_1, q) = 1 \} \) if \( q \in \Theta_0 \) and, similarly, \( \{ \ell(\theta_0, q) = 1, \ell(\theta_1, q) = 0 \} \) if \( q \notin \Theta_0 \), so that the \( \text{advantage} \) \( \Delta \ell(q) \) of rejecting \( H_0 \) is 1 if \( q \notin \Theta_0 \) and it is -1 otherwise. With this, rather naive, loss function the optimal action is to reject \( H_0 \) if (and only if) \( \Pr(q \notin \Theta_0|D) > \Pr(q \in \Theta_0|D) \). Notice that this formulation requires that \( \Pr(q \in \Theta_0|D) > 0 \), that is, that the hypothesis \( H_0 \) has a strictly positive prior probability. If \( \theta \) is a continuous parameter and \( \Theta_0 \) consists of a single point \( \theta_0 \) (sharp null problems), this requires the use of a non-regular highly informative prior which places a positive probability mass at \( \theta_0 \). This posterior probability approach is therefore only appropriate if it is sensible to condition on the assumption that \( \theta \) is indeed concentrated around \( \theta_0 \).

Frequently, however, the observability of the data with \( H_0 \) is to be judged without assuming such a sharp prior knowledge. In those situations, the \( \text{advantage} \) \( \Delta \ell(q) \) of rejecting \( H_0 \) as a function of \( \theta \) may be typically assumed to be of the general form \( \Delta \ell(q) = \delta(\Theta_0, q) - d^* \), for some \( d^* > 0 \), where \( \delta(\Theta_0, q) \) is some measure of the discrepancy between the assumed model \( P(D|q) \) and its closest approximation within the class \( \{ P(D|q_0), q_0 \in \Theta_0 \} \) and such that \( \delta(\Theta_0, q) = 0 \) whenever \( q \in \Theta_0 \), and \( d^* \) is a context dependent \( \text{utility constant} \) which measures the (necessarily positive) advantage of being able to work with the restricted model when it is true. For reasons similar to those supporting its use in estimation, an attractive choice for the loss function \( \delta(\Theta_0, q) \) is an appropriate extension of the intrinsic discrepancy loss; when there are no nuisance parameters, this is given by \( \delta(\Theta_0, q) = \inf_{q_0 \in \Theta_0} \delta(q_0, q) \) where \( \delta(q_0, q) \) is the intrinsic discrepancy loss defined by (6). The corresponding optimal strategy, called the ‘Bayesian reference criterion’ (BRC), is then to reject \( H_0 \) if, and only if,

\[
d(\Theta_0|D) = \int_{\Theta} \delta(\Theta_0, q) P(q|D) \, dq > d^*.
\]

The choice of \( d^* \) plays a similar role to the choice of the significance level in conventional hypothesis testing. Standard choices for scientific communication may be of the form \( d^* = \log k \) for, in view of (6) and of (7), this means that the data \( D \) are expected to be at least \( k \) times more likely under the true model than under \( H_0 \). This is actually equivalent to rejecting \( H_0 \) if \( \Theta_0 \) is not contained in an intrinsic \( q_0 \)-credible region for \( \theta \) whose size \( q_0 \) depends on \( k \). Under conditions for asymptotic posterior normality.

\[ q_k \approx 2 \Phi \left( (2 \log \theta - 1)^{1/2} \right) - 1, \]

where \( \Phi \) is the standard normal distribution function. For instance, if \( k = 100, q_k \approx 0.996 \), while if \( k = 11.25, q_k \approx 0.95 \). The Bayesian reference criterion provides a general objective procedure for multivariate hypothesis testing which is invariant under re-parametrization.

**Example 2.** Exponential data, continued. The intrinsic discrepancy loss for an exponential model is \( \delta(\tilde{\theta}, \theta) = g(\varphi), \) if \( \varphi \leq 1 \), and \( \delta(\tilde{\theta}, \theta) = g(1/\varphi), \) if \( \varphi > 1 \), where \( g(\varphi) = \varphi - 1 - \log \varphi \), and \( \varphi = \tilde{\theta} / \theta \). Using (7) with the data from Example 1, the expected intrinsic loss \( a(\tilde{h}|x) \) is the function represented in the lower panel of Figure 1. The intrinsic estimate is the value which minimizes \( a(\tilde{h}|x) \), \( \tilde{h}_{\text{in}} = 1.546 \) (marked with a solid dot in the figure), and the intrinsic 0.90-credible set is \((0.720,3.290)\), the set of parameter values with expected loss below 1.407 (corresponding to the shaded area in the upper panel of the figure).

Bayesian time series analysis

Mark F.J. Steel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article describes the use of Bayesian methods in the statistical analysis of time series. The use of Markov chain Monte Carlo methods has made even the more complex time series models amenable to Bayesian analysis. Models discussed in some detail are ARIMA models and their fractionally integrated counterparts, state space models, Markov switching and mixture models, and models allowing for time-varying volatility. A final section reviews some recent approaches to nonparametric Bayesian modelling of time series.

Article

Bayesian methods
The importance of Bayesian methods in econometrics has increased rapidly since the early 1990s. This has, no doubt, been fuelled by an increasing appreciation of the advantages that Bayesian inference entails. In particular, it provides us with a formal way to incorporate the prior information we often possess before seeing the data, it fits perfectly with sequential learning and decision making, and it directly leads to exact small sample results. In addition, the Bayesian paradigm is particularly natural for prediction, since we take into account all parameter or even model uncertainty. The predictive distribution is the sampling distribution where the parameters are integrated out with the posterior distribution and provides exactly what we need for forecasting, often a key goal of time-series analysis. Usually, the choice of a particular econometric model is not pre-specified by theory, and many competing models can be entertained. Comparing models can be done formally in a Bayesian framework through so-called posterior odds, which is the product of the prior odds and the Bayes factor. The Bayes factor between any two models is the ratio of the likelihoods integrated out with the corresponding prior and summarizes how the data favour one model over another. Given a set of possible models, this immediately leads to posterior model probabilities. Rather than choosing a single model, a natural way to deal with model uncertainty is to use the posterior model probabilities to average out the inference (on observables or parameters) corresponding to each of the separate models. This is called Bayesian model averaging. The latter was already mentioned in Leamer (1978) and recently applied to economic problems in, for example, Fernández, Ley and Steel (2001) (for growth regressions) and in Garratt et al. (2003) and Jacobson and Karlsson (2004) (for macroeconomic forecasting).

An inevitable prerequisite for using the Bayesian paradigm is the specification of prior distributions for all quantities in the model that are treated as unknown. This has been the source of some debate, a prime example of which is given by the controversy over the choice of prior on the coefficients of simple autoregressive models. The issue of testing for a unit root (deciding whether to difference the series before modelling it through a stationary model) is subject to many difficulties from a sampling-theoretical perspective. Comparing models in terms of posterior odds provides a very natural Bayesian approach to testing, which does not rely on asymptotics or approximations. It is, of course, sensitive to how the competing models are defined (for example, do we contrast the stationary model with a pure unit root model or a model with a root larger than or equal to 1?) and to the choice of prior. The latter issues have lead to some controversy in the literature, and prompted a special issue of the Journal of Applied Econometrics with animated discussion around the paper by Phillips (1991). The latter paper advocated the use of Jeffreys’ principles to represent prior ignorance about the parameters (see also the discussion in Bauwens, Lubrano and Richard, 1999, ch. 6).

Like the choice between competing models, forecasting can also be critically influenced by the prior. In fact, prediction is often much more sensitive than parameter inference to the choice of priors (especially on autoregressive coefficients) and Koop, Osiewalski and Steel (1995) show that imposing stationarity through the prior on the autoregressive coefficient in a simple AR(1) model need not lead to stabilization of the predictive variance as the forecast horizon increases.

**Computational algorithms**

Partly, the increased use of Bayesian methods in econometrics is a consequence of the availability of very efficient and flexible algorithms for conducting inference through simulation in combination with
Bayesian time series analysis: The New Palgrave Dictionary of Economics

ever more powerful computing facilities, which have made the Bayesian analysis of non-standard problems an almost routine activity. Particularly, Markov chain Monte Carlo (MCMC) methods have opened up a very useful class of computational algorithms and have created a veritable revolution in the implementation of Bayesian methods. Whereas Bayesian inference before 1990 was at best a difficult undertaking in practice, reserved for a small number of specialized researchers and limited to a rather restricted set of models, it has now become a very accessible procedure which can fairly easily be applied to almost any model. The main idea of MCMC methods is that inference about an analytically intractable posterior (often in high dimensions) is conducted through generating a Markov chain which converges to a chain of drawings from the posterior distribution. Of course, predictive inference is also immediately available once one has such a chain of drawings. Various ways of constructing such a Markov chain exist, depending on the structure of the problem. The most commonly used are the Gibbs sampler and the Metropolis Hastings sampler. The use of data augmentation (that is, adding auxiliary variables to the sampler) can facilitate implementation of the MCMC sampler, so that often the analysis is conducted on an augmented space including not only the model parameters but also things like latent variables and missing observations. An accessible reference to MCMC methods is, for example, Gamerman (1997).

As a consequence, we are now able to conduct Bayesian analysis of time series models that have been around for a long time (such as ARMA models) but also of more recent additions to our catalogue of models, such as Markov switching and nonparametric models, and the literature is vast. Therefore, I will have to be selective and will try to highlight a few areas which I think are of particular interest. I hope this can give an idea of the role that Bayesian methods can play in modern time series analysis.

ARIMA and ARFIMA models

Many models used in practice are of the simple ARIMA type, which have a long history and were formalized in Box and Jenkins (1970). ARIMA stands for ‘autoregressive integrated moving average’ and an ARIMA\((p,d,q)\) model for an observed series \(\{\nu_t\}\), \(t = 1, \ldots, T\) is a model where the \(d\)th difference \(\nu_t - \nu_{t-d}\) is taken to induce stationarity of the series. The process \(\{z_t\}\) is then modelled as \(z_t = \mu + \varepsilon_t\) with

\[
\varepsilon_t = \psi_1 \varepsilon_{t-1} + \cdots + \psi_p \varepsilon_{t-p} + \nu_t - \theta_1 \nu_{t-1} - \cdots - \theta_q \nu_{t-q}
\]

or in terms of polynomials in the lag operator \(L\) (defined through \(L^s \xi_t = \xi_{t-s}\)):

\[
\psi(L) \varepsilon_t = \theta(L) \nu_t
\]
where \( \{u_t\} \) is white noise and usually distributed as \( u_t \sim N(0, \sigma^2) \). The stationarity and invertibility conditions are simply that the roots of \( \Phi(L) \) and \( \Theta(L) \), respectively, are outside the unit circle. An accessible and extensive treatment of the use of Bayesian methods for ARIMA models can be found in Bauwens, Lubrano and Richard (1999). The latter book also has a useful discussion of multivariate modelling using vector autoregressive (VAR) models and cointegration. The MCMC samplers used for inference in these models typically use data augmentation. Marriott et al. (1996) use a direct conditional likelihood evaluation and augment with unobserved data and errors to conduct inference on the parameters (and the augmented vectors \( \varepsilon_a = (\varepsilon_0, \varepsilon_1, \ldots, \varepsilon_{1-p})' \) and \( \eta_a = (\eta_0, \eta_1, \ldots, \eta_{1-q}) \)). A slightly different approach is followed by Chib and Greenberg (1994), who consider a state space representation and use MCMC on the parameters augmented with the initial state vector.

ARIMA models will either display perfect memory (if there are any unit roots) or quite short memory with geometrically decaying autocorrelations (in the case of a stationary ARMA model). ARFIMA (‘autoregressive fractionally integrated moving average’) models (see Granger and Joyeux, 1980) have more flexible memory properties, due to fractional integration which allows for hyperbolic decay. Consider \( z_t = \Delta_{\delta} v_t - \mu \), which is modelled by an ARFIMA(\( p, \delta, q \)) model as:

\[
\phi(L)(1-L)^{\delta} z_t = \theta(L) u_t,
\]

where \( \{u_t\} \) is white noise with \( u_t \sim N(0, \sigma^2) \), and \( \delta \in (-1, 0.5) \). The fractional differencing operator \((1-L)^{\delta} \) is defined as

\[
(1-L)^{\delta} = \sum_{j=0}^{\infty} c_j(\delta) L^j,
\]

where \( c_0(\cdot)=1 \) and for \( j>0 \):

\[
c_j(\alpha) = \prod_{k=1}^{j} \left(1 - \frac{1 + \alpha}{k}\right).
\]
This model takes the entire past of $z_t$ into account, and has as a special case the ARIMA($p,1,q$) for $y_t$ (for $\delta = 0$). If $\delta > -1$, $z_t$ is invertible (Odaki, 1993) and for $\delta < 0.5$ we have stationarity of $z_t$. Thus, we have three regimes:

- $\delta \in (-1, -0.5)$: $y_t$ trend-stationary with long memory
- $\delta \in (-0.5, 0)$: $z_t$ stationary with intermediate memory
- $\delta \in (0, 0.5)$: $z_t$ stationary with long memory.

Of particular interest is the impulse response function $I(n)$, which captures the effect of a shock of size one at time $t$ on $y_{t+n}$, and is given by

$$I(n) = \sum_{i=0}^{n} c_i (-\delta - 1) J(n - i),$$

with $J(i)$ the standard ARMA($p,q$) impulse responses (that is, the coefficients of $\phi^{-1}(L)\theta (L)$). Thus, $I(\infty)$ is $0$ for $\delta < 0$, $\theta (1)/\phi (1)$ for $\delta = 0$ and $\infty$ for $\delta > 0$. Koop et al. (1997) analyse the behaviour of the impulse response function for real US GNP data using a set of 32 possible models containing both ARMA and ARFIMA models for $z_t$. They use Bayesian model averaging to conduct predictive inference and inference on the impulse responses, finding about one-third of the posterior model probability concentrated on the ARFIMA models. Koop et al. (1997) use importance sampling to conduct inference on the parameters, while MCMC methods are used in Pai and Ravishanker (1996) and Hsu and Breidt (2003).

**State space models**

The basic idea of such models is that an observable $y_t$ is generated by an observation or measurement equation

$$y_t = F_t' \theta_t + v_t,$$

where $v_t \sim N(0, V_t)$, and is expressed in terms of an unobservable state vector $\theta_t$ (capturing, for example, levels, trends or seasonal effects) which is itself dynamically modelled through a system or transition equation

$$\theta_t = C_t \theta_{t-1} + w_t.$$
Bayesian time series analysis: The New Palgrave Dictionary of Economics

with $w_t \sim N(0, W_t)$ and all error terms $\{v_t\}$ and $\{w_t\}$ are mutually independent. Normality is typically assumed, but is not necessary and a prior distribution is required to describe the initial state vector $\theta_0$. Models are defined by the (potentially time-varying) quadruplets $\{F_t, G_t, V_t, W_t\}$ and the time-varying states $\theta_t$ make them naturally adaptive to changing circumstances. This feature also fits very naturally with Bayesian methods, which easily allow for sequential updating. These models are quite general and include as special cases, for example, ARMA models, as well as stochastic volatility models, used in finance (see below).

There is a relatively long tradition of state space models in econometrics and a textbook treatment can already be found in Harvey (1981). Bayesian methods for such models were discussed in, for example, Harrison and Stevens (1976), and a very extensive treatment is provided in West and Harrison (1997), using the terminology ‘dynamic linear models’. An accessible introduction to Bayesian analysis with these models can be found in Koop (2003, Ch. 8).

Online sequential estimation and forecasting with the simple Normal state space model above can be achieved with Kalman filter recursions, but more sophisticated models (or estimation of some aspects of the model besides the states) usually require numerical methods for inference. In that case, the main challenge is typically the simulation of the sequence of unknown state vectors. Single-state samplers (updating one state vector at a time) are generally less efficient than multi-state samplers, where all the states are updated jointly in one step. Efficient algorithms for multi-state MCMC sampling schemes have been proposed by Carter and Kohn (1994) and de Jong and Shephard (1995). For fundamentally non-Gaussian models, the methods in Shephard and Pitt (1997) can be used. A recent contribution of Harvey, Trimbur and van Dijk (2006) uses Bayesian methods for state space models with trend and cyclical components, exploiting informative prior notions regarding the length of economic cycles.

Markov switching and mixture models

Markov switching models were introduced by Hamilton (1989) and essentially rely on an unobserved regime indicator $s_t$, which is assumed to behave as a discrete Markov chain with, say, $K$ different levels. Given $s_t = i$ the observable $y_t$ will be generated by a time series model which corresponds to regime $i$, where $i = 1, \ldots, K$. These models are often stationary ARMA models, and the switching between regimes will allow for some non-stationarity, given the regime allocations. Such models are generally known as hidden Markov models in the statistical literature. Bayesian analysis of these models is very natural, as that methodology provides an immediate framework for dealing with the latent states, $\{s_t\}$, and a simple MCMC framework for inference on both the model parameters and the states was proposed in Albert and Chib (1993). A bivariate version of the Hamilton model is analysed in Paap and van Dijk (2003), who also examine the cointegration relations between the series modelled and find evidence for cointegration between US per capita income and consumption. Using a similar model, Smith and Summers (2005) examine the synchronization of business cycles across countries and find strong evidence in favour of the multivariate Markov switching
model over a linear VAR model. When panel data are available, another relevant question is whether one can find clusters of entities (such as countries or regions) which behave similarly, while allowing for differences between the clusters. This issue is addressed from a fully Bayesian perspective in Frühwirth-Schnatter and Kaufmann (2006), where model-based clustering (across countries) is integrated with a Markov switching framework (over time). This is achieved by a finite mixture of Markov switching autoregressive models, where the number of elements in the mixture corresponds to the number of clusters and is treated as an unknown parameter. Frühwirth-Schnatter and Kaufmann (2006) analyse a panel of growth rates of industrial production in 21 countries and distinguish two clusters with different business cycles. This also feeds into the important debate on the existence of so-called convergence clubs in terms of income per capita as discussed in Durlauf and Johnson (1995) and Canova (2004).

Another popular way of inducing nonlinearities in time series models is through so-called threshold autoregressive models, where the choice of regimes is not governed by an underlying Markov chain but depends on previous values of the observables. Bayesian analyses of such models can be found in, for example, Geweke and Terui (1993) and are extensively reviewed in Bauwens, Lubrano and Richard (1999, ch. 8). The use of Bayes factors to choose between various nonlinear models, such as threshold autoregressive and Markov switching models is discussed in Koop and Potter (1999).

Geweke and Keane (2006) present a general framework for Bayesian mixture models where the state probabilities can depend on observed covariates. They investigate increasing the number of components in the mixture, as well as the flexibility of the components and the specification of the mechanism for the state probabilities, and find their mixture model approach compares well with ARCH-type models (as described in the next section) in the context of stock return data.

Models for time-varying volatility

The use of conditional heteroskedasticity initially introduced in the ARCH (autoregressive conditional heteroskedasticity) model of Engle (1982) has been extremely successful in modelling financial time series, such as stock prices, interest rates and exchange rates. The ARCH model was generalized to GARCH (generalized ARCH) by Bollerslev (1986). A simple version of the GARCH model for an observable series \( \{y_t\} \), given its past which is denoted by \( I_{t-1} \), is the following:

\[
y_t = \omega_t \sqrt{h_t} \\
(1)
\]

where \( \{\omega_t\} \) is white noise with mean zero and variance one. The conditional variance of \( y_t \) given \( I_{t-1} \) is then \( h_t \), which is modelled as

Models for time-varying volatility

The use of conditional heteroskedasticity initially introduced in the ARCH (autoregressive conditional heteroskedasticity) model of Engle (1982) has been extremely successful in modelling financial time series, such as stock prices, interest rates and exchange rates. The ARCH model was generalized to GARCH (generalized ARCH) by Bollerslev (1986). A simple version of the GARCH model for an observable series \( \{y_t\} \), given its past which is denoted by \( I_{t-1} \), is the following:

\[
y_t = \omega_t \sqrt{h_t} \\
(1)
\]

where \( \{\omega_t\} \) is white noise with mean zero and variance one. The conditional variance of \( y_t \) given \( I_{t-1} \) is then \( h_t \), which is modelled as
Bayesian time series analysis: The New Palgrave Dictionary of Economics

\[ h_t = \omega + \sum_{i=1}^{p} \alpha_i v_{t-i}^2 + \sum_{j=1}^{q} \beta_j h_{t-j} \]

(2)

where all parameters are positive and usually \( p = q = 1 \) is sufficient in practical applications. Bayesian inference for such models was conducted through importance sampling in Kleibergen and van Dijk (1993) and, with MCMC methods, in Bauwens and Lubrano (1998).

An increasingly popular alternative model allows for the variance \( h_t \) to be determined by its own stochastic process. This is the so-called stochastic volatility model, which in its basic form replaces (2) by the assumption that the logarithm of the conditional volatility is driven by its own AR(1) process

\[ \ln(h_t) = \alpha + \delta \ln(h_{t-1}) + \nu_t, \]

where \( \{\nu_t\} \) is a white noise process independent of \( \{u_t\} \) in (1). Inference in such models requires dealing with the latent volatilities, which are incidental parameters and have to be integrated out in order to evaluate the likelihood. MCMC sampling of the model parameters and the volatilities jointly is a natural way of handling this. An MCMC sampler where each volatility was treated in a separate step was introduced in Jacquier, Polson and Rossi (1994), and efficient algorithms for multi-state MCMC sampling schemes were suggested by Carter and Kohn (1994) and de Jong and Shephard (1995). Many extensions of the simple stochastic volatility model above have been proposed in the literature, such as correlations between the \( \{u_t\} \) and \( \{v_t\} \) processes, capturing leverage effects, or fat-tailed distributions for \( u_t \). Inference with these more general models and ways of choosing between them are discussed in Jacquier, Polson and Rossi (2004).

Recently, the focus in finance has shifted more towards continuous-time models, and continuous-time versions of stochastic volatility models have been proposed. In particular, Barndorff-Nielsen and Shephard (2001) introduce a class of models where the volatility behaves according to an Ornstein–Uhlenbeck process, driven by a positive Lévy process without Gaussian component (a pure jump process). These models introduce discontinuities (jumps) into the volatility process. Barndorff-Nielsen and Shephard (2001) also consider superpositions of such processes. Bayesian inference in such models through MCMC methods is complicated by the fact that the model parameters and the latent volatility process are often highly correlated in the posterior, leading to the problem of over-conditioning. Griffin and Steel (2006b) propose MCMC methods based on a series representation of Lévy processes, and avoid over-conditioning by dependent thinning methods. In addition, they extend the model by including a jump component in the returns, leverage effects and separate risk pricing for the various volatility components in the superposition. An application to stock price data shows substantial empirical support for a superposition of processes with different risk premiums and a leverage effect. A different approach
to inference in such models is proposed in Roberts, Papaspiliopoulos and Dellaportas (2004), who suggest a re-parameterization to reduce the correlation between the data and the process. The re-parameterized process is then proposed only in accordance with the parameters.

Semi- and nonparametric models

The development and use of Bayesian nonparametric methods has been a rapidly growing topic in the statistics literature, some of which is reviewed in Müller and Quintana (2004). However, the latter review does not include applications to time series, which have been perhaps less prevalent than applications in other areas, such as regression, survival analysis and spatial statistics.

Bayesian nonparametrics is sometimes considered an oxymoron, since Bayesian methods are inherently likelihood-based, and thus require a complete probabilistic specification of the model. However, what is usually called Bayesian nonparametrics corresponds to models with priors defined over infinitely dimensional parameter spaces (functional spaces) and this allows for very flexible procedures, where the data are allowed to influence virtually all features of the model.

Defining priors over collections of distribution functions requires the use of random probability measures. The most popular of these is the so-called Dirichlet process prior introduced by Ferguson (1973). This is defined for a space \( \Theta \) and a \( \sigma \)-field \( B \) of subsets of \( \Theta \). The process is parameterized in terms of a probability measure \( H \) on \( (\Theta, B) \) and a positive scalar \( M \). A random probability measure, \( F \), on \( (\Theta, B) \) follows a Dirichlet process \( DP(MH) \) if, for any finite measurable partition, \( B_1, \ldots, B_k \), the vector \( (F(B_1), \ldots, F(B_k)) \) follows a Dirichlet distribution with parameters \( (MH(B_1), \ldots, MH(B_k)) \). The distribution \( H \) centres the process and \( M \) can be interpreted as a precision parameter.

The Dirichlet process is (almost surely) discrete and, thus, not always suitable for modelling observables directly. It is, however, often incorporated into semiparametric models using the hierarchical framework

\[
y_i \sim g(y_i | u_i) \text{ with } u_i \sim F \text{ and } F \sim DP(MH),
\]

where \( g(\cdot) \) is a probability density function. This model is usually referred to as a ‘mixture of Dirichlet processes’. The marginal distribution for \( y_i \) is a mixture of the distribution characterized by \( g(\cdot) \). This basic model can be extended: the density \( g(\cdot) \) or the centring distribution \( H \) can be (further) parameterized, and inference can be made about these parameters. In addition, inference can be made about the mass parameter \( M \). Inference in these models with the use of MCMC algorithms has become quite feasible, with methods based on MacEachern (1994) and Escobar and West (1995).

However, the model in (3) assumes independent and identically distributed observations and is, thus, not directly of interest for time series modelling. A simple approach followed by Hirano (2002) is to use (3) for modelling the errors of an autoregressive model specification. However, this does not allow for the distribution to change over time. Making the random probability measure \( F \) itself depend on lagged values of the variable under consideration \( y_t \) (or, generally, any covariates) is not a straightforward
Bayesian time series analysis: The New Palgrave Dictionary of Economics

Müller, West and MacEachern (1997) propose a solution by modelling $y_t$ and $y_{t-1}$ jointly, using a mixture of Dirichlet processes. The main problem with this approach is that the resulting model is not really a conditional model for $y_t$ given $y_{t-1}$, but incorporates a contribution from the marginal model for $y_{t-1}$. Starting from the stick-breaking representation of a Dirichlet process, Griffin and Steel (2006a) introduce the class of order-based dependent Dirichlet processes, where the weights in the stick-breaking representation induce dependence between distributions that correspond to similar values of the covariates (such as time). This class induces a Dirichlet process at each covariate value, but allows for dependence. Similar weights are associated with similar orderings of the elements in the representation and these orderings are derived from a point process in such a way that distributions that are close in covariate space will tend to be highly correlated. One proposed construction (the arrivals ordering) is particularly suitable for time series and is applied to stock index returns, where the volatility is modelled through an order-based dependent Dirichlet process. Results illustrate the flexibility and the feasibility of this approach. Jensen (2004) uses a Dirichlet process prior on the wavelet representation of the observables to conduct Bayesian inference in a stochastic volatility model with long memory.

**Conclusion: where are we heading?**

In conclusion, Bayesian analysis of time series models is alive and well. In fact, it is an ever growing field, and we are now starting to explore the advantages that can be gained from using Bayesian methods on time series data. Bayesian counterparts to the classical analysis of existing models, such as AR(F)IMA models, are by now well-developed and a lot of work has already been done there to make Bayesian inference in these models a fairly routine activity. The main challenge ahead for methodological research in this field is perhaps to further develop really novel models that not merely constitute a change of inferential paradigm but are inspired by the new and exciting modelling possibilities that are available through the combination of Bayesian methods and MCMC computational algorithms. In particular, nonparametric Bayesian time-series modelling falls in that category and I expect that more research in this area will be especially helpful in increasing our understanding of time series data.

Article

Italian economist, philosopher and statesman, Beccaria was born in Milan in 1738, educated at Parma and in law at Pavia, appointed Professor of Political (Public) Economy or Cameral Science in Milan (1768), resigned his chair to enter public service (1772), where he encouraged and implemented monetary, general economic and penal reforms and advocated a decimal system of weights, measures and coin. He died in Milan in 1794. Beccaria's greatest fame derives from his *Essay on Crimes and Punishment* (1764a), which made his European reputation almost overnight and ensured his magnificent reception when he visited Paris in 1766. Among others, it exerted considerable influence on Bentham's utilitarian philosophy (Halévy, 1928) and popularized the phrase, ‘the greatest happiness of the greatest number’ (Beccaria, 1764a, Introduction). He also enjoyed considerable reputation as an economist. This was based on his work on Milanese monetary problems of 1762 and the outline of his teaching programme and inaugural lecture of 1769 (translated into French and English). His most important economic work is an unfinished treatise, *Elementi di economia pubblica* (written in 1771 but not published till 1804), but his mathematical contribution to the economics of taxation and smuggling (1764b) is also of considerable interest (see Theocharis, 1961).

Beccaria (1764b) starts with a methodological point on the use of algebra in political and economic reasoning. He considered such use only legitimate when the analysis concerned quantities, hence not all subject matter of these sciences was amenable to mathematical reasoning. He then illustrates the use of algebra for solving an economic problem, namely, how much of a given quantity of merchandise must merchants smuggle in order to break even, even if the remainder of the goods is confiscated. The essay may have been inspired by Hume's ‘Of the Balance of Trade’ (1752, p. 76) with its comment on ‘Swift's
maxim’ [that] ‘in the arithmetic of the customs, two and two make not four, but often only one’, because alterations in rates may alter revenue quite disproportionately.

Beccaria's plan for university instruction in economics and his inaugural lecture develop a classification of the subject matter into five, interconnected parts: general principles and overview, agriculture, trade, manufactures and public finance. Further subdivisions into chapters are reminiscent of the table of contents of Cantillon (1755), a work he appears to have studied closely, though the historical part of his inaugural lecture only acknowledges Vauban, Melon, Montesquieu, Uztariz, Ulloa, Hume and Genovesi. The last is described as the father of Italian economics (Beccaria, 1769). Groenewegen (1983) demonstrates that Beccaria's economic sources also included Locke and Quesnay's articles published in the French Encyclopédie. The last gave parts of the Elementi a Physiocratic flavour; for example, in the analysis of large- and small-scale farming, productive and unproductive labour and, more generally, its emphasis on the importance of agriculture.

Beccaria sees political economy as a highly practical subject, because it is part of the science of legislation and politics. Its purpose is to ‘increase the wealth of the state and its subjects, by giving instruction on the most appropriate and useful management of the national revenue and that of the sovereign’ (1769, p. 341). Although abstract treatment of the science is therefore largely rejected as inappropriate for such a practical subject, Beccaria maintains that serious discussion of its elements needs an introduction of general principles. A definition of wealth as ‘things not only necessary but also convenient and elegant’, starts these principles in Part I of the Elementi. Because wealth consists of goods designed to meet the needs of food, shelter and clothing, the science can be justifiably subdivided into parts derived from the sectors of production and exchange which supply the various wants of mankind. Raw materials are drawn from farming, pastoral activity, mineral exploitation and fishing, hence agriculture is the first part of political economy. Raw materials require work and preparation before they can be used, hence manufacturing is the second part. Efficient production of wealth creates a surplus available for exchange, hence commerce including value, money and credit constitutes the third part to be treated. Since protection of property is a prerequisite for efficient production and trade, public finance explaining how these expenses of government are met is the fourth element. Finally, Beccaria suggests a fifth topic to cover police and other government activity, but nothing of this nor the public finance part of his Elementi were ever completed. Having defined the scope of the subject in terms of wealth and the component parts helping its production, Beccaria elaborates on the principles in his theory of reproduction, or the combination of labour, time and capital which ensures the continuation of production activity. Here Beccaria demonstrates awareness of the links between division of labour and trade and recognizes that the prices which circulate commodities are regulated by necessary costs of production. A general analysis of the cost of labour or wages, of the advances and other means of production and of those incurred by the state in its essential protection of production activity, is therefore required. Beccaria further develops these general principles by examining the nature and interdependence of work and consumption, introducing considerations of thrift, value, profit, useful work, variability of wants and difficulties in measuring the subsistence wage of workers. A discussion of the principle of population concludes the analysis of the ‘simple truths’ and ‘self-evident axioms’ from which the whole science of political economy can be deduced, as Beccaria intended to demonstrate in the other parts of his work. Of these, the completed chapters in Part IV on value, money and exchange are of the greatest interest.

The New Palgrave Dictionary of Economics Online

Becker, Gary S. (born 1930)

Casey B. Mulligan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Gary S. Becker has produced major economics books and articles for more than 50 years. His studies dominate labour economics and have significantly impacted studies of crime, habit formation, and other important behaviours once considered beyond the scope of economics. Some of Gary's lasting impact can be attributed to abstraction from institutional detail and his ‘thinking problems through fully’.

Article

I walk over to my collection of The American Economic Review, and pick up the very first (and now disintegrating) issue, dated 1952, and notice an article entitled ‘A Note on Multi-Country Trade’. Its author is Gary S. Becker. By the time you read this, you probably can pick up the very latest issue from your collection and find an article by Gary S. Becker! If you did so in 2005, I can guarantee it: the article was entitled ‘The Quality and Quantity of Life and the Evolution of World Inequality’. Gary published an important article in the very first issue of the Journal of Law and Economics, ‘Competition and Democracy’ (1958). He published an article, ‘Deadweight Costs and the Size of Government’ in the 46th volume of the same journal (Becker and Mulligan, 2003a); it may have the same potential, although I must admit that its importance cannot yet be judged impartially.

Figure 1 quantitatively examines Gary's work over a half century. The vertical axis measures, from the Social Science Citation Index (SSCI), the number of articles citing each of Gary's books and major research projects. Each citation has a citer and a citee. The citees are Gary's Economics of Discrimination (1957, various editions), Human Capital (1964, various editions), A Treatise on the Family (1981, various editions), Accounting for Tastes (1996), ‘A Theory of the Allocation of Time’ (1965), ‘Crime and Punishment: An Economic Approach’ (1968), four journal articles on addiction (Becker and Murphy, 1988a; Becker, Grossman and Murphy, 1991; 1994; and Becker, 1992), and four journal articles on fertility (Becker and Lewis, 1973; Becker and Tomes, 1976; Becker and Barro, 1988; Barro and Becker, 1989). The citers are social science journal articles published in the year indicated on the horizontal axis. Since the articles are typically peer-reviewed and the journals are academic, the vertical axis is a measure (admittedly imperfect) of how important Gary's various works were in making intellectual progress, or in shaping the thinking behind intellectual progress, in social science. Notice the scale on the vertical axis – it reaches past 100 citations per year per work of Gary's – and remember that there are tenured professors at leading economics departments whose citations combined for all of their works and all of their lives do not reach these levels. Also notice the scale on the horizontal axis: it begins in 1960. (A fuller analysis of citations would separate year effects from other determinants of citations – for example, the number of journals covered by SSCI may increase over time; I owe this point to Bill Landes. However, the reader might make some guess at the year effects from the fact that Human Capital's citation time series is quite similar to those of Schumpeter, 1942, and Downs, 1957. Human Capital's citations significantly exceed and grow faster than those of Friedman, 1957, and Friedman and Schwartz, 1963.) Discrimination and Treatise are both heavily cited, but their first editions appeared 24 years apart. The addiction work first appeared 31 years after Discrimination. (The two pressure group papers, discussed later, appeared 26 and 28 years respectively after Discrimination, and surpassed 50 combined citations per year by 1990.) If Gary manages another big hit during the next few years, that would be a 50-year span.
Figure 1
Citations of Becker's major books and articles, excluding those on political economy. Note: For Addiction and Fertility, I sum citations for the four articles in each class; some double counting may occur due to articles that cite more than one of the four. Becker's political economy articles may be more important than the Fertility and Addiction articles, but for clarity the former are omitted from Figure 1 and deferred until later. Social Economics (Becker and Murphy, 2003b) is also omitted because, as of 2005, its annual citations were fewer than ten.

before coming to Chicago, or shortly after.)

Before coming to Chicago, Gary was already dissatisfied with the lack of applications of economics to important social problems, although his Princeton work does not yet show any success at resolving his discontent. Perhaps Chicago, and especially Milton Friedman, inspired or at least encouraged the application of economics beyond the usual areas. As Gary says, ‘[Friedman] emphasized that economic theory was not a game played by clever academicians, but was a powerful tool to analyse the real world. His course was filled with insights both into the structure of economic theory and its application to practical and significant questions’ (Becker, 1993). Gary is now known for his application of economic theory to practical and significant questions, from time allocation and fertility to inequality and addictions.

Gary sometimes explains, ‘I was such an outsider from the eastern and western establishments for so long’. Universities like Stanford, Harvard, and Yale have never showed any interest in hiring him, although Harvard granted him an honorary degree in 2003. Gary’s abilities as an economist are so extraordinary that, despite being an outsider, and having such a large fraction of his productivity ahead of him, he was recognized in 1967 by the American Economic Association as the best young economist at the time (he won the their John Bates Clark Medal in that year). Gary’s outsider position would have been different had he turned down Chicago’s fellowship, but fortunately for him citations and academic job offers have very different production functions, at least as regards their use of personal acquaintances as inputs.

At Chicago Gary met, loved, and improved the workshop system. Columbia University was the first beneficiary of those improvements when he and Mincer created the Labor Economics workshop (Landes, 1998). Gary started a workshop when he returned to Chicago in 1970, which for many years was co-organized with Sherwin Rosen, and is now affectionately known as the ‘Applications Workshop’. By the time I began attending economics workshops in 1991, practically all had become (and maybe had always been?) something like lecture series, and were a form of output of the idea production process, namely, a process for disseminating finished research results. But the Applications Workshop was and is deliberately different; research papers are invited in their infancy, and 85 of the 90 minutes consist of the audience’s (especially Gary’s; Gary carefully reads the paper beforehand) trying to push the author in new and better directions. Students regularly come to the workshop to hear what Gary has to say, and, in the midst of a graduate programme that can easily overwhelm them with technical detail, learn that good choices of research question and basic strategy for seeking an answer are important and scarce academic skills.

Gary later organized with the late James Coleman (Richard Posner continues the tradition) an interdisciplinary workshop on applications of rational models to economics, sociology, law, politics, anthropology, and so on. The success of these two workshops make Chicago a unique and highly stimulating experience for faculty and students, and probably would not be possible if it weren’t for Gary’s extraordinary breadth of knowledge, quickness of mind, and insatiable appetite for workshops.

Abstracting from institutional detail

The workshop system and Economics 301 (Chicago’s first Ph.D. course in price theory) were important means by which Gary received his inheritance from Chicago, and made his bequest to students at Chicago and Columbia, where Becker was an economics professor from 1957 to 1970. I mentioned Friedman’s lesson that economic theory was not a game played by clever academicians, but was a powerful tool to analyze practical and significant questions. Chicago was methodologically unique in two other ways. Despite their working on practical questions, Chicago economists were willing, and even eager, to abstract from institutional details, and view price theory as a general method to understanding many different behaviors. This approach was particularly novel in labor economics, where labor unions, marriage bars, and other personnel practices were often interpreted as having an independent influence on labor market outcomes, rather than as outcomes themselves of more basic and ubiquitous forces. Columbia’s Jakob Mincer also practised this methodology in his enduring work on labor supply (for example, Mincer, 1962). Labor market institutions like trade unions and monster.com (an internet site where employers can read resumes posted by potential employees) come and go, but the fundamental economic forces include the income and substitution effects on labor supply featured at Columbia by Mincer and at Chicago by Lewis (Lewis, 1956), and are an important part of explanations of why labor market outcomes vary over time and across regions. It’s no coincidence that Becker and Mincer together created the Labor Economics workshop at Columbia, and work appearing during these years by Becker, Mincer, and students continued the practice. (William Landes – Gary’s student, colleague and friend during both the Chicago and Columbia years – wrote in 1998 an excellent biography of Becker which explains more about the Columbia days and Gary’s influence on the law and economics field. To Landes’ account I would add that Gary still credits the City of New York with inspiring ‘Crime and punishment’. One day he illegally parked his car near Columbia’s campus because he calculated it to be more important to attend a dissertation defense than to avoid the city’s illegal parking fine.)

*Human Capital* also has some roots in Gary’s time at Chicago before 1957. Chicago’s agricultural economics group (Gary was one of the participants in those days), especially Ted Schultz, had attributed much of the underdevelopment problem to a lack of human capital investment. Gary’s *Human Capital* explains why some people have more income from employment than others by viewing labor income as a dividend on historical investments, which in turn are understood as particular instances of capital accumulation. The basic concepts do not include labor market institutions, but rather the time value of money, aging, the allocation of time, and other determinants of the costs and benefits of enhancing a person’s productivity in the marketplace. Becker’s abstractions facilitated applications of human capital theory beyond (perhaps) even what he had anticipated, including the determinants of sickness and health (Grossman, 1972, a Columbia Ph.D. student 1964–70), and the evolution of species (Robson and Kaplan, 2003).

‘A Theory of the Allocation of Time’ introduced the concepts of ‘full income’ and the ‘full price’ of a commodity. A commodity’s full price combines the expenditures of money and time required to acquire one unit of its services. Because households differ in terms of the opportunity cost of their time, and perhaps also their time-efficiency in obtaining...
commodities, they will face different full prices even though they face the same money price. For example, the substitution effect suggests that richer households (to the extent that the market rewards them highly for their time) would have fewer children and, per unit consumed, would replenish less often their inventories of household commodities (and currency: Karni, 1973). (For the same reason, Gary is perennially puzzled why rich people play golf; he plays tennis.) Full income is the money income that would be obtained if time were allocated in order to maximize money income. In many ways, full income permits time allocation to be studied as a particular application of consumer demand, because full income is spent on some combination of market expenditures on commodities and implicit expenditures on non-work time. Full income and full price are not institution-specific concepts, permitting ‘Time’ to be applied in so many different sub-fields, including monetary economics, fertility, lobbying (Mulligan and Sala-i-Martin, 1999), altruism (Mulligan, 1997), and even Communism (Boycko, 1992).

Public policy schisms

Milton Friedman's *Capitalism and Freedom* (1962) and *Free to Choose* (1981) clearly advertise the view that inefficient public policies are bad ideas unfortunately and inexplicably hatched by policy-makers, which can be rectified merely by giving some combination of voters, politicians, and bureaucrats a better economic education. If Gary continued that tradition, as with his *Business Week* column and internet blog, he did so with much less vigour. One of Chicago's important influences on Gary came from George Stigler, who often viewed public policies as the rational choices of politicians and the people who can influence them. Perhaps Stigler's influence was stronger because Friedman was there to contrast it, but in any case it's hard to see any Friedman in ‘Pressure Groups’ (1983) or ‘The Family and the State’ (1988b).

Interestingly, this schism persists today in Chicago's Economics Department and the economics profession more widely. A public finance group, embodied at Chicago in its macro group (for example, Lucas and Stokey, 1983; Shimer and Werning, 2003), aims at technical and normative public policy improvements, whereas political economists (for example, Becker and Murphy, 1988; Mulligan, Gil, and Sala-i-Martin, 2004) view public policies and their imperfections as the outcomes of other economic forces, such as demography, political competitiveness, and the technology of tax collection.

Becker (1983) also tries to bridge a gap among political economists – a gap defined according to whether they see special interests or efficiency as the primary determinant of actual public policies. He points out that a huge number of groups would like special favours from the government, but only a few can ultimately be successful. These groups compete with each other to obtain the favours. All else the same, groups advocating efficient public policies have an advantage because (by definition of efficiency) their policy proposals would hurt relatively little. Of course, group cohesion, political entry barriers, group size, and other variables may give particular groups an intrinsic advantage, but the competitive activity of special interest groups helps deliver efficient policies to the public sector rather than crowding out such policies with inefficient special favours.

Unfortunately, Becker has not (yet) bridged another gap among political economists – a gap defined by the degree of attention to institutional detail. It's interesting that labour economics work done by Gary and others at Chicago is praised for its lack of institutional detail (detail now considered unnecessary for understanding the major economic forces at work), whereas the political economics work is criticized, at least so far, for the same lack of detail.

Timing in the marketplace for ideas: human capital or luck?

*Human Capital* and ‘Time’ had some good fortune in their timing, both in terms of the ultimate demand for these ideas and in terms of the supply of intellectual building blocks. For example, *Human Capital*s citations accelerated in the late 1980s as the profession came to realize the important wage structure changes that were occurring and began to write about them; human capital theory is probably the most common way of organizing and interpreting such observations. It may also be fortunate that, since 1940, the Census Bureau has been asking more people more questions about wages and schooling than about household expenditure, hence stimulating more empirical research on wages and schooling than empirical research on consumption.

Perhaps there was also good fortune on the input side. Mincer was making significant progress in the empirical analysis of labour supply and the empirical analysis of wage determinants. The economics of consumption was a very lively subject at Chicago in the 1950s, as evidenced by Friedman's *A Theory of the Consumption Function* (1957), work by Margaret Reid (1957), and the beginnings of Chicago's workshop system by Chicago's agricultural economics group. Gary's work on the value of time and life-cycle profiles must have been stimulated in this environment, in part because labour supply and human capital accumulation are such natural applications of the life-cycle way of thinking already apparent in *A Theory of the Consumption Function*. Remember also that Friedman (1957) was preceded by *Income From Independent Professional Practice* (1945), which straddled the fields we now call consumption and labour economics. (Gregg Lewis was probably yet another Chicago influence in these days.) The economic concept of ‘full income’ first appeared in ‘Time’, where Becker credits the phrase to a conversation with Milton Friedman.

Gary adopted and improved the analytical style of *A Theory of the Consumption Function* and the methodology of positive economics more generally. Some consider Friedman's *A Theory of The Consumption Function* the best economics book since the 19th century, and perhaps earlier, because of its convincing and systematic applications of economic theory to important questions. But *Human Capital* may be even better. Both books clearly aim to develop refutable empirical implications from their theories, but *Human Capital* probably
does more to help its reader distinguish the important implications from the secondary ones. Gary always advises his students and colleagues to ‘think a problem through fully’ and apparently he followed his own advice in *Human Capital*. Not only is the importance of the basic ‘human capital’ concept appreciated several decades later, but modern analysis of the labour market still displays more detailed similarities, including attention to specific versus general human capital, comparisons between financial and human capital rates of return, the distinction between the forgone earnings and tuition components of human capital acquisition costs, and so on. Friedman's basic concept of permanent income and the details of his analysis of it (such as ‘distributed lags’) are less prevalent today, having been displaced by consumption Euler equations. (Almost immediately after *Human Capital*'s publication, its citation flow exceeded and grew faster than that of *A Theory of the Consumption Function*.) By thinking through the problem fully, Gary had produced in the early 1960s an analysis that would depreciate slowly, and thereby still be available in the 1980s to take advantage of the real-world events that drew attention to human capital questions.

Unrealized potential?

Only people who know Gary personally would know, or dare to believe, that he may have some regrets that he did not realize his full potential. His political economics work is an important instance. He regrets the obscurity of ‘Competition and democracy’, which has been cited only 33 times – less than once per year. He partly blames editor Aaron Director for forgetting to request revisions or proofs of the manuscript, and himself for not following up on work that he knew to be incomplete.

Political economics research has proliferated since the mid 1980s. Gary feels that progress might have been more significant if ‘A Theory of Competition Among Pressure Groups for Political Influence’ had received more attention. I am inclined to agree (Mulligan, Gil and Sala-i-Martin, 2004), but it would be much too extreme to say the article was ‘ignored’. Yes, it was rejected by the *American Economic Review* and perhaps another journal (Gary does not remember). Nevertheless, it may ultimately be the most cited article appearing in the *Quarterly Journal of Economics* since 1983. It has been cited almost 50 times every year since the 1980s. Only three articles – which happen to be from the economic growth literature: Heston and Summers (1991), Barro (1991), and Mankiw, Romer and Weil (1992) – have been cited more than 50 times per year for more than a couple of years, and their citation flows have regressed back to Gary's since 2000. (I thank Andrei Shleifer for suggesting comparisons between Becker, 1983, and other top *QJE* articles.) Two other *QJE* articles – Katz and Murphy (1992) since 1997 and Fehr and Schmidt (1999) since 2003 – enjoy about the same citation flow as Gary's, but over a much more recent period of time.

‘Pressure Groups’ citations are in the stratosphere in the universe of journal articles, but nevertheless it has been losing political economics market share as its annual cites have been pretty steady at 50 while the political economics literature has exploded. Figure 2 compares ‘Pressure Groups’ citations (summed here for the *QJE* and *Journal of Public Economics* articles) with some other political economics work. This time citations are displayed on a log scale. ‘Pressure Groups’ citations are shown as a thick solid line. Buchanan and Tullock's *Calculus of Consent* (1962) – maybe Nobel Laureate Buchanan's best known work – has had the same flow of citations since 1990, although of course the *Calculus of Consent* was published much earlier and deserves enormous credit for introducing to economics the principle of modelling policy-makers as self-interested. Perhaps more striking is the fact that ‘Pressure Groups’ citations have not grown with the political economics literature since 1985. For example, Alberto Alesina now accumulates about 200 citations per year (of all of his papers combined, see the dashed line in Figure 2). Meltzer and Richard's (1981) paper is actually older than Gary's, but it received very few citations until the late 1990s, when its citation flow increased by almost an order of magnitude. Downs (1957, dotted line) and Schumpeter (1942, circles) have also benefited from the growth of political economics. (Mancur Olson's *Logic of Collective Action*, 1965, might have been included in Figure 2; since 1980 its citation flow is about 50 per cent more than Downs's.)

**Figure 2**

Citations of major political economy works
Perhaps ‘Pressure Groups’ should have been part of, or led to, a Becker political economics book that worked more fully through the implications of competition for the supply of public policies. Does it matter whether competition is time-intensive or goods-intensive? How competitive are authoritarian regimes? To judge from Gary’s treatment of labour economics questions, it seems very likely that a Becker political economics book would have treated fundamental economics forces like deadweight costs, competition, and the allocation of time with little attention to institutional detail. Would such a book have succeeded in the current marketplace for political economics ideas? On the one hand, the answer
seems to be ‘no’ because the current literature prides itself on its analysis of those details; Persson and Tabellini (2004, p. 76) explain, ‘...the devil is in the details, especially the
details of electoral systems’; see also Besley and Case (2003, p. 11). On the other hand, Gary’s book may have pushed, or at least nudged, the literature in a different direction.

Waan’t it all obvious?

Perhaps this is a slight exaggeration, but some of Gary’s results have been criticized as being too obvious, or adding too little value to simpler non-economic models or common-sense interpretations. I have to admit that I sometimes found it easier to remember the basic results of Gary’s journal articles, and to produce simple derivations of my own (for example, Mulligan, 1997, ch. 3), than to follow Gary’s published derivations. (I don't remember the derivations presented in Gary’s University of Chicago courses to be so clear, either. But maybe I deserve much of the blame here; I am much better at following a geometric proof than an algebraic one, whereas Gary seems to prefer the latter.) To some extent, these critiques have the advantage of hindsight; it is quite normal for original ideas to be expressed later by followers in simpler terms, after a period of what Gary calls ‘cleaning up’. However, I believe that Gary’s books are easier to follow than several of his journal articles, because the process of writing a whole book was complementary with some cleaning up on his own. This is also part of the reason why Becker and Murphy make such a good team; one of Murphy’s extraordinary talents is to quickly conceive of a concise mathematical expression of a new economic idea.

Becker and Tomes (1979; 1986) reinterpret inter-temporal consumption theory and combine it with human capital theory to form a theory of the evolution of inequality from one generation to the next. In the model, altruistic parents allocate dynastic resources between themselves and their children. The opportunities for doing so depend on the process of monetary inheritance (for example, inheritance taxes) and on the technology for investing in the human capital of children. The model predicts that earnings regress to the mean across generations because ability, talent, and so forth (which determine the rate of return to human investment) regress to the mean. Perhaps the most explicit form of the ‘too obvious’ criticism appeared as Goldberger’s (1989) contention that this approach to inheritance is an excessively complicated way of saying ‘economic characteristics regress to the mean’. Becker’s (1989) reply lists some implications that are more than regression to the mean, although in some cases I think the results still derive from statistical rather then economic modelling assumptions (see Mulligan, 1997, and the references cited therein). Nevertheless, Becker’s ‘micro-economic-optimizing approach’ is the only one, to my knowledge, predicting that consumption would regress to the mean more slowly than earnings. It’s a nice bonus that, so far, the empirical evidence seems to support Gary in this regard.

For many years, and perhaps even now, it was far from obvious that wages are largely determined by human capital, as evidenced, for example, by the various debates on wage gaps by industry, race, and gender. The opponents of the human capital interpretation of industry gaps have, after several years, softened their view. Gender and race gaps are sometimes attributed to discrimination (Gary gets some credit under this interpretation, too), although there seem to be steady streams of new evidence showing that the effects of human capital have been too quickly misinterpreted as effects of discrimination (see, for example, Smith and Welch, 1989, and Neal and Johnson, 1996, on race gaps, and Mulligan and Rubinstein, 2005, on gender gaps).

As Gary began working on the family, he found ‘redistribution of income among members does not affect the consumption or welfare of any member because it simply induces offsetting changes in transfers from the head. As a result, each member is at least partially insured against disasters that may strike him’ (Becker, 1974, p. 1091). Put this way, the result seems obvious. However, the result could not have been fully understood at the time – otherwise the rotten kid theorem, the Ricardian equivalence result, and a number of other results would not have shaken the profession so much. Indeed, Gary himself did not fully appreciate its implications, because he admits not foreseeing how the macroeconomics of fiscal policy would change after 1974 thanks to Barro's (1974) article in the same issue of the Journal of Political Economy. (Barro's focus at the time was probably contemporaneous work on fiscal policy, such as Feldstein's famous 1974 article in the previous JPE. Barro, 1998, explains how the links between Ricardian Equivalence and the Rotten Kid Theorem began to be appreciated only when the JPE began preparing the November 1974 issue in which the two articles were to appear.) Peter Diamond's reaction (as reported second-hand by Barro, 1998) demonstrates the fallacy of dismissing these results as obvious, ‘[Ricardian equivalence is] obvious, of no practical significance, and surely not worth … research time.’ Professor Diamond was giving this advice in 1967 to student Bob Hall, who, if it weren't for his listening, was on the verge of scooping both Becker and Barro.

During the 1996 US presidential campaign, Republican primary candidate Steve Forbes revitalized the idea of replacing the current income tax with a ‘flat tax’: a tax with no deductions and low marginal rates. I was concerned that a painless tax would be a tax that Congress would exploit to obtain ever larger amounts of revenue, but to me this point was just something clever to publish in the op.-ed. pages or to make people pause at cocktail parties. I vividly remember mentioning this to Gary in March 1996. He was a flat tax fan at the time (see Becker et al., 1996), and told me ‘I'm not sure how you would analyse that formally and, besides, Hong Kong refutes your hypothesis: they have a flat tax and a small government’. A few days later he apparently saw the empirical evidence differently, and was excited enough to interrupt his trip in France to type a short first draft of our ‘Deadweight Costs and the Size of Government’ and attach it to an e-mail to me back at the University of Chicago. By then he was sure how to analyse it: using a simple version of his 1983 price pressure group model. The lesson for the young assistant professor: think a problem through fully, regardless of how obvious the answer might seem at first glance. The rewards in this case were, among other things, a consistent analysis of tax reforms, spending reforms, and ‘flypaper effects’ (the tendency of governments to spend non-tax revenue rather than refund it to taxpayers), and a better understanding of the relations between democratic and authoritarian public sectors.

behavioural economics and game theory

Faruk Gul
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Behavioural economics, broadly defined, refers to the research programme that investigates the relationship between psychology and economic behaviour. The purpose of this article is to provide an outline of behavioural economics research and to describe where research in behavioural game theory stands within this outline. The aim is not to assess the impact of particular contributions or describe and interpret specific applications. Rather, the goal is to provide an organization of the literature based on the type of departures from standard theory.

Keywords

ambiguity; ambiguity aversion; asymmetric information; auctions; behavioural economics; behavioural economics and game theory; commitment; evolutionary games; expected utility hypothesis; fixed point theorems; framing effects; game theory; independence axiom; interdependent preferences; mechanism design; neuroeconomics; preference reversals; probability distributions; prospect theory; psychological games; social preferences; ultimatum game; uncertainty

Article

In traditional economic analysis, as well as in much of behavioural economics, the individual’s motivations are summarized by a utility function (or a preference relation) over possible payoff-relevant outcomes while his cognitive limitations are described as incomplete information. Thus, the standard economic theory of the individual is couched in the language of constrained maximization and statistical inference.

The approach gains its power from the concise specification of payoff-relevant outcomes and payoffs as well as a host of auxiliary assumptions. For example, it is typically assumed that the individual’s preferences are well behaved: that is, they can be represented by a function that satisfies conditions appropriate for the particular context such as continuity, monotonicity, quasi-concavity, and so on.
When studying behaviour under uncertainty, it is often assumed that the individual’s preference obeys the expected utility hypothesis. More importantly, it is assumed that the individual’s subjective assessments of the underlying uncertainty are reasonably close to the observed distributions of the corresponding variables. Even after all these bold assumptions, the standard model would say little if the only relevant observation regarding the utility function is one particular choice outcome. Thus, economists will often assume that the same utility function is relevant for the individual’s choices over some stretch of time during which a number of related choices are made. One hopes that these observations will generate enough variation to identify the decision-maker’s (DM’s) utility function. If not, the analyst may choose to utilize choice observations from different contexts to identify the individual’s preferences or make parametric assumptions. The analyst may even pool information derived from observed choices of different individuals to arrive at a representative utility function.

1 Experimental challenges to the main axioms of choice theory

The simplest type of criticism of the standard theory accepts the usual economic abstractions and the standard framework but questions specific assumptions within this framework.

1.1 The independence axiom

Allais (1953) offers one of the earliest critiques of standard decision-theoretic assumptions. In his experiment, he provides two pairs of binary choices and shows that many subjects violate the expected utility hypothesis, in particular, the independence axiom. Allais’s approach differs from the earlier criticisms: Allais questions an explicit axiom of choice theory rather than a perceived implicit assumption such as ‘rationality’. Furthermore, he does so by providing a simple and clear experimental test of the particular assumption. Subsequent research documents related violations of the independence axiom and classifies them. Researchers have responded to Allais’s critique by developing a class of models that either abandons the independence axiom or replaces it with weaker alternatives. The agents in these models still maximize their preference and still reduce uncertainty to probabilistic assessments (that is, they are probabilistically sophisticated), but have preferences over lotteries that fail the independence axiom. Non-expected utility preferences pose a difficulty for game theory: because many non-expected utility theories do not lead to quasi-concave utility functions, standard fixed point theorems cannot be used to establish the existence of Nash equilibrium. Crawford (1990) shows that if one interprets mixed strategies not as random behaviour but as the opponents’ uncertainty regarding this behaviour, then the required convex-valuedness of the best response correspondence can be restored and existence of Nash equilibrium can be ensured.

In dynamic games, abandoning the independence axiom poses even more difficult problems. Without the independence axiom, conditional preferences at a given node of an extensive form game (or a decision-tree) depend on the unrealized payoffs earlier in the game. The literature has dealt with this problem in two ways: first, by assuming that the DM maximizes his conditional preference at each node (for a statement and defence of this approach, see Machina, 1989). This approach leads to dynamically consistent behaviour, since the DM ends up choosing the optimal strategy for the reduced (normal form)
behavioural economics and game theory: The New Palgrave Dictionary of Economics

game. However, it is difficult to compute optimal strategies once conditional preference depends on the entire history of unrealized outcomes. The second approach rejects dynamic consistency and assumes that at each node the DM maximizes his unconditional preference given his prediction of future behaviour. Thus, in the second approach, each node is treated as a distinct player and a subgame perfect equilibrium of the extensive form game is computed. Game-theoretic models that abandon the independence axiom have favoured the second approach. Such models have been used to study auctions.

1.2 Redefining payoffs: altruism and fairness

The next set of behavioural criticisms question common assumptions regarding deterministic outcomes. Consider the ultimatum game: Player 1 chooses some amount $x \leq 100$ to offer to Player 2. If Player 2 accepts the offer, 2 receives $x$ and 1 receives $100-x$; If 2 rejects, both players receive 0. Suppose the rewards are measured in dollars and Player 1 has to make his offer in multiples of a dollar. It is easy to verify that if the players care only about their own financial outcome, there is no subgame perfect Nash equilibrium of this game in which Player 1 chooses $x>1$. Moreover, in every equilibrium, any offer $x>0$ must be accepted with probability 1. Contrary to these predictions, experimental evidence indicates that small offers are often rejected. Hence, subjects in the Player 2 role resent either the unfairness of the (99,1) outcome, or Player 1’s lack of generosity. Moreover, many experimental subjects anticipate this response and make more generous offers to ensure acceptance. Even in the version of this game in which Player 2 does not have the opportunity to reject (that is, Player 1 is a dictator), Player 1 often acts altruistically and gives a significant share to Player 2.

More generally, there is empirical evidence that suggests that economic agents care not only about their physical outcomes but also about the outcomes of their opponents and how the two compare. Within game theory, this particular behavioural critique has been influential and has led to a significant theoretical literature on social preferences (see, for example, Fehr and Schmidt, 1999).

1.3 Redefining the objects of choice: ambiguity, timing of resolution of uncertainty, and preference for commitment

The next set of behavioural criticisms points out how the standard definition of outcome or consequence is inadequate. The literature on ambiguity questions probabilistic sophistication; that is, the idea that all uncertainty can be reduced to probability distributions. Ellsberg (1961) provides the original statement of this criticism. Consider the following choice problem: there are two urns; the first contains 50 red balls and 50 blue balls; the second contains 100 balls, each of which is either red or blue. The DM must select an urn and announce a colour. Then a ball will be drawn from the urn he selects. If the colour of the ball is the same as the colour the DM announces, he wins 100 dollars. Otherwise the DM gets zero. Experimental results indicate that many DMs are indifferent between (urn 1, red) and (urn 1, blue) but they strictly prefer either of these choices to (urn 2, red) and (urn 2, blue). If the DM were probabilistically sophisticated and assigned probability $p$ to choosing a red ball from urn 1 and $q$ to choosing a red ball from urn 2, the preferences above would indicate that $p=1-p$, $p>q$, and $p>1-q$, a contradiction. Hence, many DMs are not probabilistically sophisticated.

Ellsberg’s experiment has lead to choice-theoretic models where agents are not probabilistically sophisticated and have an aversion to ambiguity; that is, the type of uncertainty associated with urn 2.

Recent contributions have investigated auctions with ambiguity-averse bidders and mechanism design with ambiguity aversion.

Other developments in behavioural choice theory that fall into this category have had limited impact on game-theoretic research. For example, Kreps and Porteus (1978) introduce the notion of a temporal lottery to analyse economic agents’ preference over the timing of resolution of uncertainty. The Kreps–Porteus model has been extremely influential in dynamic choice theory and asset pricing but has had less impact in strategic analysis.

Kreps (1979) takes as his primitive individuals’ preferences over sets of objects. Hence, an object similar to the indirect utility function of demand theory defines the individual. Kreps uses this framework to analyse preference for flexibility. So far, there has been limited analysis of preference for flexibility in strategic problems.

Gul and Pesendorfer (2001) use preferences over sets to analyse agents who have a preference for commitment (an alternative approach to preference for commitment is discussed in Section (3.2)). The GP model has been used to analyse some mechanism design problems.

2 Limitations of the decision-maker

The work discussed in Section 1 explores alternative formulations of economic consequences to identify preference-relevant considerations that are ignored in standard economic analysis. The work discussed in this section provides a more fundamental challenge to standard economics. This research seeks alternatives to common assumptions regarding economic agents’ understanding of their environments and their cognitive/computational abilities.

2.1 Biases and heuristics

Many economic models are stated in subjectivist language. Hence probabilities, whether they represent the likelihood of future events or the individual’s own ignorance of past events, are the DMs’ personal beliefs rather than objective frequencies. Similarly, the DM’s utility function is a description of his behaviour in a variety of contingencies rather than an assessment of the intrinsic value of the possible outcomes. Nevertheless, when economists use these models to analyse particular problems, the subjective probabilities (and sometimes other parameters) are often calibrated or estimated by measuring objective frequencies (or other objective variables).

Psychology and economics research has questioned the validity of this approach. Tversky and Kahneman (1974) identify systematic biases in how individuals make choices under uncertainty. This research has led to an extensive literature on heuristics and biases. Consider the following:

1. (a) Which number is larger \( P(A|B) \) or \( P(A \lor C|B) \)? Clearly, \( P(A|B) \) is the larger quantity; conditional on \( B \) or unconditionally, \( A \lor C \) can never be more likely than \( A \). Yet, when belonging to set \( C \) is considered ‘typical’ for a member of \( B \), many subjects state that \( A \lor C \) conditional on \( B \) is more likely than \( A \) conditional on \( B \).

2. (b) Randomly selected subjects are tested for a particular condition. In the population, 95 per cent are healthy. The test is 90 per cent accurate; that is, a healthy subject tests negative and a subject...
having the condition tests positive with probability 0.9. If a randomly chosen person tests positive, what is the probability that he is ill? In such problems, subjects tend to ignore the low prior probability of having the condition and come up with larger estimates than the correct answer (less than one-third in this example).

Eyster and Rabin’s (2005) analysis of auctions offers an example of a strategic model of biased decision-making. This work focuses on DMs’ tendency to overemphasize their own (private) information at the expense of the information that is revealed through the strategic interaction.

2.2 Evolution and learning

As in decision theory, it is possible to state nearly all the assumptions of game theory in subjectivist language (see, for example, Aumann and Brandenburger, 1995). Hence, one can define Nash equilibrium as a property of players’ beliefs. Of course, Nash equilibrium beliefs (together with utility maximization) will impose restrictions on observable behaviour, but these restrictions will fall short of demanding that the observed frequency of actions profiles constitute a Nash equilibrium. The theory of evolutionary games searches for dynamic mechanisms that lead to equilibrium behaviour, where equilibrium is identified with observable decisions (as opposed to beliefs) of individuals. The objective is to describe how equilibrium may emerge and which equilibria are more likely to emerge through repeated interaction in a setting where the typical epistemic assumptions of equilibrium analysis fail initially. Thus, such models are used both to justify Nash (or weaker) equilibrium notions and to justify refinements of these notions.

2.3 Cognitive limitations and game theory

Some game theoretic solution concepts require iterative procedures. For example, computing rationalizable outcomes in normal form games or finding backward induction solutions in extensive form games involves an iterative procedure that yields a smaller game after each step. The process ends when the final game, which consists exclusively of actions that constitute the desired solution, is reached. In principle, the number of steps needed to reach the solution can be arbitrarily large. Ho, Camerer and Weigelt (1998) observe that experimental subjects appear to carry out at most the first two steps of these procedures. This line of work focuses both on organizing observed violations of standard game theoretic solutions concepts and interpreting the empirical regularities as the foundation of a behavioural notion of equilibrium.

3 Alternative models of the individual

The work discussed in this section poses the most fundamental challenge to the standard economic model of the individual. This work questions the usefulness of constrained maximization as a framework of economic analysis, or at least argues for a fundamentally different set of constraints.
Consider the following pair of choices (Tversky and Kahneman, 1981): an unusual disease is expected to kill 600 people. Two alternative programmes to combat the disease have been proposed. Programme A will save 200; with Programme B, there is a one-third probability that 600 people will be saved, and a two-thirds probability that no one will be saved.

Next, consider the following restatement of what would appear to be the same options:
If Programme C is adopted 400 people will die; with Programme D, there is a one-third probability that nobody will die, and a two-thirds probability that 600 people will die.

Among subjects given a choice between A and B, most choose the safe option A, while the majority of the subjects facing the second pair of choices choose the risky option D.

Kahneman and Tversky’s (1979) prospect theory combines issues discussed in Sections (1.1) and (2.2), with a more general critique of standard economic models, or at least of how such models are used in practice. Thus, while a standard model might favour a level of abstraction that ignores the framing issue above, Kahneman and Tversky (1979) argue that identifying the particular frame that the individual is likely to confront should be central to decision theory. In particular, these authors focus on the differential treatment of gains and losses. Prospect theory defines preferences not over lotteries of terminal wealth but over gains and losses, measured as differences from a status quo. In applications, the status quo is identified in a variety of ways.

For example, Köszegi and Rabin (2005–6) provide a theory of the status quo and utilize the resulting model to study a monopoly problem. In their theory, the DM’s optimal choice becomes the status quo. Thus, the simplest form of the Köszegi–Rabin model defines optimal choices from a set $A$ as $\mathcal{C}(A) = \{x \in A \mid x \succeq U(y, x) \forall y \in A\}$. Hence, $x \in A$ is deemed to be a possible choice from $A$ if the DM who views $x$ as his reference point does not strictly prefer some other alternative $y$.

The three lines of work discussed below all represent a fundamental departure from the standard modelling of economic decisions: they describe behaviour as the outcome of a game even in a single person problem.

### 3.2 Preference reversals

Strotz (1955–6) introduces the idea of dynamic inconsistency: the possibility that a DM may prefer to consume $x$ in period 2 to consuming $y$ in period 1, if he makes the choice in period 0, but may have the opposite preference if he makes the choice in period 1. Strotz suggests that the appropriate way to model dynamically inconsistent behaviour is to assume that the period 0 individual treats his period 1 preference (and the implied behaviour) as a constraint on what he can achieve. Thus, suppose the period 0 DM has a choice between committing to $z$ for period 2 consumption, or rejecting $z$ and giving his period 1 self the choice between $x$ in period 2 and $y$ in period 1. Suppose also that the period 0 self prefers $x$ to $z$ and $z$ to $y$ while the period 1 self prefers $y$ to $x$. Then, the Strotz model would imply that the DM ends up consuming $z$ in period 2: the period 0 self realizes that if he does not commit to $z$, his period 1 self will choose $y$ over $x$, which, for the period 0 self, is the least desirable outcome. Therefore, the period 0 self will commit to $z$. Hence, dynamic inconsistency leads to a preference for commitment.

Peleg and Yaari (1973) propose to reconcile the conflict among the different selves of a dynamically
inconsistent DM with a strategic equilibrium concept. Their reformulation of Strotz’s notion of consistent planning has facilitated the application of Strotz’s ideas to more general settings, including dynamic games.

3.3 Imperfect recall

An explicit statement of the perfect recall assumption and analysis of its consequences (Kuhn, 1953) is one of the earliest contributions of extensive form game theory. In contrast, the analysis of forgetfulness, that is, extensive form games where the individual forgets his own past actions or information, is relatively recent (Piccione and Rubinstein, 1997).

Piccione and Rubinstein observe that defining optimal behaviour for players with imperfect recall is problematic and propose a few alternative definitions (1997). Subsequent work has focused on what they call the multi-selves approach. In the multi-selves approach to imperfect recall, as in dynamic inconsistency, each information set is treated as a separate player. Optimal behaviour is a profile of behavioural strategies and beliefs at information sets such that the beliefs are consistent with the strategy profile and each behavioural strategy maximizes the corresponding agent’s payoff given his beliefs and the behaviour of the remaining agents. Hence, the multi-selves approach leads to a prediction of behaviour that is analogous to perfect Bayesian equilibrium.

3.4 Psychological games

Harsanyi (1967–8) introduces the notion of a type to facilitate analysis of the interaction of players’ information in strategic problems. He argues that the notion of a type is flexible enough to accommodate all uncertainty and asymmetric information that is relevant in games. Geanakoplos, Pearce and Stacchetti (1989) observe that if payoffs are ‘intrinsically’ dependent on beliefs and beliefs are determined in equilibrium, then types cannot be defined independently of the particular equilibrium outcome. Their notion of a psychological game and type (for psychological games) allows for this interdependence between equilibrium expectations and payoffs.

Gul and Pesendorfer (2006) offer an alternative framework for dealing with interdependent preferences. In their analysis, players care not only about the physical consequences of their actions on their opponents, but also about their opponents’ attitudes towards such consequences, and their opponents’ attitudes towards others’ attitudes towards such consequences, and so on. Gul and Pesendorfer provide a model of interdependent preference types similar to Harsanyi’s interdependent belief types to analyse situations in which preference interdependence may arise not from the interaction of (subjective) information but from the interaction of the individuals’ attitudes towards the well-being of others.

3.5 Neuroeconomics

The most comprehensive challenge to the standard economic modelling of the individual comes from research in neuroeconomics. Neuroeconomists argue that no matter how much the standard conventions are expanded to accommodate behavioural phenomena, it will not be enough: understanding economic behaviour requires studying the physiological, and in particular, neurological mechanisms behind
choice. Recent experiments relate choice-theoretic variables to levels of brain activity, the type of choices to the parts of the brain that are engaged when making these choices, and hormone levels to behaviour (Camerer, 2006) provide a concise summary of recent research in neuroeconomics. Neuroeconomists contend that ‘neuroscience findings raise questions about the usefulness of some of the most common constructs that economists commonly use, such as risk aversion, time preference, and altruism’ (Camerer, Loewenstein and Prelec, 2005). They argue that neuroscience evidence can be used directly to falsify or validate specific hypotheses about behaviour. Moreover, they claim that organizing choice theory and game theory around the abstractions of neuroscience will lead to better theories. Thus, neureconomics proposes to change both the language of game theory and what constitutes its evidence.

4 Conclusion

The interaction of behavioural economics and game theory has had two significant effects: first, it has broadened the subject matter and set of acceptable approaches to strategic analysis. New modelling techniques such as equilibrium notions that explicitly address biases have become acceptable and new questions such as the effect of ambiguity aversion in auctions have gained interest. More importantly, behavioural approaches have altered the set of empirical benchmarks – the stylized facts – that game theorists must address as they interpret their own conclusions.

behavioural finance

Robert Bloomfield
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Behavioural finance began as an attempt to understand why financial markets react inefficiently to public information. One stream of behavioural finance examines how psychological forces induce traders and managers to make suboptimal decisions, and how these decisions affect market behaviour. Another stream examines how economic forces might keep rational traders from exploiting apparent opportunities for profit. Behavioural finance remains controversial, but will become more widely accepted if it can predict deviations from traditional financial models without relying on too many ad hoc assumptions, and expand to settings (particularly corporate finance) in which arbitrage forces are weaker.

Article

Mounting evidence suggests that a variety of trading strategies generate returns that are larger than permitted by the reigning theory of efficient financial markets. Defenders of efficient markets theory argue that the anomalies represent methodological errors, and in many cases they appear to have been correct. In cases where the anomalies appear robust, the debates turn to two other questions. First, why would investors make systematic trading errors that could result in mispricing? Second, why wouldn't smarter traders exploit those errors, thereby driving prices to appropriate levels? Many answers to the first question have relied heavily on the branch of psychology called ‘behavioural decision theory’,
which has led to the entire body of research being dubbed ‘behavioural finance’ even though there is rarely much behavioural content in the literatures identifying pricing anomalies and explaining why price errors are not eliminated by smarter traders. The next section of this article discusses the empirical evidence that market prices deviate from levels that would reflect perfectly rational traders acting in competitive markets (the ‘anomalies’ literature). I then discuss literatures that document how behavioural forces can explain these anomalies, and that examine why irrational traders might influence prices in competitive markets. I conclude by suggesting some promising future directions in behavioural finance.

Anomalies

In 1968, two accounting professors reported that markets react sharply to earnings announcements over the course of a few days, and then continue drifting in the same direction for the better part of a year (Ball and Brown, 1968). This post-earnings-announcement drift (PEAD) appeared to provide an easy opportunity for making money: one could create a hedged portfolio that is long in firms that have just announced good news and short in firms that have just announced bad news, so that it earns positive returns from no net investment.

The fact that prices react at all to earnings was surprising enough, given that earnings was then viewed as an accounting fiction describing past events, with no bearing on the future cash flows of the firm that should entirely determine firm value. (Accounting ‘fictions’ like earnings and book value are now known to provide important information about future cash flows, spawning a large field of financial accounting research.) But the subsequent drift was even more surprising, as it flew in the face of the recently developed efficient markets hypothesis (EMH), subsequently codified by Gene Fama (1970). The EMH relies on competition among investors to assert that strategies based on public information cannot earn returns after adjusting for risk. If all investors know that holding the PEAD portfolio would allow for excess returns, they would compete to hold the portfolio, and drive prices to the level needed to eliminate those returns.

PEAD has turned out to be one of the first – and most robust – of a large number of market anomalies. Initial explanations for PEAD were that the predictable returns simply reflect the expected returns that investors demand to compensate for the risk the PEAD portfolio would impose on them. Such arguments were made much more difficult by Bernard and Thomas (1990), who showed that about half the returns to the PEAD portfolio were experienced in the three-day windows surrounding the two subsequent earnings announcements. Thus, any risk-based explanation would require firms with extremely good or bad earnings news to experience dramatic changes in systematic risk for only a few days a year, several months in the future. The alternative explanation, proffered by Bernard and Thomas, was that investors simply did not understand the implications of current earnings for future earnings – an assertion that has been repeatedly supported by studies of analysts’ earnings estimates and laboratory experiments. Researchers were successful enough in ruling out the risk explanation, and in tying future returns to the information content of current earnings, so that Fama (1998, p. 304) concluded that PEAD ‘has survived robustness checks’, and was possibly ‘above suspicion’.

Three other robust anomalies seem more likely to reflect compensation for risk than mispricing: the book-to-market effect, the size effect and the momentum effect. The book-to-market ratio is the ratio of
a firm's net assets (as reported on the firm's balance sheet) to the total market value of the firm's outstanding stock. Firms with low book-to-market ratios earn substantially higher returns than those with high book-to-market ratios (the book-to-market effect), as if the market value reverts over time to the value indicated by the accounting statements. Firms with small market capitalization earn higher returns than firms with large market capitalization (the size effect), as if small firms are consistently underpriced. Stocks that move strongly upwards or downwards over a three- to six-month period are very likely to continue moving in that direction over a subsequent three to six months (the momentum effect), as if the market responds slowly to changes in value.

Distinguishing risk and mispricing is difficult for book-to-market and size and momentum effects because researchers have no hypothesis that the mispricing will be corrected at some particular moment. (In contrast, the theory explaining PEAD suggests that mispricing will be revealed and corrected upon subsequent earnings announcements). Proponents of efficient markets have provided evidence that book-to-market and size capture systematic risk, and have expanded the traditional asset pricing model to include book-to-market, size and (less frequently) momentum as risk factors. However, analysts appear to view book-to-market as an indicator of mispricing rather than risk, as indicated by examinations of analyst reports and controlled experiments.

Researchers in finance and accounting have identified a host of other pricing anomalies. Here is a selective sampling of some of the most well known, all of which remain controversial:

- **Long-term price reversal.** Stocks that move strongly over a three- to five-year period are very likely to reverse a portion of those movements over a following three- to five-year period (DeBondt and Thaler, 1985). Evidence for long-term reversal tends to be more controversial than evidence for short-term momentum, because longer horizons make it harder to guarantee appropriate computation of risk-adjusted returns.

- **The equity premium puzzle.** A diversified portfolio of equity securities should earn higher returns than a portfolio of bonds, because of the additional risk equities impose on investors. However, the equity premium appears far too large relative to the associated risk (Mehra and Prescott, 1985).

- **The home bias puzzle.** Both institutional and individual investors tend to hold a disproportionate amount of their portfolios in firms based in their own countries and regions. This may reflect a bias to purchase familiar stocks (Huberman, 2001), or the inside information held by local investors (Coval and Moskowitz, 2001).

- **Excessive volatility and excessive volume.** Shiller (1981) has argued that market prices are excessively volatile, relative to the volatility of fundamentals. Many others, including Kandel and Pearson (1995), have argued that trade volume is far too high to be explained by traditional theory, in light of the Milgrom and Stokey (1982) ‘no-trade theorem’, which proves that, in the absence of non-informational motivations for trade, such as a need for liquidity or sharing of risk, markets should not include any trade.

- **The accruals anomaly.** Firms’ earnings can be decomposed into cash flows and accruals (defined as earnings minus cash flows). Sloan (1996) showed that firms with large positive accruals earn lower future returns than firms with large negative accruals, as if investors are unaware that accruals – which do not represent cash flows and are easily manipulated by managers – reverse
Individual behaviour

The variety of market anomalies has led some to doubt the validity of the EMH, but few researchers are likely to let go of the efficient markets perspective without a coherent and parsimonious theory of when to predict which types of anomalies. One branch of psychology, called ‘behavioural decision theory’ (BDT), appears particularly well-suited to imposing regular structure on otherwise ad hoc results. BDT researchers have shown that a variety of apparently irrational behaviours can be explained by a relatively parsimonious set of theories. For their part, behavioural finance researchers have sought to use empirical and experimental studies to show that behavioural theories can describe the actions of individual investors (as well as managers), and to use theoretical methods to show that a small set of behavioural theories can account for the wide variety of market anomalies. Four streams of results feature most prominently in behavioural finance: prospect theory, miscalibration, pattern recognition and limited attention.

Prospect theory

Throughout the 1970s, Amos Tversky and Daniel Kahneman published a series of papers characterizing how people value outcomes. This research ultimately resulted in a mathematical representation of subjective (hedonic) value called ‘prospect theory’ (Kahneman and Tversky, 1979), for which Kahneman won the 2002 Nobel Prize in economics (Amos Tversky died in 1996). Prospect theory emphasizes three features of the value function: that the hedonic value of an outcome is determined by whether the outcome is a gain or loss relative to the agent’s reference point; that the negative hedonic value of a loss more than offsets the positive hedonic value of a gain of the same size; and that the marginal effect of increasing a gain (or loss) is decreasing in the size of the gain (or loss). Prospect theory yields a variety of predictions that describe individual behaviour well, and that can also account for several market anomalies. Prospect theory helps to explain a common behaviour termed the ‘disposition effect’ (Shefrin and Statman, 1985) – traders will close out profitable investments quickly, to lock in gains, while holding on to their losing investments or perhaps even invest more in them, in hopes that the investment will turn around. Let us assume that a trader has bought a stock at 50 dollars, and that it is now priced at 80 dollars. Using the 50-dollar purchase price as a reference point, the trader has a 30-dollar gain, and (because the marginal effect of increasing a gain is decreasing in the size of the gain) the agent is risk-averse, and will want to close the position quickly to avoid risk. If the price fell to 20 dollars, however, the trader has a 30-dollar loss, and (because the marginal effect of increasing a loss is decreasing in the size of the loss) the agent is risk seeking, and will want to keep the position open to take on more risk.

Terry Odean (1998a) has shown clear evidence of the disposition effect among thousands of individual investors at a brokerage firm. Unfortunately for the investors, selling winners and holding on to losers is nearly the opposite of the profitable momentum strategy, which involves buying recent winners and selling recent losers. As a result, the stocks the investors held subsequently underperformed the stocks they sold. The disposition effect does not seem restricted to amateurs. Coval and Shumway (2005) show...
that professional commodity traders who have net losses near the end of the day tend to trade quite aggressively until trading closes, and take on significant risk. Finally, Frazzini (2006) ties the disposition effect back to price anomalies by providing evidence that disposition effects drive short-term momentum, because the relatively rapid selling of winners slows reactions to good news, while the tendency to hold losers slows reactions to bad news.

The disposition effect is driven by the different curvatures of the value function in the loss and gain realms. Curvature is important when investors evaluate the risk of relatively small changes in wealth. Investors who evaluate the risk of large wealth changes are influenced instead by the different average slopes of the value function in the loss and gain realms. Because the average slope is flatter in the realm of gains, investors with large gains in hand are likely to appear less risk-averse than those with losses or small gains. Evidence from experiments (Thaler and Johnson, 1990) and game show contestants (Gertner, 1993) are consistent with this ‘house money’ effect, named after the exaggerated risk tolerance of the behaviour of gamblers who have won money from the house, and therefore are risking only the house's money. Barberis, Huang and Santos (2001) show that the house money effect can account for both short-term momentum and long-term reversal. Short-term momentum arises because traders demand more compensation for risk after price declines, further depressing prices, while demanding less compensation for risk after price increases, further inflating prices. Similar reasoning shows that the house money effect can account for the book-to-market effect and an exaggerated equity premium.

While prospect theory is a relatively parsimonious and powerful theory, its predictions are highly sensitive to assumptions about how people identify benchmarks against which to measure gains and losses, and under what circumstances they might evaluate gains and losses of portfolios, rather than of individual securities. The field of ‘mental accounting’ (Barberis, Huang and Thaler, 2006) addresses such questions.

Miscalibrated confidence

Financial models of trade traditionally assume that agents have confidence calibrated to reflect the precision of their information. Experiments show that people rarely satisfy this requirement. People tend to be overconfident in their ability to predict events when they have very poor information, while people who are asked easy questions tend to be underconfident. Psychologists call this tendency the ‘hard–easy’ effect (Griffin and Tversky, 1992); Bloomfield, Libby and Nelson (2000) call it ‘moderated confidence’ because confidence is moderated from the optimal level towards a prior belief of moderate data reliability, as if people are rational Bayesians with imperfect information about the reliability of their data.

Because financial outcomes are so hard to predict, people are likely to be overconfident, rather than under-confident. Indeed, evidence of overconfidence is widespread. Odean (1999) finds that individual investors trade far too frequently, apparently overconfident in their ability to identify mispriced securities. Malmendier and Tate (2005) find that many executives are overconfident in their firms’ futures (as evidenced by their failure to exercise stock options before expiration), and further show that more overconfident executives are more likely to engage in value-reducing mergers. Theoretical and experimental research has shown that calibration errors can account for a variety of known anomalies. Gervais and Odean (2001) and Odean (1998b) examine how overconfidence can lead
to excessive trading. Daniel, Hirshleifer and Subrahmanyam (1998) show that overconfidence can account for both overreactions and underreactions to information. In a similar vein, Bloomfield, Libby and Nelson (2003) show that overconfident inferences from old earnings numbers, which have little information content once newer numbers are available, lead to both post-earnings-announcement drift and overreactions to earnings trends.

Pattern recognition

The human mind has a gift for finding order in chaos, even when objective analysis shows no order to be found. In such cases, people show remarkable consistency in the order they perceive. People fall prey to the gambler's fallacy when they expect that a coin that has come up 'heads' many times in a row is then more likely to come up 'tails' because such streaks are typically short-lived. People fall prey to the 'hot-hand' fallacy when they mistakenly believe that basketball players who have made ten free throws in a row are especially likely to make the next, even though this is not the case (a professional basketball player's free throw performance is not distinguishable from a random series with a constant mean). The tendency to see patterns in random sequences is likely to be particularly important in financial markets, where competitive pressures force market prices to follow a random walk (after risk premia are accounted for). Despite the randomness in stock movements, many investors subscribe to 'technical analysis' trading strategies (and expensive newsletters) based on elaborate patterns like 'head and shoulders' and 'cup with handle', even though systematic research has found little evidence that such patterns can predict future stock movements. Barberis, Shleifer and Vishny (1998) claim that people who observe a random walk are likely to fluctuate between beliefs in the gambler's fallacy (in which any trends are quickly reversed) and beliefs in the hot hand (in which trends continue), depending on how many reversals in price they have seen in recent periods. They then prove that such beliefs can account for both short-term price momentum and long-term price reversal. Bloomfield and Hales (2002) find experimental support for that assumption.

Limited attention

A fundamental tenet of cognitive science is that people have limited cognitive resources, implying that their attention to financial information and investment opportunities may be determined by economically irrelevant factors such as how information is presented or how often it is talked about by others. Experiments have found that even experienced analysts draw conclusions that are coloured by seemingly irrelevant aspects of how financial information is presented (Hirst and Hopkins, 1998). Employees’ decisions on how to invest their defined contribution pension funds are dramatically influenced by how the options are presented (Benartzi and Thaler, 2001), while their decision to enrol in such plans at all are dramatically increased by a policy that makes investment the default option, so that enrolment requires no attention at all (Benartzi and Thaler, 2004). Limited attention may determine how stocks come in and out of favour, and provides a natural explanation for the home bias puzzle – people naturally notice local firms more readily than distant firms. Limited attention may also explain the tendency of firms to attract attention (and trading volume) when their earnings are growing rapidly, but be ignored when they perform poorly for long periods. Lee
and Swaminathan (2000) argue that such tendencies might explain short-term momentum, and support their argument by showing that firms with low volume and strong returns show strong momentum in returns (as if they are underpriced while still neglected), while those with high volume and strong returns show long-term reversal (as if they are overpriced at the peak of attention).

Accounting researchers have been particularly interested in the effects of limited attention, because they may explain why people care so much about accounting regulations that alter only how information is presented, and not the information content of the complete accounting disclosure. A highly publicized example is the controversy over whether employee stock option costs should be deducted from reported earnings per share; in both cases, investors could gather all relevant information from the footnotes to the financial statements. Bloomfield (2002) argues that fewer investors attend to footnotes than to earnings, and that standard models of information aggregation predict that market prices less completely reveal information that is held by fewer investors – a result repeatedly confirmed in laboratory markets. This ‘incomplete revelation hypothesis’ runs counter to the EMH, which is typically applied to all public information regardless of how it is presented. However, accounting researchers have made considerable progress in understanding how different presentation options, such as the formatting, isolation and ordering of text can alter investors’ attention to and weighting of the information in that text (see, for example, Maines and McDaniel, 2000).

Limits to arbitrage

Studies of individual behaviour show that investors and managers make systematic errors of judgement, but do not explain how other investors fail to exploit, and thereby eliminate, any aggregate mispricing. A number of studies have noted that arbitrage may be limited by risks that cannot be captured as risk factors in traditional asset pricing models. Even if a pricing error must eventually converge (as when two securities representing claims on the same underlying assets have different prices), such convergence may not be rapid, and may even be preceded by additional divergence. While asset pricing models like the capital asset pricing model (CAPM) conclude that such idiosyncratic risk does not affect price levels, Pontiff (2006) has argued forcefully that idiosyncratic risk still hinders the correction of price errors by effectively imposing a ‘holding cost’ on arbitrageurs. Idiosyncratic risk restricts arbitrage most severely when a trader uses borrowed capital to engage in arbitrage, because a short-term loss may result in a margin call, or may lead the investors to infer that the arbitrageur has a poor strategy, and therefore withdraw their funds (Shleifer and Vishny, 1997). DeLong et al. (1990) take these arguments one step further: they assume that the noise in returns is driven by irrational traders, and then show that these traders still earn sufficient returns for them to survive indefinitely. Another line of literature notes that rational arbitrageurs might earn greater profits by exacerbating price errors rather than disciplining them. Abreu and Brunnermeier (2002) construct a model in which irrational traders drive prices too high, a fact that eventually becomes known to every arbitrageur. Because arbitrageurs do not know whether other arbitrageurs have yet learned of the overpricing, each one continues to ‘ride the bubble’ after they learn of the overpricing, rather than pop it, because they expect others to do so as well. As a result, the arbitrageurs continue magnifying the bubble even after each individual arbitrageur knows that prices are too high.

The preceding explanations of limited arbitrage are largely devoid of behavioural content – the price
behavioural finance: The New Palgrave Dictionary of Economics

errors that fail to be corrected could arise from any cause, including completely random trading. However, researchers do occasionally examine how specific biases can limit arbitrage opportunities. Overconfidence, in particular, has been shown to be difficult to arbitrage. For example, Kyle and Wang (1997) show that overconfident traders can effectively gain ‘elbow room’ in a market, just as a trader in a Cournot oligopoly game can benefit by committing to aggressive production, and forcing others to produce less. As a result, overconfident traders earn enough trading gains to persist.

Conclusion and future directions

This history of behavioural finance fits well within Kuhn's (1962) narrative of scientific revolution. Early researchers uncovered results that were anomalous within the paradigm of efficient markets; as they became convinced that the anomalies were not simply the result of methodological error, researchers sought a new paradigm that could encompass the anomalies, as well as the predictions of the traditional theory. This new paradigm assumes that markets include some participants who optimize their expected utility, along with others whose susceptibility to psychological forces leads them to behave suboptimally.

No behavioural alternative will ever rival the coherence, parsimony and power of traditional efficient markets theory, because psychological forces are too complex. Thus, behavioural researchers in finance must devote themselves to the ‘normal science’ suggested by their new paradigm: documenting and refining our understanding of how psychological forces influence individual behaviour in financial settings, and how those behaviours affect market phenomena. This will require much more attention to behavioural psychology than is evident in the existing body of research. (As of 2007, few papers in behavioural finance rely on psychological research published after the 1970s.) Perhaps more importantly, advances in behavioural finance will require more attention to the details of market microstructure, which influence individual behaviour, and how those behaviours affect market-level phenomena. Finally, researchers in behavioural finance can expand their scope beyond describing the behaviour of investors and prices in highly competitive asset markets. Behavioural theories are likely to have greater ability to explain phenomena in settings that provide fewer opportunities for others to exploit (and thereby eliminate) suboptimal outcomes. For example, decisions on how to hire and compensate executives, and on when and how to raise and invest capital, seem particularly susceptible to behavioural analysis (as in Shefrin, 2005).

behavioural game theory

Colin F. Camerer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Behavioural game theory uses experimental regularities and psychology to model formally how limits on strategic thinking, learning, and social preferences interact when people actually play games. Emerging theories of behaviour in ultimatum and trust games (and others) focus on an aversion to inequality, reciprocity, or concern for social image. Learning models often focus on numerical updating of an unobserved propensity to choose a strategy (including fictitious play updating of beliefs as a special case). Models of limits on strategic thinking assume players are in equilibrium, but respond with error, or there is a cognitive hierarchy of increasingly sophisticated reasoning.

Article

Analytical game theory assumes that players choose strategies which maximize the utility of game outcomes, based on their beliefs about what others players will do, given the economic structure of the game and history; in equilibrium, these beliefs are correct. Analytical game theory is enormously powerful, but it has two shortcomings as a complete model of behaviour by people (and other possible players, including non-human animals and organizations).

First, in complex naturally occurring games, equilibration of beliefs is unlikely to occur instantaneously. Models of choice under bounded rationality, predicting initial choices and equilibration with experience, are therefore useful.

Second, in empirical work, only received (or anticipated) payoffs are easily measured (for example, prices and valuations in auctions, or currency paid in an experiment). Since games are played over utilities for received payoffs, it is therefore necessary to have a theory of social preferences – that is, how measured payoffs determine players’ utility evaluations – in order to make predictions.

The importance of understanding bounded rationality, equilibration and social preferences is provided by hundreds of experiments showing conditions under which predictions of analytical game theory are sometimes approximately satisfied, and sometimes badly rejected (Camerer, 2003). This article describes an emerging approach called ‘behavioural game theory’, which generalizes analytical game theory to explain experimentally observed violations. Behavioural game theory incorporates bounds on rationality, equilibrating forces, and theories of social preference, while retaining the mathematical formalism and generality across different games that has made analytical game theory so useful. While behavioural game theory is influenced by laboratory regularities, it is ultimately aimed at a broad range of applied questions such as worker reactions to employment terms, evolution of market institutions, design of auctions and contracts, animal behaviour, and differences in game-playing skill.

Social preferences

Let us start with a discussion of how preferences over outcomes of games can depart from pure material self-interest. In an ultimatum game a Proposer is endowed with a known sum, say ten dollars, and offers a share to another player, the Responder. If the Responder rejects the offer they both get nothing. The ultimatum game is a building block of more complex natural bargaining and a simple tool to measure numerically the price that Responders will pay to punish self-servingly unfair treatment.

Empirically, a large fraction of subjects rejects low offers of 20 per cent or so. Proposers fear these rejections reasonably accurately, and make offers around 40 per cent rather than very small offers predicted by perceived self-interest. (The earliest approximations of whether Proposers offer expected profit-maximizing offers, by Roth et al. 1991, suggested they did. However, those estimates were limited by the method of presenting Responders only with specific offers; since low offers are rare, it is hard to estimate the rejection rate of low offers accurately and hence hard to know conclusively whether offers are profit-maximizing. Different methods, and cross-population data used in Henrich et al., 2005, established that offers are too generous, even controlling for risk-aversion of the Proposers.) This basic pattern scales up to much higher stakes (the equivalent of months of wages) and does not change much when the experiment is repeated, so it is implausible to argue that subjects who reject offers (often highly intelligent college students) are confused.

It is crucial to note that rejecting two dollars out of ten dollars is a rejection of the joint hypothesis of utility-maximization and the auxiliary hypothesis that player i’s utility depends only on her own payoff \(x_i\). An obvious place to repair the theory is to create a parsimonious theory of social preferences over \((x_i, x_j)\) (and possibly other features of the game) which predicts violations of self-interest across games with different structures. I will next mention some other empirical regularities, then turn to a discussion of such models of these regularities.

In ultimatum games, it appears that norms and judgements of fairness can depend on context and culture. For example, when Proposers earn the right to make the offer (rather than respond to an offer) by winning at a pre-play trivia game, they feel entitled to offer less – and Responders seem to accept less (Hoffman et al., 1994). Two comparative studies of small-scale societies show interesting variation across cultures. Subjects in a small Peruvian agricultural group, the Machiguenga, offer much less than those in other cultures (typically 15–25 per cent) and accept low offers. Across 15 societies, equality of average offers is positively related to the degree of cooperation in economic activity (for example, do men hunt collectively?) and to the degree of impersonal market trading (Henrich et al., 2005).

Ultimatum games tap negative reciprocity or vengeance. Other games suggest different psychological motives which correspond to different aspects of social preferences. In dictator games, a Proposer simply dictates an allocation of money and the Responder must accept it. In these games, Proposers offer less than in ultimatum games (about 15 per cent of the stakes on average), but offers vary widely with contextual labels and other variables (Camerer, 2003, ch. 2). In trust games, an Investor risks some of her endowment of money, which is increased by the experimenter (representing a return on social investment) and given to an anonymous Trustee. The Trustee pays back as much of the increased sum as she likes to the Investor (perhaps nothing) and keeps the rest. Trust games are models of opportunities to gain from investment with no legal protection against moral hazard by a business partner. Self-interested Trustees will never pay back money; self-interested Investors with equilibrium beliefs will anticipate this and invest nothing. In fact, Investors typically risk about half their money, and Trustees pay back slightly less than was risked (Camerer, 2003, ch. 2). Investments reflect expectations of repayment, along with altruism toward Investors (Ashraf, Bohnet and Piankov, 2006) and an aversion to ‘betrayal’ (Bohnet and Zeckhauser, 2004). Trustee payback is consistent with positive reciprocity, or a moral obligation to repay a player who risked money to benefit the group.

Importantly, competition has a strong effect in these games. If two or more Proposers make offers in an ultimatum game, and a single Responder accepts the highest offer, then the only equilibrium is for the Proposers to offer almost all the money to the Responder (the opposite of the prediction with one Proposer). In the laboratory this Proposer competition occurs rapidly, resulting in a very unfair allocation – almost no earnings for Proposers (for example, Camerer and Fehr, 2006). Similarly, when there is competition among Responders, at least one Responder accepts low offers and Proposers seem to anticipate this effect and offer much less. These regularities help explain an apparent paradox, why the competitive model based on self-interest works so well in explaining market prices in experiments with three or more traders on each side of the market. In these markets, traders with social preferences cannot make choices which reveal a trade-off of self-interest and concern for fairness. The parsimonious theory in which agents have social preferences can therefore explain both fairness-type effects in bilateral exchange and the absence of those effects in multilateral market exchange.

A good social preference theory should explain all these facts: rejections of substantial offers in ultimatum games, lower Proposer offers in dictator games than in ultimatum games, trust and repayment in trust games, and the effects of competition (which bring offers closer to the equilibrium self-interest prediction).

In ‘inequality-aversion’ theories of social preference, players prefer more money and also prefer that allocations be more equal (judged by differences in payoffs – Fehr and Schmidt, 1999 – or by deviations from payoff shares and equal shares – Bolton and Ockenfels, 2000). In a related ‘Rawlsitarian’ approach, players care about a combination of their own payoffs, the minimum payoff (à la Rawls) and the total payoff (utilitarian) (Charness and Rabin, 2002). These simple theories account relatively well for the regularities mentioned above across games, with suitable parameter values.

Missing from the inequality aversion and Rawlsitarian theories is a reaction to the intentions of players. Intentions seem to be important because players are much less likely to reject unequal offers that are created by a random device or third party than equivalently unequal offers proposed by a player who benefits from inequality (for example, Blount, 1995; Falk, Fehr and Fischbacher, 2007). In reciprocity theories which incorporate intentions, player A forms a judgement about whether another player B has sacrificed to benefit (or harm) her (for example, Rabin, 1993). A likes to reciprocate, repaying kindness with kindness, and meanness with vengeance. This idea can also explain the results mentioned above, and the
effects of intentions shown in other studies.

A newer class of theories focused on ‘social image’ – that is, player A cares about whether another player B believes A adheres to a norm of fairness. For example, Dufwenberg and Gneezy (2000) show that Trustee repayments in a trust game are correlated with the Trustee's perception of what he or she thought the Investor expected to be repaid. These models hinge on delicate details of iterated beliefs (A's belief about B's belief about A's fairness), so they are more technically complicated but can also explain a wider range of results (see Bénabou and Tirole, 2006; Dillenberger and Sadowski, 2006). Models of this sort are also better equipped to explain deliberate avoidance of information. For example, in dictator games where the dictator can either keep nine dollars or can play a ten-dollar dictator game (knowing the Recipient will not know which path was chosen), players often choose the easy nine dollar payment (Dana, Cain and Dawes, 2006). Since they could just play the ten-dollar game and keep all ten dollars, the ten-dollars sacrifice is presumably the price paid to avoid knowing that another person knows you have been selfish (see also Dana, Weber and Kuang, 2007).

Social preference utility theories and social image concerns like these could be applied to explain charitable contribution, legal conflict and settlement, wage-setting and wage dispersion within firms, strikes, divorces, wars, tax policy, and bequests by parents to siblings. Explaining these phenomena with a single parsimonious theory would be very useful and important for policy and welfare economics.

**Limited strategic thinking and quantal response equilibrium**

In complex games, equilibrium analysis may predict poorly what players do in unique games, or in the first period of a repeated game. Disequilibrium behaviour is important to understand if equilibration takes a long time, and if initial behaviour is important in determining which of several multiple equilibria will emerge. Two types of theories are prominent: cognitive hierarchy theories of different limits on strategic thinking; and theories which retain the assumption of equilibrium beliefs but assume players make mistakes, choosing strategies with higher expected payoff deviations less often.

Cognitive hierarchy theories describe a ‘hierarchy’ of strategic thinking and constrain how the hierarchy works to make precise predictions. Iterated reasoning surely is limited in the human mind because of evolutionary inertia in promoting high-level thinking, because of constraints on working memory, and because of adaptive motives for overconfidence in judging relative skill (stopping after some steps of reasoning, believing others have reasoned less). Empirical evidence from many experiments with highly skilled subjects suggests that 0–2 steps of iterated reasoning are most likely in the first period of play. A simple illustration is the ‘p-beauty contest’ game (Nagel, 1995; Ho, Camerer and Weigelt, 1998). In this game, several players choose a number in the interval [0,100]. The average of the numbers is computed, and multiplied by a value $p$ (say 2/3). The player whose number is closest to $p$ times the average wins a fixed prize.

In equilibrium players are never surprised what other players do. In the $p$-beauty contest game, this equilibrium condition implies that all players must be picking $p$ times what others are choosing. This equilibrium condition only holds if everyone chooses 0 (the Nash equilibrium, consistent with iterated dominance). Figure 1 shows data from a game with $p=7$ and compares the Nash prediction (choosing 0) and the fit of a cognitive hierarchy model (Camerer, Ho and Chong, 2004). In this game, some players choose numbers scattered from 0 to 100, many others choose $p$ times 50 (the average if others are expected to choose randomly) and others choose $p^2$ times 50. When the game is played repeatedly with the same players (who learn the average after each trial), numbers converge toward zero, a reminder that equilibrium concepts do reliably predict where an adaptive process leads, even if they do not predict the starting point of that process.

Figure 1

Number choices and theoretical predictions in beauty contest games. *Note:* Players choose numbers from 0 to 100 and the closest number to 0.7 times the average wins a fixed prize. *Source:* Camerer and Fehr (2006).
In cognitive hierarchy theories, players who do $k$ steps of thinking anticipate that others do fewer steps. Fully specifying these theories requires specifying what 0-step players do.
what higher-step players think, and the statistical distribution of players’ thinking levels. One type of theory assumes players who do k steps of thinking believe others do k-steps (Nagel, 1995; Stahl and Wilson, 1995; Costa-Gomes, Crawford and Broseta, 2001). This specification is analytically tractable (especially in games with n>two players) but implies that as players do more thinking their beliefs are further from reality. Another specification assumes increasingly rational expectations – k-level players truncate the actual distribution f(k) of k-step thinkers and guess accurately the relative proportions of thinkers doing 0 to k–1 steps of thinking. Camerer, Ho and Chong (2004) and earlier studies show how these cognitive hierarchy theories can fit experimental data from a wide variety of games, with similar thinking-step parameters across games.

These cognitive hierarchy theories ignore the benefits and costs of thinking hard. Costs and benefits can be included by relaxing Nash equilibrium, so that players respond stochastically to expected payoffs and choose better responses more often when costs are high, but do not maximize. Denote player i’s beliefs about the chance that other players j will choose strategy k by \( P_i(s^k_j) \). The expected payoff of player i’s strategy \( s^k_i \) is

\[
E(s^k_i) = \sum_k P_i(s^k_j) \pi_i(s^k_i, s^k_j) \]

where \( \pi_i(x,y) \) is i’s payoff if i plays x and j plays y. If player i responds with a logit choice function, then

\[
P_i(s^k_i) = \exp(\lambda E(s^k_i)) / \sum_k \exp(\lambda E(s^k_i))
\]

In this kind of ‘quantal response’ equilibrium (QRE), each player’s beliefs about choice probabilities of others are consistent with actual choice probabilities, but players do not always choose the highest expected payoff strategy (and \( \lambda \) parameterizes the degree of responsiveness; larger \( \lambda \) implies better response). QRE fits a wide variety of data better than Nash predictions (McKelvey and Palfrey, 1995; 1998; Goeree and Holt, 2001). It also circumvents some technical limits of Nash equilibrium because players always tremble but the degree of trembling in strategies is linked to expected payoff differences.

Learning

In complex games, it is unlikely that equilibrium beliefs arise from introspection or communication. Therefore, theorists have explored the mathematical properties of various rules under which equilibrium might occur when rationality is bounded. Much research is focused on population evolutionary rules, such as replicator dynamics, in which strategies which have a payoff advantage spread through the population (for example, Weibull, 1995). Schlag and Pollock (1999) show a link between imitation of successful players and replicator dynamics. Several individual learning rules have been fit to many experimental data-sets (see individual learning in games). Most of these rules can be expressed as difference equations of underlying numerical propensities or attractions of stage-game strategies which are updated in response to experience. The simplest rule is choice reinforcement, which updates chosen strategies according to received payoffs (perhaps scaled by an aspiration level or reference point). These rules fit surprisingly well in some classes of games (for example, with mixed strategy equilibrium, so that all strategies are played and reinforced relatively often) and in environments with little information, where agents must learn payoffs from experience, but can fit quite poorly in other games. A more complex rule is weighted fictitious play (WFP), in which players form beliefs about what others will do in the future by taking a weighted average of past play, and then choose strategies with high expected payoffs given those beliefs (Cheung and Friedman, 1997). Camerer and Ho (1999) showed that WFP with geometrically declining weights is mathematically equivalent to generalization reinforcement in which unchosen strategies are reinforced as strongly as chosen ones. Building on this insight, they create a hybrid called experienced weighted attraction (EWA). The original version of EWA has many parameters because it includes all the parameters used in the various special cases it hybridizes. The EWA form fits modestly better in some games (it adjusts carefully for overfitting by estimating parameters on part of the data and then forecasting out-of-sample), especially those with rapid learning across many strategies (such as pricing). In response to criticism about the number of free parameters, Ho, Camerer, and Chong (2007) created a version with zero learning parameters (just a response sensitivity \( \lambda \) as in QRE) by replacing parameters by ‘self-tuning’ functions of experience. Some interesting learning rules do not fit neatly into the class of strategy-updating difference equations. Often it is plausible to think that players are reinforcing learning rules rather than strategies (for example, updating the reinforcement rule or the WFP rule; see Stahl, 2000). In many games it is also plausible that people update history-dependent strategies (like tit for tat; see Erev and Roth, 2001; McKelvey and Palfrey, 2001). Selten and Buchta (1999) discuss a concept of ‘direction learning’ in which players adjust based on experience in a ‘direction’ when strategies are numerically ordered.

All the rules described above are naive (called ‘adaptive’) in the sense that they do not incorporate the fact that other players are learning. Models which allow players to be ‘sophisticated’ and anticipate learning by other players (Stahl, 1999; Chong, Camerer and Ho, 2006) often fit better, especially with experienced subjects. Sophistication is particularly important if players are matched together repeatedly – as workers in firms, firms in strategic alliances, neighbours, spouses, and so forth. Then players have an incentive to take actions that ‘strategically teach’ an adaptive player what to do. Models of this sort have more moving parts but can explain some basic stylized facts (for example, differences in repeated-game play with fixed ‘partner’ and random ‘stranger’ matching of players) and fit a little better than equilibrium reputational models in trust and entry deterrence games (Chong, Camerer and Ho, 2006).

Conclusion
Behavioural game theory uses intuitions and experimental evidence to propose psychologically realistic models of strategic behaviour under rationality bounds and learning, and incorporates social motivations in valuation of outcomes. There are now many mathematical tools available in both of these domains that have been suggested by or fit closely to many different experimental games: cognitive hierarchy, quantal-response equilibrium, many types of learning models (for example, reinforcement, belief learning, EWA and self-tuning EWA), and many different theories of social preference based on inequality aversion, reciprocity, and social image. The primary challenge in the years ahead is to continue to compare and refine these models – in most areas, there is still lively debate about which simplifications are worth making, and why – and then apply them to the sorts of problems in contracting, auctions, and signalling that equilibrium analysis has been so powerfully applied to.

A relatively new challenge is to understand communication. Hardly any games in the world are played without some kind of pre-play messages (even in animal behaviour). However, communication is so rich that understanding how communication works by pure deduction is unlikely to succeed without help from careful empirical observation. A good illustration is Brandts and Cooper (2007), who show the nuanced ways in which communication and incentives, together, can influence coordination in a simple organizational team game.

Abstract

The study of how variation in genetic endowment affects behaviour has shown that a surprisingly wide range of human activities are subject to substantial genetic influence. Studies of the covariance of traits in more and less distant relatives that take into account the impact of family environment have been the main method used to demonstrate this. This article provides a brief introduction to the mechanisms of heredity, and then a discussion of the methods used by behavioural geneticists and their limitations. Both the traditional variance decomposition methods and the newer molecular genetic methods are described and discussed.

Keywords

adoption studies; behavioural genetics; chopstick problem; cognitive ability; environment vs heredity; evolutionary psychology; genome; heredity; heritability; linkage studies; twin studies

Article

While defining itself as the study of genetic influences on behaviour, behavioural genetics has been mainly concerned with demonstrating and quantifying the contribution of genetic variation to variation in human behavioural traits. As such, it contrasts with the related field of evolutionary psychology that attempts to understand how some behavioural traits common to all humans have been shaped by evolution.

The large and growing literature on the impact of genetic variation on behaviour leaves no room for doubt that genetic endowment is an important influence on a surprisingly wide range of behaviours. Behavioural genetics has relied mainly on the study of relatives with different degrees of relatedness or adoption to estimate the contributions of genetic variation and shared family environment to explaining cross-sectional variation in behavioural characteristics. More recently, behavioural geneticists have been extending their methodology to use relational studies to examine the covariation of different behavioural traits, and molecular genetic methodologies to trace the sources and causes of genetically induced
behavioural genetics: The New Palgrave Dictionary of Economics

Below I give a brief introduction to the mechanics of heredity. This is a necessary introduction to the methods of behavioural genetics, which I explain next.

Mechanics of heredity

The human genetic code is contained in 23 pairs of chromosomes made up of deoxyribonucleic acid or DNA. A DNA molecule consists of two backbone strands that are held apart by molecular pairs of four bases. A sequence of these four chemicals along one of the backbone strands encodes the plans for the different proteins from which our bodies are made. Other parts of the code are thought to control when proteins are created and in what quantities. There are about three billion base pairs on just one set of 23 chromosomes. A sequence of base pairs that codes the information for a protein or some other function is called a ‘gene’.

Of the three billion base pairs all but about three million are the same in all humans. Where base pairs differ it is said that a polymorphism exists. When a gene contains one or more polymorphic base pairs there will be different versions of the gene. Different versions of the same gene are referred to as alleles. A person's genotype is determined by what alleles that person has, while the physiological characteristics or behaviours that geneticists study are referred to as the phenotype. Any given phenotypic behaviour can be the result of having a particular genotype, a particular environmental influence, or some combination of the two. Phenotypic traits are said to be qualitative if they take a limited number of discrete forms and quantitative if they vary continuously. So the presence of the symptoms of Huntington's disease, a degenerative neurological disorder that affects older people, is a qualitative trait while one's score on an IQ test is a quantitative trait.

Genetic influence on a phenotype can involve one or more genes. For example, people who have the allele for Huntington's disease in the single gene encoding the huntingtin protein will contract it. Those who don't won't. Contrast that with the genetic influence on measured cognitive ability, which is thought to involve many genes, each of which has a very small effect on scores on tests of mental ability. When many genes influence a phenotypic trait, it is said to be polygenic.

Both qualitative and quantitative traits can be polygenic. A trivial example of a qualitative trait that is polygenic would be having an IQ score over 130. Other than some psychopathologies, most of the behaviours studied are thought to be polygenic with differences in each gene, making only a small contribution to differences in behaviour. In theory a quantitative trait could be influenced by a single gene that influenced the mean of the trait while environment determined the variance around the mean, but no examples of this have been identified.

Normally people inherit 46 chromosomes – 23 from their mothers and 23 from their fathers. Since there are many genes on any one chromosome, the inheritance of different traits can be linked if genes on the same chromosome influence the traits. However, the linkage is not perfect. In the process of creating the chromosomes that will be passed on to one's children in gamete cells (ova and sperm), contiguous parts of each pair of chromosomes can be swapped so that the chromosome that is passed onto one's child is a combination of parts from both of one's parents. This happens on average about once per chromosome in humans. Thus, traits that are influenced by genes located close together on the same chromosome are more likely to be inherited together than genes on the same chromosome that are at distant loci. As will be described later, this fact can be used to identify the location of the genes that affect a particular trait.

http://www.dictionaryofeconomics.com.proxy.library.csi...du/article?id=pde2008_H000165&goto=B&result_number=124
If one has different alleles for the same gene on each of a pair of chromosomes there are different possible impacts. In some cases, certain alleles will always be expressed (influence phenotype) if they are present. Such alleles are termed ‘dominant’. Other alleles for the same gene are called ‘recessive’ and will be expressed only if they are not paired with a dominant allele. In other cases, having two different alleles will have an effect on phenotype halfway between the effect of having two of the one allele and the effect of having two of the other. In this case genetic effects are termed ‘linear and additive’.

There can be interactions between multiple genes in creating effects on phenotype. The phenomenon is called ‘epistasis’. For example, there is epistasis if two different alleles of two different genes must be present for a phenotypic trait to be present. In this case, genetic effects on this trait will not be linear and additive.

Relational studies

Arguably the first behavioural genetics study was Galton's *Hereditary Genius* (1869) in which he looked at patterns of career success in English families. He showed that close relatives of prominent men were also likely to achieve distinction, but that the probability fell with more and more distant relatives. While a genetic basis for ability would explain this pattern, so would family connections and a host of other environmental factors. Modern behavioural genetics research uses relational data, but in a way that attempts to control for family environment.

The simplest version of this type of study looks at the behavioural similarity of identical (or monozygote) twins who are raised apart. Such twins are genetic copies of each other as they grew from the same fertilized egg, but, if they are reared apart, then environmental similarities can't explain any behavioural similarities. If one assumes that genetic and environmental influences on a trait are linear and additive, then one can write

\[
P = hG + cS + eN
\]

(1)

where \( P \) is a measure of the phenotypic behaviour, \( G \) is genetic endowment, \( S \) is an index of the influence of shared family environment, and \( N \) is an index of the influence of environmental factors not shared by family members. The variables \( G, S \) and \( N \) are not observed, but the parameters \( h, c \) and \( e \) can still be estimates. If all variables are measured as standard deviations from their means, and \( G, S \) and \( N \) are uncorrelated, then \( h, c \) and \( e \) will be the correlations of the respective variable with \( P \) and their squares will be the fraction of variance in \( P \) that is explained by each. The fractions of variance in \( P \) explained by genetic endowment, shared family environment, and non-shared environment are commonly denoted \( h^2 \), \( c^2 \) and \( e^2 \). The sum of the squared coefficients will be one. Under the assumptions that the \( S \)'s and \( N \)'s of identical twins raised apart are uncorrelated, the expected correlation of \( P \) for pairs of twins is \( h^2 \) or the fraction of variation in the population explained by differences in genetic endowments. This statistic is referred to as the heritability of the trait \( P \).
If one also has data on the correlation of the behaviour for identical twins raised together, one can construct an estimate of the fraction explained by the two environmental components as well. Under the assumption that identical twins raised together have both the same $G$ and the same value for $S$, the correlation of $P$ across pairs of identical twins raised together will be $h^2+c^2$. So the difference between the correlation of $P$ for identical twins raised apart and those raised together will be the fraction of variance explained by shared family environment, and $1\cdot$minus that correlation will equal the share explained by non-shared environment.

With one additional assumption it is not necessary for the adopted siblings to be identical twins. Since natural siblings receive half of their genes from each parent and the genes received from each parent are in some sense a random subset of the parents’ genes, it is not unreasonable to assume that the correlation of $G$ for siblings who are not identical twins will be .5. In that case the expected correlation of a phenotype behaviour for siblings raised apart will be $.5\cdot h^2$, and multiplying that value by 2 yields an estimate of the fraction of variance in the population explained by variation in genetic endowments. Once again, the difference between the correlation for siblings raised apart and those raised together will provide an estimate of the fraction of variance explained by shared family environment. The share attributable to non-shared environment can be computed as $1\cdot$minus the sum of the shares of genetic endowment and family environment.

If the effects of genetic endowment are not linear, then heritability estimates derived from studying twins adopted apart will be larger than those for siblings raised separately. Since monozygote twins are genetically identical, they will be affected by dominant genes and interaction effects between genes (epistasis) in exactly the same way. Thus, studies of identical twins measure what is called ‘broad-sense heritability’ (denoted $H^2$) unless dominance and epistasis effects are absent. In the presence of dominance and epistasis effects the correlation of phenotypes between normal sibling pairs raised apart will be less than half of that of identical twins raised apart. Twice the correlation for normal siblings raised apart is said to measure narrow-sense heritability since it doesn't reflect the contribution of nonlinear genetic effects.

Estimated variance shares from adoption studies can be criticized on a number of grounds. Siblings raised apart, and particularly twins, will share aspects of their prenatal environment at least. They may also share their post-natal environment if they are not adopted away immediately. Also, siblings who are put up for adoption may end up in similar environments for a number of reasons. They may be adopted by relatives, or they may be adopted through the same agency that places children with parents of a particular social class in a particular geographic area. Adopting families may be matched to the socio-economic status of the biological mother. Similar environments will cause adoptees to resemble each other even if there is no effect of genetic endowment and will bias estimates of heritability upward. Adoption itself may affect the trait, leading to an overestimate of heritability and an underestimate of the role of shared environment.

Even if adoption doesn't place siblings in similar environments, it almost certainly restricts the range of environments compared with those occupied by children living with their natural parents, as adoption agencies rigorously screen parents wishing to adopt. Stoolmiller (1999) argues that this restriction of range leads adoption studies to underestimate the role of shared family environment and overestimate the importance of genetic differences in explaining variance in the general population, since there is much more variation in family environment in the general population than in adopting families. This illustrates an important characteristic of heritability estimates – they apply only to the population in
which they are estimated. Populations with different amounts of variation in environment or genetic endowment would exhibit different heritabilities. Finally, the assumption that the correlation of normal siblings with no environment in common will be exactly $0.5 \cdot h^2$ is probably wrong for another reason. It assumes that each parent’s genes for a trait are a random draw from the population – that is, that men and women don’t choose each other as mates on the basis of the characteristic being studied or anything related to it. If parents are likely to have genes for the trait in common, then the expected correlation will be higher and multiplying it by 2 will overestimate heritability. If opposites attract, then multiplying the sibling correlation by 2 will understate heritability. Estimates of the variance explained by shared family environment will be affected and biased in the opposite direction to heritability.

An alternative to adoption studies are those that contrast the similarity of identical twins with that of fraternal twins. Identical twins are genetic copies of each other while fraternal twins are no more alike genetically than brothers and sisters. Thus we would expect identical twins to be more similar for traits that are subject to genetic influence. Again, under the standard assumptions, the correlation of identical twins in a population will be $h^2 + c^2$. If one assumes that fraternal twins’ genetic endowments have a correlation of $0.5$, then their correlation will be $0.5 \cdot h^2 + c^2$. Thus, twice the difference between the correlation for identical and fraternal twins is an estimate of heritability. The fraction of variance explained by shared environment will be equal to the identical twin correlation minus the estimate of heritability, and that of non-shared environment will equal $1 - \text{minus the identical twin correlation.}$

Twin studies, too, can be criticized on a number of grounds. The assumption that the correlation of genetic endowment for fraternal twins will be $0.5$ rests on random mating. If husbands and wives tend to have similar genetic endowments for the characteristic being studied, then the fraternal twin correlation will be greater than $0.5$, and doubling the difference between fraternal and identical twins will understate heritability and overstate the role of shared environment. On the other hand, if there are dominance and epistasis effects, doubling the difference will overstate both broad and narrow sense heritability.

A common criticism of twin studies is that identical twins have more similar environments than fraternal twins and that accounts for some of their greater similarity. Whether or not this is a valid criticism, it certainly illustrates a common misunderstanding about the meaning of heritability. If identical twins have more similar environments because they behave in more similar ways and create for themselves more similar environments, some would say that it is legitimate to attribute the influence of environment of this sort to genetic endowment. In the same sense, natural siblings may have more similar environments than adopted siblings – even if they are raised apart – because their more similar genes induce more similar behaviour which induces more similar responses from their environment. If two siblings are both genetically predisposed to be taller, they may both end up playing on the high-school basketball team, where they receive professional coaching which greatly improves their skills. The similarity of their basketball skill is a direct effect of similar environments, but it is also an indirect effect of genetic endowment. Both twin and adoption studies will attribute such induced environmental effects to genetic endowment.

A common error in the interpretation of heritability estimates is the assumption that, if heritability is high, the effects of environment must be small and the trait not easy to change through environmental intervention. However, if heritability estimates attribute to genetic endowment indirect effects that come through environment, it’s easy to see that this is not the case (see the discussion of malleability in the entry on cognitive ability). If a tall person is good at basketball mainly because he has received good coaching, then the skill of shorter people can probably be improved a great deal by coaching as well.
(even if they can never be quite as good as the tall person). When genetic endowment has both direct physiological effects on a trait and indirect effects through induced environment, there is gene × environment correlation. Relaxing the assumption that genetic endowment and environmental influences are correlated doesn't invalidate heritability estimates, but it does change their interpretation as just explained. The fractions of variance explained by shared and non-shared environment in twin and adoption studies are not the full effect of environment, but the fractions explained by the residual environment – that part that can't itself be explained by differences in genetic endowment.

There is another reason why high heritability estimates do not mean that the effects of environment are necessarily weak. Recall that heritability estimates are valid only in the population in which they are estimated. If we were to study nearsightedness in a population of people who were not wearing corrective lenses, we would find it highly heritable. If we studied scores on an eye test allowing people to wear their corrective lenses, we would probably find very low heritability of test scores. The high heritability of nearsightedness in the first case certainly wouldn't mean that we couldn't treat it with corrective lenses.

Interaction of environment and genotype can create problems of interpretation similar to the just-described problems caused by the correlation between genotype and environment. Interaction is said to exist when environment has different effects depending on a person's genotype. In this case genetic effects are not linear and additive and the variance shares computed using standard behavioural genetic methods do not provide a meaningful measure of effects of genetic endowment and environment on the trait. None the less, high estimates of heritability for a population still indicate a substantial role for genetic variation in causing variation in the trait.

Some of the shortcomings of twin studies and adoption studies can be overcome by combining data from the two. Since they are subject to different biases, if results for the two types of studies are very similar, one can have some confidence that the biases are not important. Data from the two types of studies can be formally combined and used to estimate more elaborate models of inheritance that relax one or more assumptions such as linearity, random mating, or similar treatment of identical and fraternal twins.

Information on other types of relations and more distant relations can be added to model building studies as well.

Of all the behaviours to which relational methods have been applied, the one that has received the most attention is scores on tests of cognitive ability. These studies have been extremely controversial -- at least in part because of the widespread misunderstanding that high heritability precluded an important role for environment. Today it is widely accepted that the heritability of cognitive test scores in adults is very high (0.6 or more; Neisser et al., 1996; Plomin et al., 2000, pp. 164–77), but it is understood that this does not imply a limited role for environment (as genetic endowment may be acting indirectly through the environment).

Besides cognitive ability, a wide range of other behaviours have been studied. The degree to which people display the symptoms of a number of psychopathologies has been shown to be subject to genetic influence (Plomin et al., 2000, chs 8 and 12). Major measurable aspects of personality (Loehlin, 1992), religiosity (Waller et al., 1990), attitudes towards one's job (Lykken et al., 1993), social attitudes (Martin et al., 1986) (including political conservatism; Eaves et al., 1997), education (Behrman and Taubman, 1989), earnings (Taubman, 1976), and even the amount of time spent watching television (Plomin et al., 1990), have all been shown to be subject to genetic influence. In most cases, studies find that the fraction
of variance explained by variation in genetic endowment is large and greater than the fraction explained by family environment (Turkheimer, 2000). Also interesting are the exceptions that have been found to this general pattern. For example, how often one attends church is influenced by one's genetic endowment, but not the type of church one attends.

A relatively recent development in relational studies is their use to analyse the sources of covariance between different measures of behaviour. By using similar assumptions to those used to identify variance shares, it is possible to tell whether correlations between variables are due mainly to common genetic factors, common environmental factors or both. For example, tests of cognitive ability are strongly correlated with scores on achievement tests and both are highly heritable. Are the same genetic factors responsible for both (as would be the case if genetic influence on achievement came entirely through its effects on cognitive ability)? For the most part they are, though some genetic influence is specific to achievement (Plomin et al., 2000, p. 201).

Animal models and molecular genetics studies

Work with animals allows behavioural geneticists to do many things that are impossible with human subjects. For example, animals can be bred for certain behavioural traits and then the specially bred animals can be used in experiments. One of the most interesting demonstrations of gene\(\times\)environment interaction comes from a study of two strains of rats that had been bred for their performance in solving mazes (Cooper and Zubek, 1958). One strain was bred for superior performance and one for inferior performance. Rats raised in very sparse environments performed poorly in solving mazes no matter what their genetic endowment. Rats raised in enriched environments performed much better and there was little effect from their genetic endowment. However, rats raised in normal laboratory environments showed large differences consistent with their genetic endowments.

Animal studies can be particularly useful when combined with some of the new molecular genetic techniques. Certain genes can be turned off and the impact on behaviour studied. Genetic mutations can be created in experimental animals and the impact of the mutation on behaviour examined. Selectively bred animals can be compared for the frequency of different alleles to determine where genes that influence a trait are located.

Searches of this sort are facilitated by the previously described tendency for genes that are located close together on a chromosome to be inherited together. Suppose, for example, that animals that had been bred for an extreme form of some behaviour showed a much higher frequency of one allele on one chromosome than did the population from which they were bred. This would not mean that that allele played a role in the development of that trait, but it would make it more likely than not that one or more genes on the chromosome on which the gene was located played some role. The allele that is found to be associated with the trait being studied is said to be a marker for the trait, while the genes with the polymorphisms that matter for the trait are said to be trait loci. If the trait is a quantitative trait, each locus is referred to as a quantitative trait locus (QTL).

If several markers are studied on the same chromosome, some may be found to be more highly associated with the trait than others. The more highly associated markers are likely to be closer to one or more trait loci since, the closer two genes are together on the same chromosome the more likely it is that they will be inherited together.

This technique has been used to identify the location of genes with a large role in determining differences in fearfulness in mice. The same sequence of genes exists in the human genome and it is possible that variations in them may explain why some people develop anxiety disorders and some don’t. Understanding the role of these genes may lead to more effective treatment.

Association techniques can also be used in humans, but are subject to a number of problems. In the example just discussed, the mice studied were all bred from the same homogenous population. The breeding for the trait is likely to have induced any association found between a marker and a phenotype trait. However, in human populations markers and traits could be associated even if there was no genetic influence on the behaviour. This is referred to as the ‘chopstick’ problem, which is named after a commonly cited example of a spurious association. In a population that included native Chinese and Europeans, using chopsticks would be associated with any marker more common in Chinese. This problem can be partially overcome by studying more homogenous populations or contrasting sibling pairs, as differences in marker frequency are more likely to signal genetic causation in these cases. In the extreme, studies can be done on large extended families. The families can be studied for co-transmission of the trait and particular alleles. These are termed ‘linkage studies’. Linkage studies were used to identify the gene responsible for Huntington's disease.

Linkage studies solve another problem of association studies in humans. Within a family, even markers fairly distant from a trait locus will have some degree of association with the trait. In the general population, markers are likely to be associated with traits only if they are trait loci themselves or are located very close to them, as recombination of chromosomes will eventually break down the association of any marker that is not a trait locus with the trait after a sufficient number of generations. A much smaller number of markers can be used to scan for the location of trait loci in a linkage study than in a study looking for association in the general population. However, linkage studies are not very good at finding QTLs when there are many genes contributing to a phenotype. Association studies in large populations are more promising, but only if the area of the genome to be examined can be narrowed on the basis of hypothesis about what systems might be involved. So far this approach has shown some promise. For example, associations have been found between a particular allele for a dopamine receptor gene and hyperactivity disorder in children (Thapar et al., 1999).

The future

Relational studies have demonstrated that variation in a surprisingly wide range of behaviours is substantially influenced by genetic differences. Molecular genetics has begun to discover some of the mechanisms by which genetic differences cause differences in behaviour, but work of this sort has barely scratched the surface, and further development faces some difficult obstacles. Most of the behaviours that have been studied are thought to be affected by many different genes, each of which has a small effect. This will make identifying QTLs difficult without some theory of what physiological processes might be involved and where the genes affecting those processes are in the genome. But what theory might one have about the location of physiological processes affecting, for example, time spent watching television?

When one begins to think about the many ways in which physiological differences could affect a wide range of behaviours, the task seems daunting. Suppose there was an allele that when present made people feel more discomfort when they were cold than others without the allele. Such people might be
inclined to spend more time inside watching TV. They might also be less athletic and/or more likely to spend a lot of time reading. If they read more, they might have larger vocabularies and score better on IQ tests. If their reading made them more sceptical, they might be less likely to attend church. Depending on how myriad and diffuse such cascading effects are, it might be impossible to understand how more than a small fraction of genetically induced differences in behaviour comes about. Still, that doesn't mean that valuable knowledge can't be gained from studying the pathways that can be identified. Such knowledge might accumulate faster if those studying the genetic influences on behaviour concentrated less on refining estimates of heritability and more on analysing the role of genetic differences in explaining the covariance of different behaviours.

behavioural public economics

B. Douglas Bernheim and Antonio Rangel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Behavioural public economics incorporates ideas from behavioural economics, psychology, and neuroscience in the analysis and design of public policies. This article provides an introduction to its methods and discusses its application to savings and addiction policy.

Keywords

addiction; behavioural public economics; budget constraints; compulsory saving; default options; imperfect decision processes; intertemporal choice; lump-sum taxes; myopia; neoclassical public economics; neuroscience; Pigouvian taxes; psychology and economics; tax incentives for saving; well-being

Article

Interest in the field of psychology and economics has grown in recent years, stimulated largely by accumulating evidence that the neoclassical model of consumer decision-making provides an inadequate description of human behaviour in many economic situations. Scholars have begun to propose alternative models that incorporate insights from psychology and neuroscience. Some of the pertinent literature focuses on behaviours commonly considered ‘dysfunctional’, such as addiction, obesity, risky sexual behaviour, and crime. However, there is also considerable interest in alternative approaches to more standard economic problems such as saving, investing, labour supply, risk-taking, and charitable contributions.

Behavioural public economics (BPE) is the label used to describe a rapidly growing literature that uses this new class of models to study the impact of public policies on behaviour and well-being (see Bernheim and Rangel, 2006a, for a more comprehensive review).

Background: the neoclassical approach to public economics
Public economic analysis requires us to formulate models of human decision-making with two components – one describing choices, and the other describing well-being. Using the first component, we can forecast the effects of policy reforms on individuals’ actions, as well as on prices and allocations. Using the second component, we can determine whether these changes benefit consumers or harm them.

The neoclassical approach assumes that individuals’ choices can be described as if generated by the maximization of a well-defined and stable utility function subject to feasibility and informational constraints. Neoclassical welfare analysis proceeds from the premise that, when evaluating policies, the government should act as each individual’s proxy, extrapolating his preferred choices from observed decisions in related situations. This premise justifies the use of the as-if utility function as a gauge of well-being. In effect, this approach uses the same model for positive and normative analysis.

Within the neoclassical paradigm, government policy can affect behaviour and welfare only if it changes the decision maker's information or budget constraint. For example, vaccination campaigns may influence behaviour by providing information concerning the risks of a disease and the advantages of taking preventive action, while cigarette taxes may alter choices by raising the cost of smoking.

From the neoclassical perspective, government intervention in private markets is justified to enforce property rights, correct market failures, and address inequity by redistributing resources. Standard examples of interventions motivated by market failures include the use of taxes and subsidies to correct externalities, the provision of public goods, and the introduction of social insurance when private risk sharing is inefficient.

The accomplishments of neoclassical public economics, such as the theories of optimal income taxation and corrective environmental policy, are considerable. However, there is growing concern that this paradigm does not adequately address a number of important public policy challenges – for example, what to do about ‘self-destructive’ behaviours such as substance abuse, or about the apparently myopic choices of those who save ‘too little’ for retirement. Since the neoclassical welfare criterion respects all voluntary consumer choices (conditional on the information in the consumer's possession), it rules out the possibility of enhancing well-being by correcting ‘poor’ choices (except through the provision of information).

The behavioural approach to public economics

A key feature of BPE is the potential divergence of positive and normative models. Even when it is assumed that individuals are endowed with well-behaved lifetime preferences, decision processes may translate these preferences to choices imperfectly. To conduct positive analysis, one employs a model of the potentially imperfect decision process. To conduct normative analysis, one uses a well-defined welfare relation. In stark contrast to the neoclassical approach, the welfare relation may prescribe an alternative other than the one that the individual would choose for himself, at least under some conditions.

The analysis of addiction presented in Bernheim and Rangel (2004) illustrates this approach. Our model assumes that people attempt to optimize given their preferences, but randomly encounter conditions that trigger systematic mistakes, the likelihood of which evolves with previous substance use. The model is based on the following three premises. First, use among addicts is sometimes a mistake and sometimes rational. Second, experience with an addictive substance sensitizes an individual to environmental cues...
that trigger mistaken usage. Third, addicts understand their susceptibility to cue-triggered mistakes and attempt to manage the process with some degree of sophistication. The first two premises are justified by a body of research in psychology and neuroscience, which shows that, after repeated exposure to an addictive substance, the brain tends to overestimate the hedonic consequences of drug consumption upon encountering environmental cues that are associated with past use. The third premise is justified by behavioural evidence indicating that users are often surprisingly sophisticated and forward looking. The \((\beta, \delta)\)-model of intertemporal choice (Strotz, 1956; Phelps and Pollack, 1968; Laibson, 1997; O'Donoghue and Rabin, 1999; 2001) also illustrates the BPE approach. Psychologists have found that people often act as if they attach disproportionate importance to immediate rewards relative to future rewards, especially in situations where cognitive systems are overloaded. (For a recent review of this literature, see Frederick, Loewenstein and O'Donoghue, 2002; Loewenstein, Read and Baumister, 2003.)

To capture this tendency, the \((\beta, \delta)\)-model assumes that, in each period \(t\), individuals behave as if they maximize a utility function of the form

\[
u(c_t) + \beta \sum_{k=t+1}^{T} \delta^{k-t} u(c_k),\]

where \(0 < \beta < 1\). In this framework, the parameter \(\beta\) represents the degree of present bias or myopia. The neoclassical model corresponds to the special case where \(\beta = 1\). With \(\beta < 1\), behaviour is dynamically inconsistent. This complicates positive analysis, since behaviour no longer corresponds to the solution of a single utility maximization problem.

Many analysts interpret present bias as a mistake. They argue that the individual's underlying well-being actually corresponds to the preferences revealed through choices that do not involve immediate rewards:

\[
u(c_1, \ldots, c_T) = \sum_{t=0}^{T} \delta^{t} u(c_t).
\]

Under this interpretation, \(\beta < 1\) creates a tendency to consume excessively in the present. These examples illustrate some important conceptual and methodological aspects of BPE. First, with behaviour and welfare modelled separately, BPE allows for the possibility of mistakes. In contrast to a neoclassical analyst, a BPE analyst can pose questions that presuppose possible divergences between behaviour and preferences, such as whether Americans save too little for retirement, or whether addicts engage in self-destructive behaviour. Within the BPE framework, one can test the hypothesis that individuals maximize their well-being, and measure the magnitude of their errors. Second, to justify either a positive representation of choice or a particular welfare criterion, a BPE analyst relies on evidence from psychology and neuroscience. This evidence can help economists pin down underlying...
preferences by identifying the mechanisms responsible for the decision-making errors. Good structural models of decision-making processes may also improve the quality of out-of-sample behavioural predictions, which are often required for policy evaluation.

**Behavioural policy analysis**

BPE models are extensions of neoclassical models. Thus, they imply that public policy can modify behaviour by changing budget constraints and/or information. For example, cigarette prices affect cigarette consumption in the Bernheim–Rangel addiction model, and savings are responsive to interest rates in most specifications of the \((\beta, \delta)\)-model.

In addition, the BPE framework introduces new channels through which public policy can affect behaviour and welfare. In particular, it allows for the possibility that some public policies can influence behaviour *directly* by activating particular cognitive processes, even when they leave budget constraints and information unchanged.

For example, Brazil and Canada require every pack of cigarettes to display a prominent, viscerally charged image depicting some deleterious consequences of smoking, such as lung disease and neonatal morbidity. Since the consequences of smoking are well known, this policy has no effect in information or budget constraints. And yet the Bernheim–Rangel theory of addiction allows for the possibility that a sufficiently strong counter-cue could reduce the probability of a mistake by triggering thought processes that induce users to resist cravings. When successful, this policy affects behaviour by activating particular cognitive processes.

Another striking example involves the effects of default options in employee-directed pension plans. A ‘default option’ is the outcome resulting from inaction. For a neoclassical consumer, choices depend only on preferences, information, and constraints. Consequently, in the absence of significant transaction costs, default options should be inconsequential. However, in the context of decisions concerning saving and investment, defaults seem to matter a great deal. For example, with respect to 401(k) plans (employer-sponsored retirement savings accounts in the United States that receive preferential tax treatment), there is considerable evidence that default options affect participation rates, contribution rates, and portfolios (Madrian and Shea, 2001; Choi, Laibson and Madrian, 2004). Yet, arguably, a default neither affects opportunities (since transaction costs are low) nor provides new information. While BPE models admit traditional justifications for government intervention in private markets (the enforcement of property rights, the correction market failures, and the redistribution of resources), they also introduce novel justifications. For example, public policy may improve welfare by reducing the size, likelihood, or consequences of mistakes. As shown in the next two sections, this can lead to conclusions that are strikingly at odds with those generated by the neoclassical model.

**Example: addiction policy**

In the neoclassical theory of rational addiction (Becker and Murphy, 1988), government intervention may be justified *only* when it corrects market failures involving addictive substances, such as second-hand smoking, or when it combats ignorance or misinformation. In contrast, in our model of addiction (Bernheim and Rangel, 2004), government intervention may also be justified when it reduces the
frequency, magnitude, and consequences of mistakes. These considerations give rise to a number of non-standard policy implications.

Limitations of informational policy. In practice, public education campaigns (such as anti-smoking and anti-drug initiatives) have achieved mixed results. Our view of addiction highlights a fundamental limitation of informational policy: contrary to standard theory, one cannot assume that even a highly knowledgeable addict always makes informed choices. Information about the consequences of substance abuse may affect initial experimentation with drugs, but cannot alter the neurological mechanisms through which addictive substances subvert deliberative decision-making.

Beneficial harm reduction. If addiction results from randomly occurring mistakes, various interventions can serve social insurance objectives by ameliorating some of its worst consequences. For instance, subsidization of rehabilitation centres and treatment programmes (particularly for the indigent) can moderate the financial impact of addiction and promote recovery. Likewise, the free distribution of clean needles can moderate the incidence of diseases among heroin addicts. In some cases, it may even be beneficial to make substances available to severe addicts at low cost, a policy used in some European countries.

Counterproductive disincentives. Policies such as ‘sin taxes’ strive to discourage use by making substances costly. This is potentially justifiable on the grounds that use generates negative externalities. Even higher taxes (whether implicit or explicit) might be justified if they also reduce ‘unwanted’ use. Unfortunately, the compulsive use of addictive substances is probably much less sensitive to costs and consequences than is deliberative use. Consequently, imposing costs on users in excess of the standard Pigouvian levy will likely distort deliberate choices detrimentally, without significantly reducing problematic compulsive usage. In addition, policies that impose high costs on use may thwart social insurance objectives by exacerbating the consequences of uninsurable risks associated with the use of addictive substances, such as poverty and prostitution. Accordingly, for some substances the optimal rate of taxation for addictive substances may be significant lower than that the standard Pigouvian levy (see Bernheim and Rangel, 2005, for simulation results).

Policies affecting cues. Since environmental cues appear to trigger addictive behaviours, public policy can also influence use by changing the cues that people normally encounter. One approach involves the elimination of problematic cues. For example, advertising and marketing restrictions of the type imposed on sellers of tobacco and alcohol suppress one possible artificial trigger for compulsive use. Since one person’s decision to smoke may trigger another, confining use to designated areas may reduce unintended use. Another approach involves the creation of counter-cues, which we discussed above. Policies that eliminate problematic cues or promote counter-cues are potentially beneficial because they combat compulsive use while imposing minimal inconvenience and restrictions on rational users.

Facilitation of self-control. Most behavioural theories of addiction potentially justify policies that provide better opportunities for self-regulation without making particular choices compulsory. In principle, this helps those who are vulnerable to compulsive use without encroaching on the freedoms of those who would deliberately choose to use. Laws that limit the sale of a substance to particular times, places, and circumstances may facilitate self-regulation. Well-designed policies could in principle accomplish this objective more effectively. For example, a number of states have enacted laws allowing problem gamblers to voluntarily ban themselves from casinos. Alternatively, if a substance is available only by prescription, and if prescription orders are filled on a ‘next day’ basis, then deliberate forward-looking planning becomes a prerequisite for availability. In the absence of a pervasive black market,
recovering heroin addicts could self-regulate problematic compulsive use by carefully choosing when, and when not, to file requests for refills.

**Example: savings policy**

The \((\beta, \delta)\)-model of savings also exemplifies the novel policy insights generated by the BPE approach. For example, this model implies that many individuals will save too little for retirement, and that there may be Pareto improving policy interventions even in the absence of capital market distortions – a conclusion that is at odds with the neoclassical framework. Other notable implications include the following:

*Mandatory savings policies.* Within the \((\beta, \delta)\) framework, compulsory saving may be welfare-enhancing if it fully crowds out private saving (in the form of liquid assets) at some point during the life cycle (Imrohoroglu, Imrohoroglu and Joines, 2003; Diamond and Koszegi, 2003). This provides a rationale for mandatory savings programmes, which are pervasive across the world, and which are more difficult to justify within the neoclassical framework.

*Saving subsidies.* On the assumption that (a) the population includes some individuals with self-control problems and (b) the social welfare function is continuous and concave, a small subsidy for saving financed with lump-sum taxes is welfare improving (O'Donoghue and Rabin, 2006; Krusell, Kuruscu and Smith, 2000; 2002). Intuitively, the subsidy produces a first-order improvement in the well-being of individuals with self-control problems (since they save too little), and only a second-order reduction in the well-being of those without self-control problems. This provides a possible rationale for tax-favoured savings programmes, such as, in the United States, 401(k) plans and Individual Retirement Accounts (IRAs).

*Credit restrictions.* Introducing restrictions on the availability of credit, for example, by regulating the distribution of revolving credit lines and mandating credit ceilings, can potentially enhance the well-being of those with self-control problems. For example, Laibson, Repetto and Tobacman (2004) estimate that the representative \((\beta, \delta)\) consumer would be willing to pay $2000 at the age of 20 to exclude himself from the credit card market.

**Behavioural public economics circa 2006**

As of 2006, the rapidly growing field of BPE has demonstrated its value by enhancing our understanding of public policy in several areas, including savings and addiction. Nevertheless, the literature is still in its infancy. As time passes, we anticipate that the methods and tools of BPE will contribute new insights in these areas, as well as to other difficult public policy issues involving poverty, crime, corruption, violence, obesity, and charitable giving, among others.

In addition to providing new insights concerning the effects of familiar policies, research in BPE can also guide the design of new policies. One obvious goal is to reduce the frequency of mistakes among those who behave suboptimally without interfering with the choices of those who behave optimally. Some recent fieldwork by Thaler and Bernartzi (2004), who advocate a savings programme called Save More Tomorrow, illustrates the potential value of this approach. In this programme, a worker can allocate a portion of her future salary increases towards retirement savings. Subsequently, she is allowed...
to change this allocation at a negligible transaction cost. In practice, 78 per cent of those who were eligible for the plan chose to participate, 80 per cent of participants remained in the plan through the fourth pay raise, and the average contribution rate for programme participants increased from 3.5 per cent to 13.6 per cent over the course of 40 months.

To date, progress in BPE has been somewhat hampered by the absence of a general framework for behavioural welfare analysis. Analysts tend to devise and justify welfare criteria on a case-by-case basis, rather than through the application of general principles. Ongoing research aims to fill this gap (see Bernheim and Rangel, 2006b).

Bellman equation

Yongseok Shin
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Bellman equation; consumption smoothing; convergence; dynamic programming; Markov processes; neoclassical growth theory; value function

Article

Dynamic programming is a method that solves a complicated multi-stage decision problem by first transforming it into a sequence of simpler problems. Bellman equations, named after the creator of dynamic programming Richard E. Bellman (1920–84), are functional equations that embody this transformation.

Take, for example, a typical maximization problem in economics:

\[
\max_{(u_t)_{t=0}^\infty} \sum_{t=0}^{\infty} \beta^t F(x_t, u_t),
\]

s.t. \(x_{t+1} = g(x_t, u_t)\) and \(u_t \in \Gamma(x_t)\), with \(x_0\) given.

The set \(\Gamma(x_t)\) consists of admissible values of the control variable \(u_t\) given the state variable \(x_t\). We assume that \(\Gamma(x_t)\) is non-empty for all \(x_t\). We also assume that \(F(x_t, u_t)\) is concave and that the set \(\{(x_t, x_{t+1}) : x_{t+1} = g(x_t, u_t), \ u_t \in \Gamma(x_t)\}\) is compact and convex. It is further assumed that \(\beta \in (0,1)\).

This so-called sequence problem has an infinite number of controls \(\{u_t\}_{t=0}^\infty\), and is generally intractable as it is. Dynamic programming reduces this infinite-dimensional problem into an infinite sequence of one-dimensional problems:
\[
\max_{u \in \Gamma(x)} F(x, u) + \beta V(x'), \tag{2}
\]

s.t. \( x' = g(x, u) \).

The unknown function \( V(x) \) represents the maximized value of the original problem starting from an arbitrary initial condition \( x \), and is called the value function. In particular, \( V(x_0) \) must be equal to the maximized value of the objective function in the original problem (1). Once \( V(x) \) is known, the maximizer of (2) would take the form of an optimal decision rule, or a policy function: \( u^* = h(x) \). Let the maximizer of the original problem (1) be \( \{u_t^*\}_{t=0}^{\infty} \). Then \( \{u_t^*\}_{t=0}^{\infty} \) can be generated from (2) recursively by \( u_t^* = h(x_t) \) and \( x_{t+1} = g(x_t, u_t^*) \), starting from the given \( x_0 \). Bellman called this connection between the sequence problem (1) and the recursive problem (2), the principle of optimality.

Now we have to solve for \( V(x) \) and, subsequently, \( h(x) \). To this end, we re-write (2) as follows:

\[
V(x) = \max_{u \in \Gamma(x)} F(x, u) + \beta V(g(x, u)). \tag{3}
\]

This functional equation in \( V(x) \) is the Bellman equation. From the definition of \( h(x) \), it follows that \( V(x) = F(x, h(x)) + \beta V(g(x, h(x))) \).

Typically, the Bellman equation can be solved for the unknown \( V(x) \) by value function iteration. This method can be described as follows.

1. 1. Guess an arbitrary function \( V_j(x) \), \( j=0 \).
2. 2. Given \( V_j(x) \), compute \( V_{j+1}(x) = \max_{u \in \Gamma(x)} F(x, u) + \beta V_j(g(x, u)) \).
3. 3. Repeat Step 2 until the sequence of functions \( \{V_j\}_{j=0}^{\infty} \) thus constructed converge. The limit of this sequence is the solution to the functional equation (3), \( V(x) \).

Under some conditions (for example, Blackwell's sufficient conditions), it is proven that value function iteration recovers the unique solution to (3) starting from an arbitrary initial guess \( V_0(x) \). See Bertsekas (1976) or Stokey and Lucas (1989) for detailed expositions on convergence. The procedure may sound straightforward, but, in practice, it is impossible (with few exceptions) to compute even one iteration of
Step 2 by hand. One has to use numerical approximation and maximization routines on computers. It is known that the value function inherits monotonicity and concavity properties of the one-period return function $F$. In addition, Benveniste and Scheinkman (1979) showed that the value function is once differentiable under fairly general conditions. See Stokey and Lucas (1989) for more on the properties of the value function.

Dynamic programming enables researchers to analyse interesting economic problems that cannot be solved otherwise. Thus, it is no surprise that Bellman equations are widely used in economics. Below, I provide two examples of such usage.

**Example 1: Neoclassical growth model**

Brock and Mirman (1972) set up a neoclassical growth model with log preference and full depreciation. This example is one of the few cases where one can actually solve the Bellman equation by hand, using the value function iteration method. The planner's problem is to maximize $\sum_{t=0}^{\infty} \beta^t \ln (c_t)$, subject to the resource constraint of $c_t + k_{t+1} \leq A k_t^\alpha$, with $A > 0$, $\alpha \in (0, 1)$ and $\beta \in (0, 1)$. In this problem, $k_t$ is the state variable and $c_t$ is the control, with $\Gamma(k) = \{c: 0 < c \leq A k_t^\alpha \}$, $g(k, c_t) = A k_t^\alpha - c_t$ and $F(k, c_t) = \ln (c_t)$. The Bellman equation for this problem is:

$$V(k) = \max_{0 < c \leq A k_t^\alpha} \ln (c) + \beta V(A k_t^\alpha - c).$$

Let's solve the Bellman equation by iterating on the value function. Begin by guessing $V_0(k) \equiv 0$. Following the procedure outlined above, we obtain:

$$V_1(k) = \ln (A k_t^\alpha) = \ln (A) + \alpha \ln (k),$$

$$V_2(k) = \ln \frac{A}{1 + \alpha \beta} + \beta \ln (A) + \alpha \beta \ln \frac{\alpha \beta A}{1 + \alpha \beta} + \alpha (1 + \alpha \beta) \ln (k).$$

Iterating onwards and using the summation formula for geometric series, we arrive at:
The optimal decision rule can now be easily computed: 
\[ c^* = h(k) = (1 - \alpha \beta) \Delta k^\alpha. \]

**Example 2: Consumption smoothing**

Our discussion of Bellman equations up to this point has been limited to deterministic models. However, as long as the objective function is additively separable over time and is linear in probability, we can easily accommodate uncertainty. For example, Miller (1974) analyses a consumer's utility maximization in the face of a stochastic income stream using dynamic programming. What follows is an adapted version of Miller's model.

Think of an infinitely lived consumer or dynasty that maximizes the discounted sum of the expected utility stream. The consumer derives utility from consumption \( c_t \), and we denote the utility function with \( U(c_t) \). Her income follows a Markov process \( \{Y_t\}_{t=0}^{\infty} \), and the distribution of \( Y_{t+1} \) given \( Y_t \) is represented by the cumulative density function \( G(Y_{t+1}|Y_t) \). We assume that \( Y_t \in [0, Y_{\text{max}}] \), \( \forall t \). The consumer’s discount factor is \( \beta \in (0,1) \) and the market interest rate is \( r \). It is assumed that \( \beta (1+r) < 1 \). She can borrow and lend at the market interest rate, but her debt cannot exceed \( B_{\text{max}} < \infty \). We denote her asset holdings at the beginning of period \( t \) with \( a_t \). To be precise, \( c_t \) and \( a_t \) are measurable functions with respect to the \( \sigma \) -algebra generated by the income process. For notational convenience, we suppress this history dependence. Now we write down the consumer's problem:

\[
\max_{\{c_t\}_{t=0}} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t U(c_t),
\]

s.t.
\[
\frac{a_{t+1}}{1+r} \leq a_t + Y_t, \quad a_t \geq -B_{\text{max}} \text{ and } Y_{t+1} \sim G(Y_{t+1}|Y_t), \quad \text{with } a_0 \text{ and } y_0 \text{ given.}
\]

To obtain a recursive formulation, it must be noted that \( (a_t, y_t) \) are the relevant state variables. Without loss of generality, assume that there is no borrowing. The Bellman equation for this consumer's problem is then:

\[
V(a, y) = \max_{0 \leq c \leq a+y} U(c) + \beta \int V((1+r)(a+y-c), y') dG(y'|y).
\]

Unlike in the first example, this Bellman equation cannot be solved by hand in general, and necessitates numerical methods.

Yoram Ben Porath's paper ‘The Production of Human Capital and the Life Cycle of Earnings’ (1967) is still regarded as one of the path-breaking papers in the economics of human resources. Following Mincer and Becker, the paper uses the framework of optimum control to analyse the joint decision of investment in human capital and market work over the life cycle. Diminishing marginal productivity in the investment process results in the process being spread over a lengthy period of time. A shrinking horizon results in the time devoted to the investment diminishing over the life cycle, an increasing fraction of time being diverted to market work. The model, part of Ben Porath's doctoral dissertation, provides an elegant economic explanation for the concentration of formal studies (that is, ‘full-time’ investment) early in life, and the concave shape of the age-earning profile.

Ben Porath's MA thesis (1966) was the most comprehensive economic study of the Arab labour force and the Arab sector in the Israeli economy at the time of its composition. Like his doctorate, it reflects Ben Porath's lifetime interest in the interaction between human resources and growth. In a series of studies on fertility patterns in Israel he explored the substitution between quality and quantity, sex preferences and family size (1976; 1981), the effect of child mortality on family size (1976), and the interaction between fertility and women's labour supply (1985), combining theory and empirical research.

Ben Porath's interest in the economics of fertility led him to widen the scope of investigation, focusing on the economic functions of the family. In his 1980 essay ‘The F-connection: Families, Friends and Firms and the Organization of Exchange’ he explored the social and economic role of families, contrasting the exchange taking place within the family (or other small socially knit groups) which are characterized by ‘specialization by identity’ and the conventional view of market exchange between anonymous buyers and sellers. In a world of imperfect information the transactional advantages of trade
within a small group plays an important role in explaining the shifting border between the family and the market.

In 1979, when Ben Porath became the director of the Maurice Falk Institute for Economic Research in Israel, he initiated a comprehensive study of the economy of Israel, an economy plagued by an uncontrollable inflation and halting growth. In the opening paper of the volume that he edited, *The Israeli Economy: Maturing through Crisis* (1986), he returned to tackle the question that puzzled him throughout his career – the interaction between output and population growth: is population growth the engine of output growth, or does output growth encourage immigration?

Yoram Ben Porath was born in Tel Aviv in 1937. He started his studies in economics at the Hebrew University in Jerusalem in 1957, and received his Ph.D. from Harvard in 1967, studying with Simon Kuznets. In 1986 he was elected Deputy Provost of the Hebrew University, and later became Provost. In 1990 he was elected president of the university. In 1992, during his term as president, he was killed in a car accident.

Bentham, Jeremy (1748–1832)

Philip Schofield
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Jeremy Bentham, English philosopher and reformer, was the founder of classical utilitarianism, the doctrine that an action was morally right to the extent that it promoted the greatest happiness of the greatest number. In Bentham's hands, the principle of utility provided a critical standard by which to test the value of existing practices, laws, and institutions, and to suggest reform and improvement. His basic premise in political economy was that wealth would be most effectively produced where the individual was left free from government intervention, though government had a crucial role in providing the background conditions of security without which civilized life was impossible.

Article

Jeremy Bentham, English philosopher and reformer, was the founder of classical utilitarianism, and, thereby, arguably the founder of the modern discipline of economics.
Bentham was born in Church Lane, Houndsditch, London on 15 February 1748. His father Jeremiah Bentham (1712–1792) was a solicitor, with a practice in the Court of Chancery, and wealthy and important clients in the City of London. Of his six siblings, only one younger brother Samuel (1757–1831) survived into adulthood, becoming a prominent naval architect and engineer. His mother Alicia died on 6 January 1759. A precocious child, he was educated at Westminster School until 1760 when his
father entered him, at the age of 12, into the University of Oxford, where he graduated in 1764, reputedly the youngest person ever to have done so. In the meantime, in accordance with his father's wish to see him pursue a career in the law, he had entered Lincoln's Inn in 1763, and was admitted to the bar in 1769. In that same year, however, he convinced himself that he should not practise law but rather devote himself to legal reform. Bentham thought of himself as ‘the Newton of legislation’—just as Isaac Newton (1642–1727) had brought order to the physical sciences, so would Bentham to the moral sciences. He adopted the principle of utility (an action was judged to be morally right to the extent that it promoted the greatest happiness of the greatest number) as a critical standard by which to test the value of existing practices, laws, and institutions, and to suggest reform and improvement. He set about composing a comprehensive code of laws, to which his best-known work, An Introduction to the Principles of Morals and Legislation (printed 1780, published 1789), was intended to form a preface. He announced that his enterprise was ‘to rear the fabric of felicity by the hands of reason and of law’ (Bentham, 1970, p. 11).

**Principle of utility**

Bentham's critical standard, the principle of utility, was based on the psychological insight that sentient creatures were motivated by a desire for pleasure and an aversion to pain. An individual had a motive to perform an action – or, put another way, had an interest in performing it – if he expected to gain some pleasure or avert some pain from doing so, and the greater or more valuable the pleasure experienced or pain averted, the stronger the motive or greater the interest. The value of a pleasure or pain was determined by its quantity, which, in the case of a single individual was a product of its intensity, duration, certainty, and propinquity. Where the value of a pleasure or pain was considered in relation to more than one person, then, in addition to these circumstances, the circumstance of extent, that is, the number of persons affected by it, had to be taken into account. At this point, a statement of psychological fact became a statement of moral science. An act was morally good if, after calculating all the pains or pleasures produced in the instance of every individual affected, the balance was on the side of pleasure, and morally evil if on the side of pain. Psychology and ethics were both founded on, and therefore linked by their relation to, pleasure and pain. Hence, Bentham's statement that, ‘Nature has placed mankind under the governance of two sovereign masters, pain and pleasure. It is for them alone to point out what we ought to do, as well as to determine what we shall do.’ The ‘sovereign masters’ of pain and pleasure not only accounted for human motivation, ‘govern[ing] us in all we do, in all we say, in all we think’, but also provided ‘the standard of right and wrong’. (Bentham, 1970, p. 11).

**Panopticon**

The middle part of Bentham's life, from about 1790 to 1803, was dominated by his attempt to build a panopticon prison in London. The panopticon design was the brainchild of Bentham's brother Samuel, when employed in the 1780s on the estates of Prince Grigoriy Aleksandrovich Potemkin (1724–1791) at Krichev, in Russia. He found that, by organizing his workforce in a circular building, with himself at the centre, he could supervise its activities more effectively. On a visit to his brother in the late 1780s and seeing the design, Bentham immediately appreciated its potential. Enshrining the principle of inspection, the panopticon might be adapted as a mental asylum, hospital, school, poor house, factory, and, of
course, prison. The prison building would be circular, with the cells, occupying several storeys one above the other, placed around the circumference. At the centre of the building would be the inspector's lodge, which would be so constructed that the inspector would always be capable of seeing into the cells, while the prisoners would be unable to see whether they were being watched. The activities of the prisoners would be transparent to the inspector; his actions, in so far as the prisoners were concerned, were hidden behind a veil of secrecy. On the other hand, it was a cardinal feature of the design that the activities of the inspector and his officials should be laid open to the general scrutiny of the public, who would be encouraged to visit the prison. When the panopticon scheme effectively collapsed in 1803, Bentham was left embittered by what he regarded as the bad faith of successive ministries, and he became increasingly committed to political radicalism.

Defence of Usury

While in Russia, Bentham composed *Defence of Usury* (1787), which proved to be one of his most successful attempts to influence economic policy. Bentham greatly admired Adam Smith's *Wealth of Nations*, which he studied in detail. He was not, however, an uncritical admiral, and argued that Smith had contradicted his own free market principles by defending the legal prohibition against exorbitant rates of interest. Countering the popular sentiment which condemned the moneylender for his avarice and pitied the borrower, Bentham argued that the former embodied the virtues of frugality, thrift, and prudence, and the latter, whether described as an entrepreneur or a prodigal, should be allowed to decide for himself whether to enter into a particular money bargain. In other words, Bentham saw no reason why the freedom of commerce should not be extended to the lending and borrowing of money. At the same time, Bentham defended the projector from the criticisms of Smith, who had linked the projector with the prodigal, and contrasted both with the sober person. The projector (and Bentham, with his panopticon prison scheme, placed himself in this category) promoted utility by improving existing products and processes or by inventing new and better ones: in short, projectors were the agents of progress.

Political economy and the four sub-ends of utility

Bentham's most intense period of work on questions of political economy took place between 1793 and 1801. Political economy, like all other fields of knowledge, had a place in Bentham's classification of knowledge, and consequently a place in his conception of a comprehensive code of laws. It was the task of the utilitarian legislator to introduce measures which would increase the overall happiness (understood in terms of a balance of pleasure over pain), or, more centrally, which would prevent a decrease in happiness. This task would be undertaken by promoting what Bentham termed the four sub-ends of utility – subsistence, abundance, security and equality – using, where appropriate, sanctions (punishments and rewards), themselves composed of pain and pleasure, to discourage actions detrimental to the happiness of the community, and (to a lesser extent) to encourage those which were beneficial. More specifically, it was the task of the civil law to distribute rights and duties in such a way as to promote the four sub-ends of utility. Security consisted in the protection of the basic interests of the individual – his person, property, reputation, and condition in life – which constituted a major component of his well-being. Security was closely related to the notion of expectations, for it involved...
both the present possession and the future expectation of possessing the property or other subject-matter in question. Without security, and thus the confidence to project oneself and one's plans into the future, there could be no civilized life. In short, security was a product of law, resulting from the imposition of rules on conduct.

The subject of political economy was more particularly concerned with subsistence and abundance, though the significance of security and equality should not be overlooked. For instance, without the security provided by law, no one would have an incentive to labour, and, therefore, to create wealth (abundance). Moreover, abundance itself was a security for subsistence, that is, the minimum quantity of resources which an individual needed to survive. Indeed, it was subsistence which had a prior claim on all resources in that an individual could be happy only if he were alive. Once wealth had been created, the principle of equality – in essence, the principle of diminishing marginal utility – demanded that it be distributed equally. Bentham argued that, if subsistence required £10 per annum, the most important £10 which an individual could possess was the first £10. Thereafter, each increment of £10 was worth something less than the previous increment. To put this another way, £10 given to an individual who had nothing constituted the difference between life and death, whereas £10 given to a rich man made hardly any difference at all. Bentham did not, however, advocate the levelling of property, for two reasons. First, if everyone began one morning with the same amount of property, by the end of the afternoon the intervening transactions would see inequality re-established. Second, the levelling of property would constitute an attack on security. Indeed, security, with its attendant expectations, was so important, that it was only in exceptional circumstances, such as providing subsistence to those who might otherwise starve to death, that it was legitimate to redistribute resources, and even here Bentham partly justified the redistribution on the grounds of security, in that such redistribution would render the property of the rich less liable to violent invasion by the poor.

In relation to abundance, or the creation of wealth, Bentham's basic principle was that of economic freedom. Each individual was most likely to be the best judge of his own interest, since he was most likely to be best informed about his own peculiar circumstances, and most likely to be motivated to act on that information in order to maximize his wealth, and thence his happiness. In a large number of areas in which government had traditionally intervened in economic matters, its intervention was counter-productive. Trade bounties, prohibitions, monopolies, and encouragements to population growth belonged to what Bentham termed the ‘non-agenda’ (although there might always be exceptions). Taking his lead from Smith, Bentham argued that since trade was limited by capital, government could not favour one branch of trade unless it discouraged another branch, since the capital applied to the former must be taken from the latter. In general, government was best advised not to interfere with the economy, and this included interference in the form of taxation. The imposition of taxation was a form of coercion, and all coercion was an evil in itself. As Bentham remarked: ‘The best use that government can make of money in the hands of the lawful possessors is: to leave it where it is’ (Bentham, 1989, p. 251). He argued that, in order to judge the utility of any element of public expenditure, one needed to compare the benefits produced by the expenditure with the burden produced by imposing an equivalent degree of taxation in the most aggravated form in which taxation was imposed. Hence, he recommended the immediate repeal of several particularly burdensome taxes – for instance those on legal proceedings, medicines, insurance, and newspapers (the latter constituting a tax on information). The taxation which remained should be imposed where there existed an ability to pay. Hence, the best form of taxation was that on consumption, followed by that on property and the transfer of property. As an alternative source
of public revenue, he advocated a revival of the medieval practice of escheat, whereby the state appropriated property where there was no other than a collateral heir. The money raised would be earmarked for a sinking fund, which would eventually redeem the national debt. The appropriation of collateral successions was a measure which Bentham believed could reconcile the otherwise conflicting demands of security and equality. Providing that individuals knew in advance that their potential to inherit would be limited according to law, they would not suffer any disappointed expectations, and their security would not be infringed. Apart from providing the background conditions of security which ensured that economic actors had the incentives to accumulate wealth (for instance security of person and property), there was, nonetheless, a limited ‘agenda’ for government, for instance to establish corn magazines to provide a security against dearth, to provide information, and to commission and disseminate research.

**Monetary regulation**

Following the suspension of payments in *specie* at the Bank of England in 1797, Bentham turned his attention to monetary regulation, devising his annuity note scheme, with the aim of redeeming the national debt. The annuity notes would in effect serve as paper currency, but at the same time earn compound interest, and, therefore, act as an investment. Depending on the prevailing rates of interest, holders of the notes would either use them as currency or horde them as savings. The government would issue the notes in order to buy up existing public debt, and thereafter successively reduce the rate of interest payable. The annuity notes as a circulating medium would replace an equivalent amount of bank notes, and lead to an earlier redemption of the national debt than would otherwise have been possible. It seems that Bentham abandoned the scheme because he did not, to his own satisfaction, solve the problem of inflation, which, he feared, would stifle the growth of national wealth and unfairly reduce the real value of fixed incomes.

In 1801 Bentham calculated that prices had increased by 50 per cent since 1760. He argued that this inflation had been caused by an increase in the amount of paper money in circulation. This increase was to be welcomed in that it represented a growth in national prosperity. However, it also represented an unfair tax on fixed incomes, and threatened a general bankruptcy. His remedy was to limit and to tax the issue of paper money by provincial banks, who were prone to over-issue bank notes since this was the main source of their profit. In return, a licensing system would be introduced which would, in effect, grant a monopoly to existing banks. In December 1801, in the extraordinary circumstances brought about by scarcity and dearth of provisions, he came to advocate legislative intervention in the economy in the form of the statutory imposition of a maximum price for wheat. This would have the immediate effect of bringing relief to the poor and security to the propertied, in that it would avoid the creation of a potentially revolutionary situation fuelled by the discontent of the destitute. Scarcity, he argued, could only permanently be remedied by the establishment of corn magazines and the promotion of emigration, both of population and of capital. In short, while favouring economic liberty as a leading principle, he was always prepared to consider state intervention should the principle of utility demand it.

**Colonies**

Bentham's opposition to the holding of colonies was grounded initially on economic arguments, though
he later developed political and constitutional objections to the practice. Given that the trade of a nation was limited by the quantity of capital it possessed, he argued that colony-holding could not bring any economic advantages. The extension of markets which the acquisition of colonies appeared to provide did not in itself affect the amount of trade. New markets were advantageous only to the extent that the profit made upon the capital employed in the new trade was greater than the profit made on the established trade. It was unlikely that the distant markets represented by colonies would offer a higher rate of return than those closer to home. Any benefit from a trade monopoly imposed on the produce of the colony was illusory, since a monopoly could not force the price of a commodity lower than the level to which it would be driven by competition, and it could not force anyone to produce a commodity at a loss. Finally, to the argument that trade with colonies was a source of revenue, Bentham responded that revenue could be raised on goods exchanged with all other countries, not just colonies, providing of course that the duties were not so high as to make smuggling attractive. The emancipation of colonies would also save the mother country the massive expense of defending them, particularly in time of war. Nonetheless, there were certain circumstances in which Bentham was prepared to defend the establishment of colonies. He approved the colonization of vacant lands in response to the pressure of population growth and the existence of an excess of capital in the mother country, and of colonial rule in countries where the native rulers were unfit to govern. The benefits, however, accrued to the colonists, and not to the mother country, and he recommended that dominion should be relinquished as soon as was practicable.

**Political reform**

By the 1820s Bentham was convinced that the only regime with an interest in enacting good legislation was a representative democracy. A crucial development took place around 1804 with the emergence in Bentham’s thought of the notion of sinister interests, that is, the systematic development of the insight that rulers wished to promote not the happiness of the community, but their own happiness. There was no point in showing rulers what the best course of legislation might be unless they had an interest in adopting it. Only a legislature elected by a democratic suffrage had such an interest. Following the quashing of the panopticon scheme in 1803, Bentham became convinced that nothing worthwhile could be achieved through the existing political structure in Britain, or through similar regimes elsewhere. Having concentrated on questions of law reform from 1803, he was in the summer of 1809 prompted to compose material on political reform, eventually bearing fruit in *Plan of Parliamentary Reform* (1817). In this work he called for universal manhood suffrage (subject to a literacy test), annual parliaments, equal electoral districts, payment of MPs, and the secret ballot. Bentham then went a stage further and drew up a blueprint for representative democracy which would have abolished the monarchy, the House of Lords and any other second chamber, and all artificial titles of honour, and would have rendered government entirely open and, he hoped, fully accountable. These proposals were developed in astonishing detail in the magisterial *Constitutional Code* (partly printed 1827 and 1830, partly published 1830).

For Bentham the key principle of constitutional design was to ensure the dependence of rulers on subjects. Instead of the traditional theory of the separation of powers, he proposed lines of subordination, based on the ability of the superior to appoint and dismiss (in Bentham's terminology to locate and dislocate) the inferior, and to subject the inferior to punishment and other forms of ‘vexation’.
The supreme power or sovereignty in the state would be vested in the people, who held the constitutive power. Immediately subordinate to the people would be the legislature, elected by universal manhood suffrage, and subordinate to the legislature would be the administrative (that is, the executive) and judicial powers. The system of representative democracy was not an end in itself – the end was the greatest happiness – but was an indispensable means to that end, in that it was only under such a constitution that effective measures could be implemented to secure the good behaviour (appropriate aptitude) of officials and minimize the expense of government. The securities for official aptitude – otherwise termed securities against misrule – included the exclusion of factitious dignities (titles of honour), the economical auction (whereby officials made bids for the salary attached to the office), subjection to punishment at the hands of the legal tribunals of the state, the requirement to pass an examination, and, most importantly, publicity. Bentham went to great lengths to ensure that government would be open to public scrutiny, and thence subject to the force of the moral or popular sanction operating through the public opinion tribunal, which consisted in all those who commented on political matters, and of whom newspaper editors were the most important. Bentham saw the freedom of the press as a vital bulwark against misrule: hence his proposal to encourage the diffusion of literacy by making the suffrage dependent on a literacy test. These measures were intended to ensure that rulers would be so situated that the only way they could promote their own interest was by promoting the interest of the community.

Death and afterwards

Having lived in Lincoln's Inn from 1769 to 1792, he had then inherited his father's home in Queen's Square Place, Westminster, where he died on 6 June 1832. It was Bentham's wish that his body be dissected for the advancement of medical science, and that his remains then be used to create an ‘auto-icon’ or self-image. Bentham's auto-icon, assembled by his surgeon Thomas Southwood Smith (1788–1861), and consisting in a waxwork head mounted on Bentham's articulated skeleton and wearing his clothes, is now kept at University College London.

bequests and the life cycle model

John Laitner
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The standard life cycle model emphasizes a household's concerns over events within its lifetime, including providing for its own retirement and for its young children. However, in a more elaborate formulation, the household may care about its descendants when they are grown just as when they are young, causing the household to want to leave bequests. Its time horizon may expand to a dynastic scale, and new public policy implications, including so-called Ricardian neutrality, may emerge. Alternatively, bequests may signal non-market exchanges between parents and their adult children, perhaps arising to mitigate transactions costs or informational asymmetries.

Article

In the life-cycle model of household behaviour, each household expects a lifetime pattern of rising earnings in youth and middle age followed by retirement. Hence, households plan to save in their first segments of life in order to build resources to dissave, and from which to accrue interest income, during the last (Modigliani, 1986). The framework easily incorporates children, with consumption early in a household's life driven higher and saving for retirement perhaps delayed until middle age (Tobin, 1967). In a standard life-cycle model, parents plan for their own life and assume financial responsibility for their children until the latter reach adulthood (say, age 18 or 22) – but not beyond. Elaborations of the framework, on the other hand, extend parental concern, or interest in non-market transactions, to encompass a household's grown children. Such elaborations expand the scope of the life-cycle model to include bequests.
Conceptually, there are at least three broad categories of models in which bequests play a role. The first, which is often called the ‘altruistic model’, assumes that parents care about the well-being of their grown children. The second, which one might call the ‘joy of giving model’, assumes that parents derive pleasure from making transfers to their adult children's households but that the pleasure is not specifically dependent upon the children's utility gain. In the third formulation, parent-to-child emotional and social ties favour and facilitate non-market exchanges that may generate bequests – for example, bequests may emerge as payments to heirs for personal services rendered.

**Altruistic model**

A model with ‘altruistic bequests’ (Becker, 1974; Barro, 1974) extends to grown children parental concerns for minor children typical of standard life-cycle analyses.

Consider a specific example in which each household has one adult, raises one child, and lives two periods. Suppose that a household begun at time $t$ has earnings $y_t$ in youth but is retired in old age. It rears its child during its first stage of life; the child initiates its own household thereafter, with the descendant household passing its first stage of life as the parent household lives through its second stage.

The time-$t$ parent chooses consumption $c^1_t$ and $c^2_t$, respectively, for its two stages of life; derives utility $u(c^1_t, c^2_t)$ from this consumption; inherits $i_t$ in youth; and transfers $i_{t+1}$ in old age to its adult child. Let the interest rate be $r$. Given $i_t$ and $i_{t+1}$, the parent household's *lifetime utility* is $U(\cdot)$ such that

$$U(i_t, i_{t+1}, y_t) = \max_{c^1_t, c^2_t} u(c^1_t, c^2_t)$$

subject to: $c^1_t + \frac{c^2_t}{1+r} + \frac{i_{t+1}}{1+r} \leq i_t + y_t$.

Let the parent household care $\delta$ times as much about its adult child's lifetime utility as about its own, $\delta^2$ times as much about its grandchild's lifetime utility, and so on. Then the parent household's *dynastic utility* is
$\sum_{s=0}^{\infty} \delta^s \cdot U(i_t + s, i_t + s + 1, V_t + s)$.  

If $y_t = y$ all $t$, if institutions force bequests to be nonnegative, and if descendant households share the same preference ordering, we can characterize the time-$t$ parent household's dynastic utility as $V(i_t, y)$ with

$$V(i_t, y) = \max_{i_{t+1} \geq 0} \left\{ U(i_t, i_{t+1}, y) + \delta \cdot V(i_{t+1}, y) \right\}.$$  

(1)

If $\delta = 0$, we have a ‘pure life–cycle model’; if $\delta > 0$, we have an altruistic model in which positive bequests may emerge.

Laitner (1992) studies a second altruistic formulation, one allowing heterogeneous earning abilities. In terms of the framework above, a parent household with earnings $y_t$ may know the random variable, say, $\tilde{y}$, from which the earnings of its descendants will be (independently, in the simplest case) sampled, but the parent cannot observe the sampling outcomes as it makes its bequest plans. Then dynastic utility is

$$V(i_t, y) = \max_{i_{t+1} \geq 0} \left\{ U(i_t, i_{t+1}, y) + \delta \cdot E[V(i_{t+1}, \tilde{y})] \right\}.$$  

(2)

where $E[.]$ is the expectations operator.

Conceptually, a model with altruistic bequests provides an extension of the life-cycle model's parental concern for minor children's well-being to a more or less symmetric concern for grown children. Empirically, bequests and inter vivos transfers to adult children certainly occur in practice (Modigliani, 1986; Kotlikoff, 1988). The formulation with heterogeneous earnings predicts that bequests need not be universal but are most likely in the case of very prosperous parents. Social commentators frequently criticize bequests as a source of inequality, and the second point in the preceding sentence shows how bequests can contribute to cross-sectional dispersion of private wealth holdings. Bequests may have played a larger role in national wealth accumulation in the past, when long retirement spells were perhaps less common (Darby, 1979), and a model with both life-cycle saving and altruistic bequests can provide a framework for analysing the change (Laitner, 2001).

Loans for education fail to generate collateral for creditors; hence, parental and/or public support may be
important for ensuring efficient educational investment. Since benefits of education last long into adulthood, the model with altruistic bequests provides a logical framework for studying parental contributions (for example, Tomes, 1981). For instance, suppose that a child's earnings are an increasing, concave function $f(\cdot)$ of ability, $a$, and parental support for education, $\varepsilon$, in the child's youth:

$$V_{t+1} = f(a_t, \varepsilon_t).$$

With homogeneous agents, $a_t = a_t$ all $t$, and (1) becomes

$$V(i_t, y) = \max_{i_{t+1} \geq 0, \varepsilon_{t+1} \geq 0} \left\{ U(i_t, i_{t+1} + \varepsilon_t \cdot (1 + r), y) + \delta \cdot V(i_{t+1}, f(a, \varepsilon_t)) \right\}.$$  

(3)

Then $i_{t+1} > 0$ ensures efficient provision of education $e_t$ regardless of the degree of parental concern for the child, $\delta$. If, on the other hand, the tangible bequest is zero, investment in education can be inefficiently low.

A second prominent application of the altruistic model relates to fiscal policy. In a standard life-cycle model, when government turns from tax to deficit finance, national consumption may rise for a time, and the economy's long-run capital intensity may decline. Reformulating the life-cycle model to include altruistic bequests can overturn this result (for example, Barro, 1974). Debt service and repayment for current government borrowing may extend far beyond the life span of existing households, but not beyond the time horizon of dynasties. Maximization in (1) may yield an outcome in which the non-negativity constraint never binds, and Barro (1974) shows that in that case tax and deficit finance may have identical implications for aggregate consumption, capital accumulation, and interest rates. The latter equivalence is often referred to as 'Ricardian neutrality'. (With heterogeneity of agents, as in formulation (2), non-negativity constraints will, on the other hand, tend to bind for some households – Laitner, 1992 – and then outcomes resembling Ricardian neutrality, while still possible, may be more in doubt – for example, Bernheim, 1987.)

Recent dynamic general equilibrium analyses of long-run growth and business cycles frequently employ the so-called 'representative agent' paradigm. Utility maximization over an infinite time horizon for a set of identical agents determines desired private consumption, saving, and labour supply. It seems fair to say that the life-cycle model with altruistic bequests, as in Barro (1974) and related papers, provides the most basic motivation for this approach.

Turning to empirical findings, the widespread existence of bequests (and inter vivos gifts) within family lines is well established (Modigliani, 1986; Kotlikoff, 1988). The pure life-cycle model does not seem able to explain as much national wealth as we see, and estate building seems a plausible explanation for the remainder (Kotlikoff, 1988). However, despite some consistency with the altruistic model, empirical evidence often seems to fail to support the implications of pervasive Ricardian neutrality (for example, Altonji, Hayashi and Kotlikoff, 1992; 1997). Long-standing evidence that households with multiple children tend in practice to divide their bequests equally (for example, Menchik, 1988) also seems contrary to implications of the simplest versions of the altruistic model. Perhaps altruistic bequest
behaviour is, in practice, concentrated among the highest-income households (as might be implied by formulation (2)).

Conceptually, as one considers couples instead of single parents, dynasties will interact through marriage. Assortative mating can preserve the logic of the analysis of the parthenogenetic theoretical construct (Laitner, 1991). Mating patterns that are random theoretically could, in contrast, expand to an overwhelming degree the scope of interpersonal connections that ‘neutralize’ incentives for self-interested behaviour (Bernheim and Bagwell, 1988).

The preceding formulations assume that a parent cares about his child but that the reverse is not true. A number of papers analyse two-sided altruism. Implicitly, in fact, all formulations with altruistic transfers are two sided – in model (1), for example, the parent cares about his child's utility relative to his own with a ratio of weights $\delta : 1$, while the child cares about his parent's utility relative to his own with weights in a ratio of 0:1. Unless parents and children agree on each other's relative importance, strategic behaviour may arise if agents have sufficient latitude in their set of feasible actions. In Laitner (1988), for instance, though parents and children care about each other, each may care less about the other than about itself – in which case a parent with low earnings may intentionally limit his life-cycle saving in youth in order to induce a larger transfer from his child during his retirement.

In the simplest life cycle model, a household saves before retirement in order to preserve an even level of consumption for the remainder of its life. An altruistic model extends the time frame of such behaviour: a household may use bequests (and *inter vivos* gifts) to promote evenness of consumption for its entire family line.

**Joy of giving model**

A joy-of-giving model provides a donor with pleasure that is independent of recipient utility and outside resources. For example, our two-period household above might solve

$$
\max_{i_{t+1} \geq 0} \left\{ U(i_t, i_{t+1}, y_t) + W(i_{t+1}) \right\},
$$

with the new function $W(.)$ being unrelated to lifetime utility $U(.)$ or to recipient earnings $y_{t+1}$. In this approach, the parent household has preferences over its own lifetime consumption and the size of the bequest that it provides to its offspring, rather than over the descendant's consumption or utility. An example is Blinder (1974).

A possible advantage of this framework is that it does not require as great an ability on the part of donors to manifest empathy and rationality as the altruistic model. Another advantage is its analytic simplicity. In applications, authors may seek to specify the utility function $W(.)$ in a manner that can mimic, at least to some degree, the model with altruistic bequests (for example, Modigliani, 1986).
The emotional ties of parents and their children may lead parents to prefer attentions from their grown children over services purchased in markets. Similarly, emotional bonds, tradition, or social norms may give trades between relatives lower transaction costs than those based on market contracts. Relatives may also have more complete information about one another than anonymous market participants do. Such factors may lead parents to make transaction and insurance arrangements with their grown children, and parental payments may take the form of bequests or *inter vivos* gifts.

In traditional societies, a household's eldest son might labour on his parents' farm, supporting his parents in their old age. In return, the son might expect to inherit the farm at his parents' death. One can view such a bequest as a payment for services, and neither altruistic nor joy-of-giving impulses on the part of parents (or their son) need be determinants of the transfer's size.

Bernheim, Shleifer and Summers (1985) provide a model in which elderly parents desire attention from their adult children, and the parents can be thought of as paying for the services through their bequest. Many economists note the relative infrequency with which households purchase annuities. Transactions costs and adverse selection, due to private information about one's likely longevity, may be the underlying reason. In practice, parents may circumvent annuity markets by making implicit contracts with their grown children: in return for care and support in old age, the parents agree to bequeath their assets to their children. The children take the place of an insurance company: if their parents die young, the children's efforts receive generous remuneration; if the parents live a long time, their bequest may be small or non-existent, and the children's reward per hour of effort will be low. Kotlikoff and Spivak (1981) show that such arrangements can be surprisingly efficient. Friedman and Warshawsky (1990) illustrate a related point: they show that parents who have some inclination (either joy of giving or altruistic) to bequeath to their children may eschew market annuities with even modest transactions costs, preferring self-insurance, under which their children can inherit unspent parental resources.

Article

Bergson was the intellectual father of US studies of the Soviet economy during the Second World War as chief of the Russian Economic subdivision of the Office of Strategic Services (OSS). After the war he played the major role in founding the US tradition of description and analysis of Soviet economic institutions, measurement of Soviet economic growth and evaluation of that growth. He had earlier made a major contribution to the development of welfare economics. His work on the Soviet economy was marked by a combination of encyclopaedic knowledge of Soviet statistics, theoretical analysis and immense industry. It had an enormous influence on the development of US studies of the Soviet economy and established itself as the dominant paradigm in that field.

Bergson's main contribution to the study of the Soviet economy concerned the measurement of Soviet economic growth. The result of the combination of the ‘propaganda of success’ with Soviet economic institutions and the material product system (MPS) method of calculating national income was that the data on economic growth published by the Soviet authorities were both incredible and clearly non-comparable with the data on economic growth of other countries. Bergson both developed a method which enabled internationally comparable national income statistics and growth rates to be calculated for the USSR and applied it to the USSR for 1928–55. The method was the ‘adjusted factor cost’ method. In essence it consisted of adjusting actual Soviet transactions prices so as to bring them into line with the prices that would have been observed if the USSR's prices had been determined in accordance with neoclassical theory. These adjusted prices were then used as weights to aggregate the physical output series of branches and sectors of the economy as known from Soviet official data into a system of national accounts (SNA)-type aggregate. This had the great advantage of producing data comparable to SNA data and hence suitable for international comparisons. At the same time, Bergson argued, this
procedure enabled a ‘production potential’ and possibly even a welfare interpretation to be given to the resulting national income data.

The development of this method and its application to the USSR for the period 1928–55 were enormous achievements. They clearly indicated that assessment of socialist economies did not have to remain at the level of ideological confrontation but was amenable to rational discourse and scientific inquiry. Both the method and its results were controversial. The rationality of the adjusted factor cost prices, the representativeness of the physical products selected, the huge data requirements and skilled labour inputs necessary to apply the method, the relevance of neoclassical theory for interpreting Soviet economic data, and the accuracy of the picture of the Soviet economy resulting from application of the method, all came under fire. Others used different methods of generating internationally comparable data (for example, the physical indicators method, or scaling up from net material product, NMP, to GNP using data for the missing sectors).

In welfare economics Bergson is famous for his 1938 paper which defined and discussed the concept of an individualistic social welfare function. The latter enables necessary conditions for an economic optimum to be calculated without the assumption of cardinal utility. This concept was subsequently utilized and developed by Samuelson and became an integral part of the welfare economics literature. Its usefulness remains a matter of controversy. According to Samuelson's contribution to the Bergson Festschrift it was a major contribution, a ‘flash of lightning’ after which ‘all was light’ in the hitherto extraordinarily confused subject of welfare economics. A number of opinions of a less positive kind can be found in M. Dobb (1969). Bergson also wrote on socialist economics and Arrow's Impossibility Theorem.

Besides his purely academic work on the Soviet economy, Bergson, with his OSS experience, played a major role in establishing and maintaining the close links between US academic studies of the Soviet economy and the intelligence community and other branches of the federal government. Besides being a professor of economics for many years, first at Columbia and then at Harvard, he was director of the Harvard Russian Research Center (1964–8, 1969–70), consultant to the RAND Corporation, member and subsequently chairman of the Social Science Advisory Board of the US Arms Control and Disarmament Agency, and consultant to various federal agencies. In addition, he served as president of the Association for Comparative Economic Studies and several times testified before the US Congress. Many years after Bergson's publications, access to Soviet economic archives demonstrated the significance and accuracy of Bergson's analysis of discrepancies in Soviet labour statistics (‘the Bergson gap’). It also demonstrated the usefulness of his approach for studying the Soviet national accounts during the Second World War.

Bergson made a major contribution to 20th-century economics by establishing a school of economists who transformed the study of the Soviet economy, hitherto a reserve of partisan émigré and committed writers, into a field of sober academic inquiry.

A graduate at an early age of Harvard College and the Harvard Law School, Berle served in Army Intelligence in World War I and on the American delegation to the Paris Peace Conference, from which he emerged to denounce the terms of the Treaty, as did Keynes, though to a lesser audience. After practising law in New York, he joined the law faculty of Columbia University, where he became a member of the famous Brains Trust of Franklin D. Roosevelt. He was a close adviser of Roosevelt's, both before and after the latter's election to the Presidency.

In the later New Deal years, Berle served as an Assistant Secretary of State, then a senior position in the Department, and thereafter as ambassador to Brazil. In the years following World War II, he was chairman of the Liberal Party in New York and the long-time head of the Twentieth Century Fund, a foundation engaged in the active sponsorship of research in economic and social issues.

Berle's major contribution to economics, made in 1932 in conjunction with Gardiner C. Means in The Modern Corporation and Private Property, was in showing that authority in the modern large business enterprise moves ineluctably away from the owners of property to the managers and that by the time of research for the book the process was already far advanced. As a conclusion for conventional economics this, it is not too much to say, ranked in inconvenience with that of Keynes. Ownership no longer conveyed power in the great enterprise. Profit maximization was now by managers, not on behalf of themselves but for others largely unknown or, in pay and perquisites, for the managers themselves.

Berle's conclusions also denied the independent, self-motivated, heroic role of the entrepreneur as offered in conventional economics, notably by Schumpeter.

Berle's contribution came from outside the conventional boundaries of the profession – from, of all things, a lawyer. Perhaps for this reason its importance was discounted, even denied, by many economists. In recent times, however, the truth of Berle's contentions has been recognized as personal.
profit maximization of managers – salaries, diverse perquisites, stock options, golden parachutes – has become one of the accepted scandals of the time. Nonetheless, Berle's role as one of the major innovating figures in economics has never been adequately recognized. In his textbook Paul Samuelson acknowledges *The Modern Corporation* as a classic; in Campbell R. McConnell's *Economics*, the most widely used text in the United States, Berle's name does not even appear. In his later years Berle returned in a perceptive and informative way to the subject of power, though not with the innovative force of his earlier work.

Bernácer contributed to macroeconomics the concept of ‘disposable funds’ and a new theory of interest. A lag between received and disbursed income underlies his view that aggregate equilibrium in the goods market emerges only if the amount of disposable funds is the same at the beginning and at the end of the period. Bernácer also argued that the rate of interest was determined outside the production system by land purchases and sales in the assets market. Economic fluctuations are decided by oscillations in the amount of disposable funds determined by the interaction between the markets for goods and for old assets.

Article
Bernácer was born in Alicante, Spain, on 29 June 1883, and died on 22 May 1965 in the same city. He may be regarded as the first major monetary economist in the Spanish language since the School of Salamanca in the 16th century. Bernácer completed his studies at the Alicante School of Commerce (Escuela Superior de Comercio de Alicante) in 1901, where he was awarded the chair of industrial physics (Tecnología Industrial) in 1905. In that same year he started working on his big book *Sociedad y Felicidad – Ensayo de Mecánica Social*, which shows the influence of his physics background in the study of the economic aspects of social life, especially his distinction between the ‘static and dynamics of wealth’ in the study of ‘social problems’ such as business cycles and unemployment. That book was...
eventually published in 1916, some time after a study tour of eight months that had taken him to several European countries in 1911. In the next ten years, some of the main ideas presented in incipient form in *Sociedad y Felicidad* were further developed in two publications by Bernácer. His 1922 essay introduced into the economic literature the concept of ‘disposable funds’ (‘disponibilidades’) and its implications for the treatment of the demand for money and monetary dynamics. Bernácer sent 150 copies of that essay (with a French summary) to prominent economists and journals around the world. His 1925 book advanced a new approach to the origins and determination of interest as a variable decided outside the production system.

In the early 1930s Bernácer moved to Madrid to become the first director of the Research Service of the Bank of Spain. His appointment was probably influenced by his long 1929 article about the determination of the exchange rate as an equilibrium variable, in which he discussed in detail how to stabilize the external and internal values of the Spanish peseta and the conditions for returning to the gold standard system. He continued to teach, this time as professor of physics and chemistry at the School of High Commercial Studies of Madrid (Escuela de Altos Estudios Mercantiles). In 1940 long extracts from Bernácer’s 1922 article were translated into English and published in *Economica* with a commentary by Dennis Robertson, who had been one of the recipients of that article in the 1920s. Robertson’s article made Bernácer known to the Anglo-Saxon world and led him to restate the main theoretical and methodological features of his approach to monetary economics in a volume published in 1945. In the 1950s he wrote his last two books, dealing with economic integration and economic geography (1953) and summing up his views about economic dynamics and economic reform (1955). At about this time Bernácer retired from both his appointments as professor in Madrid and as director of research at the Bank of Spain.

**Period analysis and disposable funds**

Bernácer’s main contribution to economics is his analysis of the role played by money in the determination of economic variables such as income, employment, the rate of interest and the rate of exchange. He introduced the concept of a lag between received and disbursed income, which provided the starting-point of his discussion of aggregate disequilibrium in the market for goods. Bernácer’s lag probably influenced the well-known Robertsonian related lag between received and disposable income. It follows from his concept of disposable funds ($A$) held at the beginning of the economic period, which, when added to the income ($R$) received during the period, give the upper limit of effective demand ($A + R$). Money balances are functionally classified into three grades, from minimum to maximum degree of disposability: (a) money demand by families to meet consumption; (b) money demand by businessmen for the conduct of their enterprises; and (c) new savings which have not yet been put by their owners to remunerative employment. Bernácer used the phrase ‘disponibilidades’ to refer to the last two classes. In order to determine the flow of ‘effective demand’ ($D$) it is necessary to subtract from $A$ the amount of disposable funds left at the end of the period ($A'$), which gives the equation $R + (A - A') = D$, or, since $R$ is identical with output $P$, the equation $P + (A - A') = D$. The last equation indicates that there is aggregate equilibrium (in the sense that production is equal to effective demand and the output produced is sold at the expected price) if the amount of disposable funds is the same at the beginning and at the end of the period ($\Delta A = 0$). The key to Bernácer’s monetary economics is his notion that the spending
decisions of economic agents (firms and families alike) in any given period of time are constrained by
the amount of money they possess at the outset of that period. Bernácer was probably the first to
introduce the main elements of what would become known in the literature as the ‘cash-in-advance
constraint’ models developed in the 1960s.

Bernácer’s approach to the business cycle was based on his distinction between the market for goods
(‘circulación productiva’), which decides the price level, and the market for ‘valores de renta’ or income-
yielding assets (‘circulación especulativa’ or ‘circulación financeira’), where the rate of interest is
determined. Similar distinctions between aggregate markets for flows and stocks respectively would be
deployed later in macroeconomic models put forward by John Hicks (IS–LM model), James Tobin and
others. The interplay between those two markets explains fluctuations in income and employment in
Bernácer’s framework. The use of disposable funds to buy ‘valores de renta’ in the financial or
speculative market does not change the condition of disposable funds, as they remain disposable in the
hands of the sellers of assets. On the other hand, the use of disposable funds to purchase consumption
goods and new capital goods brings about a change in their degree of disposability, as they are turned
into money income of the individuals involved in the production of goods. This constitutes ‘effective
demand’, as opposed to ‘potential demand’ that does not involve a change in liquidity. Aggregate
equilibrium can now be also described by the equality between saving and investment, which is the case
if the saving flow is not directed to the purchase of ‘valores de renta’. Economic fluctuations result from
the opposite effects on the price level and the rate of interest of changes in disposable funds. When $\Delta A$
is negative in the upswing, prices of consumption goods are higher than anticipated and, since wages
and salaries are temporarily fixed, employers will see their ‘residual profits’ increase. The ensuing
stimulus to production and employment will cease when, under the impact of an increasing shortage of
disposable funds in the ‘speculative market’, the rate of interest rises and saving is gradually directed to
that market. This way, $\Delta A$ becomes positive, which explains the upper turning point of the business
cycle. During the downswing, unanticipated falling prices bring about losses, which contributes
(together with the constraint represented by a reduction of firms’ liquidity) to a contraction in production
and employment. The depression is characterized by widespread ‘forced [or involuntary]
unemployment’ (‘paro forsozo’), which is not solved by money-wage reductions, since lower wages will
bring about a further fall in consumption demand and ensuing price reductions.

The speculative market and the rate of interest

The main factor in Bernácer’s account of the business cycle is not the variability of investment demand
by entrepreneurs, but the savers’ decisions on how to allocate their disposable funds – purchase of new
capital goods in the goods market or of old assets in the speculative market. The banking and credit
system is incidental to Bernácer’s framework, which is different from the well-known Wicksellian
distinction between the ‘natural’ and the ‘market’ rates of interest. Bernácer’s explanation of
macroeconomic disequilibrium is based on another sort of divergence, that is, on differences between
the rate of interest decided by the expected rate of return on new capital goods on one side, and the rate
of interest determined by the relative yields of ‘valores de renta’ in the speculative market. The notion
that the rate of interest is determined outside the system of current production is a crucial feature of the
Bernácerian theoretical system. He argued that the rate of interest is determined not by the scarcity of
capital goods as such, but by the scarcity of disposable funds. Moreover, given the identity between
aggregate income and output, the rate of interest cannot be determined simply by saving and investment: if the disposable funds were used only to purchase the current output (of consumption and capital goods), the saving flow would necessarily be identical with the output of new capital goods, with no scarcity of funds in that market. The rate of interest can be positive only if a scarcity of disposable funds comes about because of the possibility of employing them outside the production system, that is, in the speculative market. The problem of the origin and determination of interest, according to Bernácer, consists in the search for an asset able to yield a ‘free’ rent without any production costs. He found it in land (in the broad sense of agricultural and urban land, as well as mines), not because of its productivity, but because it has a price and is exchangeable for other assets through money. In particular, the rate of interest is the determined variable in the equation relating its value to the price and the rent of land. Land, however, is not capital, and its purchase is not a real investment, since money remains disposable; hence, Bernácer explained how land's ability to produce rent is transmitted to other applications of money – especially to new capital goods – through the equilibrium between the marginal rates of return of old and new assets in the market. Such a mechanism, however, cannot work if the rate of return of investment in new capital goods falls to zero or below (which, of course, cannot happen to land and other income-yielding assets) in the depression, as pointed out by Bernácer. After he had put forward the main elements of his interest theory in 1916, Bernácer noticed several similarities with what Böhm-Bawerk used to call Turgot's ‘fructification theory’ of interest, but observed that, in contrast with Turgot's, his approach was not based on the Physiocratic framework.

Bernácer would claim, after the publication of Robertson's article in 1940, that the dynamic approach to monetary economics introduced in his 1922 essay was the source of Robertson's own formulation of period analysis in 1926 and, via Robertson, of the ‘fundamental equations’ of Keynes's 1930 Treatise on Money. Whereas there are some grounds to substantiate Bernácer's claim, it should be noted that the economic policy conclusions he drew from his theoretical framework are far apart from those advocated by Robertson or Keynes. Bernácer was critical of attempted stabilization policies of both fiscal and monetary sorts, because of the crowding out effect and of the (destabilizing) impact of monetary and credit changes on prices. Instead, he believed that the market economy was an essentially efficient institution, except for the existence of the speculative market for income-yielding assets that kept the economy in a chronic state of unemployment. Bernácer's suggested solution was to make the amount of disposable funds constant by suppressing that market through the legal prohibition of the sale of land, which would bring the rate of interest to zero. Although this is somewhat reminiscent of Henry George's reform proposals in the 19th century, it should be noted that Bernácer supported neither George's tax reform nor George's approaches to economic fluctuations and the determination of interest. It is likely that Bernácer's idiosyncratic ideas about economic reform, as well as his rejection of macroeconomic stabilization policies, contributed to distracting interest from the depth of his economic theory and to explaining its relative lack of influence in Spain throughout his lifetime.

Bernoulli, Daniel (1700–1782)

S.L. Zabell
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Bernoulli, D.; Bernoulli, N.; Cramer, G.; D'Alembert, C.; Euler, L.; Goldbach, C.; Laplace, P. S.; logarithmic utility; maximum likelihood; moral expectation; probability; St Petersburg paradox; utility

Article
Swiss mathematician and theoretical physicist; born at Groningen, 8 February 1700; died at Basel, 17 March 1782.
Daniel Bernoulli was a member of a truly remarkable family which produced no fewer than eight mathematicians of ability within three generations, three of whom – James I (1654–1705), John I (1667–1748) and Daniel – were luminaries of the first magnitude.
Although initially trained in medicine, in 1725 Daniel Bernoulli accepted a position in mathematics at the newly founded Imperial Academy in St Petersburg, but returned to Basel in 1733, holding successively the chairs in anatomy and botany, physiology (1743), and physics (1750–77). He was elected to membership in all of the major European learned societies of his day, including those of London, Paris, Berlin and St Petersburg, and maintained an extensive scientific correspondence which included both Euler and Goldbach.
Original in thought and prolific in output, Bernoulli worked in many areas but his most important contributions were to the fields of mechanics, hydrodynamics and mathematics. He enjoys with Euler, his close friend from childhood, the distinction of having won or shared no fewer than ten times the annual prize of the Paris Academy. His masterpiece, the Hydrodynamica (1738), contains a derivation of the Bernoulli equation for the steady flow of a non-viscous, incompressible fluid, and the earliest mathematical treatment of the kinetic theory of gases, including a derivation of Boyle's Law.
Bernoulli also made important contributions to probability and statistics, including an early application of the method of maximum likelihood to the theory of errors and an investigation of the efficacy of smallpox inoculation (Todhunter, 1865, ch. 11). Nevertheless, his best-known contribution to this subject is unquestionably his 1738 paper ‘Specimen theoriae novae de mensura sortis’, which discusses utility, ‘moral expectation’ and the St Petersburg paradox.
The St Petersburg paradox (so called because Bernoulli's paper appeared in the Commentarii of the St Petersburg Academy) concerns a game, first suggested by Nicholas Bernoulli (Daniel's cousin) in correspondence with Montmort: a coin is tossed \( n \) times until the first head appears; \( 2^n \) ducats are then paid out. Paradoxically, the mathematical expectation of gain is infinite although common sense suggests that the fair price to play the game should be finite.

Bernoulli proposed that the paradox could be resolved by replacing the mathematical expectation by a moral expectation, in which probabilities are multiplied by personal utilities rather than monetary prices. Arguing that incremental utility is inversely proportional to current fortune (and directly proportional to the increment in fortune), Bernoulli concluded that utility is a linear function of the logarithm of monetary price, and showed that in this case the moral expectation of the game is finite.

Strictly speaking, Bernoulli's advocacy of logarithmic utility did not 'solve' the paradox: if utility is unbounded, then it is always possible to find an appropriate divergent series. Nor was he the first to adopt such a line of attack; the Swiss mathematician Gabriel Cramer had earlier written to Nicholas Bernoulli in 1728, noting that if utility were either bounded or proportional to the square root of monetary price, then the moral expectation would be finite. But it was via Bernoulli's paper that the utility solution entered the literature, and despite initial (and eccentric) criticism by D'Alembert, by the 19th century most treatises on probability would contain a section on moral expectation and the paradox.

For further biographical information about Daniel Bernoulli and a detailed scientific assessment of his work, see the article by Hans Straub in Dictionary of Scientific Biography, vol. 2 (1970). The DSB also contains excellent entries on several other members of the Bernoulli family. Eric Temple Bell's Men of Mathematics (1937) contains a spirited, if not necessarily reliable, account of the Bernoullis.

Todhunter (1865, ch. 11) is still valuable as a summary of Bernoulli's work in probability; Todhunter's book is, as Keynes justly remarked, 'a work of true learning, beyond criticism'. For further information on Bernoulli's contributions to probability and statistics, see also Sheynin (1970; 1972) and Maistrov (1974, pp. 106–7, 110–18). The dispute with D'Alembert is discussed by Baker (1975, pp. 172–5); see also Pearson (1978, pp. 543–55, 560–65) and Daston (1979, pp. 259–79).

Useful discussions of Bernoulli's paper on the St Petersburg paradox include Leonard J. Savage (1954, pp. 91–5) and J.M. Keynes (1921, pp. 316–20). The mathematician Abel once wrote that one should read the masters and not the pupils; those who wish to follow Abel's advice will find challenging but rewarding Laplace's discussion of moral expectation in his Théorie analytique des probabilités (1812, ch. 10: 'De l'espérance morale').

The literature on the St Petersburg paradox up to 1934 is surveyed in Karl Menger (1934); an English translation of Menger's paper appears in M. Shubik (ed., 1967). For a discussion of the St Petersburg paradox in the context of an axiomatization of utility and probability other than that of Ramsey and Savage, see Jeffrey (1983, pp. 150–5). The paradox still continues to inspire interest and analysis; a
recent example is Martin-Lof (1985).

Bernstein, Eduard (1850–1932)

Tom Bottomore
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Bernstein, E.; class; class conflict; Engels, F.; Kautsky, K.; Marx, K. H.; social democracy; socialism; Weber, M.; Winstanley, G.

Article

Born in Berlin, 6 January 1850; died in Berlin, 18 December 1932. The son of a Jewish railway engineer and the seventh child in a large family of 15 children, Bernstein grew up in a lower middle-class district of Berlin in ‘genteel poverty’. He did not complete his studies at the Gymnasium, and in 1866 he began an apprenticeship in a Berlin bank. Three years later he became a bank clerk and remained in this post until 1878, but he continued to study independently and for a time aspired to work in the theatre. He became a socialist in 1871, largely through sympathy with the opposition of Bebel, Liebknecht and others to the Franco–Prussian war, and strongly influenced by reading Marx's study of the Paris Commune, The Civil War in France (1871). In 1872 Bernstein joined the Social Democratic Workers’ Party, and in 1875 he was a delegate to the conference in Gotha which brought about the union of that party with Lassalle's General Union of German Workers to form a new Socialist Workers’ party, later the Social Democratic Party (SDP). From that time Bernstein became a leading figure in the socialist movement, and in 1878, just before Bismarck's anti-Socialist law was passed, he moved to Switzerland as secretary to a wealthy young socialist, Karl Höchberg, who expounded a form of utopian socialism in the journal Die Zukunft which he had founded. It was in 1878 also that Bernstein read Engels's Anti-Dühring, which, he said, ‘converted me to Marxism’, and he corresponded with Engels for the first time in June 1879. After some misunderstandings with Marx and Engels, who were suspicious of his relationship with Höchberg, Bernstein won their confidence during a visit to London and in January 1881, with their support, he became editor of Der Sozialdemokrat (the newspaper of the SDP, established in 1879). It was, as Gay (1952) notes, ‘the beginning of a great career’.

In 1888 the Swiss government, under pressure from Germany, expelled Bernstein and three of his colleagues on the Sozialdemokrat, and they moved to London to continue publication there. The period of exile in England, which lasted until 1901, was crucial in the formation of Bernstein's ideas. He
Bernstein, Eduard (1850–1932) : The New Palgrave Dictionary of Economics
became a close friend of Engels, who made him his literary executor (jointly with Bebel), and developed a stronger interest in historical and theoretical subjects, contributing regularly to Kautsky's *Die Neue Zeit* and publishing in 1895 his first major work, a study of socialism and democracy in the English revolution (entitled *Cromwell and Communism* in the English translation). Bernstein's major contributions in this study, which he later described as 'the only large scale attempt on my part to discuss historical events on the basis of Marx's and Engels's materialist conception of history', were to analyse the civil war as a class conflict between the rising bourgeoisie and both the feudal aristocracy and the workers, and to give prominence to the ideas of the radical movements in the revolution (the Levellers and Diggers), and in particular those of Gerrard Winstanley, who had been ignored by previous historians.

At the same time Bernstein established close relations with the socialists of the Fabian Society and came to be strongly influenced by their ‘gradualist’ doctrines and their rejection of Marxism. In a letter to Bebel (20 October 1898) he described how, after giving a lecture to the Fabian Society on ‘What Marx really taught’, he became extremely dissatisfied with his ‘well-meaning rescue attempt’ and decided that it was necessary ‘to become clear just where Marx is right and where he is wrong’. Soon after Engels's death Bernstein began to publish in *Die Neue Zeit* (from 1896 to 1898) a series of articles on ‘problems of socialism’ which represented a systematic attempt to revise Marxist theory in the light of the recent development of capitalism and of the socialist movement. The articles set off a major controversy in the SDP, in which Kautsky defended Marxist orthodoxy and urged Bernstein to expound his views in a more comprehensive way, as he then proceeded to do in his book on ‘the premisses of socialism and the tasks of social democracy’ (1899; entitled *Evolutionary Socialism* in the English translation), which made him internationally famous as the leader of the ‘revisionist movement’.

Bernstein's arguments in *Evolutionary Socialism* were directed primarily against an ‘economic collapse’ theory of the demise of capitalism and the advent of socialism, and against the idea of an increasing polarization of society between bourgeoisie and proletariat, accompanied by intensifying class conflict. On the first point he was attacking the Marxist orthodoxy of the SDP, expounded in particular by Kautsky, rather than Marx's own theory, in which the analysis of economic crises and their political consequences was not fully worked out, and indeed allowed for diverse interpretations (Bottomore, 1985). The central part of Bernstein's study, however, concerned the changes in class structure since Marx's time, and their implications. In this view, the polarization of classes anticipated by Marx was not occurring, because the concentration of capital in large enterprises was accompanied by a development of new small and medium-sized businesses, property ownership was becoming more widespread, the general level of living was rising, the middle class was increasing rather than diminishing in numbers, and the structure of capitalist society was not being simplified, but was becoming more complex and differentiated. Bernstein summarized his ideas in a note found among his papers after his death: ‘Peasants do not sink; middle class does not disappear; crises do not grow ever larger; misery and serfdom do not increase. There is increase in insecurity, dependence, social distance, social character of production, functional superfluity of property owners’ (cited by Gay, 1952, p. 244).

On some points Bernstein was clearly mistaken. With the further development of capitalism, peasant production has declined rapidly and has been superseded to a great extent by ‘agri-business’; economic crises did become larger, at least up to the depression of 1929–33. It was his analysis of the changing class structure which had the greatest influence, becoming a major issue in the social sciences, and above all in sociology, in part through the work of Max Weber, whose critical discussion of Marxism in
his lecture on socialism (1918) largely restates Bernstein's arguments. There is a more general sense in which Bernstein's ideas have retained their significance; namely, in their assertion of the increasingly 'social character' of production and the likelihood of a gradual transition to socialism by the permeation of capitalist society with socialist institutions. In a different form the same notion is expressed by Schumpeter (1942) in his conception of a gradual 'socialization of the economy'; a conception which can also be traced back to Marx (Bottomore, 1985).

One other aspect of Bernstein's thought should be noted. Influenced by the neo-Kantian movement in German philosophy and by positivism (in an essay of 1924 he noted that 'my way of thinking would make me a member of the school of Positivist philosophy and sociology') Bernstein made a sharp distinction between science and ethics and went on to argue, in his lecture 'How is scientific socialism possible?' (1901), that the socialist movement necessarily embodies an ethical or 'ideal' element: 'It is something that ought to be, or a movement towards something that ought to be.' From this standpoint he criticized in a more general way a purely economic interpretation of history, and especially the kind of 'economic determinism' that was prevalent in the orthodox Marxism of the SDP; but in so doing he cannot be said to have diverged radically from the conceptions of Marx and Engels (and indeed he cited Engels's various qualifications of 'historical materialism' in support of his own views).

Bernstein's book met with a vigorous and effective response in Rosa Luxemburg's *Sozialreform oder Revolution* (1899), and the SDP became divided between 'radicals', 'revisionists', and the 'centre' (represented by Bebel and Kautsky); and although the latter retained control Bernstein remained a leading figure in the party until 1914. But his growing opposition to the war led him to form a separate organization in 1916 and then to join the left-wing Independent Social Democratic Party of Germany (USPD) in 1917. After the war Bernstein became increasingly disillusioned with the ineffectualness of the SDP in countering the reactionary nationalist attacks on the Weimar Republic, his influence waned, and his last years were spent in isolation.

Bertrand competition

Michael R. Baye and Dan Kovenock
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article presents the classic Bertrand model of oligopolistic price competition and shows how alternative assumptions on economic primitives – such as the structure of demand and cost functions, tie-breaking rules, and product differentiation – shape Nash equilibrium prices and profits. We also discuss the related Bertrand–Edgeworth model of price competition in which consumers may be rationed – either strategically or due to capacity constraints – and illustrate how alternative rationing rules influence equilibrium.

Keywords

Bertrand competition; Bertrand equilibrium; Bertrand paradox; Bertrand, J. L. F.; Bertrand–Edgeworth competition; best response (reply); capacity; Cournot, A. A.; duopoly; Edgeworth cycles; homogeneous products; mixed-strategy equilibria; monopoly; Nash equilibrium; oligopoly; price competition; product differentiation; pure-strategy equilibria; rationing rules; residual monopoly price; strategic complements; supermodularity; winner-take-all

Article

‘Bertrand competition’ refers to a model of oligopoly in which two or more firms compete by simultaneously setting prices and in which each firm is committed to provide consumers with the quantity of the firm’s product they demand given these ‘posted prices’. The concept is named after the French mathematician Joseph Louis François Bertrand (1822–1900) who, in an 1883 review of Cournot (1838), was critical of Cournot’s use of quantity as the strategic variable in his famous duopoly model of market rivalry. In his critique, Bertrand described how, in Cournot’s duopoly environment where identical firms produce a homogeneous product under a constant unit cost technology, price competition would lead to price undercutting and a downward spiral of prices. Bertrand erroneously reasoned that this process would continue indefinitely, thereby precluding the existence of an equilibrium. It is now
widely recognized that an equilibrium exists not only in Bertrand's original formulation but in a plethora of other environments in which firms sell either homogeneous or differentiated products.

Formally, *Bertrand competition* is a normal form game in which each of \( n \geq 2 \) players (firms), \( i = 1, 2, \ldots, n \), simultaneously sets a price \( p_i \in \mathbb{P}_i = [0, \infty) \). Under the assumption of profit maximization, the payoff to each firm \( i \) is

\[
\pi_i(p_b, p_{-i}) = p_i D_i(p_b, p_{-i}) - C_i(D_i(p_b, p_{-i}))
\]

where \( p_{-i} \) denotes the vector of prices charged by all firms other than \( i \), \( D_i(p_b, p_{-i}) \) represents the total demand for firm \( i \)'s product at prices \( (p_b, p_{-i}) \), and \( C_i(D_i(p_b, p_{-i})) \) is firm \( i \)'s total cost of producing the output \( D_i(p_b, p_{-i}) \). A *Bertrand equilibrium* is a Nash equilibrium of this game; that is, a vector of prices \( (p_i^*, p_{-i}^*) \) such that, for each player \( i \),

\[
\pi_i(p_i^*, p_{-i}^*) \geq \pi_i(p_b, p_{-i}) \quad \text{for all } p_i \in \mathbb{P}_i.
\]

**The Bertrand paradox**

In the 'classic' model of Bertrand competition, each of the \( n \) firms produces an identical product at a constant unit cost of \( c \); that is, \( C_i(q_i) = cq_i \). Since their products are perfect substitutes, firms effectively compete for the total demand, \( D(p) \), that a monopolist serving the entire market would obtain by pricing at \( p \). The firm setting the lowest price gets all of this demand; in the event of a tie, the firms charging the lowest price share total demand equally. Total demand is sufficiently well-behaved to ensure that the corresponding monopoly profit function, \( \pi(p) = pD(p) - C(D(p)) \), is not only continuous, but (a) has a unique maximizer, the monopoly price \( p^M \); (b) satisfies \( \pi(p) < \pi(c) = 0 \) for \( p < c \); and satisfies (c) \( 0 < \pi(p) < \pi(p^M) < \infty \) for all \( p^M > p > c \). Despite the continuity of \( \pi(p) \), each firm faces a discontinuous profit function

\[
\pi_i(p_b, p_{-i}) = \begin{cases} (p_i - c)D(p_i) & \text{if } p_i < p_j \text{ for all } j \neq i \\ (p_i - c)D(p_i) / m & \text{if } i \text{ ties } m - 1 \text{ other firms for low price} \\ 0 & \text{otherwise} \end{cases}
\]

because a firm that prices even slightly above the lowest price gets no demand. In this classic setting with 'well-behaved' demand and constant marginal cost, \( (p_i^*, p_{-i}^*) \) is a *Bertrand equilibrium* if and only if \( p_j^* \geq c \) for every firm \( j \) and at least two firms set price equal to \( c \). Consequently, all firms earn zero profits in equilibrium, a result that has come to be known as the *Bertrand paradox*. The paradox stems from the fact that, while a monopolist would earn strictly positive profits by charging a price in excess of marginal cost, it takes only two firms to completely dissipate the monopoly profits and achieve the competitive outcome. In a Bertrand equilibrium, all transactions take place at marginal cost \( c \), and all firms earn zero profits.

The proof of this proposition follows in part from the original intuition of Bertrand. Since the products are perfect substitutes, consumers will purchase only from a firm that charges the lowest price in the
market, $\varrho_L \equiv \min_j \varrho_j$. First, $\varrho_L \leq \varrho^M$ in any equilibrium; otherwise, any firm could profitably deviate by lowering its price to $\varrho^M$. Second, $\varrho_L \geq c$ in any equilibrium; otherwise, a firm charging $\varrho_L$ (and thus earning strictly negative profits) could profitably deviate by increasing its price to $c$. Third, if $\varrho^M \geq \varrho_L > c$, then at least one firm could increase its profit by unilaterally undercutting $\varrho_L$ by a small amount. Hence, $\varrho_L = c$ in any equilibrium. Fourth, if only a single firm charged a price of $\varrho_L = c$, it would earn a payoff of zero, and could increase its price to $\varrho' > c$ (but below the second-lowest price) to earn a positive profit. Thus, in any equilibrium at least two firms charge a price of $\varrho_L = c$. Finally, since the only firms attracting any consumers are those pricing at $\varrho_L = c$, all firms earn zero profits. Furthermore, no firm can unilaterally change its price to earn positive profits.

One consequence of this argument is that when $n = 2$ there is a unique Bertrand equilibrium in the classic model: both firms set the common price $\varrho^* = \varrho^* = c$. When $n > 2$, there is a unique symmetric equilibrium (in which $\varrho^*_i = c$ for all $i$) and a continuum of asymmetric equilibria (where two or more firms price at $c$ and one or more firms charge prices arbitrarily higher than $c$).

Although the Bertrand paradox result summarized above for the case of identical constant unit costs is stated in terms of pure strategies and a symmetric tie-breaking rule, the paradox also obtains for the extension of strategy spaces to allow for mixed-strategies as well as other tie-breaking rules. Alternative tie-breaking rules include ‘winner-take-all sharing’ (where a fair randomizing device is used to determine the identity of the firm that serves the entire market in the event of a tie for the lowest price) and ‘unequal sharing’ (where firms tying for the lowest price receive an unequal fraction of total market demand in the event of a tie for the lowest price).

Baye and Morgan (1999) have shown that if the monopoly profit function, $\Pi(p)$, is unbounded, there exists (in addition to the Bertrand paradox equilibria) a continuum of non-degenerate mixed strategy equilibria in which each firm earns positive profits. For instance, suppose market demand is given by $D(p) = p^\alpha$, where $\alpha \in (-\infty, -1/n]$ is the elasticity of market demand. In this case, one can show that there is a unique symmetric Cournot (quantity-setting) equilibrium in which each firm earns positive profits and the equilibrium market price is $\varrho^* = [n\alpha / (1 + n\alpha)] c$. In contrast, under Bertrand competition any symmetric profit level $\Pi^* \in (0, \infty)$ (including profit levels above the Cournot profit) can be achieved in an (atomless) symmetric mixed strategy equilibrium. Equilibrium mixed strategies that support these positive profit levels are described by the cumulative distribution function $F(p) = 1 - \Pi^* / \Pi(p)$ on $[\Pi^{-1}(\Pi^*), \infty)$, where $\Pi(p) = (p - c) p^\alpha$.

Even with a bounded monopoly profit function $\Pi(p)$, the coexistence of positive profit equilibria and (zero profit) Bertrand paradox equilibria can arise for alternative cost functions and sharing rules. For instance, with a symmetric tie-breaking rule (see Dastidar, 1995), if firms have identical cost functions that are increasing and strictly convex in output, a symmetric zero profit equilibrium may exist in which each firm prices at $p^0$, where $p^0$ satisfies $p^0 D(p^0) / n - c(D(p^0) / n) = 0$. In addition, however, a continuum of positive profit symmetric pure-strategy equilibria can arise in which each firm charges a price contained in an interval above $p^0$. Intuitively, with strictly convex costs, a firm that deviates by undercutting such a price would increase its demand (and revenues) by a factor of $n$, but the firm's cost
would increase by a factor greater than $n$.

This result for bounded demand and identical convex costs is based on a symmetric tie-breaking rule; with convex costs, different results generally obtain for other tie-breaking rules. For instance, under the winner-take-all tie-breaking rule (see Baye and Morgan, 2002), any firm charging the price $p_L$ earns a payoff of $\pi(p_L) / \#L$, where $\#L$ is the number of firms charging the price $p_L$. In this case, if $\pi(p_L) > 0$, some firm could gain by undercutting $p_L$ by a small amount (a firm pricing above $p_L$ could increase its payoff from zero to $\pi(p_L - \varepsilon) > 0$; a firm that tied another firm at $p_L$ could increase its profits from $\pi(p_L) / \#L$ to $\pi(p_L - \varepsilon)$ by slightly undercutting $p_L$). Consequently, an argument similar to that for the case of constant unit costs implies that, with bounded demand and convex costs, any equilibrium under the winner-take-all sharing rule involves at least two firms charging a price $p_L$ such that $\pi(p_L) = 0$, so that the (zero profit) Bertrand paradox is the only configuration of firm profits.

With bounded demand and identical concave costs, a similar argument reveals that any equilibrium under the winner-take-all sharing rule involves at least two firms charging a price $p_L$ such that $\pi(p_L) = 0$ (Baye and Morgan, 2002). However, under a symmetric sharing rule, concave costs (increasing returns) are problematic for the existence of a Bertrand equilibrium in either pure or mixed strategies. To illustrate, consider a duopoly in which market demand is given by $D(p) = 1 - p$ for $p \in [0, 1]$, and in which each firm has an identical concave cost function

$$
C_i(q_i) = \begin{cases} 
0 & \text{if } q_i = 0 \\
 f + cq_i & \text{if } q_i > 0 
\end{cases}
$$

where $1 > c > 0$ and $f < [(1 - c) / 2]^2$. Note that $c$ represents marginal cost and $f$ is a fixed cost that may be avoided by producing zero output. One may readily verify that a monopolist would earn strictly positive profits by pricing at the monopoly price $p_M = (1 + c) / 2$, and that the minimum 'breakeven price' is $p^0 = [(1 + c) - ((1 - c)^2 - 4f)^{1/2}] / 2$; that is, $0 = \pi(p^0) > \pi(p)$ for all $p < p^0$. Under a winner-take-all sharing rule, $p_1 = p_2 = p^0$ is a pure-strategy Nash equilibrium and firms earn zero profits in this 'Bertrand paradox' equilibrium. In contrast, under a symmetric tie-breaking rule there does not exist an equilibrium (in pure or mixed strategies).

The intuition for the failure of existence of equilibrium with a symmetric tie-breaking rule in this example is as follows. Clearly, neither firm has an incentive to price below $p^0$ (since monopoly profits are negative for such prices and a firm can guarantee a payoff of zero by pricing at $p^i = 1$). If both firms priced at $p^0$ with probability one, symmetric sharing implies that they would earn negative profits, since $\zeta_i(D(p^0) / 2) > \zeta_i(D(p^0)) / 2$. Thus, $p^0$ is strictly less than the upper bound of the support of at least one firm's (possibly degenerate) mixed strategy. Let $p^H > p^0$ denote highest of the upper bounds of the supports of the two firms' mixed strategies. In any equilibrium, at most one firm has a mass point at $p^H$; otherwise, there would be a positive probability of a tie at this price and a firm could gain by
reallocating mass to lower prices. If there is a mass point at $p^{H}$, the firm charging $p^{H}$ with positive probability must earn its equilibrium profits at this price, which are necessarily zero since it is undercut with certainty. If there is no mass point at $p^{H}$, then a firm whose support includes $p^{H}$ must achieve its equilibrium payoff when pricing at $p^{H}$, and since $p^{H}$ is undercut with certainty, this equilibrium payoff is zero. Therefore, at least one firm $i$ whose support includes $p^{H}$ earns an equilibrium payoff of zero.

Moreover, since firm $i$ earns an equilibrium payoff of zero, $p^{0}$ must be the upper bound of the support of the other firm $j$’s mixed strategy; if the upper bound of $j$’s support was $p^{'} \in (p^{0}, p^{H}]$, firm $i$ could increase its profits by reallocating probability mass to some price below $p^{'}$. Thus, if there is an equilibrium, at least one firm must charge a price of $p^{0}$ with probability one. However, since firm $i$ charges prices in the interval $[p^{0}, p^{H}]$, and not all mass is at $p^{0}$, it follows that there exists some price $p^{''} \in (p^{0}, p^{H}]$ such that firm $j$ could gain by reallocating mass from $p^{0}$ to $p^{''}$, a contradiction. Hence, there does not exist an equilibrium in pure or mixed strategies.

**Bertrand–Edgeworth competition**

In an early critique of Bertrand and Cournot, Edgeworth (1925) observed that the Bertrand paradox may not obtain if firms are capacity constrained. Indeed, in the analysis above, if firm $i$’s demand $D_{i}(p_{i}, p_{-i})$ is greater than firm $i$’s largest competitive supply at $p_{i}$, $s_{i}(p_{i}) = \max \{\arg \max q p_{i}q - C_{i}(q)\}$, then firm $i$ would earn higher profits by supplying a quantity strictly less than that demand and rationing customers. A variant of Bertrand competition, known as ‘Bertrand–Edgeworth competition’, allows any firm to ration the demand that it faces at given prices by only providing its optimal or competitive supply at its price. Rationing may stem from a physical capacity constraint, $k_{i}$, that prevents firm $i$ from producing more than $k_{i}$ units (as in Edgeworth’s original formulation), or more generally, from a firm’s strategic incentive to refuse to fulfil the quantity demanded of all consumers at a given price. Under Bertrand–Edgeworth competition one must therefore specify how demand is rationed when a firm’s quantity demanded at given prices exceeds the amount of product it produces.

Two prominent rationing rules used in this context are efficient rationing (in which case the good is first allocated to consumers who most highly value the product) and proportional rationing (in which case the good is allocated to a fraction of consumers without regard to their valuations of the product). In the duopoly case, for instance, efficient rationing means that if $p_{i} > p_{j}$, firm $i$’s ‘residual’ demand is $D_{i}(p_{1}, p_{2}) = \max \{0, D(p_{i}) - s_{j}(p_{j})\}$. Under proportional rationing, firm $i$’s demand is $D_{i}(p_{1}, p_{2}) = \max \{0, D(p_{i}) [1 - s_{j}(p_{j}) / D(p_{j})]\}$. Under both rationing rules, the firm charging the lowest price enjoys a demand of $D(p_{j})$. It is typically assumed that, in the event of a tie, total demand is allocated in proportion to firms’ competitive supplies; that is, if both firms charge a price of $p$, firm $i$ gets a share $\alpha_{i} = s_{i}(p) / (s_{1}(p) + s_{2}(p))$.

For the special case of a duopoly in which each firm has a constant marginal cost ($c$) up to a capacity of $k_{i}$, the cost functions are:
In this case, under the assumption of well-behaved demand, \( s_i(p_i) = k_i \) for all \( p_i \geq c \); that is, each firm opts for a ‘corner solution’ at full capacity when price exceeds marginal cost. Under both efficient and proportional rationing, if \( D(c) \leq k_i, i = 1, 2 \), then neither firm's capacity constraint ever binds and the Bertrand paradox arises under the same conditions as set forth above; the unique equilibrium is \( p_1^* = p_2^* = c \). Characterization of equilibrium when one or more firms is capacity constrained at a price equal to \( c \) depends on whether each firm is capacity constrained at its ‘residual monopoly price’ when its rival sets \( p_j = D^{-1}(k_1 + k_2) \). The term ‘residual monopoly price’ refers to a firm’s optimal price, given its capacity constraint and residual demand (the demand that remains after the other firm has sold its capacity). Note that, in equilibrium, neither firm would ever set a price below \( D^{-1}(k_1 + k_2) \), for at such a price total demand exceeds total capacity, and a firm could increase its price without losing sales. Characterization of equilibrium when \( D(c) > k_i \) for one or more firms then depends on whether \( p_1 = p_2 = D^{-1}(k_1 + k_2) \) is an equilibrium. If, for each firm \( i, D^{-1}(k_1 + k_2) \) is the residual monopoly price when firm \( j \) sets \( p_j = D^{-1}(k_1 + k_2) \), then \( p_1^* = p_2^* = D^{-1}(k_1 + k_2) \) is the unique Bertrand–Edgeworth equilibrium. If some firm \( i \)’s residual monopoly price exceeds \( D^{-1}(k_1 + k_2) \) when \( p_j = D^{-1}(k_1 + k_2) \), then the unique equilibrium is in non-degenerate mixed-strategies.

The residual monopoly price depends on the rationing rule. For proportional rationing, \( D_i(p_1, p_2) \equiv \max \{0, D(p_i) [1 - k_j / D(p_j)]\} \) for any given \( p_j \), and hence firm \( i \)'s demand is proportional to \( D(p_i) \). This implies that, ignoring firm \( i \)'s capacity constraint, the residual monopoly price based on \( D_i(p_1, p_2) \) corresponds to the standard monopoly price, \( p^M \equiv \arg \max \rho \{ (p - c)D(p) \} \). When \( p_j = D^{-1}(k_1 + k_2) < p^M \), firm \( i \) has sufficient capacity to satisfy residual demand at \( p^M \), and hence \( p^M \) is firm \( i \)'s residual monopoly price; if \( p_j = D^{-1}(k_1 + k_2) \geq p^M \), concavity of the monopoly profit function implies that \( p_i = D^{-1}(k_1 + k_2) \) is firm \( i \)'s residual monopoly price. It follows that, for proportional rationing, \( p_1^* = p_2^* = D^{-1}(k_1 + k_2) \) is the unique Bertrand–Edgeworth equilibrium as long as \( D^{-1}(k_1 + k_2) \geq p^M \). Under efficient rationing, \( D_i(p_1, p_2) = \max \{0, D(p_i) - k_j\} \), so that ignoring firm \( i \)'s capacity constraint, the residual monopoly price is \( p_i^R = \arg \max \rho_i \{ (p_i - c) \max (0, D(p_i) - k_j) \} \). It follows that \( p_i^R < p^M \). When \( p_j = D^{-1}(k_1 + k_2) < p_i^R \), firm \( i \) has sufficient capacity to satisfy residual demand at \( p_i^R \), and hence \( p_i^R \) is firm \( i \)'s residual monopoly price; if \( p_j = D^{-1}(k_1 + k_2) \geq p_i^R \), concavity of the monopoly profit function implies that \( p_i = D^{-1}(k_1 + k_2) \) is firm \( i \)'s residual monopoly price.
price. Hence, $D^{-1}(k_1 + k_2)$ is firm $i$'s residual monopoly price when firm $j$ sets $p_j = D^{-1}(k_1 + k_2)$ if and only if $D^{-1}(k_1 + k_2) \geq p^R_i$. This implies that the region in which a pure strategy equilibrium arises is larger for the case of efficient rationing than under proportional rationing. In fact, since the unconstrained residual profit-maximization problem faced by firm $i$ under efficient rationing may be written in terms of either price or quantity, $p^R_i$ is the price arising in a Cournot setting where firm $i$'s output is a best response to an output of $k_j$ by the rival. Hence, if $k_j$ is less than or equal to firm $i$'s Cournot best response to $k_j$, firm $i$ is capacity constrained and its residual monopoly price equals $D^{-1}(k_1 + k_2)$. Consequently, $p^*_1 = p^*_2 = D^{-1}(k_1 + k_2)$ is the unique Bertrand–Edgeworth equilibrium when each firm's capacity is less than or equal to its Cournot best response (given unit cost $c$) to the other firm's capacity.

Outside of the above regions of capacity, the only Bertrand–Edgeworth equilibria are in non-degenerate mixed strategies in which firms randomize prices over a common interval of prices that exceed $c$ and earn positive expected profits. This corresponds to the regions of capacities in which ‘Edgeworth cycles’ arise (Edgeworth, 1925). As before, these mixed strategies depend on the rationing rule. For proportional rationing, these mixed strategies are generally difficult to derive; see Davidson and Deneckere (1986) for a characterization. For efficient rationing, these mixed strategies have been characterized by Kreps and Scheinkman (1983), and entail the firm with the larger capacity earning an expected payoff that equals the monopoly profit associated with the residual demand (with symmetric capacities, each firm earns this expected payoff). The firm with the larger capacity earns the higher payoff.

To summarize, only two types of pure-strategy equilibria exist under Bertrand–Edgeworth duopoly with constant unit cost. When capacity constraints do not bind, the classic Bertrand equilibrium arises and the unique equilibrium is for each firm to price at marginal cost to earn zero profits. When capacities are sufficiently small, firms price above marginal cost (at a price that clears all capacity) and earn positive profits in the unique Bertrand–Edgeworth equilibrium. When capacities are in an intermediate range, the equilibrium is generally unique, but in non-degenerate mixed strategies. Firms’ prices exceed marginal cost with probability one, and firms earn positive profits.

Positive profit equilibria can also arise in homogeneous product Bertrand settings in which firms endogenously choose capacities. Specifically, consider a two-stage game where, in the first stage, firms simultaneously commit to a capacity, and in the second stage firms simultaneously engage in Bertrand–Edgeworth competition. Under both efficient and proportional rationing, capacity commitment in the first stage permits both firms to avoid the Bertrand paradox in the second stage to earn positive profits. Under efficient rationing, capacity choice followed by Bertrand–Edgeworth competition leads, under fairly general conditions, to equilibrium prices that are identical to those that would arise in a Cournot (quantity setting) duopoly where firms’ unit costs are the sum of capacity and production costs; see Kreps and Scheinkman (1983) and Deneckere and Kovenock (1996). Under proportional rationing, the Cournot outcome arises only if per unit capacity costs are sufficiently large. Otherwise, equilibria may arise in which capacities are asymmetric and non-degenerate mixed strategies are played at the pricing stage; see Davidson and Deneckere (1986).
Product differentiation

Bertrand competition with differentiated products is fundamentally different from Bertrand competition with homogenous products. With differentiated products, the demand for a firm's product is not generally discontinuous at \( p_L \); a firm does not generally lose all of its demand by pricing slightly above \( p_L \), nor does it steal all of rival firms’ demands by pricing below \( p_L \). In the classical model of differentiated-product Bertrand competition with downward sloping demands and costs that are non-decreasing in output, each firm's profit function, \( \pi_i(p_i, p_{-i}) \), is assumed to be twice continuously differentiable, with \( \frac{\partial \pi_i}{\partial p_i} \frac{\partial \pi_i}{\partial p_j} > 0 \) (strategic complements) and \( \frac{\partial^2 \pi_i}{\partial p_i^2} < 0 \).

With suitable assumptions on firms’ demands and costs, a Bertrand equilibrium, \( (p_i^*, p_{-i}^*) \), is simply the solution to the system of first-order conditions implied by each firm's profit-maximizing pricing decision:

\[
\frac{\partial \pi_i(p_i^*, p_{-i}^*)}{\partial p_i} = 0 \text{ for all } i = 1, 2, ..., n.
\]

Alternatively, one may use the implicit function theorem and use firm \( i \)'s first-order condition to obtain firm \( i \)'s optimal price as a function of the prices charged by the other firms: \( p_i = \rho_i(p_{-i}) \). The function \( \rho_i \) is called firm \( i \)'s best-response (best-reply, reaction) function, and a Bertrand equilibrium in the case of differentiated products corresponds to the intersection of the firms’ best-response functions. Total differentiation of firm \( i \)'s first-order condition reveals that

\[
\frac{\partial \rho_i}{\partial \rho_j} = -\left( \frac{\partial \pi_i}{\partial p_i} \frac{\partial \pi_i}{\partial p_j} \right) \left( \frac{\partial^2 \pi_i}{\partial p_i^2} \right) > 0;
\]

that is, strategic complementarities and the concavity of firm \( i \)'s profits in \( p_i \) imply that firm \( i \)'s best response function is upward sloping.

Notice that, at \( (p_i^*, p_{-i}^*) \),

\[
\frac{\partial \pi_i(p_i^*, p_{-i}^*)}{\partial p_i} = [p_i^* - C_i'(D_i(p_i^*, p_{-i}^*))] \frac{\partial D_i(p_i^*, p_{-i}^*)}{\partial p_i} + D_i(p_i^*, p_{-i}^*) = 0.
\]

Consequently, under mild regularity conditions firm \( i \)'s equilibrium price exceeds its marginal cost. Furthermore, firms may charge different prices and earn positive profits in a differentiated product Bertrand equilibrium. These results may be extended to the case where \( \pi_i(p_i, p_{-i}) \) is not differentiable by appealing to the more general notion of supermodularity (Vives, 1990; Milgrom and Roberts, 1990) rather than strategic complementarity (Bulow, Geanakoplos and Klemperer, 1985).
For the duopoly case with linear demands and constant unit costs, strategic complementarity \((\partial n_i / \partial p_i \partial p_j > 0)\) arises naturally when the duopolists’ products are substitutes in consumption \((\partial D_i / \partial p_j > 0)\). In this case the firms’ best-response functions are not only upward sloping (as is implied by strategic complementarity) but linear; consequently, there is a unique Bertrand equilibrium (see Cheng, 1985). Singh and Vives (1984) have shown that, in this linear duopoly case, even though each firm prices above its marginal cost in a differentiated-product Bertrand equilibrium, prices are lower under Bertrand competition than would arise in a differentiated-product Cournot (quantity setting) model. This result for linear demand and costs extends to markets with more than two firms when all firms’ products are substitutes in consumption (Häckner, 2000).

Bertrand, Joseph Louis François (1822–1900) was born and died in Paris. He was an eminent but not great mathematician, graduate and professor of mathematics at the Ecole Polytechnique and from 1862 to 1900 a member of the Collège de France. His relevance to economic thought comes in his criticism of ‘pseudo-mathematicians’ in the *Journal des Savants* (1883) where he reviewed *Théorie mathématique de la richesse sociale* of Walras and *Recherches sur les principes mathématiques de la théorie des richesses* of Cournot. It is doubtful if Bertrand considered the problems of formal economic modelling more than casually, viewing the two works through the eyes of a mathematician with little substantive interest or understanding. His comments on Cournot were not only somewhat harsh, but as the subsequent developments in oligopoly theory and the theory of games have shown, both Cournot's model of duopoly and Bertrand's remodelling of duopoly with price rather than quantity as a strategic variable are worth investigation. Cournot's model has been (until recently) more generally treated than Bertrand's model. It remained for Edgeworth to point out the limitations of Bertrand's model (see Shubik, 1959). Bertrand also raised objections to the reference and realism of the process description of Walras of ‘tâtonnement’. It has been suggested (Blaug and Sturges, 1983) that Bertrand's critical review was used by opponents of mathematical economics as the basis for their position. Although explicit proof of this is hard to establish the tone and force of Bertrand's critique makes this highly probable.

The Beveridge curve depicts a negative relationship between unemployed workers and job vacancies, a robust finding across countries. The position of the economy on the curve gives an idea as to the state of the labour market. The modern underlying theory is the search and matching model, with workers and firms engaging in costly search leading to random matching. The Beveridge curve depicts the steady state of the model, whereby inflows into unemployment are equal to the outflows from it, generated by matching.

Article

The Beveridge curve depicts a negative relationship between unemployed workers \((u)\) and job vacancies \((v)\). The interest in the curve is related to the role it plays in aggregate models, which study labour market outcomes and dynamics. The position of the economy on the curve gives an idea as to the state of the labour market; for example, a high level of vacancies and a low level of unemployment would indicate a ‘tight’ labour market. The literature has attempted to explain the coexistence of unemployment and vacancies, their negative relationship, and the implied dynamics.

The curve is named after William Beveridge, a British lord, lawyer, head of academic institutions, Member of Parliament, and founder of the modern British welfare state. In a 1944 report (Beveridge, 1944), Beveridge discussed the relationship between the demand for workers, captured by vacancies, and the rate of unemployment. While he did not plot a curve or present a table with a comparison of \(u\) and \(v\), he offered detailed data on these variables and discussed them at some length. His analysis
implied that there is a negative relationship between them. In this early work he tackled many of the issues that remain under study in this field: the potential mismatch between unemployed workers and job vacancies, aggregate demand factors versus reallocation factors (for example, deficient overall demand for labour as opposed to low demand in particular industries), trend versus cyclical changes (for example, changes in $u$ and $v$ along the business cycle versus long-run changes), and measurement issues (such as the various possible ways of mismeasuring vacancies).

The negative $u - v$ relationship is a robust finding across countries, though shifts of the curve over time are often observed. This can be seen, for example, in a 16-country graphical description of the curve presented in Layard, Nickell and Jackman (2005, pp. 36–7). Detailed descriptions and analyses of the empirical findings concerning the Beveridge curve for the United States are to be found in Blanchard and Diamond (1989), and for the UK in Pissarides (1986).

What underlies this negative relationship? The early literature of the late 1950s and in the 1960s dealt with the curve in the context of exploring excess demand in the labour market and its influence on wage inflation. This was motivated by the extensive study of the Phillips curve that took place in those years. The literature typically defined excess demand as unfilled vacancies less unemployed workers, considered the data on these variables, and then looked at the relationship between measures of excess demand and wage behaviour. This literature recognized that, even when there is no excess supply, there is positive unemployment due to frictions. It derived a negatively sloped $u - v$ curve from a model of distinct labour markets, interacting at different levels of disequilibrium, with the markets at points off both labour supply and labour demand curves. The $u - v$ curve was shown to be stationary and observed $u$ and $v$ points were expected to cycle around it. Movements up and down the curve reflect increases and decreases in the excess demand for labour. The curve itself can shift as a result of changes in the speed of market clearing or changes in the sectoral composition of labour demand. The observed $u - v$ data may be a compound of structural shifts of the curve together with cyclical movements about it. Key contributions to this strand of work were progressively made by Dow and Dicks-Mireaux (1958), Lipsey (1960), Holt and David (1966), Hansen (1970), and Bowden (1980).

In the 1970s and 1980s an alternative approach was developed – the search and matching model. A key difference between this model and the early literature is its derivation of vacancies and unemployment as equilibria, rather than disequilibria, phenomena. The model was developed in the work of Peter Diamond, Dale Mortensen, and Christopher Pissarides (see Pissarides, 2000, for a detailed exposition, and Yashiv, 2006, for a recent survey). The model may be briefly described as follows. Workers and firms engage in costly search to find each other. Firms spend resources on advertising, on posting job vacancies, on screening and, subsequently, on training. Workers spend resources on job search, with costs pertaining to activities such as collecting information and applying for jobs. Workers and firms are assumed to be randomly matched. After matching, the worker and the firm engage in bilateral bargaining over the wage. The matching process assumes frictions such as informational or locational imperfections. It is formalized by a ‘matching function’ that takes searching workers and vacant jobs as arguments and produces a flow of matches ($m$), and is given by $m = m(u, v)$. It is continuous, non-negative, increasing in both its arguments, and concave. Typically, it is assumed to be constant returns to scale. The flow into unemployment results from job-specific shocks to matches that arrive at the Poisson rate $\lambda$. These shocks may be explained as shifts in demand or productivity shocks. Once a shock arrives, the firm closes the job down. The evolution of the unemployment rate ($\dot{U}$) is therefore given by
the difference between the separation flow \((\lambda \times \text{employment rate } 1 - u)\) and the matching flow:

\[
\dot{u} = \lambda (1 - u) - m(u, v).
\]

(1)

Denote the rate at which workers are matched to jobs (the job finding rate) by \(p = \frac{m}{u}\) so that \(m = pu\). In the steady state the rate of unemployment is constant, so setting \(\dot{u} = 0\) the following obtains:

\[
u = \frac{\lambda}{\lambda + p}.
\]

(2)

This is the Beveridge curve: as \(p\) depends on \(m\), it depends on both \(u\) and \(v\), and this equation can be represented in vacancy \((v)\) – unemployment \((u)\) space by a downward-sloping curve. The mechanism is the following. When vacancies \(v\) rise, matching \(m\) rises, and so the job finding rate \(p\) rises. Workers find jobs at a faster rate and unemployment \(u\) declines. Vacancies themselves are determined by a firm optimality equation, equating vacancy costs and benefits at the margin.

As can be seen in the equations above, the matching function plays a crucial role in generating the Beveridge curve. Petrongolo and Pissarides (2001) provide a comprehensive survey of estimation of this function, finding the following main features: (a) the prevalent specification is Cobb–Douglas, that is, \(m = uu^{\alpha}v^{\beta}\); (b) usually constant returns to scale \((\alpha + \beta = 1)\) is found, though some studies have produced evidence in favour of increasing returns to scale; (c) many studies have added other variables – such as demographical or geographical variables, incidence of long-term unemployment, and UI – finding some of them significant, but not changing the preceding findings; (d) these general patterns are robust across countries and time periods.

Research along the lines of this model – in progress – is likely to provide a richer account of the Beveridge curve: the matching function is studied for microfoundations, heterogeneity is explicitly explored, endogenous separations are allowed for, interactions with capital investment are considered, and learning and on-the-job search leading to job-to-job movements are incorporated. Going beyond this strand of the literature, research is also beginning to explore equilibrium search models, which feature a Beveridge curve, with alternative \(u - v\) meeting processes, not modelled as matching functions. Thus, the Beveridge curve remains a topic of active research in macroeconomics and labour economics, more than 60 years after it was first studied.

Beveridge is chiefly remembered as a social and administrative reformer, whose *Social Insurance and Allied Services* (1942) set out the basic principles and structure of the post-war welfare state. Paradoxically, however, he thought of himself chiefly as an academic economist whose significance for posterity would lie in the fields of manpower policy and the theory of prices. Throughout his life his approach to economic problems was resolutely inductive and empirical, in contrast with the deductive and analytical method characteristic of most English economists. His early work, *Unemployment: A Problem of Industry* (1909), was based on detailed statistical analysis of the case-papers of applicants for unemployment relief. It drew attention to the structural, geographical and informational barriers that stood in the way of a perfect market for labour; and although its challenge to orthodox theory was practical rather than theoretical, it helped to erode belief in a natural economic equilibrium. Later editions of *Unemployment* (revised with the help of Lionel Robbins) were more strongly influenced by classical economic thought, but Beveridge never abandoned his belief that unemployment could only be cured by state intervention to organize and rationalize the market for labour. Beveridge in the 1930s was initially highly critical of the Keynesian analysis of unemployment; and although during the early 1940s he gradually absorbed many aspects of Keynesian thought, his *Full Employment in a Free Society* (1944) differed markedly from Keynes in its emphasis on the need for physical as well as fiscal controls over the economy and, in particular, on manpower planning. Beveridge's early work on unemployment convinced him that there was a close and measurable connection between levels of economic activity and movements of prices. In the early 1920s he embarked upon what he came to see as his life's work; namely, the compilation of historical and statistical data relating to movements of prices since the 12th century. Beveridge's data convinced him...
that unemployment was caused, both nationally and internationally, by falls in the prices of primary products (though he failed to consider the possibility that the sequence of causation might lie in the other direction). Beveridge's resistance to the use of analytical models meant that his data was of limited value to (and indeed often mocked by) economic theorists. Since his death, however, his material has been a seam of gold to many economic historians. Only one volume of the proposed project was ever published, *Prices and Wages in England from the Twelfth to the Nineteenth Century*, vol. I (1939), but much unpublished material survives among Beveridge's papers in the British Library of Political Science and the Institute of Historical Research.

Although Beveridge is often seen as a leading protagonist of the ‘mixed’ economy, his writings on economic policy displayed a recurrent scepticism about how far it was possible to reconcile state intervention with consumer sovereignty. His study of *British Food Control* (1928) suggested that there were advantages and disadvantages in both a ‘laissez faire’ and a ‘command’ economy, but that it was both logically and practically impossible to have the two in combination. Such doubts were partially allayed by the transformation of popular attitudes which appears to have occurred during the Second World War, but were never fully resolved. In his writings on social welfare, Beveridge appears to have been little influenced by, and indeed largely unconscious of, the growing body of contemporary writings on welfare economics produced by theorists like Pigou. His approach to social insurance, and to transfer payments generally, was that of an early 19th-century utilitarian, modified by a sociological and humanitarian perspective. All his proposals on social security display a concern to maintain some of the central economic tenets of the Poor Law (maintenance of incentives, encouragement to private saving, strict avoidance of relief-in-aid-of-wages) together with more ‘organic’ goals such as national efficiency and the maintenance of civilized minimum standards. His arguments for or against various methods and degrees of ‘redistribution’ were nearly always rooted in pragmatism or rule-of-thumb propositions about human behaviour, rather than in rigorous marginal analysis. Even in the most collectivist and ‘socialistic’ period of his career, he was insistent that claims to welfare should be rooted as far as possible in ‘contract’ rather than ‘status’. His general perception of social welfare should be seen as that of a popular political theorist rather than that of an academic economist; though clearly his ideas in this field were both influenced by, and had wider implications for, economic thought.

Bias correction is a statistical technique used to remove the bias of an estimator. An unbiased estimator is such that its expectation is equal to the parameter of interest. Many introductory statistics textbooks discuss the desirability of having an unbiased estimator, although it is quickly pointed out that unbiasedness alone cannot be a good criterion for an estimator. This is usually illustrated by comparing two estimators with the use of a concrete loss function, where it is noted that an unbiased estimator with a large variance may be inferior to a biased estimator with a small variance.

Analysis of exact finite sample theory is difficult, or impossible, for many estimators. Therefore, sampling properties of econometric estimators are usually discussed in the context of asymptotic approximation. Many estimators used in econometrics are consistent and asymptotically efficient, so the bias is usually a non-issue in such first-order asymptotic theory. On the other hand, the first-order asymptotic theory may fail to provide a good approximation to the exact finite sample distribution of an estimator, and even an asymptotically unbiased estimator may have a significant bias under small sample sizes. Higher-order asymptotic approximation may then be used to understand the finite sample properties, including the approximate bias. To be more specific, suppose that we use an estimator \( \hat{\theta} \) to estimate the parameter of interest \( \theta_0 \). For many cases, \( \hat{\theta} \) allows a three term stochastic expansion

\[
\sqrt{n}(\hat{\theta} - \theta_0) = \hat{T}_1 + \hat{T}_2 / \sqrt{n} + \hat{T}_3 / n + O_p(n^{-3/2}),
\]
where $n$ is the sample size. The higher-order asymptotic bias of $\hat{\theta}$ is given by $b_0/n$, where

$$b_0 = \lim_{n \to \infty} E[\hat{\theta}^2].$$

In the recent literature, bias correction is usually understood to be a method of removing such approximate bias $b_0/n$. These methods include analytical corrections such as the standard textbook expansion for functions of sample means, and the more complicated formulas required for other estimators. They also include jackknife and bootstrap bias corrections. Correction of approximate bias is usually accompanied by increase of variance, and early literature such as Pfanzagl and Wefelmeyer (1978) focused on the efficiency aspects of bias correction. In general, bias correction cannot be always advocated on efficiency grounds.

Bias correction has received renewed attention in the more recent literature. When there are many nuisance parameters, the parameters of interest are typically estimated with significant biases. The biases are often so severe that removal of such biases almost always results in efficiency gain. Two strands of literature deal with models with many nuisance parameters. First, when a parameter of interest is estimated with many instruments, the resultant estimator may be quite biased. For example, the two-stage least squares estimator (2SLS) tends to be severely biased when there are many first-stage coefficients to be estimated; see for example Bekker (1994). It has been noted that some estimators are not sensitive to the presence of such nuisance parameters, and the instrumental variables literature is focused on developing such robust estimators. For linear simultaneous equations models, the limited information maximum likelihood estimator (LIML) was shown to have very little bias for linear models. For nonlinear models, it was shown that the empirical likelihood (EL) estimator tends to be less biased than the generalized method of moments estimator (GMM) when there are many moment restrictions; see Newey and Smith (2004).

The second strand of literature in which bias correction has played an important role is concerned with panel models. Parameters of interest in panel models are usually estimated with substantial bias when fixed effects are estimated; see Neyman and Scott (1948). The literature examined methods of removing such bias. Hahn and Newey (2004) proposed that the bias be estimated and subtracted from the estimator itself. Arellano (2003) and Woutersen (2002) proposed that the moment equation be modified.

Abstract

This article provides working definitions of biased and unbiased technological change based on the relative responses of the marginal products of capital and labour that occur in the face of economic shocks. These Hicksian definitions are distinguished from others that focus on how technology augments the production function. The bias and augmentation of technical progress are then linked through the substitutability of labour and capital. Examples of ‘labour-biased’ and ‘capital-biased’ technological change from the 19th century to the present illustrate these ideas.

Keywords

biased and unbiased technological change; CES production function; Cobb–Douglas functions; elasticity of substitution; information technology; neutral production functions; skill-bias; technical change

Article

Among the central problems in growth economics is how to organize thinking about technological progress and its role in macroeconomic outcomes. In *The Theory of Wages* (1932), John Hicks offered a set of classifications for technical change that remains in common use. These classifications are based on the observation that inventions are unlikely to increase the marginal products of all factors of production in the same proportion, but rather will affect the marginal products of some factors more than others. Take, for example, the baseline two-factor neoclassical production function:

\[
Y = F(K, L),
\]

(1)
where \( Y \) is aggregate output, \( K \) is the capital stock, and \( L \) is labour. One way to introduce a technology parameter \( A \) is to place it at the front of the production function as

\[
Y = AF(K, L).
\]

(2)

Notice that \( A \) enters linearly, so that a doubling of the technology parameter also doubles output. Technological progress of this type is said to be ‘unbiased’ or ‘Hicks neutral’ in that the ratio of the marginal products of capital and labour used in the production process does not change. In this case, progress simply requires a renumbering of production isoquants. Innovations are rarely neutral, however, and for this reason economists have naturally been more interested in cases where technological change alters the ratio of marginal products. When this occurs, technological change is said to be ‘biased’. Hicks defines the bias as ‘labour-saving’ when the marginal product of capital increases more than that of labour for a given capital-labour ratio, thereby increasing the demand for capital. ‘Capital-saving’ technical progress occurs when the marginal product of labour rises more than that of capital for a given capital–labour ratio, thereby increasing the demand for labour. Nowadays economists simply refer to technological change that is labour-saving in the Hicksian sense as having a ‘capital bias,’ and change that is capital-saving in the Hicksian sense as having a ‘labour bias.’ This avoids confounding the bias of a given technological change with the way that it enters the production function.

An alternative concept proposed by R.F. Harrod (1937; 1948) defines technological change as neutral if the marginal product of capital is unchanged at a given capital–output ratio. Another way of stating this is that, under a constant rate of interest and an infinite supply of capital at that rate, a technological change is ‘Harrod-neutral’ if it leaves the length of the production process unaltered. H. Uzawa (1961) shows that this implies a production function of the form

\[
Y = F(K, AL),
\]

(3)

where \( AL \) is a unit of ‘effective’ labour. Note that this formulation is not neutral in the Hicksian sense unless the production function is Cobb–Douglas. Economists commonly refer to (3) as a ‘labour-augmenting’ production function, but it does not follow that technological change is necessarily labour-biased in the Hicksian sense of relative marginal products.

The opposite symmetric case to Harrod-neutrality defines an invention as neutral if the wage rate remains unchanged at a constant labour-output ratio. This implies a production function of the form
where $AK$ is a unit of ‘effective’ capital. Economists often refer to this ‘capital-augmenting’ form of the production function as ‘Solow-neutral,’ but only because Robert Solow (1959) was first to use this form to model technological progress. Once again, this formulation is not neutral in the Hicksian sense unless the production function is Cobb–Douglas, and changes in $A$ are not necessarily capital-biased in the Hicksian sense. R. Sato and M.J. Beckmann (1968) offer a useful taxonomy of these and other ‘neutral’ production functions.

Of the three output equations shown above, it turns out that only the second (that is, labour-augmenting) form is consistent with a settling down to constant growth under steady technological progress and assumptions of constant returns to scale and diminishing marginal rates of substitution in production. Thus, if we are interested in neoclassical models that move beyond Cobb–Douglas production and possess a steady state, it is useful for technology to multiply labour and make it more effective. Since US wages have risen over the past century while the rental rate has remained relatively steady, the labour-augmenting formulation is at least a priori consistent with the evidence from the United States. To distinguish technological progress that is factor-augmenting from their underlying Hicksian factor-biases, it is necessary to consider the elasticity of substitution between the factors as technical change occurs. Daron Acemoglu (2002) illustrates this with a CES (that is, constant elasticity of substitution) production function of the form

$$Y = F(AK, L),$$

(4)

where $\sigma$ is the elasticity of substitution between capital and labour, $A_L$ and $A_K$ are factor-specific technology parameters, and $w$ is a weight ($0 \leq w \leq 1$) that measures the relative importance of each factor. The factors are gross substitutes when $\sigma > 1$, whereas they are gross complements when $\sigma < 1$. With $\sigma > 1$, substitutability between factors allows both the augmentation and bias of technological change to lean towards the same factor. In the case where $\sigma < 1$, however, a capital-augmenting technological change (or a rise in $A_K$) actually increases demand for the complementary input (that is, labour) more than it increases the demand for capital. The excess demand for labour raises its marginal product more than that of capital, leading to a labour bias in production. Similarly, a labour-augmenting technological change (or a rise in $A_L$) leads to a capital-bias when $\sigma < 1$. When $\sigma = 1$ the production function is Cobb–Douglas and an increase in $A$ does not produce a bias towards either factor.

Hicks and A.C. Pigou (1920) have contended that most technological change is capital biased, and the American experience in the latter half of the 19th century would seem to support this view. Innovations such as the Bessemer process of steelmaking, new distillation methods in petroleum refining, and the
adoption of European reduction methods in flour milling, as noted by John James (1983), led to capital
depening and economies of scale in these industries that increased concentration. Such technological
changes seem so important that the rise of big business around the turn of the 20th century is sometimes
attributed to them. Though this view probably overstresses the role of technology in the evolution of
industrial structure over this period, it is interesting that the capital bias observed in industries for which
the story fits were a result of labour augmentation (that is, a rise in $A_L$) and inelastic factor substitution
(that is, $\sigma < 1$).

Electrification offers another example. Prior to its arrival, manufacturing had been designed around the
rigidities of steel shafts that ran through the length of a factory and were turned in unison by a single
water or steam-powered generator. Afterwards, as Warren Devine (1983) describes, the organization of
work gradually evolved to exploit the open factory structure that electric unit drive made possible. Unit
drive meant less time spent maintaining complex systems of leather straps and pulleys that transferred
power from the rotating steel shafts to the machines, and less down time caused by the need to stop all
production to repair a single machine. Electrification and unit drive also made it economical for factories
to stay open longer. These innovations made labour more productive (that is, raising $A_L$), but more
focused machinery also reduced the amount of labour that was needed to operate a factory ($\sigma < 1$),
raising the marginal product of capital more quickly than that of labour and producing a capital bias. The
bias leaned even more towards capital as the diffusion of electricity began to mature, and labour-saving
innovations such as vacuum cleaners, toasters, and electric blast furnaces became commonplace.

But is the apparent capital-bias in technological change largely ‘induced’ by changes in factor prices?
Charles Kennedy (1964) points out that falling capital prices will motivate individuals to build more
inventions that economize on labour than they would build at constant factor prices. Since the prices of
capital goods have declined fairly consistently for more than a century and a half, it seems natural that
the vast majority of induced inventions would have been capital biased. At the same time, it is important
to distinguish biased technological progress (that is, an outward movement and shift along an isoquant)
from movements along a fixed isoquant that arise from changes in factor prices, since such changes do
not represent technological progress at all. Noting these potential biases, Hicks concludes that
‘autonomous’ inventions, meaning those not prompted by decline of a relative factor price, need not be
predominantly capital biased. Indeed, information technology (IT) presents an example where the bias
may have moved in the opposite direction.

Computers reduced expenditures on specialized and/or mechanical office machines, thereby making
capital more productive (that is, raising $A_K$). At the same time, labour also became more productive as
skilled individuals learned how to use computers to perform complex tasks and less-skilled individuals
accomplished routine tasks much more quickly (that is, raising $A_L$). Thus, there seem to be
complementarities between IT and skilled workers, raising the return to skill and producing a ‘skill bias’,
while there has been some substitution of computers for less skilled individuals, pressing towards a
capital bias. On the whole, however, the complementarity effects so far have outweighed substitution
effects, leading to a labour bias. As an invention in the method of inventing, IT has also led to a wide
range of induced innovations, both capital- and labour-saving. Design tools used by engineers, for
example, have improved the quality of capital goods and allowed more new products to be created. The
availability of a broad base of knowledge on the World Wide Web from all over the globe has also
transmitted the information needed to make labour more productive.
Is IT typical of the type of technological change that is likely to continue, starting with a labour bias but spawning new innovations that are for the most part labour-saving? If so, parsing out the components of labour bias, and particularly understanding the role of skill bias in the post-war US economy, seems at the core of understanding the role that technology will play in 21st century economic growth.

Bibliography

Bickerdike was born in England (whereabouts unknown) on 15 May 1876 and died in Wallington, Surrey, on 3 February 1961. He studied at Oxford from 1895 to 1899 where he received his BA degree in 1899 and MA in 1910. Upon winning the Cobden Prize for an essay summarized in Bickerdike (1902) he became a protégé of Edgeworth. After serving briefly as Lecturer on Economics and Commerce at the University of Manchester (1910–12) he entered the civil service with a position in the Board of Trade, where he remained until his retirement in 1941.

Bickerdike's published work consists of 15 articles and 38 book reviews, all (save two of the articles) in the *Economic Journal*. He is chiefly known as the originator of the theory of incipient and optimal tariffs (1906; 1907), according to which a country can always gain by imposing a sufficiently small tariff on its imports and can maximize its welfare by imposing a suitable tariff. To derive these results he developed a model (1907) in which nominal import and export prices were expressed as functions of the quantities of imports and exports respectively (with no cross-effects), each country being assumed to stabilize the value of its currency. The elasticities of demand for imports and supply of exports were defined as the reciprocals of the elasticities of these functions (with opposite sign). This has come to be known as the 'elasticity approach'. (For an interpretation of these demand and supply prices as prices relative to the price – assumed stabilized – of a non-tradable in a general-equilibrium model, see Chipman, 1978.)

Bickerdike derived formulas for the effect on national 'advantage' of a small tariff (p. 100n) and for the optimal tariff (p. 101n), and remarked – anticipating Lerner (1936) – that identical expressions would be obtained for an export tax. He noted that the optimal tariff depended only on the foreign elasticities...
also Kahn, 1947); this apparent paradox was explained by Graaff (1949, p. 56). The now-familiar, simpler and more general optimal-tariff formula expressed in terms of Marshallian elasticity was first introduced by Johnson (1950), who showed its relation to Bickerdike's formula. Edgeworth (1908, p. 544) showed that the positive sign of the denominator of Bickerdike's expression for the advantage from an incipient tariff followed from dynamic stability. A related stability condition was later derived by Bickerdike (1920) for the analysis of a regime of fluctuating exchange rates, and was obtained as a condition for a transfer to lower the paying country's exchange rate. Equivalent formulas were subsequently adopted by Robinson (1937, p. 194n) and Metzler (1948), and – for the special case indicated by Bickerdike of infinite elasticities of supply of exports – by Lerner (1944, p. 378).

Bickerdike's other contributions include two essays on local public finance (1902, 1912), a paper (1911) correcting a statement of Edgeworth's that price discrimination could improve upon competitive pricing, and papers on a number of other topics, the most noteworthy relating to business cycles and economic growth.

Although preceded by Carver (1903), Aftalion (1909, pp. 219–20) and Pigou (1912, pp. 144–5), Bickerdike (1914) may be considered one of the original developers of the acceleration principle (cf. Hansen, 1927, p. 112; Haberler, 1937, p. 87), providing a detailed numerical example and emphasizing (in contrast to Aftalion) the importance of durability of capital rather than the gestation period.

Bickerdike regarded the phenomenon as an example of market failure. The paper was cited by Frisch (1931) – who erroneously attributed it to J.M. Clark – in the course of his criticism of Clark (1923) and reformulation according to which a deceleration of consumption will call forth a fall in gross investment only if it exceeds the rate of depreciation of capital. Bickerdike (1924; 1925) went on to develop an interesting mathematical model of economic growth according to which labour – the only factor – grows at a constant rate and produces only capital goods – of various durabilities and with various gestation periods – the services of which are consumed. On a path of balanced growth, the rate of interest is equal to the rate of growth, and interest is reinvested. The money supply grows at the same rate in order to maintain constant prices – or else it is constant and prices fall at a constant rate. Bickerdike's main object was to determine whether the process of saving benefited non-savers; in this he was not entirely successful, since his techniques limited him to balanced-growth paths. Nevertheless this work foreshadowed that of Lerner (1944, ch. 20) as well as many features of contemporary growth models, and attracted the attention of Hansen (1927, pp. 173ff).

Information on Bickerdike's life and work may be found in Jha (1963) and in Larson (1983; 1987), where other relevant literature is also cited. According to Larson, after Bickerdike's death his papers, including some 50 letters from Edgeworth and 20 from Edwin Cannan, passed into the hands of one Godfrey Alan Dick who died in Oxford in 1981. They are presumed lost.

A bimetallic monetary standard is a combination of two metallic standards, each of which could in principle stand alone. Bimetallism has advantages over monometallism; but can be an unstable system, with legal bimetallism becoming de facto monometallism. The Persian and Roman Empires practised bimetallism. England's de facto bimetallism was short-lived, and US bimetallism difficult to maintain. French bimetallism in 1815–73 stabilized the gold–silver market price ratio and also exchange rates among gold, silver, and bimetallic countries. Bimetallism ended in the 1870s.

Article

A bimetallic monetary standard is a combination of two metallic standards, each of which could in principle stand alone, and often evolved into de facto monometallism.

The nature of bimetallism

Bimetallic metals are usually gold and silver, but there are exceptions. Ancient Rome was temporarily on a silver-bronze standard; in the 18th century Sweden and Russia experienced a silver–copper standard.

Under bimetallism, both gold and silver coins are full legal tender. The unit of account (dollar, franc, and so on) is defined in terms of a fixed weight both of pure gold and of pure silver. So there is a fixed legal (mint, coinage) gold–silver price ratio: number of grains or ounces of silver per grain or ounce of
Bimetallism has four advantages. First, it embodies two sets of coins – one from a metal with a high value–weight ratio (gold), the other from a metal with a low ratio (silver). These provide a medium of exchange for a wide range of economic transactions. The range can be extended in both directions: upper, via paper currency and deposits; lower, via token subsidiary coins. Neither is incompatible with a bimetallic standard. Second, as does a monometallic standard, the bimetallic standard provides a constraint on the money supply and therefore inflation; for the legal-tender coins constitute the monetary base (given government-issued legal-tender paper, perhaps the ‘super monetary base’), and the government must acquire one or the other metal to increase the base. Because there is coinage on demand, there is also a check on reduction to the monetary base, and on deflation. Third, a bimetallic country or bloc of countries accommodates shocks so that resulting effects on monometallic countries’ money supplies are dampened. This is done by stabilizing the gold–silver price ratio (‘market ratio’) on the world market, the bullion market, where non-monetary gold and silver (generally bars) are traded either among themselves or individually for some important currency. Fourth, in stabilizing the market gold–silver price ratio, the bimetallic country or bloc also stabilizes the exchange rates between ‘gold currencies’ and ‘silver currencies’. Otherwise, these exchange rates would fluctuate, defeating one of the usual purposes of metallic standards.

The alleged disadvantage of bimetallism (relative to monometallism) is that it is unstable. Suppose the bimetallic-country’s mint ratio initially is in the neighbourhood of the market ratio. A shock in the world supply of one metal can change the market ratio so that the mint ratio is now outside its neighbourhood. If the resulting market ratio is above (below) the mint ratio, then silver (gold) is ‘bad’ money, overvalued at the mint; domestic payments will tend to be made in that, relatively cheaper, coin rather than gold (silver), the ‘good’ money, undervalued at the mint and relatively expensive in the market. Good money will tend to be exported to settle balance-of-payments surpluses, bad money imported to finance balance-of-payments deficits. If the divergence between the market and mint ratio is large, ‘bimetallic arbitrage’ occurs, whereby good money is melted and traded on the bullion market for the bad metal, and the bad metal imported to be coined. In both situations, Gresham's law is operative: bad money drives out good.
Given sustained payments imbalances and/or a large and persistent divergence between the market and mint ratio, bad-money monometallism results. (The good money may be eliminated from the money supply, or circulate at a market-determined value – available only at a premium.) To avoid this, the mint ratio could be altered to remain in conformity with the market ratio. If the mint ratio is under-corrected, monometallism is not stemmed; if the mint ratio is over-corrected, monometallism in the opposite metal can occur. Successive changes in the market ratio can lead to alternating effective gold monometallism and silver monometallism, under the rubric of legal bimetallism. There are costs to such an alternating monetary standard; there are also costs in periodically altering the mint ratio.

Theories of bimetallic stabilization

Stabilizing bimetallic arbitrage occurs as follows. Suppose a shock occurs, new gold discoveries, that decrease the market ratio: the market price of non-monetary gold falls relative to silver. The market ratio now is below the mint ratio, so gold is ‘bad’ (overvalued) and silver ‘good’ (undervalued) money. Silver leaves the monetary system to be sold in the world (bullion) market, with gold purchased with the proceeds and coined. First, the arbitrageurs make a profit: the value of the gold coins they obtain is greater than the value of the silver coins they initially sold. Second, there is increased supply of silver (the appreciated metal) and increased demand for gold (the depreciated metal) in the bullion market – the two transactions constituting one arbitrage transaction. The result is an increase in the market ratio, which rises toward the mint ratio. Thus, the incentive for the arbitrage is eliminated. Third, the composition of the money supply of the bimetallic country changed, with a higher proportion of gold to silver. The bimetallic country stabilized the market ratio (and incidentally the exchange rates between gold and silver currencies), via the endogenous gold–silver composition of its money supply. This mechanism is effective only to the extent that the bimetallic country has sufficient stock of the undervalued metal to return the market ratio close to the mint ratio, so that the incentive to arbitrage vanishes before monometallism in the overvalued metal results. However, the situation is not so dire, because costs of arbitrage imply ‘gold–silver price–ratio’ points that define a band for the market ratio within which the ratio can fluctuate without triggering bimetallic arbitrage. If the bimetallic-country’s commitment to its mint ratio is absolutely credible, then stabilizing speculation exists within the bimetallic-arbitrage band, such that the market ratio turns away from its nearest bound and towards the mint ratio. The situation is analogous to stabilizing speculation within gold-point spreads, under the international gold standard.

Two other forces making for bimetallic stability have been suggested by Marc Flandreau. The first is ‘metal-specific arbitrage’ between the bullion and monetary markets. If a metal depreciates on the bullion market by more than coinage and associated costs, then owners of bars in that metal will coin them in lieu of supplying them to the bullion market. If a metal appreciates by more than melting and associated costs of bringing that coined metal to the market, then holders of coin of that metal will melt them and supply them to the market. The reduced supply of the depreciated metal and increased supply of the appreciated metal act to return the market ratio towards the mint ratio. Unlike bimetallic arbitrage, these are independent transactions. Therefore the costs of metal-specific arbitrage are below the costs of bimetallic arbitrage, and the former provide a ‘metal-specific band’ located within the ‘bimetallic arbitrage band.’ So metal-specific arbitrage is a stabilizing mechanism that becomes operative before bimetallic arbitrage.
The second force involves the bimetallic country (France) transacting with a gold-currency country (England) and a silver-currency country (Germany). There are franc–sterling gold points, and franc–mark silver points. Expressing exchange rates as percentage deviations from parity and specie points in percentage terms, the franc/sterling– franc/mark exchange-rate differential (via triangular arbitrage) proxies the mark/sterling exchange rate. Also, implicit mark–sterling parity (via franc bilateral parities) corresponds to the mint ratio. On the assumption of no bilateral specie-point violations, the mark–sterling exchange rate has as upper (lower) bound the sum (negative sum) of the franc–sterling export (import) point and the franc–mark import (export) point. Now, the mark–sterling exchange rate is itself a good representation of the gold–silver market price ratio, because the Bank of England (Bank of Hamburg) supports, within a narrow band, a fixed sterling (mark) price of gold (silver). For the market ratio above the mint ratio (parity), so that silver is overvalued, the upper bound correctly involves exporting gold (sterling) and importing silver (marks). The gold–silver market price ratio has a bimetallic-arbitrage band that is approximately double the width of the franc–sterling and franc–mark bilateral specie-point spreads. Hence specie flows to settle and adjust payments imbalances occur prior to bimetallic arbitrage.

Suppose that a bimetallic country has lost all its undervalued ('good') metal, so it has become monometallic in its overvalued coinage. Nevertheless, Oppers (2000) shows that a bimetallic-arbitrage band could exist, given that there is a second bimetallic country with a different mint ratio. The two countries’ mint ratios each constitute a bound to the market ratio, with, as usual, a market ratio beyond a bound giving rise to arbitrage that returns the market ratio to the band. For this mechanism to operate, both countries must actually or potentially have large amounts of both coined metals in their money stock, where ‘large’ means relative to shocks in the bullion market.

**Bimetallism prior to the 19th century**

The Persian Empire had the first bimetallic standard, with a mint ratio of $\frac{13}{2}$ to 1 (all known mint ratios are in favour of gold) for a long time. This ratio undervalued silver relative to the ratio elsewhere, and presumably merchants took advantage of the price-ratio discrepancies in their regular dealings. The Roman Empire was often gold–silver bimetallic, but periodically debased the coinage. The likely reason was to increase seigniorage rather than to realign the mint ratio in conformity with the market ratio or the mint ratio in other lands. Until the mid-19th century, bimetallism was the legal standard in Europe (including England), though the mint ratio was often altered. Traditionally, the gold–silver price ratio was lower in China and India than in Europe. England was legally on a bimetallic standard from the mid-13th century, when gold was first coined. The mint ratio was often changed. England was effectively on a silver standard until late in the 17th century, because the British mint ratio was generally below European gold–silver price ratios. Gold coins passed at a market price (in terms of the silver shilling) rather than face value, again indicative of a silver standard. In 1663 the (gold) guinea was coined, with a legal value of 20 (silver) shillings. The silver coins in circulation were in horrible condition, due in part to past debasement, in part to private clipping and sweating of the coins. So the market price of the guinea increased above 20 shillings – to as much as 30 shillings – implying a gold–silver price ratio that effectively overvalued gold relative to Continental ratios. England was in process of switching from an effective silver to an effective gold...
bimetallism: The New Palgrave Dictionary of Economics

standard. In 1696 silver was recoined, so the coins became full-bodied again, and a ceiling (periodically reduced) was placed on the market price of the guinea. The result was that, for a brief period at the turn of the 18th century, England had effective bimetallism, with full-bodied coins of both metals in circulation. However, gold continued to be overvalued and silver undervalued; silver was exported, gold imported; and a de facto gold standard resulted. It became a de jure standard, via legislations restricting the legal-tender power of silver (1774) and effectively ending free coinage of silver (1816).

The Coinage Act of 1792 placed the United States on a legal bimetallic standard. The mint ratio (15 to 1) – selected because it was approximately the market ratio at the time – turned out to overvalue silver, because the market ratio increased. By 1823 gold had virtually gone from circulation, and an effective silver standard resulted. In 1834 Congress increased the ratio to 16.0022 (in 1837, revised slightly, to 15.9884). From 1834 to 1873, the world gold–silver price ratio was consistently below 16, so the new ratio overvalued gold, and an effective gold standard resulted. However, the export of full-bodied Mexican (silver) dollars and US subsidiary silver protected the circulation of underweight foreign silver pieces, which circulated at face value; so in a sense effective bimetallism continued. Only in the early 1850s, when the market gold–silver price ratio fell (due to gold discoveries and new production), did the United States begin to lose its remaining silver coins. In 1853, to retain the silver, Congress reduced subsidiary coins (below a dollar) to token status, with limited legal-tender power. The United States now was on a de facto gold standard. Legal bimetallism remained until 1873, when coinage of the silver dollar was terminated. One year later, silver was virtually demonetized; all silver coins (including the dollar) were restricted to maximum legal tender of five dollars in any payment.

Bimetallic France in the 19th century

In 1803 France made the franc the monetary unit, and solidified and made effective the mint ratio of $15 \frac{1}{2}$ that had been established in 1785. From the end of the Napoleonic Wars until 1873, while France retained that bimetallism, the market gold–silver price ratio remained in the neighbourhood of $15 \frac{1}{2}$. (Also, exchange rates among gold, silver, and bimetallic countries were stable.) The stability of the market ratio was remarkable in the face of severe shocks to the bullion market. In the 1850s gold production increased tremendously due to gold discoveries in California and Australia, putting strong downward pressure on the market price ratio. In the 1860s gold production stopped increasing, and exploitation of Nevada silver discoveries put strong upward pressure on the ratio. The steady market gold–silver price ratio was due primarily to the continued bimetallism of France, which acted as a buffer to shocks and thus stabilized the gold–silver market price ratio. What gave France this power were its large economic size, the substantial amounts of both gold and silver coins in its circulation, and its credible commitment to bimetallism at an unchanged mint ratio. Therefore, French bimetallic arbitrage operated – in the 1850s and early 1860s via gold imported and coined and silver melted and exported, in the later 1860s via the opposite activities. Stabilizing speculation within the bimetallic-arbitrage band, stabilizing bilateral specie flows, and metal-specific arbitrage were also elements in the French stabilization service. In 1865 the French stabilizing force was enhanced by formation of the Latin Monetary Union (LMU), in which France, Belgium, Switzerland, and Italy adopted a common bimetallism.
Some scholars, especially Oppers (1995; 2000), believe, rather, that France underwent serial monometallism, with bimetallism transformed to a de facto silver standard in the 1830s and 1840s, and the latter yielding to a de facto gold standard in the 1860s. Yet a parity band (with stabilizing speculation within the band) existed, with the French mint ratio the lower bound and the US mint ratio the upper bound in 1834–61, followed subsequently by the French ratio the upper bound and the Russian ratio the lower bound. This interpretation of history is doubtful, for the strong propensity to use both metallic currencies was characteristic only of France. Also, Russia's mint ratio was inoperative at the time, as the country had an inconvertible paper currency.

In the early 1860s the future LMU countries, if not on a de facto gold standard, were certainly moving towards it. With the market ratio below the mint ratio, silver was being lost. To protect silver circulation, the individual countries made subsidiary coins token currency; while in 1866 the LMU came into effect, mandating reduction of the silver content and restriction of the legal-tender power of all silver coins except the largest, that is, the five-franc piece, which remained full-bodied.

French, LMU, and world bimetallism ended in the 1870s. The proximate cause was Germany's move to a gold standard, financed by the French indemnity that resulted from the Franco–Prussian War. Germany's release of silver put upward pressure on the gold–silver market price ratio. France was not prepared to accept the gold loss and silver inflow that would result from continued adherence to bimetallism. France (and Belgium) limited silver coinage in 1873, followed by the LMU mandating limits on coinage of the five-franc silver piece in 1874–6. In 1878 coinage of that piece was terminated. The existing five-franc coins retained full legal-tender power. France, along with Belgium and Switzerland, went on a ‘limping’ gold standard, redeeming government-issued paper money in either gold or silver at the discretion of the authority.

Black, Duncan (1908–1991)

Bernard Grofman

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Black, D.; Borda, J.-C. de; Carroll, Lewis; Condorcet, Marquis de; game theory; majority rule; median voter; public choice; single-peaked preferences; spatial voting game; voting paradoxes

Article

Born on 23 May 1908 in Motherwell, Scotland, Black studied at the University of Glasgow, where he received an MA (Mathematics and Physics) in 1929, an MA (Economics and Politics) in 1932, and a Ph. D. (Economics) in 1937. He also served there as Senior Lecturer in Social Economics, 1946–52. The bulk of his teaching career was at the University College of North Wales, Bangor: Lecturer in Economics, 1934–45; Professor of Economics, 1952–68; and Professor Emeritus 1968 onwards. Black's very early research was in public finance, of which the major work is Black (1939). It is, however, his work in the 1940s and early 1950s (notably Black, 1948a; 1948b; 1948c; 1949; 1950, and Black and Newing, 1951), work which was integrated and expanded in Black (1958), which is the basis for his status as a father of the modern theory of public choice.

More than two centuries ago Condorcet (1785) demonstrated that majority rule need not yield a stable outcome when there are more than two alternatives to be considered. Although periodically rediscovered or reinvented by succeeding generations of scholars, the ‘paradox of cyclical majorities’ was, for all practical purposes, unknown to modern students of democratic theory until called to their attention by Duncan Black (see especially Black, 1948a; 1958). Black demonstrated that the ‘paradox’ was not just a mathematical curiosity but rather was connected to important political issues such as manipulability of voting schemes (1958, p. 44; see also 1948a, p. 29) and the absence of strong similarity of citizen preference structures (Black, 1958, pp. 10–14).

Although Black was not the first to discover this phenomenon, his work is the foundation of all subsequent research on the problem. The investigations in this field of his principal predecessors, Condorcet and Lewis Carroll, had made no impact on the intellectual community of their day and had been completely forgotten. Their work is known today
only because Black, after discovering the phenomenon himself, discovered his predecessors. (Campbell and Tullock, 1965, p. 853)

Duncan Black's vision in the 1940s was a grand yet simple one: to develop a pure science of politics as a ramified theory of committees, so as to place political science on the same kind of theoretical footing as economics, with voters substituting for consumers. Because many of the basic ideas in his 1958 classic, *The Theory of Committees and Elections*, appear so ‘obvious’ in retrospect that it is hard to believe that they have not always been part of the stock of general human knowledge, and because this work understates by its silence the magnitude of Black's originality, the magnitude of Black's own contributions is often underappreciated. Black's great strength is that he has served as both synthesizer and pioneer. He rediscovered and reinterpreted for contemporary social science the strikingly modern probabilistic and game theoretic insights of long-dead theorists such as Dodgson (Lewis Carroll), Borda and Condorcet (for example, the paradox of cyclical majorities, the Condorcet criterion, the Borda criterion, optimizing strategies under the limited vote, results on manipulability of voting schemes, the Condorcet jury theorem); while himself developing such seminal ideas as single-peakedness, the importance of the median voter given ordinal preferences, and the notion of equilibrium in a spatial voting game (Black and Newing, 1951; Black, 1958; 1967; 1969; 1976). Black's work on Lewis Carroll (McLean, McMillan and Munroe, 1996) emphasizes Carroll's contributions to logic and the importance of his work on representation (under his real identity, that of the mathematician C.L. Dodgson) as a precursor to the modern theory of games and economic behaviour.

Underpinning virtually all of Black's work was the deceptively simple insight of modelling political phenomena in terms of the preferences of a given set of individuals in relation to a given set of motions, the same motions appearing on the preference schedule of each individual, where motions can be represented as points on a real line or in an N-dimensional space. Black's work on what (after him) has come to be called ‘the theory of committees and elections’ has been ‘one of the pillars on which rests the contemporary theory of public choice’ (Grofman, 1981).

Fischer Black is best known for the Black–Scholes option pricing formula, which he regarded as an application of the capital asset pricing model (CAPM). He understood the CAPM as a model of general economic equilibrium and extended it from finance to macroeconomics, including the theory of money and the theory of business cycles. His work reveals that finance was the origin of the dramatic changes in macroeconomic thinking in the last quarter of the 20th century.

Article
Fischer Black is best known for the eponymous Black–Scholes option pricing formula that laid the foundations for so much of modern finance (Black and Scholes, 1973), a contribution that was recognized posthumously in the citation for the 1997 Nobel Prize in Economics that was awarded to Robert C. Merton and Myron Scholes. Today, the best known derivation of the famous formula follows the no-arbitrage argument laid out in Merton (1973), but Black approached the problem as simply an application of the capital asset pricing model (CAPM) developed by Sharpe (1964), Lintner (1965), and especially Jack Treynor (1962), whose version of CAPM was Black's first introduction to finance. Indeed, it is no exaggeration to say that not just the options formula but also everything Black ever wrote has its roots in CAPM, which Black always understood quite broadly as a model of general economic equilibrium, not just a model of how to price risky capital assets (Black, 1972b). Born 11 January 1938, Fischer Black grew up in Bronxville, New York, before attending both college...
and graduated school at Harvard University. After earning his Ph.D. in applied mathematics in 1964 for a thesis in the new area of artificial intelligence, Black took his first job as an analyst in the operations research section of the consulting firm Arthur D. Little, Inc. That's where he met Treynor and learned CAPM. Although he never took even a single course in either economics or finance, Black subsequently built a career as a financial consultant, a research professor (University of Chicago 1971–5, Massachusetts Institute of Technology 1975–83), and then a partner in the Wall Street investment firm Goldman Sachs (1984–95). He died prematurely on 30 August 1995, shortly after the publication of *Exploring General Equilibrium*, the book he considered to be his magnum opus.

Straddling the worlds of academia and business, Black developed his ideas by using practical problems in business as the stimulus for his abstract theorizing. The accessible early paper with Treynor, ‘How to use security analysis to improve portfolio selection’ (Treynor and Black, 1973) set the agenda that would occupy Black and the generation of financial engineers that grew up after him, namely, to find practical applications of the new academic theories of finance. Just so, Black's early work with Myron Scholes for the Wells Fargo Bank sought to develop a new ‘passive’ portfolio strategy from the implications of CAPM, a kind of leveraged index fund that anticipated the later development of portfolio insurance (Black and Scholes, 1974; Black, 1988a; Black and Perold, 1992). Similarly, his paper on ‘Bank funds management in an efficient market’ (1975) anticipated the eventual consequences of bank deregulation, and his paper ‘Toward a fully automated stock exchange’ (1971) anticipated the eventual consequences of computerized trading.

All of this was about remaking the world in the image of CAPM, an image that kept expanding in Black's mind as he worked to extend CAPM to a world without any riskless asset in his famous zero-beta model (1972a), to a world with long-term debt in the famous BDT term structure model (Black, Derman and Toy, 1990; Black, 1995b), and to an international environment in his controversial universal hedging model (1974; 1990) that formed the analytical core of the Black–Litterman model of global asset allocation (Black and Litterman 1991; 1992).

The irony is that the world of the original CAPM is a world of debt and equity only, no options at all. That explains why Black was not sure that the opening in April 1973 of the Chicago Board Options Exchange was a good thing, even though it provided an immediate application for the Black–Scholes formula. Similarly, Black's extension of the options analysis to the problem of pricing commodity futures (1976), although immediately useful in the currency futures markets that sprang up after the collapse of the Bretton Woods fixed exchange rate system, left him unsure whether he was helping to move the world toward CAPM or away from it. From this point of view, his work on pension fund investment policy, the theory of business accounting, and a practical method of capital budgeting more clearly contributed to the creation of a CAPM world (1980b; 1980a, 1993; 1988b).

Only after leaving academia for Goldman Sachs did Black come to fully appreciate the positive contribution of options and other derivatives to the brave new world of finance. The turning point was the theory of noise trading that he revealed for the first time in his presidential address to the American Finance Association (1986). Noise traders are people who trade, knowingly or not, without any information advantage. Earlier in his career, Black had assumed that such traders would eventually be driven out as markets become more and more efficient, but he changed his mind once he realized that ‘Noise trading actually puts noise into prices’. As a consequence, ‘we might define an efficient market as one in which price is within a factor of 2 of value; i.e. the price is more than half of value and less than twice value’ (1986, 532–3). Because of noise trading, psychology matters for asset pricing, and it is
in options prices that this effect can most clearly be seen; it shows up in the Black–Scholes formula as volatility.

Black's intellectual strategy to understand the world through the equilibrium lens of CAPM, as properly extended, was not confined to finance. He also used CAPM to lay the foundations of an alternative equilibrium understanding of macroeconomics, including the theory of money and the theory of business cycles, and he always considered this work at least as important as his work in finance. In this respect, his very first published paper, ‘Banking and interest rates in a world without money: the effects of uncontrolled banking’ (1970), set the agenda that would occupy him for the rest of his life. His two subsequent books Business Cycles and Equilibrium (1987) and Exploring General Equilibrium (1995a) had little impact on economics at the time they were published. In retrospect, however, they can be seen to have anticipated themes that eventually did enter economics, through the new classical revolution of Robert Lucas and his associates and the real business cycle revolution of Edward Prescott and his associates. More than anyone else, Fischer Black demonstrated that we must look to finance to discover the origin of the dramatic changes in macroeconomic thinking in the last quarter of the 20th century (Mehrling, 2005).

black–white labour market inequality in the United States

Derek Neal
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

During much of the 20th century, each successive generation of black Americans came closer to its white counterparts in terms of educational achievement and labour market success. This pattern of black–white progress has stalled since the mid-1980s. This chapter documents the current levels of black-white inequality in terms of human capital and labour market outcomes and then discusses factors that may sustain and perpetuate current levels of black–white inequality. It is much easier to understand the record of black–white progress during earlier decades than to understand the lack of progress in recent years.

Article

Gunnar Myrdal won a Nobel Prize in economics in large measure for path-breaking work that documented the magnitude and scope of black–white inequality in the United States prior to the Second World War. Blending social science with social commentary, Myrdal argued that the contrast between American ideals and the existing legal and social institutions that oppressed blacks created An American Dilemma (1944) that was moral and social as well as economic.

A record of progress
In subsequent decades, blacks have made much relative economic progress in the United States, but the pace of this progress has not been steady. For example, during the 1940s, 1960s, and 1970s the earnings of black men rose rapidly relative to those of white men, but this did not occur during the 1950s, 1980s, or 1990s. In fact, in recent decades the pace of relative economic progress for blacks has slowed and may be on the verge of stalling completely.

Table 1 presents data on the black–white earnings gap. The data come from the 1940–2000 decennial census files. Inconsistencies in the survey instrument as well as data-quality problems in some years make it difficult to create a consistent measure of hourly wages across census years. Here, I present data on annual labour earnings for workers who report working at least 48 weeks in the previous calendar year. For each year, numbers are given, separately for men and women, of the black–white ratio of average earnings and of the average percentile rank that black workers would have occupied in the white earnings distribution. I restrict the samples to ages 26–46 to minimize the number of lost of observations due to schooling or early retirement.

Black–white ratio of average annual earnings and average black percentile in the white earnings distribution

Note: Data are from the Integrated Public Use Microdata Series (IPUMS) decennial census 1940–2000. The sample includes individuals between the ages of 26 and 45 who report positive wage and salary income and working at least 48 weeks in the previous calendar year. Sample weights ‘slwt’ are used for 1940 and 1950 and ‘perwt’ for 2000.

The results in Table 1 echo a common theme in the literature on black–white inequality. The 1960s and 1970s were decades when blacks made exceptional labour-market gains relative to whites both in terms of their position in the distribution of earnings and in terms of earnings levels. A significant literature debates whether government action during and after the civil rights era was a catalyst for black progress during the 1960s and into the 1970s. Smith and Welch (1989) and others emphasize the role of long-term improvements in the quality of black education as sources of black economic progress during the 20th century (see Card and Kruger, 1992; 1996). While not disputing the importance of relative improvements in black education, Donohue and Heckman (1991) build a compelling case that federal government intervention did play a significant role in black progress during the civil rights era. They stress that black relative earnings rose significantly during the 1960s and 1970s within cohorts who were already adults at the beginning of these decades. They also note that black relative earnings rose
during the 1960s primarily because of gains in the South, where civil rights laws were imposed on local communities by the federal government. Finally, they note that the decades-long wave of massive net black migration from the South to northern cities came almost to a complete stop around 1965. This one fact is strong prima facie evidence that the Civil Rights Act of 1964 did improve economic opportunity for blacks in the South.

Progress stalled

The results in Table 1 also indicate that black economic progress since 1980 has been mixed at best. The male black–white earnings ratio fell slightly between 1980 and 2000, but black men did enjoy modest improvements in their relative position in the male earnings distribution over the 1980s and 1990s. (A dramatic increase in earnings dispersion over the period accounts for the different trends in these two measures of black–white earnings inequality among men.) Black women actually lost ground relative to white women according to both relative earnings measures over the 1980–2000 period. However, it is not clear that black men fared better than black women relative to their white peers over this period. Neal (2004) points out that, even though black and white women have had similar labour force participation rates for several decades, racial differences in patterns of selection suggest that measured black–white earnings and wage gaps among women understate actual gaps in earnings opportunities. This bias arises because white women who do not work are more likely to be well-educated and married to a working spouse while black women who do not work are more likely to be single, less educated mothers receiving means-tested public assistance. The importance of this bias may have diminished since 1980 as government assistance to single mothers has decreased and the number of married career women has increased.

Further, the results in Table 1 are likely to overstate how well black men have fared relative to white men since 1980. Table 2 presents employment rates and institutionalization rates for black and white men by age group and year of birth. Each diagonal row presents results from a particular census year, that is, 1980, 1990 or 2000. The employment rates refer to the past calendar year, and the institutionalization rates refer to the census date. Table 2 shows that the fraction of men who worked during the past calendar year has declined among both blacks and whites in recent decades (see Chandra, 2000, for more details on patterns of male labour force participation by race). However, the rate of decline is much more dramatic among black men. By 2000, roughly 30 per cent of prime-age black men did not report any market work in the previous year. Further, in all age groups the relative decline in black employment rates is more than five percentage points. Thus, while Table 1 shows that black male workers continued to improve their position in the earnings distribution relative to working white men during the 1980–2000 period, it is not certain that black men continued to make relative gains in the distribution of potential earnings.

Notes: Data for this table are from the decennial census IPUMS 1980–2000. The table displays the fraction of males who worked last year and fraction of males institutionalized. In order to be counted as working in the previous calendar year, a respondent must have (a) an affirmative, non-allocated response to the question ‘Did this person work …[during the previous calendar year]?’ or (b) positive, non-allocated weeks worked or (c) positive non-allocated earned income or (d) positive, allocated weeks worked and a non-allocated indication of working since 1 January of the census year in question. Sample weights ‘perwt’ are used for 2000.

The most certain inference that one can draw from Table 2 is that the population of institutionalized black men has grown dramatically since 1980. In addition, since most institutionalized young adult men are incarcerated, Table 2 suggests that roughly one in ten black men aged 26–35 was housed in some type of prison or jail when the 2000 census was taken. (Neal, 2006, shows that this rate is much higher among less-educated black men and dramatically lower among black college graduates.) Taken as a whole, Tables 1 and 2 suggest that black economic progress relative to whites has been anaemic at best since 1980.

Neal (2006) points out that, around 1990, black–white gaps in both educational attainment and achievement stopped closing among young adults and youth respectively. Thus, roughly since the mid-1980s, black youth and young adults have either barely kept pace or fallen farther behind their white peers with respect to numerous measures of human capital, such as achievement scores, total grade attainment, college graduation rates, and work experience. The National Assessment of Educational Progress, 2004, Long Term Trend scores provides some suggestive evidence that since 1999 black children have again begun to close the black–white gap in reading scores, but there is at best weak evidence of renewed progress in math. Overall, black–white math and reading gaps in 2004 among 9- and 13- year-olds are quite similar to the gaps observed in the late 1980s (NCES, 2005).
The recent stability of black–white gaps in educational attainment and measured cognitive skills is an alarming development because the black–white skill gap is an important source of economic inequality between blacks and whites. Neal and Johnson (1996) and Johnson and Neal (1998) show that a large portion of black–white differences in earnings and wages can be accounted for by differences in basic reading and math skills among teenagers that pre-date labour market entry. Black–white skill gaps are a driving force behind black–white differences in labour market outcomes among adults for several reasons. First, the black–white skill gap among the current generation of adults is quite large. For example, respondents in the National Longitudinal Survey of Youth (NLSY), 1979, are in their forties now, and the black–white gap in Armed Forces Qualifying Test (AFQT) scores for this sample was over one standard deviation. (The black–white AFQT gap is smaller among youth tested as part of the NLSY, 1997, but the gap remains close to one standard deviation.) Second, measured labour market returns to skill are now at historical highs in the United States. Third, the current market gradients between labour market outcomes and various measures of human capital are even steeper for blacks than for whites. Black and white high-school dropouts, on average, experience markedly different labour market outcomes but, among persons with a college degree and strong reading and math skills, race is much less salient as a predictor of labour market outcomes (Neal, 2006). Because the black–white skill gap is so costly to the current generation of black adults, economists are hard-pressed to explain the recent stability of the black–white skill gap. The 20th century saw several generations of black children make important human capital gains relative to their white peers during times when public expenditures on schooling and pre-school programmes available to black communities were not nearly as high as they are now relative to comparable spending in white communities and when government did much less to ensure that skilled blacks would be treated fairly in the labour market as adults.

What went wrong?

This record of progress is a key starting place for discussing black–white inequality. The logic of basic models of the intergenerational transmission of human capital suggests that one should expect black–white skill convergence. Because the time and attention of each child is a fixed factor in the production of the child's human capital, there are decreasing returns to investments in any child. Thus, in the absence of spillover effects, any group of parents who are more skilled than some other group of parents by a factor k must invest more than \( k \) times as much in their children to maintain the same inter-group skill gap in the next generation. In many models, diminishing returns force skill convergence between two groups unless there is a barrier that hinders investment among one group. The challenge for economists is to understand what barriers are present now in the black community that were not present during 1940–90.

Economists have put forth several theories concerning potential obstacles to skill investment by blacks. None fits all the facts. Coate and Loury (1993) described a model of statistical discrimination in which blacks do not invest because they expect employers to be less likely to reward them for investing. Employers do not see investment levels but rather a noisy signal of worker skill. Because employers believe that black workers are less likely to invest, they screen black workers more stringently, thus lowering the returns to black skill investments, as black workers anticipated. Further, the rational reluctance of black youth to invest confirms the beliefs of employers concerning black investment.
The Coate and Loury model has been quite influential because it provides an elegant theory of endogenous racial differences in human capital and labour earnings. However, the model is squarely at odds with a key feature of data on skills and labour market outcomes. As I note above, gradients between earnings and wages on the one hand and measures of achievement and attainment on the other are almost always as steep among blacks as among whites, and often steeper. This directly contradicts the scenario described in Coate and Loury (1993), and one cannot rescue their approach by arguing that the gradients observed in the data do not necessarily answer counterfactual questions concerning what less-skilled blacks would have earned if they had invested in skills. This model and others that explain statistical discrimination as a coordination failure are describing a market equilibrium and the resulting market gradients between skill and earnings in that equilibrium. However, no study has yet shown that there exists a gradient between any measure of labour market success and some dimension of worker skill that is systematically steeper among whites than among blacks in the post-civil rights era. (Precise tests of the model are difficult because the skill in question should be observed by the econometrician but not by employers. Nonetheless, blacks do enjoy equal or greater measured returns to the measures of skill and attainment available in current data sets; see Neal, 2006; Levy, Murnane and Willett, 1995.)

A satisfactory explanation of the recent stagnation of black–white skill gaps must begin on the supply side by describing the factors that raise the cost of investing in skills within the black community. Recent work by Austen-Smith and Fryer (2005) provides a model of ‘acting white’. In their model, loss of social cooperation constitutes an additional cost of human capital investment in the black community, and only the most gifted in the community actually invest. This model can produce the steep gradients that we observe between skills and both earnings and wages in the black community because blacks who invest in market skills enjoy expected returns from these investments that are high enough to offset any social sanctions they may suffer. However, the basic argument advanced by Austen-Smith and Fryer (2005) cannot account for all we know about black–white skill differences. Their model is presented as a description of peer pressure, but black–white skill gaps are quite large when children begin school, widen during elementary school, and do not increase much if at all after students enter high school (Neal, 2006). The gaps that exist prior to school entry are more likely to be connected to black–white differences in home environment than black–white differences in peer interactions. Further, it is not obvious why fears of being sanctioned for ‘acting white’ should have a more deleterious effect on black achievement during elementary school than during the teen years. Finally, if the social stigma of ‘acting white’ is sustaining the large black–white gaps in achievement and attainment that remain in 2005, we may need to think more carefully about potential sources of change in black culture during recent decades. It is logically possible but hard to imagine that the dramatic black progress observed during the 1940–90 period could have taken place in black communities where achievement and attainment were accompanied by sanctions for ‘acting white’.

Because black–white skill gaps are quite large even among young children, it is natural to examine the roles of parents and families when trying to understand why recent cohorts of black children have failed to continue closing the black–white skill gap. Neal (2006) discusses changes in the wage structure and contemporaneous changes in family structure within the black community since 1980 that have reduced the resources available to children in black families. These changes may have adversely affected
investment in black children, and if this is the case, the recent stability of the black-white skill gap will be temporary. Negative shocks to black wealth should only slow the process of black-white skill convergence. Even in models with imperfect credit markets, the standard expectation is that pure wealth effects will not persist indefinitely over generations. (See Loury, 1981, and Mulligan, 1997. Neal, 2006, provides a detailed discussion of factors that influence black-white skill convergence.) Recent studies of parenting behaviours do indicate that there are important black-white differences in ways that parents interact with children and that these differences contribute to black-white differences in cognitive development at an early age (see Brooks-Gunn, Duncan and Klebanov, 1996; Brooks-Gunn et al., 1998), but it is not clear whether these parenting differences should be understood as differences in culture or differences in parenting practices that are driven by differences in family resources.

**Conclusion**

In closing, I must note that black workers may well face problems other than skill deficits. In particular, the extremely low earnings and employment levels currently observed among less-skilled black men may be more than the results of an interaction between low skill levels and economy-wide shifts in labour demand that favour skilled labour. Mailath, Samuelson and Shaked (2000) construct an informative model of discrimination against minority groups based on search behaviour, and in their model equilibria exist in which members of minority groups suffer wage discrimination and higher rates of unemployment because employers direct search effort to networks populated by majority group members. Because minority workers and firms know that employers are not searching in minority networks, minority workers have little bargaining power when they do create an encounter with an employer through their own search efforts. In this model, affirmative action policies that mandate colour-blind search eliminate inter-group wage differences because they give all workers the same bargaining power.

In light of the Mailath, Samuelson and Shaked model, consider the real possibility that skilled labour markets may be more heavily influenced by government anti-discrimination efforts. (There is suggestive evidence that this is the case; see Smith and Welch, 1984; Leonard, 1990. Further, Holzer, 1998, provides evidence that large firms, which tend to hire more skilled workers and use formal hiring methods, are significantly more likely to hire black workers than small firms.) If so, the forces identified by Mailath, Samuelson and Shaked are a potential reason that less-skilled blacks fare so much worse relative to their white peers than highly skilled blacks. Further, the Mailath, Samuelson and Shaked reasoning helps us understand why gradients between skill and labour market outcomes have been relatively steep in the black community following the Civil Rights Act, but not before. (Welch, 1973, was the first to note this reversal; see Neal, 2006, for later results.) Current black-white inequality is much less extreme than the inequality Myrdal observed, but the black-white inequality that remains is more ominous in some respects. The destitution of Southern blacks that Myrdal wrote about was clearly related to direct and oppressive action on the part of state and local governments that intentionally limited the educational and economic opportunities available to black citizens. Nonetheless, blacks made substantial economic and educational progress in the 1940s, and a combination of legal challenges and legislative efforts gradually began to undercut the systems of school financing and Jim Crow employment practices that afflicted blacks so greatly. In contrast, at the
beginning of the 21st century blacks no longer face overt government oppression. Yet, since the mid-1980s, black–white differences in potential wages and earnings have remained roughly constant or grown slightly, incarceration rates among black men have exploded, and black–white skill gaps have remained large and roughly constant. We still face An American Dilemma, but the primary causes of our current dilemma and the policy changes necessary to foster further progress are less clear than in Myrdal's day. The current experiences of blacks in the United States present a challenge for economists who wish to understand the dynamics of group outcomes within developed economies.

French labour economist, economic historian and first major historian of economic thought, Blanqui was born in Nice and educated both there and in Paris, subsequently teaching humanities at the Institution Massin. His teaching brought him into contact with J.B. Say, who ‘wished him for a disciple’ (Blanqui, 1880, p. ix) and to whose chair of political and industrial economy at the Conservatoire des Arts and des Métiers he succeeded in 1833. In addition, he was head of the Ecole Speciale du Commerce from 1830 to 1854, first editor of the *Journal des économistes* and from 1846 to 1848 served as member for Bordeaux in the Chamber of Deputies. In 1838 he was elected to the Académie des Sciences Morales et Politiques. He died in 1854 in Paris, more than a quarter of a century before his notorious younger brother, Louis Auguste, the revolutionary and member of the Paris Commune, with whom he is often confused.

Blanqui was a prolific writer but is now mainly remembered for his *Histoire de l'économie politique en Europe* (1837) which went through five editions. This is generally regarded as the first major history of political economy. In addition to doctrinal history it covered an enormous amount of economic history from the ancient world to the early 1840s. McCulloch (1845, p. 25) states that Blanqui’s ancient economic history is ‘brief and superficial; but his accounts of the political economy of the middle ages and modern times are more carefully elaborated, interesting and valuable.’ Blanqui’s treatment of history reflects his support of free trade and sympathy for the working class. Schumpeter (1954, p. 498, n.18) praises Blanqui’s 1826 *Resumé de l'histoire du commerce et de l'industrie* as a valuable historical monograph, while his *Précis élémentaire d'économie politique* is also worthy of notice.

Jean Bodin was born at Anger, France, in 1530 and died of plague at Laôn in 1596. Bodin is chiefly famous to a wider public for works in history and philosophy. His first work to attract widespread attention has become known in English as *Method for the Easy Comprehension of History* (1566). But his *Republic* (1576), which deals with sovereignty as well as social justice (including proportional taxation), is generally regarded as his masterpiece. However, it is Bodin’s work on inflation which is the most important part of his output for economists.

In developing this part of his work, Bodin had as background two key elements. The first was the 16th-century European inflation, triggered by imports of silver from the New World. Remarkable work by the American economic historian Earl J. Hamilton indicates something like a fourfold rise in prices in Spain during the 16th century (Hamilton, 1934, 390–1, 493; see also Hauser, 1932, xi–xix, xlvi–xlix). The Spanish inflation necessarily spread to Spain’s immediate trading partner France, through official channels, informal ones (including smuggling), and piracy (Hauser, 1932, xix–xxiv).

The second factor underlying Bodin’s work was the contribution of Scholastic writers, stemming initially from an analysis of the effects of debasement, itself building upon the doctrine of the Just Price as founded on relative scarcity in a competitive market. If debasement of the currency increased its nominal amount, its relative scarcity would decrease accordingly. A leading member of the School of Salamanca, Martín de Azpilcueta Navarro (1493–1586), applied this to money in general, whether debased or not, arguing that the purchasing power of money was inversely related to its quantity (Grice-Hutchinson, 1952, 94–5).

Following Scholastic procedures, Bodin developed his own monetary analysis in the form of a critique of *Paradoxes* put forward by a writer called Malestroit. Malestroit’s basic thesis was that, while prices...
had risen in terms of currency units as a result of debasement, they had not risen in terms of the precious metals. Utilizing data on changes in the price of land, Bodin's estimate of monetary inflation arising from depreciation of precious metals was in excess of 2.5 times, which is remarkably close to the level of 3.0 calculated by 20th-century economic historians.

Bodin's analysis of this inflation involved a treatment of the demand for money (he argued that this depended on the stage of economic development); of the importance of changes in the supply of money; of the idea that the money market clears; of disturbances to either demand for or supply of money producing price and/or income changes; and of the direction of causality running clearly from monetary disturbances to the price level. All of these elements can be found in Bodin's response to Malestroit. He had thus arrived at an important statement of the quantity theory. He did not claim that the fall in the value of silver was the sole cause of inflation; he certainly recognized the importance of debasement, and mentioned also monopolies, scarcity due to exports, and fashionable demand. But the increased supply of precious metals in France was of key importance.

Finally, Bodin recognized that inflation created economic uncertainty and interfered with economic activity. While changes in the supply of precious metals had to be treated as exogenous disturbances, inflation resulting from debasement should be checked, and he put forward a detailed case for currency reform.

Article

As civil servant and economic theorist, Böhm-Bawerk was one of the most influential economists of his generation. A leading member of the Austrian School, he was one of the main propagators of neoclassical economic theory and did much to help it attain its dominance over classical economic theory. His name is primarily associated with the Austrian theory of capital and a particular theory of interest. But his prime achievement is the formulation of an intertemporal theory of value which, when applied to an exchange economy with production using durable capital goods, yields a theory of capital, a theory of interest, and indeed a theory of distribution in which the time element plays a crucial role. Both this construction and his equally famous critique of Marx's economics strongly influenced the development of economic theory from the 1880s until well into the 1930s.

Eugen Böhm Ritter von Bawerk was born in Brünn (now Brno) in Moravia on 12 February 1851, the youngest son of a distinguished civil servant who had been ennobled for his part in quelling unrest in Galicia in 1848, and who died in 1856 as deputy governor and head of the Imperial Austrian administration in Moravia. After reading law at the University of Vienna, Böhm-Bawerk entered the prestigious fiscal administration in 1872. In 1875, however, after taking his doctorate in law, Böhm-Bawerk obtained a government grant to do graduate work abroad and prepare himself for a teaching

position in economics at an Austrian university, as did his classmate and future brother-in-law Friedrich von Wieser. He worked for a year at Heidelberg with Karl Knies, and spent a term each at Leipzig, where Roscher taught, and at Jena, where Hildebrand taught. After working for another three years in the fiscal administration and the ministry of finance, he obtained his Habilitation (licence to teach) in 1880, and was immediately afterwards appointed to a professorship in economics at the University of Innsbruck, which he held until 1889. From a scholarly point of view, Böhm-Bawerk's years in Innsbruck were the most fruitful of his life. A book on the theory of goods, based on his Habilitation thesis, appeared in 1881, the first volume of Kapital und Kapitalzins in 1884. In 1886 he published a monograph on the theory of value in the most influential German language journal in economics, and in 1889 the second volume of Kapital und Kapitalzins. These publications established him as one of the leading members of the group of economists around Carl Menger who came to be known as the 'Austrian School'. In 1889 Böhm-Bawerk preferred an appointment in the Austrian ministry of finance to a chair at the University of Vienna because it carried the assignment to work out a reform of the Austrian income tax. He distinguished himself in the execution of this task, and rapidly rose in rank, obtaining the position of a permanent secretary in 1891, and in 1892 also the vice-presidency of a commission to assess the proposal of a return to the gold standard. Having been appointed minister of finance in a caretaker government in 1893, Böhm-Bawerk was considered to have risen too high to return to his former position when it was replaced by a parliamentary post after a few months, and he was made president of one of the three senates of the Verwaltungsgerichtshof, the highest court of appeal in administrative matters. In 1896 he was again made minister of finance in a caretaker government, but returned once more to the Verwaltungsgerichtshof in 1897. He was yet again appointed minister of finance in 1900, this time in a civil servants’ government which fell when he resigned in 1904 after large increases in military expenditure had been voted which he deemed threatened financial stability. This time he was offered, among other positions, the post of governor of the central bank, the most lucrative position in the monarchy. Yet he turned it down in favour of a chair at the University of Vienna which was especially created for him. Alongside Friedrich von Wieser (who had succeeded Menger in 1902) and Eugen von Philippovich, Böhm-Bawerk lectured on economic theory and conducted a seminar that soon attracted many able students, among them Joseph Schumpeter, Rudolf Hilferding, Otto Bauer, Ludwig von Mises, Emil Lederer and Richard von Strigl. He did not, however, return to the quiet life of a scholar. Having been elected a member of the Austrian Academy of Sciences in 1902, he was elected its vice president in 1907, and its president in 1911. He had also been made a Geheimrat (privy councillor) in 1895, had been appointed to a seat in the upper house of the Austrian parliament in 1899, and was from time to time given various other official assignments. Böhm-Bawerk died on 27 August 1914 at Rattenberg-Kramsach in Tyrol where he had tried to restore his health after having fallen ill on his way to a congress of the Carnegie Foundation in Switzerland as the official Austrian representative.

Böhm-Bawerk was as much a civil servant as a scholar, and in his later years an elder statesman in academic affairs as much as in the public realm of what was still a great power. He was extremely successful as an administrator and economic policymaker. But it is for his contributions to economic theory that he is chiefly remembered today. Kapital und Kapitalzins has become an economic classic even though it is defective in both construction and exposition. The first edition was written in great haste, and although Böhm-Bawerk responded over-conscientiously and meticulously to almost every criticism in the two further editions which appeared in his lifetime, adding so much material that two
Böhm-Bawerk's theoretical endeavours is the development of an intertemporal theory of value, capital and interest. This attempt owes much to his teachers in economics. A.E.F. Schäffle, Menger's predecessor in Vienna, seems to have convinced him that it was necessary to respond on a theoretical plane to the social question, the most pressing economic policy problem of the day, by developing a satisfactory theory of distribution (see Schäffle, 1870). Karl Knies (1873–79) drew his attention to the problems of capital theory and the work of Marx. Carl Menger, finally, provided the starting point for his own theory.

In his Grundsätze der Volkswirtschaftslehre (1871), Menger had developed an atemporal theory of value, allocation and exchange. In his exposition and elaboration of that theory, Böhm-Bawerk (1886) strongly emphasized two of its aspects. Firstly, consumer behaviour is sharply distinguished from producer behaviour because only the former can evaluate goods directly; producers can do so only indirectly on the basis of their expectations of consumers’ evaluations because production, being roundabout production, is necessarily time-consuming. Secondly, in both cases the evaluation of a commodity involves both the marginal utility of the commodity to the evaluating agent, and the marginal utility of the income available to him. In Böhm-Bawerk's usage, therefore, evaluations are shadow prices, or inverse demand schedules which imply an optimal allocation of commodities in the light of an agent's preferences as well as his income.

On the basis of such inverse demand schedules it was easy to show that the market price of a commodity could not be lower than the lowest price the ‘last’ buyer is prepared to offer, nor higher than the highest price the ‘last’ seller demands; here the ‘last’ seller is defined as the seller whose asking price is low enough to prevent any other seller from selling to the ‘last’ buyer: and the ‘last’ buyer as that buyer whose price offer is high enough to prevent any other buyer from buying from the ‘last’ seller. This definition, complicated as it is, is adapted to include the case of indivisible commodities which Böhm-Bawerk for one reason or another considered relevant.

Böhm-Bawerk also elaborated on Menger's seminal contribution by refining the analysis of distribution: he showed how inputs are evaluated by imputation, that is, by imputing to them their proper share of the value of the output they help to produce. In essence this amounted to a marginal productivity theory along lines laid down by J.H. von Thünen, but again adapted to his peculiarly Austrian assumptions of limited substitutability and finite divisibility of inputs.

Böhm-Bawerk generalized (in 1889) this theory of price formation in atemporal exchange to include intertemporal exchange by assuming that agents evaluate and trade not only currently available commodities, but also subjectively certain prospects of commodities available in the future. In his theory of goods, Böhm-Bawerk (1881) had shown in a surprisingly modern manner that such prospects exist, and how they can be evaluated. Assuming further that a market exists on which currently available
commodities can be exchanged for subjectively certain prospects of commodities available in the future, the same argument can be applied to intertemporal exchange as was applied to atemporal exchange. Böhm-Bawerk did so in two stages, first considering a pure exchange economy without production, and then analysing an exchange economy with production.

In a pure exchange economy, all agents are consumers. Their inverse demand schedules, Böhm-Bawerk argued, involve for each agent a subjective rate of interest at which he is prepared, given his preferences over time and his (expected) income over time, to exchange subjectively certain prospects of commodities available in the future for the same amount of commodities available in the present. They also, Böhm-Bawerk maintained, typically exhibit positive time preference: commodities available in the present are typically evaluated at higher prices than subjectively certain prospects of the same commodities available in the future. This assertion is contained in the first two of three reasons he adduced for the positivity of the rate of interest. The first reason postulates that the marginal utility of income will decline over the planning horizon because of higher expected incomes in the future. The second reason postulates that for psychological reasons such as the finiteness of life, the marginal utility of a commodity declines as a rule with the length of time that elapses before it becomes available. As both these postulates have been much disputed it should be added immediately that Böhm-Bawerk regarded them as no more than testable assumptions which he deemed realistic but which admit exceptions. If these postulates are granted for all agents, their subjective rates of interest will always be positive, so that the market rate of interest will always be positive. The same will hold true if only the majority of agents behave according to these postulates. Böhm-Bawerk admitted that not all agents will always behave as postulated by him: but argued that as an empirical regularity they almost always did, and that his theory was applicable also when they did not. All that follows in the latter case is that the rate of interest is not positive.

In order to extend the model just considered to include production Böhm-Bawerk argued that producers can be shown to have intertemporal inverse demand schedules like consumers, and postulated in his third reason that producers under-evaluate commodities available in the future on technical grounds. These assertions he derived from his analysis of the nature of production, and the role of capital in it. Production is assumed to be roundabout. It transforms non-produced or ‘original’ factors of production into consumable output with the help of capital goods which are internal to the production process. Because some capital goods are durable, production takes time. Böhm-Bawerk emphasized strongly the heterogeneity and specificity of capital goods. He also denied that they can be aggregated into some physical measure for the capital stock; aggregation is in his view possible only by valuing capital goods.
He employed a forward-looking measure of capital value in which durable capital goods are valued by the present value of their services, and indeed generalized this procedure to all durable goods by showing that their valuation involves a subjective rate of interest which is equalized when durable goods are traded on markets.

The view of production as roundabout led Böhm-Bawerk to postulate a correspondence between the amounts of different capital goods used in production and the time which elapses before a particular dose of non-produced inputs has matured in the form of consumable output. This correspondence he formalized in the concept of a period of production which is defined as the average period for which the various doses of non-produced inputs required for the production of a unit output remain ‘locked up’ in the production process. This definition was a mistake which got him into more than one difficulty, and provided material for heated debates. To get round all the difficulties raised in these debates, assume that it is possible to define a period of production as a technical property of a particular production system which does not depend on factor prices; and assume further (with Böhm-Bawerk) that it can be used to order different methods of production in such a way that methods with a longer period of production can be said to be more capital intensive. More specifically, assume a temporal production function which (for a unit output) has only the period of production as argument, and which exhibits diminishing returns but is not homogeneous.

On this basis Böhm-Bawerk formulated a theory of producer behaviour in which competition forces producers to choose production methods that generate just enough output to pay the costs of production. As Böhm-Bawerk showed, this implied a discounted marginal productivity doctrine of (original) factor pricing, and hence the existence of positive quasi-rents at the margin. He also showed that this construction involved inverse demand schedules for capital goods which for each period of production define a profit maximizing rate of interest for given factor prices. At this point in his analysis, Böhm-Bawerk assumed the capital stock of an economy as given, and argued that the profit maximizing rate of profit can be determined with the help of that assumption. While that is correct it was another mistake which was duly seized upon (see for example Garegnani, 1960) and which led to many debates. For the value of the capital stock associated with any method of production is an endogenous variable in his construction, as Böhm-Bawerk realized in other contexts. Nor was it necessary to make this assumption. It is sufficient to note that a single producer is forced by competition to pay neither less nor more than the discounted marginal value for the inputs he uses, if a time-consuming roundabout method of production is in operation. Translated into output prices this implies that he under-evaluates output available in the future. This is what Böhm-Bawerk asserted in the third reason; the technical ground being the method of production in operation. Note that this is not so much a postulate or empirical regularity as it is an equilibrium condition.

Having thus established that producer behaviour can be characterized by derived inverse demand schedules for output which involve positive time preference, Böhm-Bawerk goes on to determine the market rate of interest in what is in effect a macroeconomic general equilibrium model. Attention is centred on the market for output available in the present, and the markets for claims to output available in the future. Supply on the market for output available in the present is fixed by decisions taken in the past; so is the supply available at all future dates whose production has already begun. Demand for output available in the present comes from consumers but will not exhaust supply if they save. Part of these savings will be taken up by other consumers in exchange for claims to output available in the future; transactions are consumption loans, and are likely, on Böhm-Bawerk's assumptions, to imply a
positive rate of interest. Another part of savings will be taken up by producers, again in exchange for
claims of future output, who use it to bid for more non-produced inputs in an attempt to expand the scale
of production. As Böhm-Bawerk assumed that the amount of non-produced original factors is fixed, this
results in higher factors prices and a change in the method of production (because higher factor prices
can only be sustained if more output is produced). Net savings in the form of loans for productive
purposes therefore imply a change in the method of production which, on Böhm-Bawerk's assumptions,
implies capital deepening. Both kinds of transactions together determine the market rate of interest,
which is thus seen to be determined by intertemporal consumer behaviour as summarized in the notion
of positive time preference, and based on intertemporal preferences and the (expected) intertemporal
distribution of incomes, on the one hand; and intertemporal producer behaviour as summarized in the
period of production and the marginal product of extending it, and based on the intertemporal structure
of roundabout methods of production on the other hand. Or, as Böhm-Bawerk put it, the rate of interest
is determined by the relative evaluation of (output available in) the present and the future on the part of
both consumers and producers. On his assumptions, this rate of interest is positive.

In some passages Böhm-Bawerk suggested that the rate of interest determined in his model is equal to
the marginal product of an extension of the period of production. That created the impression that he had
done no more than to establish, in a more roundabout way, what Jevons (1871, ch. 7) had already
demonstrated. In other passages, however, Böhm-Bawerk seems to be aware that a change in the method
of production involves a change in the value of the capital goods it requires, and that these Wicksell (or
revaluation) effects imply that the rate of interest is less than the marginal product of an extension of the
period of production. Böhm-Bawerk also obscured his argument by introducing the concept of a
subsistence fund, thereby suggesting that his theory was no more than a revamped wages fund theory.
Neither these nor other infelicities in his exposition should obscure the fact, however, that the hard core
of his argument is the determination of the rate of interest as the property of an intertemporal price
structure which in turn is determined by an intertemporal theory of value and allocation in consumption
and production.

Böhm-Bawerk's model consciously referred to a stationary state as he wished to show that the rate of
interest has something to do with the efficient allocation of resources in stationary as well as in non-
stationary states. This comes out most clearly when he considers a socialist economy and demonstrates
that it would require a positive rate of interest as does a capitalist economy. He did, however, consider
non-stationary states in an interesting comparative static analysis of the effects of an increase in savings,
and of technical progress. That he obtained a positive rate of interest in a stationary state is of course due
to his assumptions, and no contradiction to Schumpeter's argument (1912) which is based on a
somewhat different model (see Böhm-Bawerk, 1913, for a discussion of these differences).

The argument sketched on the preceding pages is expounded in Böhm-Bawerk's Positive Theory (1889)
which he prefaced by a ‘History and Critique of Interest Theories’ (1884) in which he critically
examined earlier (and in later editions also contemporary) attempts to explain the rate of interest. The
purpose of this volume has often been misunderstood. It is not a history of the subject which generously
corrects mistakes, nor an attempt to differentiate his own product. Rather it is a ‘negative
theory’ (Edgeworth): an attempt to survey the building blocks for his own theory and to pinpoint the
pitfalls a satisfactory theory should avoid. Yet it cannot be denied that it is often overcritical. Thus
Böhm-Bawerk shows again and again that the rate of interest cannot be said to be determined by
marginal productivity considerations, but does not add that these nevertheless have a role to play in a
more complete explanation. A similar omission occurs when he discusses abstinence or more generally intertemporal preferences.

One of the conclusions Böhm-Bawerk drew from his demonstration is that the existence of the rate of interest is not due to exploitation. It is obvious that on his argument workers can get the whole product of labour only if production is instantaneous. As long as production is roundabout, the present value of the workers’ share in the value of the output they have helped to produce is necessarily less than what it would be if production were instantaneous. This is due, of course, to the existence of capital; but Böhm-Bawerk argued that interest would have to be paid irrespective of who owns such capital goods. That was also the gist of his critique of Marx's economics (1896), in which he singled out the labour theory of value as the basis of all errors. Böhm-Bawerk was (apart from Schäffle and Knies) one of the first economists to discuss Marx's economics on a scholarly plane; but he remained curiously blind to Marx's critique of the social institutions of a capitalist society. Although his critique drew a long reply from one of his students (Hilferding, 1904) it was very influential and remained the best analytical performance of its kind until well into the 1950s (see Sweezy, 1949).

Böhm-Bawerk's single-minded concentration on economic phenomena is also evident in his discussion of the role of economic power on markets (1914): in the short run, he argued, economic power may cause deviations from the state of affairs as defined by economic forces; in the long run, however, the latter will prevail. Again he was blind to any changes economic power may cause to the environment in which economic forces operate.

The impact of Böhm-Bawerk's work was immense, but its reception was made difficult by its prolixity and its technical defects, which offered many openings to critics. In essence, Böhm-Bawerk combined elements of neoclassical economic theory with elements of classical economic theory. He was neoclassical in his concern with rational economic behaviour and its consequences for the demand and supply of commodities, their pricing on markets, the forces which bring about equilibrium on markets, and the interaction of different markets. By contrast, classical lines of thought predominate in Böhm-Bawerk's analysis of production. However much he denied any adherence to classical cost theories of value, his view of production and the role of capital and time in it bear the mark of the Ricardian tradition.

The neoclassical part of his argument, in particular his analysis of intertemporal consumer behaviour, was taken up by Irving Fisher (1907; 1930) and developed into a theory of interest which is based on the notion of time preference (which Fisher transformed into a property of utility functions) and the concept of investment opportunities; these Fisher assumed rather than derived, thus cutting away Böhm-Bawerk's analysis of production and the role of capital in it. In this form, which admittedly offers insights into the problem of intertemporal allocation Böhm-Bawerk did not offer, Böhm-Bawerk's intertemporal theory of exchange became part of the heritage of orthodox neoclassical economic theory. The more classical part of Böhm-Bawerk's model was taken up and elaborated by Wicksell (1893; 1901). In an attempt to free it of its classical garb, Wicksell turned it into a marginal productivity theory of the rate of interest. He ran into difficulties, however, not only over the proper definition of the period of production, but also because his neglect of what Böhm-Bawerk had to say about intertemporal consumer behaviour forced him to assume a given capital stock in order to close his model. Wicksell used what had by then become the standard neoclassical concept of capital as a value sum, as proposed by J.B. Clark (1899), and (with good reason) combatted by Böhm-Bawerk. The shortcomings of such an
argument, which was before long imputed to Böhm-Bawerk himself, were soon pointed out (see Cassel, 1903, and Garegnani, 1960). Nevertheless Wicksell's interpretation became the standard portrayal of the 'Austrian' theory of capital and interest (see for example Lutz, 1956; Dorfman, 1959a; 1959b; Hirshleifer, 1967).

In the 1930s various attempts were made to reformulate Böhm-Bawerk's theory in such a way that it could be used as the basis of a theory of the short-run behaviour of an economy, particularly by Hayek (1931; 1939; and see Hicks, 1967), but also by Hicks (1939, parts III and IV). This led to an intensive debate in which especially the capital theoretic foundations of his argument were examined, and found wanting (see Kaldor, 1937, and Reetz, 1971, for a survey). There were some attempts at reconstruction (Eucken, 1934; and Strigl, 1934), but the definition of the period of production provided a major stumbling block. At the same time, Hayek and Knight repeated the debate between Böhm-Bawerk and Clark about the concept of capital on a somewhat different level. Finally Hayek (1941) made a major attempt to get round the difficulties the debate had shown up, and achieved some advances: but in the end his contribution turned out to be the final word that did not persuade anybody. The major difficulty which he did not manage to overcome was the fact that Böhm-Bawerk's construction does not lend itself to dynamic analysis precisely because his classical, macroeconomic approach to production and the role of capital requires an equilibrium approach, and does not provide a suitable basis for a discussion of producer behaviour out of equilibrium, and its dynamics.

More recent restatements of Böhm-Bawerk's argument consequently emphasize its static nature (Weizsäcker, 1971; Faber, 1979), but do not really go beyond an exact formulation, in terms of modern capital theory, of some aspects of his theory. By contrast, Hicks (1973) is an innovative attempt to salvage some of the salient features of Böhm-Bawerk's view of production and capital, especially his emphasis on the role of time in production processes, in a modern framework which once more attempts to formulate a dynamic analysis (see also Belloc, 1980; or Magnan de Bornier, 1980). It centres on the concept of a 'transition' from one steady state to another, that is, a more long-term kind of economic dynamics than was considered in the 1930s; this is a promising approach which proves the vitality of Böhm-Bawerk's ideas.

Böhm-Bawerk posed a problem which had not been seen before in its full importance: the role of the rate of interest in the choice of an optimal method of production when production is roundabout, and its determination in a theory which takes seriously the impossibility of aggregating capital goods in physical terms. The solution he proposed is not without problems. But however much economic theory has progressed, some parts of his argument stand out as landmarks in the development of economic thought. Among them are his discussion of price formation on markets, especially those on which indivisible or finitely divisible commodities are traded, his analysis of time preferences, his analysis of intertemporal exchange, and his demonstration that the rate of interest is no more than a property of intertemporal price structures. His definition of the period of production turned out to be a cul-de-sac, but the possibilities his analysis of the role of time in production offers do not yet seem to have been exhausted.

Finally, the importance of his emphasis on the value aspect of the notion of aggregate capital and its implications has only recently been recognized as a seminal contribution. He can perhaps no longer be accorded the stature of a Ricardo or Marx. But the vitality of his ideas still ranks him among the great economists.

Article

French economist and lawyer. Born at Rouen into a noblesse de robe family, Boisguilbert was educated at a Jesuit college in Rouen, the city where he spent most of his life and where he died in 1714. The famous Port Royal and the Paris law school trained him as an avocat but initially inspired a literary career. This produced translations from the Greek (Dion Cassius and Herodotus) and some historical novels, one of which, Marie Stuart, Reyne d'Ecosse (1675) went through three editions. Marriage to a rich heiress in 1677 allowed him to pursue profitable activities in trade and agriculture for several years and enter the magistrature of Normandy. Such experiences brought home to him the deteriorating French economic position and the need to reverse this through fiscal and economic reform. His first economic work, Le détail de la France (1695) reflects these concerns. For the remainder of his life he unsuccessfully pressed plans for fiscal reform on various finance ministers, ultimately republishing his ideas, including the new Factum de la France, in various collected editions from 1707 (a detailed biography and bibliography is in Boisguilbert, 1966).

Boisguilbert is largely remembered as a precursor of the Physiocrats and as the economist whom Marx (1859, p. 52) linked with Petty as marking the start of classical political economy. His influence was undoubtedly more extensive: much of Cantillon's (1755) circular flow analysis appears inspired by his work; while Roberts (1935, pp. 273–320) argues for considerable similarity between his fundamental economic ideas and some of Adam Smith's. A wealth of embryonic tools and concepts can be found in his work and include:

division of labour, circular flow, velocity of money, hoarding, confidence, the multiplier, and variability of employment, supply and demand, diminishing utility, elasticity of
demand, natural and market price, price variability, price flexibility, cobweb price-model, cost of production, diminishing returns, labour supply curve, bargaining range, impulse propagation, economic equilibrium, optimum and suboptimum price structures, and competition. (Spengler, 1984, p. 77)

Tax criteria and class analysis need to be added to this list. Boisguilbert's economic analysis ascribes France's economic distress to agricultural ruin from Colbert's edict prohibiting corn exports; excessive taxation worsened by tax farming; and financiers' power transforming money from a servant of trade into its tyrant. Underlying this diagnosis are models of equilibrium trade demonstrating the interdependence of the 200 occupations and professions exchanging their products at prices proportioned to necessary costs of production including a just profit. Hence buying, as the essential counterpart of selling and consumption, stimulates production. Disruptions to consumption prevent prices from covering costs, thereby initiating a downward spiral which ends in economic stagnation. Three causes for such disruptions are identified: low agricultural prices which lower rent and hence landlords' consumption demand; second, concentration of money among rich financiers leading to hoarding; third, lower consumption potential from excessive taxation. Since the livelihood of the poor depends on the consumption of the rich, unemployment and misery follow. Boisguilbert's remedy follows from his identification of these causes of underconsumption. Free trade and encouragement of agriculture lead to a 'proper' corn price, conducive to high rents and consumption spending. Tax reform achieved by introducing a general proportional income tax removes the problem of excessive taxation and eliminates hoarding and leakages from the circular flow because the abolition of tax farming ends concentrated financier power. Subsequent encouragement of consumption allows prosperity to return and creates wealth for both the state and its citizens. Basic model, diagnosis and remedy are present with varying degrees of sophistication in Boisguilbert's major works, including Traité de la nature, culture, commerce et intérêts des grains (1704a) and Dissertation de la nature des richesses, de l'argent et des tributs (1704b), to name those not so far mentioned.

Olga Nikolajevna Bondareva was born in St Petersburg on 27 April 1937. She joined the Mathematical Faculty of the Leningrad State University in 1954, and completed a Ph.D. in mathematics at the Leningrad State University in 1963, in part under the supervision of Nicolaj Vorobiev. Her thesis was entitled ‘The Theory of the Core in an n-Person Game’. Bondareva rose through the ranks at Leningrad State University to become a senior research fellow in 1972 and a leading research fellow in 1989. Because she sympathized with a student who wished to emigrate to Israel, however, she was prohibited from teaching from 1973 until 1989. With perestroika and increased freedom to travel outside the Soviet Union, she became an active and energetic international figure in game theory. She died as a result of a traffic accident on 9 December 1991.

Bondareva published over 70 works on game theory and mathematics, supervised seven Ph.D. students, and was a member of the editorial board of Games and Economic Behavior. Her work on the core of a cooperative game plays a central role in game theory, and her insights can be seen underlying recent work on the theory of price-taking equilibrium and the core. The following is a brief description of Bondareva's celebrated result. To allow us to see the relationship of this result to more recent research on games and economies with many players, it is stated for games with player types and requiring only ‘essential superadditivity’ in the definition of feasible payoffs. Define a (pre)game with $T$ types of players as a function $\psi$ from vectors of non-negative integers $s \in \mathbb{Z}_+^T$, $s \neq 0$, called profiles of coalitions, into the non-negative real numbers $\mathbb{R}_+$. Given a vector $m \in \mathbb{Z}_+^T$, representing the total player set of the game and $s \in \mathbb{Z}_+^T$, $s \leq m$, $\psi(s)$ is interpreted as the...
total payoff to a coalition of players consisting of \( s_i \) identical players of type \( t, \ t = 1, \ldots, T \). Let \((s^\ell : \ell = 1, \ldots, L)\) denote the collection of all profiles \( s^\ell \leq m \). A partition of a profile \( s \) is determined by a collection of non-negative integers \((n_1, \ldots, n_L)\) satisfying the condition that \( \sum n_\ell s^\ell = s \). With the domain of \( \psi \) restricted to profiles \( s^\ell \leq m \), the pair \((m, \psi)\) determines a cooperative game. Let \( \psi^*(m) \) denote the maximum, over all partitions of \( m \), of \( \sum n_\ell \psi(s^\ell) \). A payoff vector \( \vec{x} \in \mathbb{R}^T \) is in the (equal treatment) core if and only it holds that, \( \vec{x} \cdot m \leq \psi^*(m) \) (\( \vec{x} \) is feasible) and for each \( \ell \), \( \psi(s^\ell) \leq \vec{x} \cdot s^\ell \).

Now consider the following linear programming (LP) problem:

\[
\min \vec{x} \cdot m \text{ subject to } \psi(s^\ell) \leq \vec{x} \cdot s^\ell \text{ for all profiles } s^\ell \leq m.
\]

A vector \( \vec{x}^* \) is in the core if it is a solution to the above LP problem and \( \vec{x}^* \cdot m = \psi^*(m) \). The dual LP problem is:

\[
\max \omega_1, \ldots, \omega_L \sum \omega_\ell \psi(s^\ell) \text{ subject to } \sum \omega_\ell s^\ell = m \text{ and } \omega_\ell \geq 0 \text{ for all } \ell
\]

From the fundamental duality theorem of linear programming, there is a solution to the first LP problem if and only if there is a solution to the second, and, in this case, it holds that the optimal values of the objective functions in the two LP problems are the same.

For the second LP problem, let \( (\omega^\ell) \) denote the solution for the ‘balancing weights’ \( (\omega, \ell) \). The game is balanced if and only if \( \sum \omega^\ell \psi(s^\ell) = \psi^*(m) \). It follows that a game is balanced if and only if it has a non-empty core, Bondareva's result. (See also Shapley, 1967.)

Numerous applications of game theory to economics have employed the concept of balancedness. An outstanding contribution is Shapley and Shubik (1969), who show an equivalence between the set of totally balanced games (balanced games with the property that every subgame also has a non-empty core) and market games (cooperative games derived from economies where all players have concave utility functions). Bondareva's result as formulated above is a key ingredient in Wooders (1994), showing that under mild conditions games with many players are market games. Scarf (1967) demonstrates non-emptiness of the core of a balanced game without side payments (where the payoff set for a coalition \( S \) is a subset of \( R^S \) rather than a real number). Bondareva's result also underlies the approximate balancedness of economies with clubs or relatively small effective or nearly effective coalitions. While this result has been demonstrated in much generality, the key is simple. Since the coefficients of the dual LP problem are integers, when the total player set is replicated (becomes \( rm, \ r = 1, 2, \ldots \)) and no new effective coalitions are permitted (that is, if \( \psi(s) \geq 0 \) then \( s \leq m \)) then there is
an integer $k$ such that all replicated games with total player profiles given by $rkm$ are balanced (Wooders, 1994, and references therein). The integer $k$ clears the denominators of the (rational) extreme points of the convex set of balancing weight vectors of the dual LP problem. In recent works on the theory of clubs and local public goods, balancedness plays a crucial role; see Demange and Wooders (2005) for several recent examples and additional references.

We refer the reader to Rosenmueller (1992) for some additional details of Olga Bondareva's life. See also Kannai (1992) for an excellent review of research on the core and balancedness.

bonds

Donald D. Hester
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A bond is commonly understood to be a debt instrument in which a borrower receives an advance of funds and contracts to make future payments of interest and principal according to an explicit schedule. The nominal return from holding a bond is the sum of its interest payments and the change in its price over an arbitrary holding period. Bonds differ in terms of face value, maturity, callability, seniority, convertibility, risk of default, and size, frequency and taxability of interest payments. Since 1970 bond markets have experienced a number of major institutional changes with enduring consequences for capital markets.

Keywords

Article

A bond is a contract in which an issuer undertakes to make payments to an owner or beneficiary when certain events or dates specified in the contract occur. The term has medieval origins in a system where an individual was bound over to another or to land. Subsequently, goods were put in a bonded warehouse until certain conditions (for example, payments of taxes or tariffs) were satisfied; individuals were released from jail when a bail bond guaranteeing their appearance in court was supplied; and individuals were allowed to perform certain tasks when a surety or performance bond guaranteeing satisfaction was provided. Governments and individuals have borrowed from others since earliest recorded history, as Sumerian documents attest. Perhaps public bonds first appeared in modern form with the establishment of the Monte in Florence in 1345. Monte shares were interest bearing, negotiable and funded by the Commune.
In contemporary economic discourse, a bond is commonly understood to be a debt instrument in which a borrower, typically a government or corporation, receives an advance of funds and contracts to make future payments of interest and principal according to an explicit schedule. The remainder of this entry focuses almost exclusively on these debt instruments. Terms of bonds are designed to protect the rights of borrowers and creditors; they are heterogeneous and their interpretations and enforceability vary across legal jurisdictions.

**Bond heterogeneity**

The distinction between bonds and other evidences of debt such as loans or notes is inherently arbitrary and imprecise. Bonds tend to have long specified maturities when issued, or none at all in the case of consols. However, issuers may reserve the right to call them after they have been outstanding for a specified time interval. Other things being equal, bonds that are callable have higher rates of return than those with no call provision, because issuers have an incentive to call them whenever market rates fall below rates that existed when the bonds were offered. While bonds ordinarily convey no equity stake in an enterprise, some corporate bonds are convertible; they include a clause that gives bondholders an option to convert bonds to shares of the issuer's common stock at a specified conversion value in some time interval. Other things being equal, convertible bonds have lower interest rates than bonds with no conversion rights, because the option to convert is valuable. Formulas for determining the values of options are discussed by Black and Scholes (1973) and Zhang (1997).

Bonds tend to be negotiable and can usually be traded on an established secondary market. Once bonds are issued, bondholders are strategically vulnerable to actions of a firm's management, equity holders, and short-term lenders, as has been argued by Bulow and Shoven (1978), especially if an issuer's financial condition deteriorates. Default occurs if a bond issuer fails to make scheduled payments of interest or principal or violates other covenants of a contract. A bondholder's rights in a default situation are circumscribed by the terms of the contract and by judicial authority.

In the event of a default by a corporation, bondholders or other interested parties may petition for protection under bankruptcy statutes. In some circumstances a bankruptcy court appoints a receiver to conserve the value of a firm's assets so as to protect creditors. The fraction of a creditor's claims that is paid is determined in part by their seniority (or priority) relative to other claims. Bonds may be either unsubordinated or subordinated to other debt. A bankrupt firm may be liquidated in favour of its creditors or be reorganized and allowed to continue with partial payouts to creditors.

In the United States, bonds issued by corporations and state and local governments are assigned credit ratings by firms such as Moody's Investors Services and Standard and Poor, Inc. Bonds with lower credit ratings are predicted to have a higher rate of default; they tend to have higher *ex ante* rates of return to compensate holders for higher expected default losses and risk of default. Bonds of state and local governments fall into two broad classes: (a) bonds which are general obligations of the issuing government and (b) revenue bonds, where interest and principal payments are dependent on income from some specific project. Because general obligation bonds are funded from taxes of the issuer, they tend to have higher ratings and lower rates of interest than revenue bonds. Corporate bonds with poor credit ratings are called ‘junk bonds’. Before 1980, most bonds had been issued with good ratings and were suitable for the portfolio of a prudent investor. If an issuer’s condition subsequently deteriorated, its bonds were downgraded and possibly became junk bonds. Beginning in about 1982, this practice
changed and large amounts of funds were raised by issuing bonds that had low ratings when first offered. The reasons for offering junk bonds are incompletely understood but include avoidance of corporate income taxes, as was predicted by Modigliani and Miller (1963). Coinciding with the issuance of junk bonds were a substantial increase in leverage (the ratio of a firm's debt to net worth) and a wave of leveraged buyouts in which publicly traded corporations were reorganized into enterprises that were narrowly held by management and a few outside investors.

The significance of these changes in imperfect capital markets is controversial; in traditional financial theory it is often argued that high leverage makes a firm vulnerable to financial shocks and recessions. High leverage is believed to reduce the probability of a firm being taken over or bought up. Leverage on the books of a firm, however, can be misleading without knowledge of the contractual rate of interest on a firm's bonds. For example, when interest rates rise a firm may call its existing low-interest rate bonds which have a low market price and finance them with a smaller quantity of new bonds that bear the new high rates. This action, ‘defeasance’, reduces the ratio of debt to equity on a firm's books without reducing its interest costs.

Bonds issued by autonomous nation states are ‘sovereign’ debt. Defaults by issuers of sovereign debt do not result in bankruptcy proceedings, because there is no world bankruptcy court and applicable code. Moreover, as Bulow and Rogoff (1988) have argued, there is no credible basis for establishing seniority among sovereign debt issues in the event of a default. Sovereign bonds that default are traded at deep discounts for indefinitely long periods. While bankruptcy is impossible, negotiations leading to the restructuring of a country’s debt obligations do occur, and sanctions against a defaulting country have been imposed by other countries where bondholders are concentrated. Credit ratings of sovereign debt vary widely across countries and, in part, are a function of the bond repayment history of a country.

**Bond yields and rates of return**

The ‘yield’ on a bond is the flow of interest income to its holders. Apart from defaults, bonds traditionally pay interest in fixed amounts on specified dates that are indicated by coupons on the bond. Coupon-bearing bonds may allow investors to choose portfolios that match interest and amortization streams with their own nominal future requirements for funds. A portfolio is said to be perfectly ‘immunized’ against interest rate fluctuations if such matching is achieved. Bonds that have no coupons are called ‘discount bonds’; they provide no interim cash flow and are retired at maturity with a payment equal to their face or par value, which is higher than the issue price. Default-free discount bonds thus afford nominal *income certainty* to investors, as was explained by Robinson (1951), but do not guarantee that an investor's spending goals can be achieved when inflation is unpredictable. Some protection against inflation is afforded by inflation-indexed bonds that first appeared in Israel in 1955, the United Kingdom in 1981 and the United States in 1997, when US Treasury Inflation-Protected Securities (TIPS) were first offered. With TIPS, protection takes the form of a percentage increase of the bond's principal that equals the rate of inflation. Because the increase is taxable and inflation is based on the rate of change of the consumer price index, TIPS only incompletely protect a representative investor against inflation. For a discussion, see Wrase (1997).

The nominal return from holding a bond is the sum of its interest payments and the change in its price over an arbitrary holding period. For example, if there are no transactions costs and taxes, the return
from holding a multi-year bond for two years is:

\[
\text{return} = y_1 + y_2 - P_p + P_s
\]  

(1)

where \( P_p \) and \( P_s \) are respectively the purchase and selling price and \( y_1 \) and \( y_2 \) are annual interest payments. If interest payments are assumed to be paid at year end, the nominal annual rate of return, \( r \), from this two-year investment is obtained by solving the polynomial:

\[
P_p = \frac{y_1}{(1 + r)} + \frac{(y_2 + P_s)}{(1 + r)^2}
\]  

(2)

If the bond is bought at \( P_p \) and sold at \( P_s \), a bond trader is said to ‘realize’ a capital gain (loss) if \( P_p \) is less (more) than \( P_s \).

A condition for equilibrium in a bond market is that expected rates of return from holding similar bonds are similar. If this condition were not satisfied, bond traders could improve portfolio earnings through arbitrage, by selling the bond with the lower rate of return and buying the bond with the higher rate of return, so long as the difference exceeds transactions costs. When transactions costs are zero, bonds are perfectly ‘reversible’. When market rates of return rise, prices on outstanding bonds fall and rates of return experienced by existing bondholders fall; capital losses are sustained by holders of all but maturing bonds. Bond traders attempt to buy bonds immediately before market rates of return fall so that they may realize capital gains by buying at a low price and selling at a high price. Similarly, speculative traders of bonds seek to sell bonds immediately before market rates of return rise. While bonds that do not default mature at par, the prices of outstanding bonds are incompletely predictable; generally bonds with more years to maturity have more price volatility.

Bond issuance considerations

Bonds are issued by governments and corporations to finance deficits and acquire assets. While neither issuer can afford to ignore imminent movements in interest rates, their time schedules of outlays are somewhat inflexible. Deficits must be financed, and it is short-sighted to delay purchasing high rate-of-return assets to take advantage of transient interest rate movements. Firms needing funds may choose to finance a long-term asset with short-term borrowings from banks, with a long-term bond whose interest rate varies (or ‘floats’) over time in a fixed relation to short-term rates, or with a long-term fixed coupon bond. Bank borrowing to finance long-term assets exposes firms to the risk that banks may unilaterally alter loan terms or refuse to renew maturing loans. Firms avoid non-renewal risk by borrowing with
bonds. A firm's choice between issuing conventional fixed-rate bonds and floating rate bonds to finance an asset depends in part on the correlation between returns from the asset being acquired and short-term interest rates for reasons that are developed by Cox, Ingersoll and Ross (1981). Other things being equal, a floating rate bond exposes a firm to less risk when the short-term rate and the rate of return on the acquired asset are positively correlated.

Government deficits are financed by issuing short-term bills, notes, bonds and ‘outside’ or fiat money. Central banks control the ratio of outside money to interest-bearing government debt when conducting monetary policy. Central bank sales (purchases) of bonds decrease (increase) bond prices and increase (decrease) bond interest rates in the market. Other things being equal, an increase in bond interest rates increases the cost of financing new capital equipment and causes marginal investment projects to become unprofitable. Control of bond and other market interest rates by central banks is one handle through which monetary policy affects the level of macroeconomic activity. It has also been argued by Tobin (1963) that the composition of outstanding interest-bearing government debt can importantly influence the level of macroeconomic activity. If bonds are closer substitutes for physical capital in investors’ portfolios than are treasury bills, a debt management policy of selling bonds and buying an equivalent amount of bills discourages private sector capital formation.

Recent innovations in bond markets

Since 1970 capital markets have experienced a number of major institutional changes and innovations that have had enduring consequences for bond markets. Arguably the most important was the introduction of securitized debt by the US government-sponsored enterprises, Federal National Mortgage Association and Federal Home Loan Mortgage Corporation, and by the Government National Mortgage Association. While they could issue conventional bonds, they also could issue what amounts to second-order bonds, such as pass-through securities or collateralized mortgage obligations. Instead of an issuer being responsible for paying interest and retiring principal, securitized debt replaces the issuer with a constructed package of mortgage loans that generates a stream of interest and principal payments to holders of the securities. Initially, the underlying loans were insured against default, but they differed from traditional bonds because mortgage loans could be paid off before their contractual maturity. Thus, these securities were bonds with discrete, stochastic call provisions. The underlying stochastic process is in part a function of past and current market interest rates, because homeowners tend to refinance their houses when market interest rates fall.

In 1985, securitized debt evolved into generalized asset-backed debt, which serves to finance a package of self-liquidating financial assets. Like bonds, some of this debt is publicly rated for safety by investment services, but much of it is privately placed and not traded on a secondary market where ratings are important. The value of the assets underlying a debt issue typically exceeds the face value of the issue by an amount called a ‘haircut’, which serves as a partial safeguard against default. Asset-backed debt is heterogeneous; interest rates may be fixed or indexed to some market rate, amortization schedules vary, and the qualities of underlying assets differ. In 2004, new issues of asset-backed debt exceeded new issues of conventional bonds by corporations and governments for the first time. Asset-backed debt tends to be less costly to issue and to service, which largely accounts for its rapid growth. It is often issued by a ‘special purpose vehicle’, a legal entity which is intended to be bankruptcy-remote and whose sole function is to service a set of debt issues. Unlike conventional bonds, such debt usually
bonds: The New Palgrave Dictionary of Economics

do not appear on government or corporate balance sheets, which partly explains its appeal in a world where leverage has been rising. However, especially in Europe there is a hybrid ‘covered bond’, which is a securitized bond that remains an obligation of the issuer and continues on balance sheets. Because it is collateralized, it retains value even when the issuer fails.

Another innovation that has partly displaced bonds are medium term notes (MTNs), which US corporations began to issue in the early 1970s. In recent years outstanding corporate MTNs have averaged about 14 per cent of corporate bonds. They tend to be issued by highly rated corporations and are distinctive in being issued through ‘shelf registrations’ rather than having a formal offering with the assistance of underwriters. In a shelf registration an issuer presents a menu of securities that it may choose to issue in a specified period, which allows it to have a closer correspondence between the time funds are needed and the time when securities are issued. MTNs range in maturity from nine months to 30 years.

A large off-shore ‘Eurobond’ market exists where governments and corporations issue bonds denominated in currencies that differ from the currency in the country where the security is issued. While recent data are unavailable, there was also a rapidly growing outstanding stock of EuroMTNs in the early 1990s. These large and expanding markets complicate the implementation of monetary policy in a country, because information about Euromarkets must be taken into account. International financial statistics often do not reveal the nationality of individuals issuing or holding securities in different countries.

The establishment of financial instrument futures markets in 1975 also modified the demand for bonds in investor portfolios. Short-term hedging and speculative positions are more inexpensively achieved in a futures market than they are by constructing forward cash flows through the assumption of long and/or short positions in a bond market.

A market for ‘stripped’ bonds, where all a bond’s coupons are separated from the body of a bond and each coupon and the body (or principal) are traded as separate entities, emerged in 1982. The body of the bond and each coupon are traded as discount bonds. The market for stripped securities greatly expanded in February 1985 when the US Treasury adopted this private sector innovation by offering its own stripped securities in book entry form and was willing to reconstruct stripped securities beginning in May 1987. These innovations increased the attractiveness of Treasury securities and arguably lowered the cost of government borrowing. The innovation is important because discount bonds are especially convenient for matching expected cash flows from other assets and liabilities and thus hedging against fluctuations in interest rates. Because discount bonds make no interest payments they are sometimes called ‘zeros’ in the financial press.

During the 1980s, a new technique emerged that broke the linkage between the choice of fixed or floating interest rates paid by a bond issuer and the form in which interest is received by a bondholder. A simple (plain vanilla) bond ‘swap’ is a transaction in which the holder of a bond trades a fixed interest-rate stream for a floating interest-rate stream. Thus, a borrower can issue a fixed-rate bond to an investor who prefers floating-rate securities, because the latter can simultaneously execute a swap with a third party. Such transactions facilitate marketing of securities in imperfectly competitive markets. Swaps also allow investors to change the currency unit in which an interest stream is denominated from, for example, euros to US dollars. They can also be used to change the base of a floating interest rate bond from, say, the US Treasury bill rate to dollar-denominated Libor, the London interbank offer rate. Swaps and put and call options are early forms of ‘derivative’ securities, which allow investors to create
synthetic bonds that effectively increase the stock of conventional corporate bonds, as can be inferred from Stoll (1969). A derivative security's value is conditional on the price or price trajectory over time of another asset. In recent decades an enormous variety of 'structured' assets has been and continues to be created by combining derivatives and conventional assets such as bonds and MTNs. For a discussion see Zhang (1997).

Finally, automation in bond markets has reduced the costs of trading bonds and made them more convenient to hold. Most government bonds in the United States are no longer issued in certificate form; they are issued in book form and exist only as computer entries. They are readily transferable in a computer and can be lent or sold at low cost whenever a borrower requires cash. By making bonds more reversible, automation has reduced the distinction between bonds and outside money, a distinction that is crucial for the success of central-bank open market operations.

books, economics of

Frederick van der Ploeg, Marcel Canoy and Jan van Ours
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The tensions between books as expressions of culture and books as profitable products are analysed using insights from the theory of industrial organization. To stimulate the diversity of books on offer, maintain the density of bookshops and to promote reading, governments grant fixed price monopolies, subsidize authors, levy a lower consumption tax on books, and provide public libraries and education. Market structures and government policies vary widely and there is no case for harmonizing European book policies. The book market is innovative in solving its problems. The main task of the government is to promote reading.

Keywords

books, economics of; business stealing; cross-subsidy; cultural policy; experience goods; market failure; monopolistic competition; non-price competition; payola; product differentiation; product life cycle; retail price maintenance

Article

The market for books is characterized by the laws of demand and supply. However, the availability of a diverse supply of quality books is also an objective of cultural policy. This, combined with market failures, may provide grounds for government intervention as discussed for the arts in general in van der Ploeg (2006). Here we focus mainly on the market for general books, paying special attention to cultural books, leaving aside educational and scientific books. Governments influence book markets through subsidies for libraries, authors and publishers, tax concessions on the sale of books, and laws concerning the pricing of books. Apart from stimulating reading, it is not clear what role there is for government intervention. After all, the book market invents solutions to specific problems (contracts for authors, literary agents, gatekeeping by publishers, joint distribution by wholesalers cooperating on distribution, agreements concerning stocks between retailers and publishers, joint publicity, best-seller lists, reviews,

**Stylized facts**

About half of Portuguese adults never read a book. This is in sharp contrast with the 20 per cent of readers in Belgium, Denmark, Italy and Norway who similarly do not read books. Reading is popular in Finland, Sweden and Switzerland where about 90 per cent of adults read. Nevertheless, even in Sweden almost 30 per cent failed to read a book during 2003. Although in most countries a majority of adults read, there are large numbers of people who never read a book.

At the low end of the distribution of book titles across countries is the United States, with 24 titles per 100,000 inhabitants, and only six of which concern arts and culture. At the high end, Denmark produces 275 titles per 100,000 inhabitants, of which 80 are devoted to the arts and culture. Most titles per inhabitant are produced in Scandinavia, in Switzerland, and in the United Kingdom. Relatively few titles are produced in Italy, Japan, Greece and Australia.

The typical average annual number of books sold per inhabitant is about five to six. The exceptions at the lower end are Portugal and Sweden with 2.6 and 3.6 books per inhabitant, while at the high end France has 6.9. Publishers’ revenues from sales vary from 20 euros per inhabitant in Greece to 115 euros in Finland. In most countries the revenue from book selling is 40–60 euros per inhabitant. The largest industries are located in the United States, Germany, the United Kingdom, France and Italy. In 2001, total value added of the book publishing industry was about 0.11 per cent of GDP with some 140,000 employees in the EU-15. The industry is stable in terms of turnover and per capita sales.

The number of books available through public libraries is low in Greece, Italy, Portugal and Spain, but much larger in Denmark, Finland and Sweden. The number of loans per inhabitant correlates nicely with the number of books available. It ranges from less than one in Greece, Portugal, Spain and Switzerland to at least ten in Denmark, Finland and the Netherlands. Differences in book-reading frequency are large. Reading a book daily varies from about a quarter of all adult males in Australia, Canada, Ireland, Sweden, Switzerland, the United Kingdom and the United States to a mere five per cent for Portuguese male adults. In most countries 10–20 per cent of adult males read daily. Females read much more than males, less so in Belgium (Flanders) and Portugal and more so in Australia, Canada, Denmark and the Netherlands.

The level of education is an important determinant of reading habits but no systematic cross-country evidence is available. However, in France 62, 78 and 92 per cent of lower-, medium-, and higher-educated individuals, respectively, read at last one book during the year 2003. There is not much cross-country information concerning trends in reading. However, in the Netherlands there is a clear downward trend in book-reading. Furthermore, fewer people indicate that they read books, though the average time spent reading has hardly changed. All readers irrespective of gender or country spend on average 6.5–8 hours per week reading books. In Europe, people spend most of their leisure time watching television. In the United States trends suggest that Internet use is increasing, mainly at the expense of watching television rather than reading.

Finland, Denmark, Ireland and Switzerland produce more than 200, the United Kingdom almost 200, Spain about 150 and the United States circa 25 book titles per 100,000 inhabitants per year. Although the number of titles produced has increased steadily in most countries, the number of publishers is stable. The average size of a publishing enterprise in the EU is small. Most enterprises publish only
between 20 and 40 titles per year. The percentage of books published on arts and literature vary from 20 to 50 per cent across countries. Differences in the number of titles published may be related to economic prosperity, to the educational level of the population, or to population density. The empirical evidence for this is mixed. For example, a rich country like the United States publishes fewer titles per capita than some poorer southern European countries.

Total European book sales amounted to 27 billion euros in 2000. The biggest market is Germany with some 9.5 billion euros. Both Germany and the United Kingdom are strong exporters of books to countries that share their languages. Other large book markets are found in France, Spain and Italy. During the first two years of the 21st century, the United Kingdom book publishing industry has grown to be the largest in Europe. In contrast, there has been a decline in Germany. About half the revenues of publishers in most countries come from general books. Most sales are through retail channels (trade), except in the United States. In some countries there are strong retailers, but in others there are many independent bookshops. In France, the multimedia retailer Fnac accounts for around 15 per cent of sales. In Italy Feltrinelli commands 25 per cent of the retail market. However, in Germany, the largest bookseller, Thalia, has only three per cent of the market and there are many small independent bookshops. The largest retailers in the United Kingdom in 1998 were Waterstones and W.H. Smith with 20 per cent and 18 per cent of the market respectively. The United States book industry has limited opportunities for growth in a mature market, and competition is focused on growth through market shares. The United States has seen consolidation among retail chains. Barnes and Noble command 30 per cent of the market and independent booksellers struggle.

The share of book clubs is high in Australia (26 per cent), about 15–20 per cent in Denmark, Finland, France, and Sweden and low in Italy, the United Kingdom and the United States. Although Internet sales have grown in importance, they are still small. In the United Kingdom around 17 per cent of book sales go through Internet retailers, a percentage that is no longer thought to be growing very fast. For Germany estimates suggest between four and five per cent of sales are made through Internet retailers, although recent growth has been much faster than in the United Kingdom. Some reports have estimated Internet sales in France and Italy at 1–1.5 per cent. Spain has even lower Internet sales than France. Internet is mainly used as a channel for books and so far not for digital products. For example, E-books are not sold much in the European market. In the United States E-books are more important; over 7,000 titles were published in 2003 while over 1.3 million E-books were sold. Concentration of firms in the worldwide online book market is high, with 60 per cent for Amazon.com.

The book market functions well

According to Caves (2000) cultural goods are characterized by nobody knows (uncertain demand), time flies (short period of profitability), infinite variety (horizontal differentiation) and A-list and B-list (vertical differentiation). Beck (2003) adds spontaneous purchases of books, non-convexities in production with large fixed costs and small marginal costs, and free entry for the book trade. A book is a private good, since its consumption is rival and excludable. This suggests there is no fundamental market failure. Books can be borrowed by other people. However, if this yields utility to the owners, there is no market failure. The market for books has a traditional supply chain: production, wholesale, distribution and retail. In each part of the chain there is competition between private entrepreneurs. Government provision occurs only with libraries, but that does not exclude competition between private...

http://www.dictionaryofeconomics.com.proxy.library.csi...du/article?id=pde2008_E000218&goto=B&result_number=152&3%202008-12-30%2020:24:46
firms in the rest of the chain. There is substantial product differentiation in each part of the chain, which generates niche markets. Branding is important. Making a new product successful often requires substantial investment and innovation. This includes accepting that some products will never make it. Most parts of the supply chain have a fairly large number of players. Consumers of books can easily switch from one product to the other. The book market knows relatively few consumer lock-ins, which helps the market to function properly. Transparency adds to that effect. Even though books are experience goods, author reputation, book reviews, book clubs and word-of-mouth ensure transparency. The book market is also dynamic: there is innovation, market shares fluctuate and there is entry and exit. All this suggests that the book market should not be exempted from competition law.

Books occupy niches, more so than publishers

The book market is characterized by monopolistic competition along the lines of Dixit and Stiglitz (1977), since (a) products are differentiated; (b) firms set the price of the goods; (c) the number of sellers is large and each firm disregards the effects of its price decisions on the actions of its competitors; (d) entry is unrestricted. There thus exists a trade-off between efficiency (exploiting scale economies by producing more of the same product type) and diversity. Consumers love variety, but variety comes at a cost and the market becomes less transparent. Since firms do not take the potential downside of the variety decisions of other firms into account (the business stealing effect), there could be a market failure and optimal product diversity is not guaranteed. But in the book market consumers do not engage in repeated purchases in the same way as they do for, say, cereals. This greatly reduces possibilities for exploiting economies of scale, especially in the light of nobody knows. This does not mean that the book market can never have too much variety, but the argument then rests on lack of transparency and not on economies of scale. The book market does not have repeated entry by publishers with each publisher filling a niche. It is books that occupy niches, not publishers. Publishers have a portfolio of authors and books that serve as a way of risk-smoothing. Some books make it while others do not, but publishers have difficulties either of forecasting the success or are happy to accept differences in success out of cultural motives. Additional complexities arise for two other reasons. First, the book market is characterized by the fact that a single product (a book) has a very short life cycle. This leads to high initial prices followed by discounts. Second, publishers face a trade-off between risk-smoothing and specialization. A science fiction publisher has a competitive edge over non-specialized publishers, but faces the risk that its clients might switch to video games.

A publisher thus has a quickly changing portfolio of books. Its strategy consists of deciding on the portfolio (trading off risks and specialization) and on the prices of the portfolio. Multi-product firms in a monopolistic competitive market face the decision whether to engage in new product lines (exploiting economies of scope) or not (reducing cannibalization). This is akin to the decision by a publisher whether to employ a new author in the same field as his current portfolio. This trade-off, combined with variety in publishers’ ‘love for culture’, leads to a mix of publisher types. There are specialized publishers, small publishers and large publishers. This has been the case for many years in many countries.

The book market plays into special features of books
Books have some special features. First, books are experience goods as one only appreciates the value after reading the book. Second, books are characterized by high fixed and low marginal costs. Third, some books are extremely successful, while most are unsuccessful. Success is hard to forecast and sometimes leads to ‘winner takes all’ economics as developed by Rosen (1981). Booksellers and publishers thus cross-subsidize higher-risk books with profits on other books. These potentially welfare-enhancing cross-subsidies can be thwarted by non-branch shops (for example, supermarkets) which sell only the bestsellers. Fourth, the opportunity costs of reading a book (that is, time) typically outweigh the price of a book. This contributes to a low price elasticity compared with other goods. The evidence suggests that the market for books other than best-sellers is price-inelastic, probably because most readers have high incomes or buy books for study purposes. Fifth, reading a book can be viewed as a private investment in culture rather than consumption. Sixth, there is an (almost) free substitute for buying books, namely, libraries. However, the quality of the service in bookshops and libraries is not the same, which makes substitutability imperfect. Seventh, books have cultural value. Books may also have option, existence and bequest value, and contribute to national identity, social cohesion, national prestige and the development of criticism and experiments. None of these values is (fully) reflected in the price, so the total value of books is higher than what has been paid.

Still, the market need not fail, since publishers, booksellers and authors find solutions to cope with these special features. The book market is relatively simple compared with other cultural markets (Caves, 2000). First, there is the motley crew property. A play or movie involves a complex set of different professionals to interact. The success of the play or movie crucially depends on how these different professionals get along. Many parts of the chain have the possibility to break it and kill the project. This leads to a complex set of contracts and other institutions, largely unnecessary and therefore absent in the book industry. Second, the nobody knows and time flies principles are even more applicable to a play or movie than to a book. Third, the production costs of a play or movie are much higher than those of a book.

Authors and publishers share the risk associated with the nobody knows and time flies principles. Authors get a percentage of the sales (typically ten per cent) and a split of the gross profits (typically 58–42) between author and publisher. Only celebrity authors receive bigger advances. While celebrity authors do reduce the risk of publishers somewhat, there are also serious large-scale flops. Some 70 per cent of former US President Bill Clinton's Between Hope and History were returned from bookstores as unsold (Caves, 2000).

Changing the terms of the contract either in favour of the author or the publisher can lead to misallocations. A higher fee for the publisher leads to a higher number of published books, since it becomes more lucrative to publish books and there still exists a reservoir of authors wanting to accept lower fees (Caves, 2000, p. 57). However, there will be less commercial success per book on average and lower quality as good authors may spend their time on more profitable activities. This could be justified if the perception is that there is a lack of supply of books. There is no evidence of that, however (the contrary is more likely). A higher percentage for the authors implies higher risk for the publisher, fewer books and fewer possibilities for new authors.

Incentives differ between publishers and authors. Publishers want to maximize profits, while many authors want to maximize sales and impact as they can often supplement their royalties with other income from lectures, TV, film, and so on. With globalization and the Internet some authors obtain
superstar incomes by using the media to leverage their incomes. Many new authors find their way into the book market. In addition, sales of a novel increase the probability of future sales, a factor that influences an author more than the publisher. Authors may thus want to use agents. There is no marketplace for the literary reputations of new authors. The chance that a publisher accepts a manuscript is extremely low; Caves (2000) mentions one in 15,000 for novels. Agents reduce the cost of publishers by filtering out good and bad manuscripts. The publisher can then use the reputation of a good agent as a proxy for quality.

Nobody knows and time flies create problems with stocks in retail outlets. If a book does not perform, the retailer wants to dump stocks as shelf space is scarce and new potentially successful books are looming. Market solutions to this problem include second-hand sales shops, sales of remainders, pricing strategies and policies that aim at sharing risks between publishers and retailers. Book retailers also have a right to return books for full credit. They can further reduce risks by smart wholesaling agreements. There are distinct differences in market shares of wholesale firms in Europe. In France, Finland, Denmark and the Netherlands the wholesale market is concentrated, but in Anglo-Saxon countries wholesale is less concentrated. If publishers are larger, it is worthwhile for them to vertically integrate into distribution. In sum, the market seems fairly able to solve the coordination problems needed to sort out the economies of scale.

There also exists a trade-off between exploiting economies of scale in retail and other policy goals. Examples are the reduction of transport costs for consumers or equity ‘universal service’ type of arguments. Various trends such as the Internet tilt towards scale. Books are easy to transport and personal contact with the seller is not always needed. In fact, interactive service and personal advice from Internet bookstores is often excellent.

Books are experience goods, so consumers have difficulty in deciding which book to buy. Book reviews in newspapers and the Internet, best-seller lists, book clubs, prizes and awards, and word of mouth facilitate choices. The market for information does not seem to fail except perhaps for payola (Caves, 2000). Payola is a system where the author (or his agent) ‘bribes’ a gatekeeper to influence his choices (as with pop music on radio). For example, an author may buy many copies of his own book in order to be high on the best-sellers lists, or chain bookstores may offer deals to book publishers to selectively display books in eye-catching positions. The problem is that payola threatens the objectivity of gatekeepers.

Does the book market achieve cultural goals such as (i) a diverse supply of cultural book titles and genres; (ii) access of books for all in term of price and distance by having sufficient density and variety of (high-quality) retailers? Since books are rival and excludable, the book market should require less government interference. With the Internet one may expect a demand-driven growth in the sale of selected parts of handbooks and guidebooks. Because books are reproductive cultural goods, large-scale distribution of books is easier than for non-reproductive forms of art. The market thus produces a large variety of books, with prices that are low enough (with libraries as a fallback as well) to make books available to everybody interested. If retailers are unsuccessful in dealing with stock risks, there may be too few cultural books, too little reading or too many authors.

Should the government tolerate retail price maintenance?
One reason to intervene is to protect a dense network of well-stocked, high-quality bookshops and stimulate the publication of a large variety of books. Indeed, the number of high-quality bookshops is decreasing in many countries. This happens if it does not pay to invest too much in variety in low-selling books. Monopoly profits and cross-subsidies from profitable to less profitable books may allow bookshops to store a greater variety of books and publishers to take more risks. The current practice in many European countries of a fixed book price (FBP) in combination with a variety of subsidies handed out by literary funds is often motivated by these considerations. Critics argue that a FBP or subsidies for high-brow books may harm reading on the part of the general public, since monopoly prices and cross-subsidies for less popular books are paid for by ordinary people reading popular books. Furthermore, subsidies for authors, translators, bookshops and publishers are paid for by ordinary people who may not be interested in more culturally valuable books or high-quality bookshops.

When considering policy instruments for reaching cultural objectives, there are at least two trade-offs. The first is between efficiency and density and distance. Increasing the scale of booksellers can enhance efficiency, but leads to longer travelling time for consumers. The second trade-off is between efficiency and cultural goals. Diversity of books in a bookstore may conflict with productive efficiency. The optimal choice of policy instruments depends on culture-political preferences and on country-specific characteristics that determine the market outcome. For example, a large ‘language size’ generates market outcomes where cultural objectives are more easily achieved. This is why the United States, Australia and Canada do not have policies aimed at the book market. Harmonizing book policies in Europe is not necessarily a good idea. Governments may wish to stimulate reading of worthwhile books, production of a diverse menu of titles and/or an extensive network of high-quality bookshops.

The FBP involves retail price maintenance by which the publisher reserves the right to set the retail prices of books. Since the publisher also influences wholesale prices, he effectively sets gross margins for retail outlets. The cultural merits ascribed to such agreements have reached almost mythical proportions in Europe. Since monopoly profits are higher than profits in competitive equilibrium, more titles are profitable and are published or sold under the FBP than in competitive equilibrium. It is possible to print and sell extra books at low and almost non-increasing marginal cost, so the producer loss is likely to be small. Also, the price elasticity of the demand for books is small as a large part of the full cost of reading is the opportunity cost of time and thus monopoly profits are large. The FBP leads to more variety in book titles, but prices will be higher and sales of each title lower as discussed in van der Ploeg (2004). The welfare costs may in practice be much larger, since much of the profit is dissipated by unproductive rent-seeking along the lines of Tullock (1980).

The FBP also has dynamic costs. Price competition between retail outlets becomes impossible but it is also more difficult to vary prices in response to local conditions. A store on a remote island may want to charge more for the same book than a store in the capital, but under the FBP it cannot do so. Also, it is more difficult to vary prices for different types of customers or for different seasons. Some customers need no service and low prices, while others prefer service at a higher price. Most important is that the FBP discourages the development of innovative distribution channels, since realized cost savings cannot be passed on to customers. With the FBP, unconventional distribution channels (bookclubs, supermarkets, petrol stations, the Internet, and so on) have less of a chance. Against these costs there is the benefit that independent small bookshops may be able to recommend interesting books and order books from the publisher or distributor.
Even though the FBP eliminates price competition, non-price competition may intensify. For example, a bigger sale margin stimulates booksellers to give better service to customers (Holahan, 1979; Mathewson and Winter, 1998; Deneckere, Marvel and Peck, 1997). With a bigger profit margin, it pays to spend more effort on service in order to get extra customers. If the extra service (more attractive presentation in bookshops, better information to customers, more promotion, and so on) generates more sales than the fallback in sales due to higher monopoly prices, the FBP may be desirable. Otherwise, the market fails to deliver sufficient service, because bookshops have an incentive to operate as free riders by offering discounts and expecting their customers to get their information and service elsewhere. Bookshops hardly refuse service or charge for information provided to people who in the end may not buy a book. Still, most customers rarely engage in such a strategy, as the costs of roaming around various bookshops seem high in relation to the possible discount one might obtain. Much of this service is already made available through publishers’ advertisements or book reviews in newspapers and other media or on the Internet. In any case, it is questionable whether the demand for books really depends on service. Better service does not seem a good argument for supporting a FBP.

The book trade also argues that a bigger margin provides incentives for better-stocked bookshops. Booksellers may take over some of the inventory risks from publishers, so that more titles will be published. At the margin it is more profitable for retail outlets with relatively high costs to open up. This argument works only if customers want to purchase their books at particular high-cost bookshops. The gain in sales from these outlets may then offset the drop in sales resulting from higher monopoly prices. Although a dense network of bookshops may be desirable from a cultural point of view, this argument for the FBP is difficult to justify on grounds of market failure. Another popular argument is that higher margins encourage more retail outlets to put new book titles with uncertain sales prospects on their shelves. Given that there seems to be no problem for new authors to get their first book published, this is not a strong argument either. Marvel and McCafferty (1984) suggest that resale price maintenance may sustain a luxury image, but that seems more relevant for the markets for perfumes and jewellery than for books.

Is the cross-subsidy argument really valid?

The novel *Endurance* by Ian McEwan is not a perfect substitute for *Il Nome della Rose* by Umberto Eco. They are different books, because the authors have different styles, the themes of the two novels are different, and last but not least the original languages in which the books are written are different. Still, Umberto Eco’s books are closer substitutes for the novels of Ian McEwan than, say, a cookbook or a travel book. On the other hand, Martin Amis may be a closer substitute than Umberto Eco for Ian McEwan. One must therefore leave the realms of homogenous goods and adopt a framework of Chamberlinian monopolistic competition in which books are imperfect substitutes. Publishers and booksellers carve out a niche and make monopoly profits, which enable them to recoup fixed costs. It is thus profitable to publish books. In fact, an important argument of the lobby of booksellers and publishers rests on imperfect competition. They argue that the FBP allows for cross-subsidies from best-sellers to less popular books and leads to a more diverse supply of book titles and bookshops. In
addition, the book lobby suggests that publishing and stocking a large selection of books enhances reputation, yields economies of scope and satisfies the idiosyncratic taste of individual publishers and booksellers even though these arguments do not seem very strong (Canoy, van Ours and van der Ploeg, 2006).

The cross-subsidy argument seems at first blush irrelevant. In competitive markets with imperfect information about the success of a product, it is common to invest in many products and reap a success on only a few. Even without a fixed horse price agreement, horse owners purchase lots of yearlings, many of which are subsequently sold to the riding school or the butcher if they do not win races. Similarly, in a market without FBP, publishers invest in new authors, just as horse owners invest in yearlings. Indeed, the industry's rule of thumb formulated by Denis Diderot in 1767 suggests that one out of ten new editions is a profitable success, four cover costs, and five make losses (Beck, 2003).

There are few barriers to new authors in the book market even though publishing is a risky business with only one-third of published books being profitable. The FBP then has all the welfare and political economy costs of a monopoly. This situation may arise if best-sellers are easily digestible, require little time to read and have high price elasticities of demand, while, say, poetry readings demand a lot of time and effort and have low price elasticities of demand. Indeed, anything worthwhile from a cultural point of view takes time and effort to appreciate and contributes to a low price elasticity of demand.

Non-fiction books (dictionaries, cookbooks, travel guides, textbooks, and so on) are likely to be close substitutes within each genre and will thus have high price elasticities. Fiction books (children books, mysteries, and so on) often have close substitutes (perhaps with the exception of Harry Potter), especially for the pocketbook versions of old titles, and thus high price elasticities. We do not expect large monopoly profits on such titles, and there is little room for cross-subsidies to books with a special or unique character. Such books have low price elasticities and generate high monopoly profits. If this is the situation, the cross-subsidy argument is likely to be wrong. The problem with a FBP is that there is no guarantee that publishers and booksellers will use the monopoly profits to make sure that more esoteric titles will be published and stocked in the stores. Monopoly profits may well be directed towards unproductive managerial slack.

Summing up

In summary, a FBP may induce higher prices and fewer sales of any book title that is published. It may also hinder innovation and distribution, but more titles will be published and there will be more bookshops with a diverse assortment of titles. However, German data suggest that retail price maintenance does not facilitate above-average focal pricing where prices are bunched around focal points (Beck, 2004). The lowering of production costs due to technological progress will benefit the diversity of books being published. In any case, many FBPs are of limited duration and characterized by sensible exceptions. The welfare costs are probably not very large, but may be reduced a little by reducing the term and coverage of the agreement. It may also be helpful to abolish certification and exclusive trade arrangements, scrap the fixed discount for recognized booksellers, and move to individual rather than vertical price agreements (see also Appelman and van den Broek, 2002). Since educational and scientific books typically have relatively low price elasticities and are more susceptible to monopoly abuse, it helps to exclude them from the FBP. As a dogma, the FBP diverts attention and
energy away from making the book trade more innovative and customer-oriented. It may be more worthwhile to stimulate reading of a wide variety of books by investing in public libraries and education, subsidising authors to write books of high cultural value, translating the best books into other languages and promoting them abroad.

Other public policies

Stimulating demand: lower value-added tax

The general consumption of books can be increased by lowering the specific value-added tax (VAT) rate on books. This is a general instrument, which is not well suited to direct at special books of literary value. The lower VAT on books applies to cookbooks as well as to poetry. This instrument is therefore mainly used to stimulate the purchasing and, it is hoped, reading of books. Administrative costs are low, since no apparatus of literary experts has to be called upon. All countries of Europe, except Denmark, use a reduced VAT rate as instrument to stimulate book purchases. The United Kingdom and Ireland even abolished VAT on books altogether. The European Commission misguidedly attempts to harmonize VAT rates on books, making it difficult for other member states to abolish VAT on books. The Commission fails to take account of the subsidiarity principle. Since the book trade, especially between the non-English speaking countries, hardly distorts the intra-European book trade, there is no danger of tax competition and no harm in countries pursuing their VAT policies on books independently of each other.

Stimulating supply: prizes and grants for writers and subsidies for bookshops

Governments and commercial sponsors do many things to encourage writers. There are many prestigious and less prestigious prizes for the best novelist, the best detective writer, the best poet, the best translator, and so on. All these are meant to encourage quality. More important, they might guide the uninitiated reader to better books. Book clubs, best-seller lists and book programmes on television also help in this respect. They also probably increase sales. Literary funds help struggling authors to make a living if their project is deemed to be of literary interest. Since only best-seller authors can make a living on royalties and related incomes, others may need some help, especially if their output has cultural value but is perhaps of less general interest. These policies are designed to stimulate quality rather than quantity. Sometimes subsidies for publishers of high-quality books may help as well (witness Sweden).

Many politicians attach cultural importance to a dense network of retail outlets. We have already noted that density seems to be falling in some countries, perhaps more in countries without a FBP; and concentration is increasing as well. From a cultural point of view this is bad news. Consumers have to travel further and there is less variety of bookshops. If the main objective of cultural policies is to increase the density of high-quality outlets, subsidies for high-quality bookshops may be more effective than the FBP. If they act as cultural centres in less populated areas, they may deserve public support. Subsidizing in order to maintain well-stocked bookshops would probably prove an administrative nightmare, which may explain why there is not much experience of this. Subsidizing publishers to publish books of literary and cultural value would also seem to hinder the market mechanism and lead to
adverse effects. In Sweden the government subsidizes in this manner roughly one-third of all fiction and
one-fifth of books for children. However, Swedish retailers do not stock all titles since the government,
rather surprisingly, does not require subsidized books to be offered for sale.

Concluding remarks

The book market ensures reasonable cultural performance with little government intervention, especially
in large language areas. Yet there are differences between countries in reading, retail outlets, wholesale
and production. Due to lack of data and research it is not easy to explain these differences. They may be
due to differences in preferences, logistics, population density or public policies or to being stuck in the
wrong equilibrium. One important trend is that people seem to read fewer books over time. Perhaps they
are reading on the Internet or spending time on other cultural leisure activities. Here are some important
areas for further research: investigating the relationship between production of titles, books sold and
prices; using survey data to study the effects of personal characteristics of readers on market outcomes;
analysing empirically differences between book and other cultural markets; and using industrial
organization to understand pricing and stocking behaviour of publishers and retailers.
The book industry is characterized by relatively few market failures and these can be relatively easily
corrected with market instruments. The book industry can fend well for itself, in contrast to opera, film
or theatre, characterized by high production costs, high risk and complex interactions between a large
number of different professionals. Even though there are obvious returns to scale, production costs are
low. Thresholds for new authors, publishers and retailers are small, contracts are relatively simple and
fairly uniform. The market is quite capable of inventing solutions for specific problems and public
policies are not always called for, except perhaps to stimulate reading.

Nevertheless, there is a strong lobby for government intervention. Prizes and grants for authors,
translators, publishers, bookshops, special VAT regimes for books, stimulating reading through public
libraries, and the FBP are possible policy instruments. The standard case against the FBP is that book
prices are higher and sales lower than under perfect competition. This hurts the interests of buyers,
particularly those with lower incomes, since prices will be higher. One possible argument in favour is
that the FBP may induce more and better-stocked bookshops and lead to publication of more marginal
book titles. The cross-subsidy argument of the lobby in favour of the FBP is not convincing, however.
First, even without the FBP, the market cross-subsidizes new authors and other risky projects in the hope
of a possible best-seller. Second, even if this policy ‘works’, there is no accounting for what is done with
the cross-subsidies and no democratic checks. Third, there is no guarantee that profits on best-sellers
will be used to cross-subsidize less popular books. In fact, publishers and booksellers have an incentive
not to do this. Fourth, if less popular books are less price elastic than popular books (perhaps as they
take more time to read), monopoly profits on less popular books are higher and the cross-subsidy
argument does not work. Fifth, even if cross-subsidization does occur, one should evaluate whether its
cultural gains outweigh the distortionary costs of the FBP. Arguments put forward to defend the FBP,
stressing improved service, better distribution and retail networks, and other forms of increased non-
price competition, do not stand up to scrutiny either. The book industry produces many titles and new
authors do not experience severe problems. The FBP may slow down or even stop the declining number
of well-stocked bookshops outside big cities, but hinders sales through the Internet and supermarkets.
A comparison of policies towards the book industry in different European countries teaches us that
Harmonization is a bad idea. There is not much inter-European book trade, so that book policies hardly distort the single European market. Also, characteristics of book industry, cultural and social features and political preferences of the different countries of Europe differ substantially. It is therefore best to allow member states of the European Union to design their own book policies. For example, a FBP makes more sense for Greece than for the United Kingdom as it has a smaller ‘language size’ and fewer people have access to the Internet. Although there may be a problem of a ‘race to the bottom’ if VAT rates are not harmonized, tax competition seems pretty irrelevant for the book market. European countries should be free to lower or abolish VAT on books in order to promote reading.

Many of the privileges granted in the book industry will eventually be undermined by technical changes. Digital cameras, recording and editing equipment have made low budget radio and television as well as narrowcasting possible, thus undermining the monopoly power of public and other broadcasters. Similarly, the Internet has stimulated virtual book suppliers, printing and publishing on demand and E-books. Virtual dictionaries, encyclopedias and other handbooks have already overtaken, to a large extent, their physical counterparts. A dense network of well-stocked bookshops remains important. Some argue that the emergence of the Internet and the integration of books in smart product and digitized communication will lead to the disappearance of the printed book (Choi, Stahl and Whinston, 1998). While more retailing will take place through the Internet and new gadgets, for some people the physical bookshop, where one can feel the book and bump into surprise titles and people, will remain indispensable.

There are, however, trends that endanger books, the most important being that people read less and less. Some worry that the next generation will stop reading books altogether, but this may be too pessimistic. First, the population is aging so that more leisure time becomes available and the opportunity costs of reading decrease. Second, books are doing well. In 1947, some 85,000 books were in print in the United States, against 1.3 million in 1996. This is, in part, due to sharp reductions in production and printing costs. Third, there is no reason to believe that a cultural carrier as old as the book will suddenly disappear. Modern technology complements books rather than substitutes for them (Cowen, 1998). Each new development in the craft has led to outbursts of cultural pessimism that allegedly indicates the end of the book. Most of the developments have only improved the book business (Cowen, 1998). Also, prices fell considerably and steadily. The future of the book market may look very different. E-books will replace parts of the market where E-reading already outperforms traditional reading. As for novels, nobody knows. Perhaps our children will read their novels directly from the screen.

The bootstrap is a method for estimating the distribution of an estimator or test statistic by resampling one's data. It is often much more accurate in finite samples than ordinary asymptotic approximations are. This is important in applied research, because the familiar asymptotic normal and chi-square approximations can be very inaccurate. When this happens, the difference between the true and nominal coverage probability of a confidence interval or rejection probability of a test can be very large, and inference can be highly misleading. The bootstrap often greatly reduces errors in coverage and rejection probabilities, thereby making reliable inference possible.

Article
The bootstrap is a method for estimating the sampling distribution of an estimator or test statistic by resampling one's data. It amounts to treating the data as if they were the population for the purpose of evaluating the distribution of interest. Under mild regularity conditions, the bootstrap yields an approximation to the distribution of an estimator or test statistic that is at least as accurate as the approximation obtained from ‘ordinary’ or first-order asymptotic theory. Thus, the bootstrap provides a way to substitute computation for mathematical analysis if calculating the asymptotic distribution of an estimator or statistic is difficult. Moreover, the bootstrap is often more accurate in finite samples than first-order asymptotic approximations are but does not entail the algebraic complexity of higher-order expansions. Thus, it can provide a practical method for improving upon first-order approximations. Such improvements are called ‘asymptotic refinements’.
The bootstrap is of considerable importance in applied research. Many important statistics in econometrics have complicated asymptotic distributions that depend on nuisance parameters and, therefore, cannot be tabulated. Examples include the conditional Kolmogorov test statistic of Andrews (1997) and Manski’s (1975; 1985) maximum score estimator for a binary-response model. The bootstrap and related resampling techniques provide practical methods for estimating the distributions of such statistics. In other cases, the statistic of interest has a familiar distribution but with a complicated standard error that is difficult to work with analytically (for example, Horowitz and Manski, 2000). Again, the bootstrap provides a practical method for carrying out inference.

The bootstrap's ability to provide asymptotic refinements is especially important in applied research. First-order asymptotic approximations (for example, asymptotic normal and chi-square approximations) can be very inaccurate with the sample sizes that are found in applications. When this happens, the difference between the true and nominal coverage probability of a confidence interval (error in the coverage probability or ECP) can be very large. Similarly, the difference between the true and nominal probability that a test rejects a correct null hypothesis (error in the rejection probability or ERP) can be very large. Consequently, inference based on first-order asymptotic approximations can be highly misleading. White’s (1982) information matrix test is a well-known example of this. There are many others. The bootstrap often greatly reduces the ECPs of confidence intervals and ERPs of tests, thereby making reliable inference possible.

Bias reduction is another use of the bootstrap's ability to provide asymptotic refinements. It is not unusual for an asymptotically unbiased estimator to have a large finite-sample bias. This may cause the estimator's finite-sample mean-square error to be very large. The bootstrap can be used to reduce the estimator's finite-sample bias and, thereby, its finite-sample mean-square error.

This article assumes that the data are an independent random sample from some distribution. Horowitz (2001) and Lahiri (2003) discuss bootstrap methods for time-series data.

1 How the bootstrap works

This section explains why the bootstrap works and how it is implemented in simple settings. The estimation problem to be solved may be stated as follows. Let the data, \( \{X_i: i = 1, \ldots, n\} \), be a random sample of size \( n \) from a probability distribution whose cumulative distribution function (CDF) is \( F \). Let \( T_n = T_n(X_1, \ldots, X_n) \) be a statistic (that is, a function of the data), possibly a test statistic. Let \( G_n(\tau, F) = P(T_n \leq \tau) \) denote the exact, finite-sample CDF of \( T_n \). Usually, \( G_n(\tau, F) \) is a different function of \( \tau \) for different distributions \( F \). An exception occurs if \( G_n(\tau, F) \) does not depend on \( F \), in which case \( T_n \) is said to be pivotal, but pivotal statistics are not available in most applications. Therefore, \( G_n(\tau, F) \) cannot be calculated if, as is usually the case in applications, \( F \) is unknown. The bootstrap is a
bootstrap: The New Palgrave Dictionary of Economics

method for estimating \( G_n(\tau, F) \) or features of it such as its quantiles when \( F \) is unknown.

First-order asymptotic distribution theory is another method for estimating \( G_n(\tau, F) \). The asymptotic distributions of many econometric statistics are standard normal or chi-square, possibly after centring and normalization, regardless of the distribution from which the data were sampled. Such statistics are called *asymptotically pivotal*, meaning that their asymptotic distributions do not depend on unknown population parameters. Let \( G_{\infty}(\tau, F) \) denote the asymptotic distribution of \( T_n \). If \( T_n \) is asymptotically pivotal, then \( G_{\infty}(\cdot, F) = G_{\infty}(\cdot) \) does not depend on \( F \). Therefore, if \( n \) is sufficiently large, \( G_n(\cdot, F) \) can be estimated by \( G_{\infty}(\cdot) \) without knowing \( F \). This method for estimating \( G_n(\cdot, F) \) is often easy to implement and is widely used. However, \( G_{\infty}(\cdot) \) can be a poor approximation to \( G_n(\cdot, F) \) with samples of the sizes encountered in applications.

The bootstrap provides an alternative approximation to \( G_n(\cdot, F) \). Whereas first-order asymptotic approximations replace the unknown distribution function \( G_n \) with the known function \( G_{\infty} \), the bootstrap replaces the unknown distribution function \( F \) with a consistent estimator such as the empirical distribution function of the data. Let \( F_n \) denote the estimator of \( F \). The bootstrap estimator of \( G_n(\cdot, F) \) is \( G_n(\cdot, F_n) \). Usually, \( G_n(\cdot, F_n) \) cannot be evaluated analytically. It can, however, be estimated with arbitrary accuracy by carrying out a Monte Carlo simulation in which random samples are drawn from the data. Thus, the bootstrap is usually implemented by Monte Carlo simulation. The Monte Carlo procedure for estimating \( G_n(\tau, F_n) \) is:

- **Step 1**: Generate a bootstrap sample, \( \{X_i^* : i = 1, \ldots, n\} \) by sampling the estimation data randomly with replacement.
- **Step 2**: Compute \( T_n^* = T_n(X_1^*, \ldots, X_n^*) \).
- **Step 3**: Use the results of many repetitions of steps 1 and 2 to compute the empirical probability of the event \( T_n^* \leq \tau \) (that is, the proportion of repetitions in which this event occurs).

If \( T_n \) is a test statistic, then the bootstrap can be used to estimate its critical value. Consider a test that rejects the null hypothesis, \( H_0 \), if \( |T_n| \) is too large. The exact \( \alpha \)-level critical value, \( Z_n(\alpha/2, F) \), is the solution to \( G_n(Z_n(\alpha/2, F)) - G_n(-Z_n(\alpha/2, F)) = 1 - \alpha \). Unless \( T_n \) is pivotal, however, this equation cannot be solved in an application because \( F \) is unknown. Therefore, the exact, finite-sample critical value cannot be obtained in an application if \( T_n \) is not pivotal. The bootstrap replaces \( F \) with \( F_n \). Thus, the bootstrap critical value, \( Z_n^*(\alpha/2, F_n) \), solves \( G_n(Z_n^*(\alpha/2, F_n)) - G_n(-Z_n^*(\alpha/2, F_n)) = 1 - \alpha \). This equation usually cannot be solved analytically, but \( Z_n^*(\alpha/2) \) can be estimated with any desired accuracy by Monte Carlo simulation. To illustrate, suppose, as often happens in applications, that \( T_n \) is an asymptotically standard normal, Studentized estimator of a parameter \( \theta \) whose value under \( H_0 \) is \( \theta_0 \). That is, \( T_n = n^{1/2}(\theta_n - \theta_0) / s_n \), where \( \theta_n \) is the estimator of \( \theta \), \( n^{1/2}(\theta_n - \theta_0) \to d N(0, \sigma^2) \) under \( H_0 \), and \( s_n^2 \) is a consistent estimator of \( \sigma^2 \). Then the Monte Carlo procedure for computing \( Z_n^*(\alpha/2) \) is:
Step 1. Use the estimation data to compute $\theta_n$.

Step 2. Generate a bootstrap sample of size $n$ by sampling the data randomly with replacement. Compute the estimators of $\theta$ and $\sigma$ from the bootstrap sample. Call the results $\hat{\theta}_n$ and $\hat{\sigma}_n$. The bootstrap version of $T_n$ is $T_n^* = n^{1/2} (\hat{\theta}_n - \theta_n) / \hat{\sigma}_n$.

Step 3. Use the results of many repetitions of step 2 to compute the empirical distribution of $|T_n^*|$. Set $z_{n,\alpha/2}$ equal to the $1-\alpha$ quantile of this distribution.

A test based on $|T_n|$ and the bootstrap critical value rejects $H_0$ at the $\alpha$-level if $|T_n| > z_{n,\alpha/2}$. A symmetrical $1-\alpha$ confidence interval for $\theta$ based on the bootstrap critical value is $\hat{\theta}_n - z_{n,\alpha/2} \hat{\sigma}_n \leq \theta \leq \hat{\theta}_n + z_{n,\alpha/2} \hat{\sigma}_n$. For reasons that are explained in Section 2, use of the bootstrap critical value $z_{n,\alpha/2}$ instead of the critical value based on the asymptotic normal distribution can greatly reduce the ERP of a test of a hypothesis about $\theta$ and the ECP of a confidence interval for $\theta$.

Since $F_n$ and $F$ are different functions, $G_n(\cdot, F_n)$ and $G_n(\cdot, F)$ are also different functions unless $T_n$ is pivotal. Therefore, the bootstrap estimators $G_n(\cdot, F_n)$ and $z_{n,\alpha/2}$ are only approximations to the exact finite-sample CDF and critical value of $T_n$, $G_n(\cdot, F)$ and $z_{n,\alpha/2}$. However, $F_n$ is close to $F$ when $n$ is large. Therefore, if $G_n$ is a sufficiently smooth function, $G_n(\cdot, F_n)$ will be close to $G_n(\cdot, F)$. Moreover, we can expect $z_{n,\alpha/2}$ to approach $z_{n,\alpha/2}$ as $n \to \infty$. In other words, the bootstrap provides an approximation to the sampling distribution and critical value of $T_n$ that becomes increasingly accurate as $n$ increases. This property of the bootstrap is called consistency. Beran and Ducharme (1991) and Mammen (1992) give formal conditions under which the bootstrap is consistent. Horowitz (2001) gives some econometrically relevant examples in which the bootstrap is not consistent and, therefore, cannot be used to estimate the distribution of a statistic. These include Manski’s maximum score estimator, the distribution of a parameter on the boundary of the parameter set, and estimation of the maximum of a sample.

When the bootstrap is inconsistent (that is, $G_n(\cdot, F_n) - G_n(\cdot, F)$ does not converge to 0), subsampling procedures can be used to estimate $G_n(\cdot, F)$. One approach to subsampling consists of drawing samples of size $m < n$ by sampling the data randomly without replacement. This produces random samples from the true population distribution of the data, $F$, not the empirical distribution, $F_n$, from which bootstrap samples are drawn. Consequently, subsampling yields a consistent estimator of $G_n(\cdot, F)$, even when the bootstrap does not. Politis, Romano and Wolf (1999) describe the theory of subsampling and methods for implementation. Subsampling is consistent in all known settings of practical importance, so it is much more widely applicable than the bootstrap. The price of this versatility, however, is reduced accuracy. The approximation provided by subsampling is typically less accurate than that provided by first-order asymptotic distribution theory, and subsampling can be much less accurate than the bootstrap when the bootstrap is consistent.

2 Asymptotic refinements
The bootstrap provides asymptotic refinements for statistics that are asymptotically pivotal. That is, the bootstrap provides a better approximation to the distribution of an asymptotically pivotal statistic than does ‘ordinary’ asymptotic distribution theory. A statistic is asymptotically pivotal if its asymptotic distribution does not depend on unknown population parameters. All the familiar test statistics whose asymptotic distributions are standard normal or chi-square are asymptotically pivotal. Estimates of regression coefficients, standard errors, and other population parameters typically are not asymptotically pivotal. The bootstrap does not provide asymptotic refinements for statistics that are not asymptotically pivotal. Whenever possible, the bootstrap should be applied to asymptotically pivotal statistics as opposed to statistics that are not asymptotically pivotal.

The bootstrap's ability to provide asymptotic refinements has important practical consequences. Specifically, the bootstrap can be used to obtain estimates of finite-sample critical values for test statistics that are more accurate than critical values obtained from the asymptotic normal or chi-square approximations. The use of bootstrap-based critical values can greatly reduce the ERP of a test and ECP of a confidence interval.

The bootstrap provides asymptotic refinements because it provides a higher-order asymptotic approximation, called an Edgeworth approximation, to $G_n(\tau, F)$. Suppose that $T_n$ is asymptotically distributed as $N(0, 1)$, and let $\Phi$ denote the standard normal CDF. Then $G_n(\tau, F_n) - G_n(\tau, F) = O_p(n^{-1})$, whereas $G_n(\tau, F) - \Phi(\tau) = O(n^{-1/2})$. Thus, the error made by the bootstrap approximation to $G_n(\tau, F)$ converges to 0 more rapidly than does the error made by the asymptotic normal approximation. For $|T_n|$ or an asymptotic chi-square statistic, the error made by the bootstrap approximation is $O_p(n^{-3/2})$ whereas the error made by the asymptotic normal or chi-square approximation is $O(n^{-1})$. See Hall (1992) and Horowitz (2001) for details.

Rejection probabilities of tests and coverage probabilities of confidence intervals based on bootstrap critical values can be even more accurate. The ERPs of symmetrical tests and ECPs of symmetrical confidence intervals are $O(n^{-2})$ when the bootstrap is used to obtain the critical value, whereas they are $O(n^{-1})$ when the asymptotic normal or chi-square approximation is used. (A test based on an asymptotic chi-square statistic is symmetrical. So is a test that rejects the null hypothesis when $|T_n|$ exceeds the critical value, where $T_n$ is asymptotically distributed as $N(0, 1)$.) Thus, the ERPs and ECPs of symmetrical tests and confidence intervals converge to 0 much more rapidly with bootstrap-based critical values than with critical values based on the asymptotic normal or chi-square approximations. The practical consequence of this is that the bootstrap often achieves spectacular reductions in the numerical values of ERPs and ECPs. Section 3 provides two examples of this. Horowitz (1997; 2001) provides others.

With one-sided tests and confidence intervals, the ERP and ECP are usually $O(n^{-1})$ with bootstrap critical values and $O(n^{-1/2})$ with asymptotic chi-square or normal critical values. However, there are cases in which the ERP of a bootstrap-based test is $O(n^{-3/2})$ (Hall, 1992; Davidson and MacKinnon, 1999).
3 Examples

This section presents two examples that illustrate the bootstrap's ability to reduce the ERP of a test or the ECP of a confidence interval.

3.1 White's (1982) information-matrix (IM) test

This is a specification test for parametric models estimated by maximum likelihood. The test statistic is asymptotically chi-square distributed, but the asymptotic distribution is a poor approximation to the finite-sample distribution.

Horowitz (1994) reports the results of Monte Carlo experiments that investigate the ERPs of the IM test with bootstrap critical values. Some of these results are summarized in Table 1, which gives the results of applying the Chesher (1983) and Lancaster (1984) form and White's (1982) original form of the test to Tobit and binary probit models. The results show that the ERPs are very large when critical values based on the asymptotic chi-square distribution are used. When bootstrap critical values are used, however, the ERPs are very small. The bootstrap essentially eliminates the differences between the true and nominal rejection probabilities of the two forms of the IM test.

3.2 Estimation of covariance structures

In estimation of covariance structures, the objective is to estimate the covariance matrix of a $k \times 1$ vector $X$ subject to restrictions that reduce the number of unique, unknown elements to $r < k(k+1)/2$. 
Estimates of the $r$ unknown elements can be obtained by minimizing the weighted distance between sample moments and the estimated population moments. Weighting all sample moments equally produces the equally weighted minimum distance (EWMD) estimator, whereas choosing the weights to maximize asymptotic estimation efficiency produces the optimal minimum distance (OMD) estimator. The OMD estimator has poor finite-sample performance in applications (Abowd and Card, 1989). Horowitz (1998) reports the results of a Monte Carlo investigation of the ability of the bootstrap to reduce the ERPs of nominal 95 per cent symmetrical confidence intervals based on the OMD estimator.

In each experiment, $X$ has 10 components, and the sample size is $n=500$. The $j$'th component of $X$, $X_j (j=1, \ldots, 10)$ is generated by $X_j = (Z_j + \rho Z_{j+1})/(1+\rho^2)^{1/2}$, where $Z_1, \ldots, Z_{11}$ are i.i.d. random variables with means of 0 and variances of 1, and $\rho = 0.5$. The $Z$'s are sampled from five different distributions depending on the experiment. It is assumed that $\rho$ is known and that the components of $X$ are known to be identically distributed and to follow MA(1) processes. The estimation problem is to infer the scalar parameter $\theta$ that is identified by the moment conditions $\text{Var}(X_j) = \theta$ ($j=1, \ldots, 10$) and $\text{Cov}(X_j, X_{j-1}) = \rho\theta/(1+\rho^2)$ ($j=2, \ldots, 10$).

The results of the experiments are summarized in Table 2. The coverage probabilities of confidence intervals based on asymptotic critical values are far below the nominal value of 0.95 except in the experiment with uniform $Z$'s. However, the use of bootstrap critical values greatly reduces the ERPs. In the experiments with normal, Student $t$, uniform, or exponential $Z$'s, the bootstrap essentially eliminates the errors in the coverage probabilities of the confidence intervals. Empirical coverage probabilities of nominal 95 per cent symmetrical confidence intervals based on the OMD estimator

Karl Borch was born in Sarpsborg, Norway, on 13 March 1919. He graduated with an MSc in actuarial mathematics at the University of Oslo in 1947, and a Ph.D. in 1962. From 1947 he worked for UNESCO and OECD until in 1959 he started his academic career at the Norwegian School of Economics and Business Administration (NHH) in Bergen, where he was appointed professor of insurance in 1963, a position he held until his untimely death on 2 December 1986, only just before his retirement was due.

In Who’s Who in Economics (1986, p. 103) he wrote: ‘When in 1959 I got a research post which gave me almost complete freedom, as long as my work was relevant to insurance, I naturally set out to develop an economic theory of insurance.’ That within a year he should have made a decisive step in that direction is amazing. What he did during these first years of his research career was to write the first of a long series of seminal papers, which were to put him on the map as one of the world's leading scholars in his field.

One important contribution of his papers in Skandinavisk Aktuarietidskrift (1960a) and Econometrica (1962) was to derive testable implications from the abstract model of general equilibrium with markets for contingent claims. In this way, he brought economic theory to bear on insurance problems, thereby opening up that field considerably; and he brought the experience of reinsurance contracts to bear on the interpretation of economic theory, thereby considerably enlivening that theory.

Practically his entire production was centred on the topic of uncertainty in economics. Many of his thoughts were formulated in his successful book The Economics of Uncertainty (1968a), also available in Spanish, German and Japanese. He gave the first graduate lectures at NHH, where he supervised many Ph.D. students.

He had more than 150 publications, among them three books (published in 1968, 1974 and 1990). The
last one, *Economics of Insurance*, has also been translated into Chinese. Best known to actuaries is perhaps his pioneering work on Pareto-optimal risk exchanges in reinsurance (for example, 1960a). Borch also made many contributions to the application of game theory to insurance: in particular, he characterized the Nash bargaining solution of a reinsurance syndicate (1960b). Borch served on many editorial boards, and he helped organize several key international conferences abroad and at NHH.

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Black, D.; Borda, J.-C. de; Condorcet criterion; Condorcet, Marquis de; Laplace, Marquis de; mathematical theory of elections; method of marks; public choice; voting

Article

The second half of the 18th century in France was one of the outstanding epochs of scientific thought and witnessed significant attempts to carry the methods of rigorous and mathematical thought beyond the physical and into the realms of the human sciences. A brilliant start was made in political science by three French academicians, namely Borda, Condorcet and Laplace, with contributions which now play a central role in the literature of public choice. It is a salutary warning to those who view science as endlessly progressive to note that the contributions of these outstanding academicians were lost for two centuries until they were rediscovered in 1958 by Duncan Black.

Borda was the first of the three to develop a mathematical theory of elections shortly after becoming a member of the Academy of Sciences. Born in 1733 in Dax, near Bordeaux, Borda was successively an officer of cavalry, a naval captain, and a scholar of mathematical physics as well as an innovator in the field of scientific instruments. Newly elected to the Academy of Sciences, Borda read a paper entitled ‘Sur la forme des elections’ on 16 June 1770. Four members were charged to report on it, but failed to do so.

The Academy was not to consider elections again during the succeeding 14 years, until Borda again read a paper on elections in July 1784 following the favourable report by Bossut and Coulomb on Condorcet's manuscript, Essai. Borda's paper had been printed in the Histoire de l' Academie Royale des Sciences in 1781, three years prior to this reading. It was finally published in 1784. In essence, it reflected the content of his 1770 paper. Condorcet had become acquainted with Borda's contribution prior to writing his Essai, as a consequence of the strong oral tradition of the Academy. He acknowledged the powerful influence of Borda's ideas upon his own writings.

Borda was concerned that the single vote system of elections might select the wrong candidate. He illustrated by reference to a situation in which eight electors had candidate A as first preference, seven
had candidate B, and six had candidate C. On the single vote, A would be elected, although the electors preferred B or C to A by a majority of 13 to 8. In essence, Borda was utilizing what later became known as the Condorcet criterion, though he failed to develop it himself. Instead, he attempted to remedy the defect of the single vote system by the method of marks, which he presented in two forms. Since one form is a special case of the other, only the more general form is here outlined.

The method of marks requires each elector to rank all the candidates by order of merit. The candidate is then allocated marks by reference to his ranking by each voter, for example, three marks for first place, two marks for second, and one mark for last in a three candidate election. The marks are then totalled across all elections. The candidate with the largest aggregate of marks is the winner.

To illustrate how the method of marks may provide a different result from that of the single vote, let us expand Borda's original example as outlined above into the form of Table 1.

<table>
<thead>
<tr>
<th>Rank order of candidates by electors</th>
<th>1</th>
<th>7</th>
<th>1</th>
<th>6</th>
<th>1</th>
<th>5</th>
</tr>
</thead>
<tbody>
<tr>
<td>A A B B C C</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>B C A C A B</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>C B C A B A</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

In the Table 1 example, Candidate A would receive an aggregate of 39 marks, Candidate B receives an aggregate of 41 marks, and Candidate C receives an aggregate of 46 marks. Candidate C is the winner, reversing the single vote outcome.

The method of marks allows a role for preference intensities, albeit only on a strictly linear scale, within the electoral process. For this reason, it has been called a ‘neo-utilitarian’ approach (Sugden, 1981). The method is not strategy proof, since voters will tend to lower the ranking of the candidate most threatening to their preferred candidate to the lowest level, irrespective of their actual preferences. Borda himself clearly recognized this danger, but, in an age more honourable than our own, was merely moved to comment: ‘My scheme is only intended for honest men.’

Borda's paper did not attempt to provide a comprehensive theory of elections. It failed to develop, though it implicitly embraced, the criterion of Condorcet. More important, it offered no real insight into the nature and/or the objectives of group decisions. It was, however, a significant first step in both directions. The method of marks is extremely effective if each elector genuinely desires to secure the election of ‘that candidate who should be the most generally acceptable’ (Black, 1958). In reality, most electors desire to secure the election of their most favoured candidate. Herein lies the weakness of the method of marks.

Shortly after hearing Borda's paper in 1784, the Academy adopted his method in elections to its membership. The method of marks remained in use until 1800, when it was attacked by a new member, and soon afterwards, was modified. The new member in question was Napoleon Bonaparte.

border effects

John H. Rogers
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

International finance and trade economists have traditionally focused on the behaviour of cross-country prices and factor returns and the flow of goods and capital across nations. Studying these same variables across locations within countries provides a baseline for measuring the influence of the border. The ‘border effect’ is the difference between international and intra-national magnitudes. Large border effects were initially found in consumer goods prices and trade volumes. Subsequent studies have examined robustness and looked for explanations of the border effect.

Article

International finance and trade economists have traditionally focused on the behaviour of cross-country prices and factor returns and the flow of goods and capital across nations. Studying these same variables across locations within countries provides a baseline for measuring the influence of the border. The ‘border effect’ is, to speak loosely, the difference between international and intra-national magnitudes. Large border effects were initially found in consumer goods prices and trade volumes (Engel and Rogers, 1996; McCallum, 1995) in data from the United States and Canada. Subsequent studies have examined robustness and looked for explanations of the border effect, often through extensions to other countries’ data-sets. The starting point of Engel and Rogers (1996) is a fundamental proposition of economic theory: in the absence of transaction costs, identical goods must sell for the same price. Prices will fail to equalize when there are barriers, natural ones or man-made, to the free movement of goods. There are several
Engel and Rogers (1996) examine the behaviour of prices of 14 categories of consumer goods and services in 14 US cities and 9 Canadian cities during the period 1978–94. They measure the border effect by comparing the extent to which prices of a particular category of goods fluctuate across cities intra-nationally with price fluctuations for city pairs that lie across the border. With $q_{ij}$ defined as the log of the price of some good in city $i$ relative to its price in city $j$, let $V(q_{ij})$ be a measure of relative price volatility over the sample time period. Engel and Rogers relate this to various explanatory variables including distance between cities and a ‘border dummy’ for whether the cities lie in different countries. They run regressions of the form:

$$V(q_{ij}) = \beta_1 d_{ij} + \beta_2 B_{ij} + \sum_{k=1}^{m} \lambda_k D_k$$  

(1)

where $d_{ij}$ is the log of the distance between cities $i$ and $j$; $B_{ij}$ is a dummy variable equal to 1 if cities $i$ and $j$ are in different countries; and $D_k$ are dummy variables for each city. Engel and Rogers (1996) consistently find that $\beta_2$ is positive, highly statistically significant, and large in magnitude. The coefficient on distance, $\beta_1$, is usually positive and significant.

McCallum (1995) estimates the effect of the border on trade flows between Canadian provinces and US states. McCallum's data-set includes imports and exports for all pairs of Canadian provinces, as well as imports and exports between each of the ten provinces and each of the 50 US states. The data are from 1988. McCallum uses a traditional gravity model, positing that trade is a function of the distance between trading partners and their individual economic sizes, measured by gross domestic product. (See Anderson, 1979, for model development, and Rose, 2000, for a noteworthy application.) McCallum augments the standard gravity model with a dummy variable equal to 1 for pairs of Canadian provinces. The coefficient on McCallum's inter-provincial trade dummy variable is estimated to be positive and highly statistically significant. The point estimate implies that, other things equal, trade between two Canadian provinces is more than 20 times larger than trade between a province and a US state.

Anderson and van Wincoop (2003) are critical of the gravity equations employed in the border effects papers on trade flows. They argue that these equations suffer from omitted variables bias (requiring that a ‘multi-lateral resistance’ term be added) and incorrect comparative statics analysis. Anderson and van Wincoop develop a methodology that allows them to get around these shortcomings. Taking up McCallum's exercise using data for 1993, these authors show that the border effect on trade flows is, although still large, considerably smaller than calculated by McCallum.

Engel and Rogers (1996) suggest several reasons why the border should matter. First, there might be direct costs to crossing the border such as tariffs and other trade restrictions. Alternatively, markups might differ across locations and vary with exchange rate changes. Markets for non-traded inputs (wages, marketing services) might be more highly integrated on a national basis than in two places separated by a border. Or productivity shocks might be more similar for city pairs that lie within a
country than for cross-border pairs. Finally, Engel and Rogers consider a sticky-price explanation.
Goods sold in the United States may be sticky in US dollar terms while goods sold in Canada are sticky
in terms of Canadian dollars. A highly variable nominal exchange rate could then give rise to a large,
positive value of $\beta_2$ because cross-border relative prices would fluctuate along with the nominal
exchange rate while relative prices within countries remained fairly stable. Although Engel and Rogers
do not conduct an exhaustive examination of different factors, they conclude, ‘Sticky prices appear to be
one explanation but probably do not explain most of the border effect’ (1996, p. 1112). (The Engel–
Rogers work has an intellectual predecessor in Mussa, 1986, who noted that CPI-based real exchange
rates are more variable for Toronto versus Chicago, Vancouver versus Chicago, Toronto versus Los
Angeles, and Vancouver versus Los Angeles, than for Toronto versus Vancouver and Chicago versus
Los Angeles under floating exchange rates. Mussa attributed this to sticky prices.)
Using updated data, Engel and Rogers (2000) examine the stability of the border effect around the
United States–Canada Free Trade Agreement. They find little evidence of a change across several break
dates corresponding with the signing or implementation of the agreement.
Subsequent studies have examined different data-sets and attempted to understand the dynamics of the
They ask two related questions. First, is there any evidence that the Japan–US ‘border’ narrows over
time? Second, is there evidence linking the evolution of the border effect with plausible economic
candidates (for example, the unit cost of international transportation)? They show that the simple
average of good-level real exchange rates tracks the nominal exchange rate closely, providing strong
evidence of sticky prices in local currencies. They find evidence that the border effect between Japan
and the United States declines over time. Furthermore, distance, shipping costs, and exchange rate
variability collectively explain a substantial portion of the border effect.
Engel and Rogers (2001) use consumer price data from European cities in 11 countries from 1981 to
1997 to explore deviations from short-run purchasing power parity (PPP) across several national
borders. The European data-set has many advantages over that consisting of observations from US and
Canadian cities only. In the latter, there is no distinction between the border dummy and a measure of
nominal exchange rate variability, since all cross-border pairs have the same nominal exchange rate.
With the European data-set, Engel and Rogers are able to include both a border dummy variable (unity
for city pairs lying across the border) and a measure of nominal exchange rate variability. This allows a
distinction between the role of sticky local currency pricing and the various other ‘real’ barriers to
market integration. The authors find that, even with nominal exchange rate variability taken into
account, distance between cities and the border continue to have positive and significant effects on real
exchange rate variability. However, these effects are smaller than the local currency pricing effect.
Gorodnichenko and Tesar (2005) re-examine the Engel–Rogers and Parsley–Wei papers. They run the
same regression as the earlier papers but propose a different measure of the border effect. To understand
their measure, let $\gamma_U$ be the average relative price variance for city pairs within the United States; $\gamma_C$
be the average for pairs within Canada; and $\beta$ be the average relative price variance for cross-border
city pairs (after controlling for distance). Engel and Rogers (1996) measure the border effect as
$\beta - 0.5(\gamma_U + \gamma_C)$. Gorodnichenko and Tesar propose the ‘conservative’ measure: $\beta - \max(\gamma_U, \gamma_C)$.
Since $\gamma_U$ is not very different from $\beta$ (a feature of the data noted by Engel and Rogers), the border
effect is small when measured in the conservative way. Under the Gorodnischenko–Tesar scheme there
are two border effects, one for a Canadian crossing into the US market and the other for an American crossing into Canada. In this case one is quite large, the other relatively small. Engel and Rogers measure the border effect as the average of the two (as do Parsley and Wei for the US–Japan data). Gorodnichenko and Tesar use the smaller of the two.

A large body of literature has expanded upon McCallum's (1995) findings. As with the literature that followed Engel and Rogers (1996), many have analysed different data-sets, especially from other countries. Examples include Helliwell (1996; 1998), Wei (1996), Anderson and Smith (1999), Yi (2003), Wolf (2000), Hillberry and Hummels (2003), and Evans (2003). One important issue highlighted by these papers is the need for accurate measures of ‘internal trade’, that is, the amount that countries trade with themselves. This literature is exhaustively surveyed by Anderson and van Wincoop (2004).

Progress in explaining the border effect on trade flows has been made by decomposing total international trade barriers into barriers associated with geographic factors such as distance and barriers due to national borders. According to Anderson and van Wincoop (2004, Table 7), estimates from several papers using different data-sets (Wei, 1996; Eaton and Kortum, 2002; Evans, 2003; Anderson and van Wincoop, 2003) put the tariff equivalent cost of total international trade barriers at around 40–80 per cent. Anderson and van Wincoop categorize further investigation of the trade barriers associated with national borders as attempts to quantify the effects due to (a) language barriers, (b) use of different currencies, (c) information barriers, (d) contracting costs and security, and (e) policy barriers. To summarize the results from this literature, these authors suggest very rough calculations of an eight per cent policy-related barrier, a seven per cent language barrier, a fourteen per cent currency barrier, a six per cent information cost barrier, and a three per cent security barrier, well within the range of 25–50 per cent for overall border barriers reported by different authors for OECD countries.

Abstract

Bouniatian argued that productive forces cannot be transferred to the future just through the accumulation of capital goods; the choice of production methods determines an equilibrium relation between aggregate consumption and the capital stock. Economic fluctuations are explained by both the increase of the proportion of income saved when output is growing and the period of time necessary for the production of capital goods. The temporary separation between investment and consumption decisions is reflected in a more than proportional increase of capital goods. Changes in the marginal utility of consumption and capital goods and a generalization of the old King's law explain changes in the price level.

Article

Bouniatian was born in Ervian (Armenia) on 22 January 1877, and died on 31 January 1969 in Montmorency (near Paris). He received a D.Sc. from the University of Munich in 1903, and then taught at the University of Moscow and at the Polytechnical Institute of Tiflis (Georgia). From 1916 to 1919 he was manager of the Merchants Bank of Tiflis. After emigrating to France in 1920 as a political refugee, Bouniatian served on the faculty of law of the University of Paris from 1925 to 1940. He later became director of the Office of Armenian Refugees (a public service of the French ministry of foreign affairs) from 1945 to 1952.

Bouniatian's main contribution to economics is contained in his Studien zur Theorie und Geschichte der Wirtschaftskrisen, published in two volumes dated 1908. (Bouniatian often pointed out that the book actually came out in October 1907; the date issue was important to his claim that many of his ideas were later incorporated in Albert Aftalion's better-known articles and books. In fact, the list of books received in the February 1908 issue of the Journal of Political Economy gives 1907 as the date of publication.) In the first volume Bouniatian put forward a theory of the business cycle based on an original combination of elements from the underconsumption tradition and the then new accelerator concept, plus a novel explanation of changes in the price level. The volume was later revised and translated into Russian (1915) and French (1922; 1930). English expositions can be found in two articles by Bouniatian (1928; 1934). The second volume of the 1908 set is a detailed historical investigation of economic crises in England in the two centuries from 1640 to 1840, which provided the empirical basis for the theoretical volume. It was written between 1899 and 1903, and then submitted as a dissertation to the University of Munich. Bouniatian's business cycle theory attracted some attention at the time (see, for example, W.C. Mitchell, 1913, pp. 9–10; J.M. Keynes, 1930, pp. 143–4) and his books were reviewed in the Journal of the Royal Statistical Society (June and September 1908), American Economic Review (June 1927, June 1936, December 1959), Economic Journal (September 1927, September 1932) and Journal of Political Economy (October 1934), among others.

Bouniatian's mix of theory and history in his Studien followed the pattern set by Mikhail Tugan-Baranovsky in his influential book about economic crises in England, published in Russian in 1894 and in a revised version in German in 1901. However, Bouniatian rejected the main elements of Tugan-Baranovsky's theory, that is, the compatibility between capital accumulation and decreasing consumption in the long run, and the notion that, in the depression, unused savings take the form of a fund of ‘free capital’ that is invested later in the upward period. It was not difficult for Bouniatian to show that actual saving and investment can never differ, although he did not consistently distinguish between desired and actual saving and investment – nor did Tugan-Baranovsky and most other contemporary economists for that matter. Concerning the first point, Bouniatian, building on J.M. Lauderdale (1804) and A.F. Mummery and J.A. Hobson (1889), carefully developed the view that there is in equilibrium a certain relation between aggregate consumption and the capital stock determined by the choice of production methods, which he called ‘degree of social capitalization’ (‘Grad der gesellschaftlichen Kapitalisierung’). This comes from Bouniatian's argument – against both Tugan-Baranovsky and the classical economists – that productive forces cannot be transferred to the future through the simple accumulation of capital goods, since these can be economically conserved only by being utilized in the process of production and sale of consumption goods.

According to Bouniatian, the evolution of the demand for investment through time is governed primarily by the evolution of consumers’ ‘new requirements’ as determined by population growth, changes in tastes and inventions. However, this cannot be a smooth process because of the characteristics of the saving function on one side and of the production process of capital goods on the other. From the savers’ side, whenever income grows there is a tendency – suggested by economic theory and confirmed by data – to increase the proportion of income saved. This ‘tendency toward excessive accumulation’ means that the demand for consumption goods tends to increase more slowly than production capacity, since saving is a ‘false demand’. Such a tendency is realized due to the existence of a period of time necessary for the production of capital goods, which allows for a temporary separation between investment and consumption decisions and a more than proportional increase of capital goods in relation to a given
intensification of ‘new requirements’, until the processes of production mature and consumers’ good start to pour out. This was an early formulation of an aspect of what would later become known as the acceleration principle. ‘Overcapitalization’ (‘Ueberkapitalisation’, a term apparently coined by Bouniatian) is the main feature of the boom, which is followed by ‘decapitalization’ in the depression period, when overproduction of consumers’ goods brings about a more than proportional fall in the value of capital goods. Equilibrium between production and consumption is restored through falling prices and depreciation of stocks and industrial plant, which transfer part of the capital to the consumption flow. However, equilibrium will not be attained if money wages are rigid downwards, as claimed by Bouniatian in his interpretation of the Great Depression of the early 1930s.

Apart from the saving function and the accelerator, another important element of Bouniatian's framework is his attempted application of the subjective theory of value to explain price level changes and, by that, the possibility of general overproduction. This was developed in detail in his 1927 book, where he used the Weber–Fechner law to generalize the old King's law – that the price of an important good varies inversely in geometrical progression as its quantity varies in arithmetical progression – to the economy as a whole. Bouniatian argued that, instead of the traditional quantity theory of money, price fluctuations should be explained by changes in the ‘absolute social value’ (marginal utility) of both consumption and capital goods, brought about by changes in their quantities throughout the business cycle. Such price changes are accompanied by changes in income distribution and, therefore, in the saving flow. This was used by Bouniatian (1908, vol. 1) to distinguish, for the first time in the literature, between ‘exogenous’ and ‘endogenous’ theories of the business cycle. In the latter, economic crises are explained as an organic part (the upper turning point) of the business cycle, not as accidents of economic history.

Bowley was born on 6 November 1869 in Bristol, and died on 21 January 1957 at Haslemere. In 1922 he was made a Fellow of the British Academy and knighted in 1950. He was educated at Christ's Hospital from 1879 to 1888, and Trinity College, Cambridge, from 1888 to 1891 (10th Wrangler, 1891). He stayed on another two terms studying physics, chemistry and, under the influence of Alfred Marshall, who remained a lifelong friend, economics. After a period as a schoolmaster, he became lecturer in mathematics, and then professor of mathematics and economics at University College, Reading, from 1900 to 1919. He concurrently taught at the London School of Economics from its inception in 1895, first as lecturer, then reader, then professor, and finally, from 1919, as the first holder of the newly established Chair of Statistics at the University of London, becoming Emeritus Professor on his retirement in 1936.

Among his other activities, he was Acting Director of the Oxford University Institute of Statistics from 1940 to 1944; foundation member in 1933, and then President from 1938 to 1939, of the Econometric Society; President of the Royal Statistical Society from 1938 to 1940, and honorary President of the International Statistical Institute in 1949.

Bowley was an outstanding economic statistician who made substantial contributions to all areas in his field, from the theory of mathematical statistics to the methodology and practice of data collecting. His courses on statistics at the LSE formed the subject matter of two very successful textbooks (Bowley, 1901; 1910). He brought together and set out in a uniform way the developments of mathematical economics from Cournot to Pigou (Bowley, 1924). He wrote a detailed account of Edgeworth's contributions to mathematical statistics (Bowley, 1928). He collaborated with R.G.D. Allen on a masterly study of family budgets which deals with individual variation as well as average behaviour...

One of his early interests was the course of wages, on which he wrote several books and over 30 articles, many jointly with G.H. Wood; his first paper on the subject was Bowley (1895) and his first book Bowley (1900). This led him to write extensively on index-numbers of prices and it is interesting that in 1899, on p. 641 of vol. III of Palgrave's Dictionary of Political Economy, he gave the index-number formula later to become famous as Irving Fisher's ideal index-number. He followed this work with studies of the national income in Bowley (1919; 1920; 1937) and jointly with J.C. Stamp in Bowley and Stamp (1927).

Bowley was a pioneer in the development of sampling methods and spoke strongly in their favour in his presidential address to the British Association in 1906. In 1912 he carried out a well-designed sample survey of Reading and soon followed this with similar enquiries in Northampton, Warrington, Stanley and Bolton (Bowley and Burnett-Hurst, 1915). A second survey of the same towns was made after the war (Bowley and Hogg, 1925). In the same period he prepared a substantial report on the precision attained in sampling (Bowley, 1926). He played an important role in Llewellyn-Smith's new survey of London life and labour (Bowley, 1930–35).

Before the French Revolution, Walter Boyd was engaged as a banker in France, but by the time his firm's property was confiscated by the French government in 1793, he was established in London as the leading member of the firm of Boyd Benfield & Co. At first this London venture was highly successful, and in 1797 Boyd entered Parliament as member for Shaftsbury, then a pocket borough owned by his partner. In this very year, however, Boyd Benfield & Co began to encounter the difficulties which were to culminate in its liquidation in 1800. The basic cause of Boyd's ruin was his having entered into engagements in the expectation that his French property would be restored to him, an expectation that was finally disappointed in September 1797, but the events which precipitated the final collapse of his firm were the government's refusal to employ it as a contractor for the loan of 1799 and the Bank of England's final refusal to grant assistance in early 1800.

When, in 1801, Boyd published his ‘Letter to William Pitt…’ attacking the Bank of England's policies since the suspension of specie convertibility of February 1797, he was hardly a disinterested observer. However, this pamphlet's appearance is widely regarded as marking the beginning of the ‘Bullionist Controversy’, and contains perhaps the first systematic, albeit crude, statement of what came to be known as the Bullionist position. It argued that exchange depreciation and food price increases since 1797 were the result of an overissue of paper money by the Bank of England; that though foreign transfers could depreciate the exchanges this factor had not been important since 1797; and that the Country Bank note issue could not affect prices independently of Bank of England policies.

Boyd's pamphlet drew a number of replies, some, as Fetter (1965) notes, aimed more at Boyd than at his case, but one by Sir Francis Baring (1801) prefigured subsequent anti-bullionist positions. Baring argued (with some justice) that food price behaviour had had more to do with bad harvests than the exchange rate (which had moved much less), and that the exchange rate's fall had been the result of British remittances to Continental allies and not of overexpansionary policy on the part of the Bank of England.
Boyd made no further contributions to wartime debates. After the Peace of Amiens (1802) he visited France, only to be trapped there until 1814 by the renewal of hostilities. Upon his return to England he re-established his fortunes sufficiently to be able to re-enter Parliament in 1823, as member of Lymington, which he represented until 1830. He published two further pamphlets, on the Sinking Fund (1815 and 1828), but neither of these has the historical significance of his 1801 contribution.

Bradford, David (1939–2005)

Daniel Shaviro
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Bradford, D.; consumption taxation; flat tax; intertemporal preferences; local public finance; progressive and regressive taxation; public goods pricing; taxation of corporate profits; taxation of income

Article

David Bradford is best known for his work on fundamental tax reform, although his contributions to public economics were more wide-ranging. His early writings, after he joined the economics department at Princeton University in 1966, largely focused on municipal finance and public goods pricing. His interests took a dramatic turn, however, when he was named Deputy Assistant Secretary for Tax Policy at the US Treasury in 1975, and given lead responsibility for a Treasury study of comprehensive tax reform. The influential *Blueprints for Basic Tax Reform* (1977), which he co-authored with the US Treasury Tax Policy Staff, set forth models for comprehensive income and consumption taxes that remain influential to this day. The *Blueprints* cash flow consumption tax in particular influenced subsequent tax reform thinking by showing how a consumption tax, levied at the individual rather than the business level, could match the progressivity of an income tax and offer self-help income averaging through a mix of ‘prepaid’ and ‘postpaid’ (that is, yield-exempt and deductible) savings accounts.

His experiences at the Treasury made Bradford a lifelong advocate of consumption taxation, based on two main considerations. The first was that he considered it inequitable for people with the same lifetime earnings to face different tax burdens, as they would under an income tax, simply by reason of having different intertemporal consumption preferences. The second was that shifting to a consumption base might permit significant tax simplification, by eliminating the timing issues that bedevil a realization-based income tax. Bradford later developed a second consumption tax prototype, the X-tax, based on the Hall–Rabushka flat tax (Hall and Rabushka, 1995) but modified to permit greater progressivity and to address transition problems, which he recognized could arise not only upon initial enactment but whenever tax rates were changed.

Bradford also helped to pioneer the contemporary understanding that the only theoretical difference between pure income and consumption taxation lies in their treatment of the risk-free return to waiting,
which the former subjects to tax and the latter exempts. In addition, he advanced understanding of the economics of a transition from income to consumption taxation, showing that the ostensibly lump-sum revenue gain resulted from wiping out assets’ income tax basis while solemnly pledging never to do so again. Bradford also helped develop the ‘new view’ of corporate taxation, which shows that a uniform tax on corporate distributions does not distort corporate decisions regarding when to pay out earnings.

Brady, Dorothy Stahl (1903– 1977)

M. Reid
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Brady, D. S.; distribution of income; survey data

Article
A mathematician and statistician, Dorothy S. Brady combined in her professional life extended periods
in both universities and US federal agencies. Most of her empirical work entailed the design and
interpretation of survey data on household income and expenditures and critiques of applications of such
data.
This began with analysis of data collected in the large 1935–6 survey of incomes and expenditures of
rural households which together with its urban counterpart provided the basis for new tests of the
validity of Commerce Department estimates of the size and distribution of national income,
consumption and savings. At the Bureau of Labor Statistics (1943–8, 1951–6) she assessed consumption
and price data in connection with efforts to control inflation, and she developed the statistical design for
pricing the city workers’ family budget which was used to estimate inter-area differences in the cost of
living.
An active participant in the Conference on Income and Wealth of the National Bureau of Economic
Research, Brady brought to its sessions a keen awareness of data limitations in the empirical
identification of key elements in an analytical structure. Using statistical analysis to randomize effective
unidentified factors, she found that the percentage of income saved by families tends to increase
systematically with relative position in an income distribution, that the secular increase of income of a
population tends to decrease the age at which children leave the family residence, often with financial
help from parents, and that such leaving tends to increase the inequality of measured income distribution.

The term ‘brain drain’ designates the international transfer of human resources and mainly applies to the migration of relatively highly educated individuals from developing to developed countries. While the brain drain has long been viewed as detrimental to poor countries’ growth potential, recent economic research emphasizes a number of positive feedback effects arising from skilled migrants’ participation in business networks, and suggests that under certain conditions the prospect of migration can positively affect human capital accumulation in the source countries.

Article
The term ‘brain drain’ designates the international transfer of resources in the form of human capital and mainly applies to the migration of relatively highly educated individuals from developing to developed countries. In the non-academic literature, the term is generally used in a narrower sense and relates more specifically to the migration of engineers, physicians, scientists and other very highly skilled professionals with university training. The brain drain has long been viewed as a serious constraint on poor countries’ development and is also a matter of concern for many European countries such as the UK, Germany or France, which have recently seen a significant fraction of their talented workforce emigrate abroad. Recent comparative data reveal that by 2000 there were 20 million highly skilled immigrants (that is, foreign-born workers with a tertiary education) living in the Organisation for Economic Co-operation and Development (OECD) area, a 70 per cent increase in ten years against only a 30 per cent increase for unskilled immigrants. Skilled migrants now represent one-third of total immigration to the OECD countries, and most of this increase is due to immigration from developing and transition countries. The causes of this growing brain drain are well known. On the supply side, the globalization of the world economy has strengthened the tendency for human capital to agglomerate where it is already abundant and has contributed to increase positive self-selection among migrants. And on the demand side, host countries have gradually introduced quality-selective immigration policies and are now engaged in what appears as an international competition to attract global talents.

How big is the brain drain?
Extending and updating the work of Carrington and Detragiache (1998), Docquier and Marfouk (2006) recently collected OECD immigration data to construct estimates of emigration rates by educational attainment (primary, secondary and tertiary schooling) for all countries in 1990 and 2000. Their figures for the highest education level may be taken as a brain drain measure. This may seem too broad a definition for the most advanced countries where the highly educated typically represent about a third of the total workforce but seems appropriate in the case of developing countries, where this share is on average just about five per cent. Note that due to data constraints, South–South migration is not taken into account in the Docquier and Marfouk (2006) data-set; this can lead to potential underestimation of the brain drain for some countries for which other developing countries are...
significant destinations. On the other hand, the very definition of immigrants as foreign-born workers does not account for whether education has been acquired in the home or in the host country; this can lead to potential overestimation of the brain drain as well as to possible spurious cross-country variation in skilled emigration rates (Rosenzweig, 2005). In an attempt to solve this problem, Beine, Docquier and Rapoport (2007a) used age of entry as a proxy for where education has been acquired and proposed alternative brain drain estimates excluding people who immigrated before a given age (12, 18 and 22); their results show country rankings by degree of brain drain intensity only mildly affected by the correction and extremely high correlations between corrected and uncorrected estimates.

Keeping this in mind, one can use a simple multiplicative decomposition of the brain drain: the skilled emigration rate is equal to the average emigration rate times the schooling gap. The average emigration rate is the ratio of emigrants to natives (residents plus emigrants) and reflects the sending country's openness to emigration. The schooling gap is the ratio of skilled to average emigration rate which, by definition, is also the ratio of the proportion of educated among emigrants to the corresponding proportion among natives.

Table 1 summarizes the data for different country groups in 2000. Countries are grouped according to demographic size, income per capita (under the World Bank classification), and region. Unsurprisingly, we observe a decreasing relationship between emigration rates and country size, with average skilled emigration rates about seven times higher in small countries than in large countries. Regarding income groups, the highest emigration rates are observed in middle-income countries, where people have both the incentives and means to emigrate. Regarding the regional distribution of the brain drain, the most affected regions are the Caribbean and the Pacific islands, sub-Saharan Africa (where the schooling gap is exceptionally high), and Central America.

It is clear that the magnitude of the brain drain has increased dramatically since 1980. However, in terms of intensity (or emigration rates), the picture is less clear as one must factor in the general progress in educational attainments observed across the world. Figure 1 presents skilled emigration rates by region computed by Defoort (2006) using a long-run perspective. Focusing on the six major destination countries (USA, Canada, Australia, Germany, UK and France), Defoort computed skilled emigration rates from 1975 to 2000 (one observation every five years). One can see that some regions experienced an increase in the intensity of the brain drain (especially Central America and sub-Saharan Africa) while significant decreases were observed in others (notably the Middle East and Northern Africa).

Figure 1
From brain drain to brain gain?

It is certainly a good thing for rich countries to host a skilled and talented workforce, and the move is also worthwhile (at least \textit{ex ante}) from the perspective of the individual migrant. However, the social return to human capital is likely to exceed its private return given the many fiscal, technological, intra- and intergenerational (or Lucas-type) externalities involved. This externality argument is central in the early brain drain economic literature (Bhagwati and Hamada, 1974), which emphasized that the brain drain entails significant losses for those left behind and contributes to increased inequality at the world level. Another negative aspect of the brain drain is that it can induce shortages of manpower in certain activities, for example when engineers or health professionals emigrate in disproportionately large numbers, thus undermining the ability of the origin country to adopt new technologies or deal with health crises. This can be reinforced by governments distorting the provision of public education away from general (portable) skills when graduates leave the country, with the country ending up educating too few nurses, doctors or engineers, and too many lawyers (Poutvaara, 2004). The argument, however, can be reversed, since the prospect for migration may create a bias in the opposite direction (see Lucas, 2005, for an illuminating analysis of the Philippines higher-education market).

The prospect of migration can also impact on the very decision as to whether to study. When education is a passport to emigration, migration prospects create additional incentives to invest in human capital. If migration is probabilistic in that people are uncertain about their chances of future migration when they make education decisions, then the incentive effect just described may move more than compensate the brain drain effect, resulting in a higher level of human capital in the source country. As demonstrated in a series of recent papers (for example, Mountford, 1997; Beine, Docquier and Rapoport, 2001), such a positive outcome is theoretically more likely when inter-country wage differentials are large enough to generate a high incentive effect and skilled emigration rates are sufficiently low. These theories have been confirmed empirically by Beine, Docquier and Rapoport (2007b), who found a positive and significant effect of migration prospects on human capital formation in a cross-section of 127 developing countries. From the latter’s perspective, however, what matters is how many of their native-born engage in higher education, but how many remain at home. To estimate the net effects country by country, Beine, Docquier and Rapoport (2007b) used counterfactual macro-simulations and found that countries combining relatively low levels of human capital and low skilled emigration rates are likely to experience a net gain. Their results show a positive effect on aggregate, but with more losers (which tend to lose a lot in relative terms) than winners. The situation of many small African and Central American countries appears extremely worrisome while the main globalizers (for example, India, China) all register moderate gains.

Feedback effects

Remittances

The literature on migrants’ remittances shows that the two main motivations to remit are altruism, on the one hand, and exchange, on the other hand (Rapoport and Docquier, 2006). Altruism is primarily directed towards the immediate family, while remittances motivated by exchange pay for services such as care of the migrant’s assets or relatives at home. Exchange-motivated transfers are typically observed in case of a temporary migration and signal the migrants’ intention to return. It is therefore a priori unclear whether educated migrants remit more than their uneducated compatriots; the former may remit more to meet their implicit commitment to reimburse the family for funding of education investments (and, in addition, they have a higher income potential), but on the other hand, they tend to emigrate with their families, and on a more permanent basis. Indeed, at an aggregate level, Faini (2006) finds that brain drain migration (as measured by the proportion of skilled among emigrants) is associated with lower remittance inflows.

Return migration and brain circulation

Return migration is rare among the highly educated unless sustained growth precedes return. For example, less than one-fifth of Taiwanese and Korean Ph.D. students who graduated from US universities in the 1970s in the fields of science and engineering returned to Taiwan or Korea, a proportion that rose to two-thirds in the course of the 1990s, after two
decades of impressive growth in these countries. The figures for Chinese and Indian Ph.D. students graduating from US universities in the same fields during the 1990s are similar to those for Taiwan or Korea in the 1980s (OECD, 2002). These numbers suggest that return skilled migration is more a consequence than a trigger of growth. On a more reduced scale, however, there are many case-studies showing clear signs of brain circulation. For example, a recent survey conducted among 225 Indian software firms concluded that 30–40 per cent of the higher-level employees had previous work experience in similar occupations in a developed country (Commander et al., 2004).

**Diaspora externalities**

A large sociological literature emphasizes the potential for skilled migrants to reduce transaction and other types of information costs and thus facilitate trade, foreign direct investment (FDI) flows and technology transfers between their host and home countries. This has first been confirmed in the field of international trade (Gould, 1994; Head and Ries, 1998; Rauch and Casella, 2003). Regarding FDI, Kugler and Rapoport (2007) used US data on immigration and FDI outflows and found that past skilled immigration significantly increases a country’s chances of attracting FDI in the subsequent period. These results complement recent case studies of the software industry showing that skilled migrants take an active part in the creation of business networks that lead to FDI deployment in their home country (Arora and Gambardella, 2005).

**Conclusion**

The number of skilled migrants from poor to rich countries has increased dramatically since the 1970s. In the face of rising wage differentials and of diverging demographic structures between rich and poor countries, this tendency is likely to be confirmed in the future. While the brain drain has long been viewed as detrimental to poor countries’ growth potential, recent economic research has emphasized that, alongside positive feedback effects arising from skilled migrants’ participation in business networks, one also has to consider the effect of migration prospects on human capital-building in source countries. This new literature suggests that a limited degree of skilled emigration could be beneficial for growth and development. Empirical research shows that this is indeed the case for a limited number of large, intermediate-income developing countries. For the vast majority of poor and small developing countries, however, current skilled emigration rates are most certainly well beyond any sustainable threshold level of brain drain.

One of the foremost social and economic historians of the 20th century, Fernand Braudel combined a perceptive grasp of historical interconnections, an exceptional skill of synthesis and an evocative, even ‘poetic’ style. Perception, scope and style were brought to successful fruition in Braudel's *La Méditerranée et le monde méditerranéen à l’époque de Phillipe II* (1949), which became a classic in historical literature and a model for a major school of French history known as the *Annales*. In this seminal volume and in many methodological articles that followed, Braudel proposed a triple notion of historical time – the long run (*longue durée*) over a millennium, trends (*conjonctures*) of a generation or more, and events (*événements*). According to Braudel, each of these notions or blocks of time involved unique historical problems, appropriate source materials, and even special approaches employing social-science disciplines neighbouring to history. Braudel's model emphasized the ‘constraints’ of human endeavour rather than the ‘permissive’ factors that had been so much a part of Whig history as practised by most early 20th-century historians. These constraints were imposed by geography, climate and soils, by demographic pressure, and by a static social structure held together by the bonds of custom. Braudel likened this ‘structure’ to a glacier or to the sea depths, imparting both a physical metaphor and a sense of timelessness or immobility. His second temporal level, the *conjoncture*, made some room for change as new technologies, new forms of economic organization (especially capitalism), and subtle shifts in social relations and customs altered the ‘structure’. Braudel likened these changes – he preferred the term ‘mutations’ – to the sea tides. Finally the ‘event’ was a kind of surface noise, an indication perhaps of deeper sea changes, but in itself of little significance for the historian. He likened these events to whitecaps on the vast ocean.

In addition to his emphasis on constraints and the obligation of historians to understand their deterministic effects on human behaviour, Braudel also stressed the cyclical nature of most of history – ‘le temps, quasi immobile, fait de répétitions, de retours insistants, de cycles sans cesse recommencés’.
There was about Braudel a strong sense of romantic conservatism that challenged Marxist and Whig historian alike. Braudel imparted to the Annales School a preference for metaphors taken from biology and anthropology (interconnection, liens, mutations, glissements) instead of the vocabulary, and indeed the goals, of physics or economics (parsimonious cause, leaness of argument, elegance of formula or theory). It is also clear that for Braudel geography and demography were basic objects of study, that technology and economic and social organization were important, but that political history, biography and the history of formal ideas were secondary and even trivial historical pursuits. In a direct attack on the kind of history taught at the Sorbonne, Braudel insisted that ‘events’ tell us little about the deeper and interlocking structures and their subtle mutations. Indeed, such surface history may suggest a misguided ‘voluntarism’ in human history. With such a perspective, it is understandable that Braudel was most comfortable in the thousands of years of pre-industrial history. The more recent 19th century and its urban-industrial dynamism were unsettling to his outlook, his methodology and even to his aesthetic sense. But, like a cultural anthropologist, Braudel never ceased to stress the fact that most of world history was pre-industrial.

Although Braudel was interested in quantification, he was never a model-builder, and in fact he used numbers illustratively rather than systematically. He had much to do with the Annales-style deployment of an array of graphic techniques – often very artfully designed – to demonstrate proportions and relationships, but as a descriptive technique in which the reader had to access the results by eye. Braudel did not use statistical measures, much less economic theory, perhaps because he considered them too abstract, and a threat to the living texture of social history that was his main concern. In the 1970s, like much of the Annales School, Braudel moved further towards cultural anthropology as reflected in his notion of ‘day-to-dayness’ (la vie quotidienne), in the cultural determinants of economic and social behaviour, in the values and attitudes (mentailities) of social groups, and in the gestes and code of an entire society or even a ‘civilization’. These features were already present in the Méditerranée, but they became even more pronounced in his more recent Civilization matérielle et capitalisme (XV–XVIIIe siècle) (1967–79).

Fernand Braudel was also director of the Maison des Sciences de l'Homme in Paris, professor at the Ecole Pratique des Hautes Etudes and at the Collège de France, and co-editor of the Annales: ESC, one of the most prestigious journals of social and economic history in the Western world today. Braudel's seminal writings, his provocative teaching, his administrative and editorial talents, and, not least, his powerful personality made him an ‘animateur’ of the ‘School of the Annales’ for more than 30 years. Yet his work stands on its own as an appeal to approach history in its widest scope in time and place (histoire totale), in alliance with neighbouring disciplines, and presented with that special verve we call ‘Braudelian’.

Harry Braverman was born in 1920 in New York City and died on 2 August 1976 in Honesdale, Pennsylvania. Born into a working-class family, he was able to spend only one year in college before financial problems forced him out of Brooklyn College and into the Brooklyn Navy Yard. He worked there for eight years primarily as a coppersmith and then moved around the United States, working in the steel industry and in a variety of skilled trades. He became deeply involved in the trade union and socialist political movements. He helped found The American Socialist in 1954 and worked as its co-editor for five years. After the journal ceased publication for practical reasons, he moved into publishing, working first at Grove Press as an editor and eventually as vice-president and general business manager. In 1967 he became Managing Director of Monthly Review Press, where he worked until his death.

Braverman is best known for his classic study of the labour process under capitalism, Labor and Monopoly Capital (1974), awarded the 1974 C. Wright Mills Award. ‘Until the appearance of Harry Braverman’s remarkable book’, Robert L. Heilbroner wrote in the New York Review of Books, ‘there has been no broad view of the labour process as a whole…’ The book was all the more remarkable because of the void it filled in the Marxian analytic tradition – a literature ostensibly grounded in the analysis of the structural effects of class conflict but persistently reticent about the actual structure and experience of work in capitalist production.

Labor and Monopoly Capital advances three principal hypotheses about the labour process in capitalist societies. First, Braverman helps formalize and extend Marx’s resonant analysis, in Volume I of Capital, of the distinction between labour and labour power. Braverman highlights the essential importance and persistence of managerial efforts to gain increasing control over the labour process in order to rationalize

Second, Braverman argues that such managerial efforts lead inevitably to the homogenization of work tasks and the reduction of skill required in productive jobs. He concludes (p. 83) that ‘this might even be called the general law of the capitalist division of labor. It is not the sole force acting upon the organization of work, but it is certainly the most powerful and general.’

Third, as a corollary of the second hypothesis, Braverman argues both analytically and with rich empirical detail that this ‘general law of the capitalist division of labour’ applies just as clearly to later stages of capitalist development, with their proliferation of office jobs and white collars, as to the earlier stages of competitive capitalism and largely industrial work.

The first analytic strand of Braverman's work was both seminal and crucial in helping foster a renaissance of Marxian analyses of the labour process. The second and third hypotheses have proved more controversial. There are two grounds for concern. Braverman's analysis tends to reduce the character of the labour process to essentially one dimension – the level of skill required and control permitted by embodied skills – and therefore unnecessarily compresses the many essential dimensions of worker activity and effectiveness in production to a single monotonic index. At the same time, there is good reason for worrying about the simplicity of Braverman's argument of historically irreversible 'deskilling' for all segments of the productive working class; it is quite plausible to hypothesize that for some labour segments in recent phases of capitalist development there has been a 'reskilling', as many have since called it, which has not in any way liberated these workers from capitalist exploitation or intensive managerial supervision.

Brentano was born in Aschaffenburg (Germany) into an old patrician family. Clemens Brentano, the poet, was his uncle; Bettina von Arnim, the writer, his aunt; and Franz Brentano, the philosopher, his brother. He was brought up in an atmosphere dominated by Catholicism (which he was later to abandon after the declaration of papal infallibility) and was particularly influenced by the anti-Prussian tradition of southern Germany. He studied law and economics in Heidelberg and Göttingen. From 1871 he taught political economy as professor in Berlin, Breslau, Strassburg, Vienna, Leipzig and Munich.

A decisive point for his later career was his participation in the Statistical Seminar connected with the Prussian Statistical Office. Its director was Ernst Engel (originator of Engel's law), whose strong interest in the social conditions of the working classes was to have a lasting influence on Brentano. Engel advocated profit-sharing schemes as a means to the solution of the social question. In 1868 Brentano accompanied him on a visit to England, where they studied the effects of such measures. His experiences in England convinced Brentano of the inadequacy of profit-sharing for the reform of capitalism, but suggested another approach, which was to remain the main topic of Brentano's intellectual work: the improvement of the worker's position in the labour market through the establishment of trade unions.

While the individual worker was forced to sell his labour power under any conditions, this would not be the case for an organized coalition of workers. Such a coalition would enable them to become as free and independent as the sellers of other commodities and would allow for an effective control of the labour supply (1871–2, vol. 2; 1877, ch. 2). It was Brentano's deep conviction that trade unions were the only means to secure an adequate participation of the working classes in the general increase of wealth. He was especially interested in the history of the trade unions, which he traced back to the medieval guilds (1871–2, vol. 1). Especially interesting – particularly for the current debate – was his discussion...
of positive productivity effects of labour time reductions (1876). He regarded the introduction of a general social security system as another important step for the reform of capitalism. He also favoured the cartelization of Germany industry. It was characteristic of him that he always intended to solve the social question within the framework of a capitalist economic system. He therefore rejected Marx and the Social Democrats of 19th-century Germany. Brentano emphasized that unequal conditions of material existence were absolutely necessary for the further cultural advancement of mankind (1877, pp. 303–4).

His concern for the social question shaped Brentano's attitude towards the classical economists: he opposed the classical notion of an abstract profit-maximizing individual as the central axiom of political economy, and found this particularly inadequate to describe working-class behaviour and the labour market (1923, ch. 1). It is in this context that his preoccupation with economic history (1916; 1927–9) must be seen. He intended to show that the relations between man and the economic system were changing through history, and that the individual of classical economics was not the starting-point, but the result of economic development (1927–9, vol. 1, pp. iii–iv).

Further fields of interest were Malthus's theory of population development (1924), the theory of value (where he favoured the subjective theory of value; 1924), the German corn tariffs (which he opposed), and different forms of the law of estate.

Throughout his life Brentano remained an open-minded and enlightened liberal of whom an English trade union leader once said: ‘He was our friend before it was fashionable to be our friend.’ Brentano was a founding member of the Verein für Socialpolitik, which he left in 1929, when he thought that it had become reactionary. He opposed Bismarck in the Kaisersreich, the extreme German annexationists during the First World War – although himself favouring limited territorial expansion – and the Socialist Revolutionaries in the post-war period. The republican government considered his appointment as first German post-war ambassador to Washington, but because of his advanced age he declined.

During the Weimar Republic Brentano was still concerned with social policy, mainly with the struggle for the eight-hour working day. He deplored the harsh austerity policy during the Great Depression. His memoirs, written in 1930, ended: ‘I do not understand this policy. Do they want a social revolution?’ (1931, p. 404).

Article

The last great exponent of old-time liberalism in Italian economics, Bresciani was an Italian counterpart of such distinguished libertarians as Robbins, Hayek or Friedman, a bit more moderate, perhaps, in his views and with a quantitative bent at least equal to Friedman's. Bresciani was born in Verona and his teachers in his homeland included Ricca-Salerno and Loria. After the completion of his studies at a number of universities in Italy, he went to the University of Berlin, at that time at the height of its prestige, to study with historical economists such as Adolf Wagner and Gustav Schmoller, and with L. von Bortkiewicz, the mathematical statistician and pioneer in Marxian econometrics. Amidst the push and pull of these intellectual influences, Bresciani preserved an admirable independence of mind. Loria did not convert him to socialism and Schmoller did not turn him into an historical economist. More influenced by Pareto and Pantaleoni than by his great teachers, he became, first of all, an economic theorist, but again not a pure one but one looking for statistical verifications of theoretical propositions.

In his writings he would give a respectful hearing to the views of the classics and provide copious references to modern authorities, foreign languages and mathematical modes of expression constituting no barriers. As an Italian and libertarian, he was especially fond of citing Galiani. After the publication of Keynes's General Theory in 1936, Bresciani, like other contemporary economists, had to come to terms with the new economics. Again he showed his independence by continuing to adhere to such established doctrines as the quantity theory of money and the productivity theory of interest. This attitude, together with his insistence on the limitations rather than opportunities of public policies, gave an old-fashioned flavour to his later writings, published, as they were, at a time when Keynes's influence...
reached its peak.

Bresciani's teaching career, which included chairs in statistics, led him eventually to the University of Milan (1926–57), but his work there was interrupted by various other activities. During the 1920s he served as an adviser to the Berlin office of the Allied Reparations Commission, and from 1927 to 1940 he lectured at the newly established Egyptian University of Cairo. This multiplication of jobs again confirmed his penchant for independence and gave him the opportunity to absent himself from fascist Italy. After the Second World War he served the new Republic of Italy as president of an important bank and for a brief period also as minister of foreign trade. In this capacity he again demonstrated his independence, this time from ideological preferences, by sponsoring a government organization for export credit and insurance.

As a writer Bresciani started out, at age 22, with a critical review of Pareto's law of income distribution, a subject to which he returned later more than once. Much of his work was devoted to the theory of prices, domestic and international, present and future, as well as the relation between prices and interest. Among other topics that he investigated were the influence of speculation on prices, which he recognized as not always beneficial, economic forecasting, the inductive verification of the theory of international payments, and the relation between the harvest and the price of cotton in Egypt. Late in life he wrote a number of broad syntheses of economics, including a two-volume *Corso* that went into many editions.

Bresciani's masterpiece, and the work for which he is best known, is *The Economics of Inflation*, published originally in Italian in 1931 and in a revised English translation in 1937. The Italian title of the book – *Le vicende del marco tedesco*, or the vicissitudes of the German mark – conveys the substance of the book better than the title of the English translation, which claims a level of abstraction far higher than that embodied in the work, and, correspondingly, a much wider applicability of the content. The subtitle of the English translation is also carelessly worded. The subject of the work is the great German inflation after the First World War, when prices had risen to astronomical heights and $1 in the end purchased 42 marks followed by 11 zeros. At that time this was considered a record, but the Hungarian inflation after the Second World War surpassed it, with the dollar then buying 145 pengö followed by 27 zeros.

Bresciani's book has been the standard work on the subject ever since. What was open to debate was never the completeness or reliability of the material that he presented but his interpretation. German students of the matter tended to adhere to the view that the rise in prices reflected the unfavourable rate of exchange, which in turn was ascribed, at least in part, to the burden of reparation payments that the Germans were eager to demonstrate as outrageously unreasonable. Bresciani opposed this interpretation. His principal argument was that foreign exchanges, by means of well-known mechanisms, will never fail to reach an equilibrium if only the external value of the currency falls deeply enough. Bresciani, instead of putting the blame on the foreign exchanges, placed it firmly on the German authorities which pursued policies of fiscal irresponsibility and unrestrained monetary expansion. Bresciani also discussed still other interpretations – conspiratorial or scandal theories – but found them unconvincing. One variant of these made the industrialists, who gained so much from the galloping inflation, responsible for it. Another one put the onus on the German authorities’ desire to prove the impossibility of reparation payments. It may be of some interest that the second variant of the scandal theory would constitute a corollary of the policy of *deflation* which Chancellor Brüning adopted a few years later during the Great Depression, a policy instrumental in helping Germany to rid herself of reparation payments.
Critics of the work brought still other points of view before the reader. Joan Robinson, to give an example, stressed the role of ever-rising money wages that became indexed and subject to automatic increases. This would seem to lend support to the view blaming the foreign exchanges, because the rise in money wages offset the forces making for equilibrium of the foreign-exchange rates. But Robinson does not fully endorse Bresciani’s or the German interpretation. In her view the eventual stabilization of the mark in November 1923 does not support the conclusion that monetary stringency is necessary and sufficient to put an end to inflation. In Robinson’s view the stabilization succeeded because by that time the old German mark had shed almost all the standard functions that money is to serve.

Bretton Woods system

Peter B. Kenen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Under the Bretton Woods System, created after the Second World War, each country had to peg its currency to gold or to the US dollar, but it could obtain temporary financing from the International Monetary Fund. In practice, countries pegged their currencies to the dollar and accumulated dollar reserves, which they could use to buy gold from the US Treasury. This regime served to finance US payments deficits but prevented the United States from changing its exchange rate. The system was undermined when other countries’ dollar holdings came to exceed US gold holdings. It was abandoned in 1973, when the major industrial countries let their currencies float.

Article

The international monetary system established at the end of the Second World War is commonly known as the Bretton Woods System. It takes its name from the conference held at Bretton Woods, New Hampshire, USA, in 1944, which adopted the Articles of Agreement of the International Monetary Fund (IMF) and thus put in place the rules and arrangements that would govern international monetary relations in the post-war world. A comprehensive history of the Bretton Woods System would have to review the monetary and fiscal policies of the major industrial countries, most notably those of the United States and United Kingdom, the key-currency countries, describe the evolution of monetary cooperation, and recite the history of the IMF itself. An analytic assessment would have to examine balance-of-payments adjustment under the
Bretton Woods System and compare the merits of pegged and floating exchange rates. This account has narrower objectives. It reviews the origins of the system, the rules adopted at Bretton Woods, the differences between those rules and the way the system worked in practice, and the forces leading to the breakdown of the system in the early 1970s. Readers who want more detailed accounts may consult Cooper (1968), Solomon (1982), de Vries (1987), James (1996), Eichengreen (2006), and the official histories of the IMF (Horsefield, 1969; de Vries, 1976; 1986).

**The origins of the system**

The design of the Bretton Woods System cannot be understood without recalling the monetary history of the interwar period and the lessons drawn from it at the time. Recent writers have drawn somewhat different lessons. Thus, Eichengreen (1991) argues that the credibility of the gold standard in the decades before the First World War depended on close cooperation among central banks, not on the exercise of hegemonic influence by the Bank of England, and that the absence of comparable cooperation doomed the gold-standard arrangements of the interwar period; he also argues that fiscal rigidities greatly compounded the problems of monetary management. But these are lessons for our time, reflecting recent concerns, not those that influenced the design of the Bretton Woods System.

At the end of the First World War, governments were firmly committed to the restoration of the gold standard, and most of them returned to gold during the 1920s. They did so unilaterally and sequentially, however, by adopting gold values for their own currencies. Although some such as Keynes (1925) warned them of the risks they were running, they paid too little attention to the pattern of exchange rates established by their actions. Nor did they understand completely the new environment in which they would have to maintain the gold standard – how monetary and fiscal policies would be constrained by the transfer of financial activity and influence from London to New York, by the domestic and foreign debt-service burdens built up by wartime borrowing, and by the increased power of the trade unions and of the political parties affiliated with them.

The new gold standard collapsed in fewer than ten years, in the same sequential way that it was put together. Country after country let go of gold and allowed its exchange rate to float – to be determined by supply and demand in the foreign-exchange market – but they soon began to intervene in that market in order to influence the behaviour of exchange rates. Even at that point, moreover, they acted unilaterally, not cooperatively. Central banks began to cooperate in the late 1930s, but the process was halted by the outbreak of war and the imposition of currency controls.

What lessons were learned from this experience? Writing for the League of Nations (1944, p. 210), Ragnar Nurkse put them in terms that were widely endorsed at the time. The setting of exchange rates, he concluded, could not be left to market forces:

> A system of completely free and flexible exchange rates is conceivable and may have certain attractions in theory. … Yet nothing would be more at variance with the lessons of the past. Freely fluctuating exchanges involve three serious disadvantages. In the first place, they create an element of risk which tends to discourage international trade…. Secondly, as a means of adjusting the balance of payments, exchange fluctuations involve
constant shifts of labour and other resources between production for the home market and production for export. Such shifts may be costly … and are obviously wasteful if the exchange-market conditions that call for them are temporary.…

Thirdly, experience has shown that fluctuating exchanges cannot always be relied upon to promote adjustment. Any considerable or continuous movement of the exchange rate is liable to generate anticipations of a further movement in the same direction.

Yet the setting of exchange rates, Nurkse argued, cannot be left to individual governments:

An exchange rate by definition concerns more currencies than one. Yet exchange stabilization [in the interwar period] was carried out as an act of national sovereignty in one country after another with little or no regard to the resulting interrelationship of currency values in comparison with cost and price levels. … The piecemeal and haphazard manner of international monetary reconstruction sowed the seeds of subsequent disintegration. (League of Nations, 1944, pp. 116–17)

Finally, governments should not be expected to sacrifice domestic economic stability merely to maintain exchange rate stability:

Experience has shown that stability of exchange rates can no longer be achieved by domestic income adjustments if these involve depression and unemployment. Nor can it be achieved if such income adjustments involve a general inflation of prices which the country concerned is not prepared to endure. It is therefore only as a consequence of internal stability … that there can be any hope of securing a satisfactory degree of exchange stability as well. (League of Nations, 1944, p. 229)

The plans that governments drafted in anticipation of the Bretton Woods conference differed in many ways but did not disagree about these matters. A new international institution would be needed to supervise exchange rate policies, in order to promote exchange rate stability and prevent competitive devaluations, but it would also have to concern itself with ‘the promotion and maintenance of high levels of employment and real income’ (Articles of Agreement, Article I (ii)).

The design of the system

The design of the new monetary system was decided before the Bretton Woods conference, in talks between British and American negotiators. The British were led by John Maynard Keynes, the Americans by Harry Dexter White, and the two countries’ proposals are known as the Keynes and White plans. They differed mainly in the way that they would provide financing for external imbalances. (On the plans and subsequent negotiations, see Gardner, 1969; Horsefield, 1969; Dam, 1982.)

The Keynes plan was quite radical and reflected Keynes's concerns about the post-war situation. In the short run, Britain would need balance-of-payments financing; in the long run, the United States was likely to experience another depression, driving other countries into balance-of-payments deficit, and
forcing them to choose between domestic stability and exchange rate stability if they could not obtain adequate financing. Hence, Keynes sought to create a monetary institution able to issue a new international currency (which Keynes called ‘bancor’); it would be held and used by governments and central banks for settling external imbalances.

The White plan was more conservative and reflected White's concern that a large and elastic supply of international money would give other countries an open-ended claim on the real resources of the United States. (In other words, the United States would wind up holding all of Keynes's bancor.) Hence, White sought to limit the supply of reserve credit by providing the new monetary institution with a finite pool of national currencies and gold, rather than the power to issue a new money of its own. (Ironically, the White plan failed to anticipate the emergence of the US dollar as a reserve currency, which made the supply of reserves very elastic and helped to undermine the Bretton Woods System at the start of the 1970s, when it became apparent that the United States could not maintain convertibility between the dollar and gold.)

The plan adopted at Bretton Woods was much like the White plan, although it made concessions to Keynes's concern about the danger of a deep US depression. If a country's currency became ‘scarce’ in world trade and in the IMF itself, because the country was running a balance-of-payments surplus, the IMF could ration that currency and authorize its members to limit imports from the surplus country. (This clause was never invoked, however, even in the years of the so-called dollar shortage.)

The Bretton Woods System imposed two major obligations on national governments but gave them something in exchange.

First, every member of the IMF had to peg its currency to gold or the US dollar (which was, in turn, pegged to gold at $35 per ounce). The IMF had to approve the initial exchange rate and every significant change thereafter. Before it could change its exchange rate, moreover, a government would have to show that it faced a ‘fundamental disequilibrium’ in its external accounts. That term was not defined, however, and led to much debate. It came to be interpreted eventually as an unsustainable conflict between ‘external’ and ‘internal’ balance – a situation in which a country could not defend its exchange rate without suffering substantial unemployment or inflation; see Nurkse (1945) and Meade (1951). (The operational issues resemble those which still bedevil attempts to define a fundamental equilibrium exchange rate; see, for example, Williamson, 1983a, and International Monetary Fund 1984.)

With one notable exception, namely Canada, the major industrial countries did peg their exchange rates until the end of the 1960s and did not change them often. There was an extensive exchange rate realignment in 1949, triggered by a devaluation of sterling, but only a handful of changes thereafter. When they did change their rates, however, they did not let the IMF exercise effective supervision; it was informed at the very last minute, too late to offer advice or object. Developing countries, by contrast, adopted many exchange rate arrangements; a few had freely floating rates, and some had separate rates for different classes of transactions, with some rates pegged and others floating.

Second, every member of the IMF was expected to make its currency convertible as soon as possible. It could continue to control capital movements; recall the view expressed by Nurkse, that capital flows had been destabilizing in the interwar years. It could likewise continue to use tariffs and other trade controls for commercial-policy purposes. But it could not keep the resident of another country from using or converting domestic currency acquired from a current-account transaction. A Dane who earned French francs from exports to France was free to use them for another current-account transaction, sell them to someone else wanting to use them, or sell them to the Danish National Bank, which could then present
them to the Bank of France for conversion into Danish currency. Britain made the pound fully convertible for foreigners in 1947, for capital as well as current-account purposes, but it had to retreat speedily when countries that had built up large sterling balances during the war rushed to exchange them for dollars and drained away a large part of a large US loan to Britain. Thereafter, most governments moved cautiously toward current-account convertibility. Western Europe did not reach it until 1958, and some European countries did not abolish all of their capital controls until 1990; see Triffin (1957) and Kaplan and Schleiminger (1989).

In exchange for these commitments, members of the IMF were entitled to draw on the Fund's holdings of currencies and gold when they ran balance-of-payments deficits and could not finance them by drawing down their own reserves. Each IMF member was given a quota that governed its subscription to the currency pool, how much it could draw from the pool, and its voting power in the IMF. The Articles of Agreement, however, did not spell out the conditions under which countries could draw on the pool, and this became a contentious issue. The United States maintained that strict policy conditions would safeguard prospects for repayment and thus protect the drawing rights of other members. Other governments maintained that access should be automatic when a member needed short-term financing. The United States won this battle too, however, and access to most of the Fund's resources was (and remains) tightly linked to policy commitments made in advance by the government involved and monitored closely by the Fund. (On the origins and evolution of IMF conditionality, see Horsefield, 1969; for criticism from various perspectives, see Dell, 1981; Williamson, 1983b; Kenen, 1986.)

The functioning of the system

Under the Bretton Woods System, all governments had the same rights and obligations. But the monetary system did not function symmetrically. (For more on the asymmetries discussed below, see Cooper, 1972; Whitman, 1974.)

First, there was a basic asymmetry between the situations of surplus and deficit countries – an asymmetry typical of pegged-rate regimes. A country can run a balance-of-payments surplus forever, although it may become uncomfortable with the domestic monetary consequences. There is no upper limit to the stock of reserves that a surplus country can acquire when it intervenes in foreign-exchange markets to keep its currency from appreciating. But a country cannot run a deficit for ever. It will exhaust its reserves as it goes on intervening to keep its currency from depreciating. The speed at which it loses them, moreover, is likely to accelerate as its holdings fall; speculative pressures will build up as foreign-exchange markets become convinced that the country will have to devalue its currency. Therefore, pegged-rate regimes tend to display a devaluation bias.

This bias would not matter in a two-country world, where the devaluation of one currency is no different from a revaluation of the other. It matters importantly in a multi-country world, where devaluation by a deficit country revalues every other currency, not just the surplus countries’ currencies, and revaluation by a surplus country devalues every other currency, not just the deficit countries’ currencies. And the bias had significant effects on the viability of the Bretton Woods System. Devaluations by deficit countries were more frequent than revaluations by surplus countries, causing a gradual revaluation of the US dollar that weakened the competitive position of the United States.
This effect could have been offset by a devaluation of the dollar, but other asymmetries made that difficult. The dominance of the US economy and the key-currency role of the US dollar conferred important privileges on the United States but also limited its policy options. The size and comparative stability of the US economy made for an asymmetry in policy determination. For most of the life of the Bretton Woods System, US monetary and fiscal policies were aimed exclusively at domestic targets—high employment, economic growth and price stability. There was no true policy coordination between the United States and the other industrial countries, although there were frequent consultations, especially in the 1960s. There were instead one-sided adaptations by the other countries, as they sought to keep their economies in line with the US economy; see, for example, Artis and Ostry (1986) and Kenen (1989).

Furthermore, the strength of the US economy permitted the United States to forgo an active exchange rate policy until the final years of the Bretton Woods System. It was the ‘nth country’ in the system, whose exchange rate reflected the exchange rate policies of all other countries. The passivity of the United States was helpful from one standpoint. In a world with $n$ countries and currencies, there are only $n-1$ independent exchange rates, which makes it impossible for all $n$ countries to pursue independent exchange rate policies (Mundell, 1969). Therefore, the passivity of the United States helped to avoid policy conflict. Nevertheless, the arrangements supporting and promoting that passivity made the Bretton Woods System too brittle, forcing the United States to take very damaging measures in 1971, when it tried to achieve an exchange-rate realignment. Most countries defined their exchange rates with reference to the dollar, not gold, and stabilized those rates by buying and selling dollars. Hence, it was unnecessary for the United States to stabilize the dollar by buying and selling other countries’ currencies. But it was also impossible for the United States to conduct an exchange rate policy of its own without other countries’ tacit consent. It could change the gold price of the dollar, but it could not change the Deutschemark, franc and yen prices if Germany, France and Japan refused to change the dollar prices of their national currencies.

These asymmetries led to others. The US dollar was the only important convertible currency at the end of the Second World War, which caused it to become the key currency of the Bretton Woods System. It was used for official intervention in the foreign-exchange market and held along with gold as a reserve asset. There was, indeed, a neat division of labour under the Bretton Woods System. By buying and selling dollars in foreign-exchange markets, other governments stabilized the value of the dollar in terms of their national currencies. For its part, the United States stood ready to swap gold for dollars at $35 per ounce, making gold and dollars nearly perfect substitutes for the holders of reserves. This arrangement imparted elasticity to the supply of reserves. Other governments wanting additional reserves could accumulate dollars, rather than compete for limited supplies of gold. But it had two serious defects.

First, it allowed the United States to run balance-of-payments deficits without necessarily suffering gold losses. When it started to lose gold in the 1960s, moreover, it negotiated ad hoc arrangements and agreements that encouraged other countries to hold dollars instead of buying gold; see Coombs (1976) and Solomon (1982). Accordingly, the United States was not obliged to deal quickly with its balance-of-payments problem. In the words of Charles de Gaulle, it enjoyed the ‘exorbitant privilege’ of using its domestic money to pay its foreign bills.

Second, the reserve-creating arrangements of the Bretton Woods System posed a basic threat to the
viability of the system – a point made emphatically by Robert Triffin (1960). Because the IMF could not create international money – the Keynes plan had been rejected – the United States had to run balance-of-payments deficits to supply reserves to the rest of the world. As it did so, moreover, its net reserve position was likely to deteriorate; its dollar liabilities were apt to grow faster than its gold stock. Any such deterioration, moreover, was bound to impair the credibility of the US promise to sell gold for dollars, reduce the attractiveness of the dollar as a reserve asset, and wreck the reserve-creating arrangement on which the system depended.

Triffin's critique of the gold–dollar standard and his own plan for reform produced a torrent of other proposals (see, for example, Grubel, 1963) and led eventually to a promising reform. In 1968, governments adopted the First Amendment to the Articles of Agreement of the IMF, allowing the Fund to create a new reserve asset, the Special Drawing Right (SDR), when and if this was required to meet the demand for reserves. The value of the SDR was defined initially in terms of gold (in a manner that priced it at one US dollar). In 1976, however, the Second Amendment to the Articles of Agreement took the IMF off gold by making the SDR the official standard of value, and the value of the SDR itself was redefined in terms of a basket of national currencies.

Small amounts of SDRs were actually created in 1970–72 and 1979–81. But the SDR arrived on the monetary scene too late to forestall the collapse of the Bretton Woods System, and has never acquired a major role in the international monetary system.

The collapse of the system

In 1960, when Triffin published his attack on the gold-exchange standard, the US reserve position was very strong; US gold holdings were far larger than US liabilities to foreign governments and central banks. But the balance-of-payments deficits of the 1960s eroded its reserve position, fulfilling Triffin's prophecy. The collapse of the Bretton Woods System, however, was not due to this development alone. It reflected the gradual deterioration in the competitive position of the United States, exacerbated by the economic consequences of the Vietnam War. By the late 1960s, the United States had ceased to be the stable centre of the monetary system; its inflation rate was rising, and its trade surplus was vanishing.

The first major break in the commitment to pegged exchange rates came in 1969. Rumours that the Deutschemark would be revalued vis-à-vis the dollar attracted huge amounts of speculative capital to Germany and caused the German authorities to let the Deutschemark float rather than accumulate more reserves and thus increase the German money supply. The Deutschemark appreciated by ten per cent during the next four weeks, after which the German authorities converted the appreciation into a revaluation by pegging the Deutschemark–dollar rate close to its new market level. The fatal break came in 1971, when the US payments deficit widened suddenly. It ran at an annual rate of $20 billion during the first quarter of 1971, four times as large as it had been in any previous calendar year, producing new rumours that the Deutschemark would be revalued. On a single day in May, the German authorities had to buy more than $1 billion in the foreign-exchange market to keep the dollar from depreciating, and they had to buy a similar amount during the first hour of the next day's trading. Therefore, they quit and permitted the Deutschemark to float again.

An appreciation of the Deutschemark, however, could not solve the basic problem – the very large increase in the US payments deficit – and American officials began to look for the best way to achieve a general exchange rate realignment. They did not want to raise the dollar price of gold, the only option
open to them unilaterally. That would break faith with the governments that had held dollars rather than
gold, and it might not work. A higher dollar price for gold would not devalue the dollar in a meaningful
way unless other governments agreed to raise the dollar prices of their currencies. (On the discussions
within the US government, see Solomon, 1982; Gowa, 1983; Leeson, 2003.)
The crisis came to a head in August, after France had bought gold from the United States to repay a
drawing on the IMF, and there were rumours of a large gold purchase by the Bank of England. The
rumours were inaccurate but influential. On 15 August 1971, President Richard Nixon announced major
changes in US policies. He froze wages and prices temporarily to combat inflation and asked Congress
to approve an investment tax credit to stimulate output and employment. He imposed a ten per cent tax
on imports and instructed the Secretary of the Treasury to close the gold window – to suspend US
purchases and sales of gold.
The last two measures were designed to achieve an exchange rate realignment. They imposed two
penalties on any foreign government that refused to revalue its currency. Its exports would be penalized
by the tariff, and it could no longer count on buying gold when it purchased dollars in the foreign-
exchange market to keep its currency from appreciating. The United States was widely criticized for
adopting ‘shock tactics’ and breaking the rules of the trading system as well as those of the monetary
system. But the tactics worked. In the weeks following the President’s speech, several governments
joined Germany in letting their currencies float temporarily, and after three months’ bargaining a
meeting at the Smithsonian Institution in Washington agreed to realign exchange rates formally. Most of
the major industrial countries revalued their currencies against the dollar, and the United States devalued
the dollar against gold. (It did not reopen the gold window, however, so that the new official price of
gold was purely notional – the one at which the US Treasury would not buy or sell.)
The new pegged-rate regime, however, fell apart rapidly. The pound sterling was allowed to float in
June 1972, and the end of the Bretton Woods System came early in 1973, after an attempt by the United
States to negotiate a second exchange-rate realignment. Japan allowed the yen to float in February, and
six members of the European Community agreed in March to allow their currencies to float jointly.
These measures were seen to be temporary at the time, but governments soon came to believe that it
would be impossible to return to pegged exchange rates, especially after the oil shock of 1973–4 and the
economic problems it produced. In 1976, the Second Amendment to the Articles of Agreement of the
IMF replaced the original commitment to pegged exchange rates with much looser obligations.
Governments would be free to choose any exchange rate arrangement except a fixed gold price, and the
IMF was told to ‘exercise firm surveillance over the exchange rate policies of members’ (Articles of
Agreement, Art. IV (3)) but was not told how to do that.
Although the term ‘Bretton Woods System’ is usually used to characterize the monetary system that
prevailed until the early 1970s, a few have used it to describe a far more recent regime, which they
describe as Bretton Woods II (Dooley, Folkerts-Landau and Garber, 2003; 2004). What do they mean?
Throughout the 1960s, the United States ran balance-of-payments deficits because net capital outflows
from the United States exceeded the US current-account surplus. In recent years, the United States has
run balance-of-payments deficits because the US current-account deficit has exceeded net private capital
inflows into the United States, and there has been as a result a huge accumulation of dollar reserves by
countries that have been reluctant to let their currencies appreciate, most notably China, other East Asian
countries, and the main oil-exporting countries. Many economists have warned that this payments
pattern is unsustainable; see, for example, Obstfeld and Rogoff (2005) and Roubini and Setser (2004).
The dissenters, however, compare it to the payments pattern of the late 1950s and early 1960s, which lasted for a decade before the Bretton Woods System collapsed. They maintain that the surplus countries, especially those in Asia, have chosen deliberately to hold down the dollar values of their currencies and thereby accumulate dollar reserves because they count on export growth to foster rapid output growth and thus the transformation of their national economies. There is, of course, no way to resolve this controversy. Time alone can do that.

bribery

Susan Rose-Ackerman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Bribery is a form of rent-seeking meant to induce officials to serve private interests. Principal–agent relations are at the heart of the economic analysis of the subject. Bribery undermines government functioning by influencing electoral outcomes, lowering the benefits from public contracts, distorting the allocation of public benefits and costs, and introducing delay and red tape. Empirical work documents the negative consequences of corruption, and economic theory helps one understand the underlying incentives for payoffs.

Article

Bribery and corruption are a form of rent seeking meant to induce official agents to serve the interests of those making payoffs. Principal–agent relations are at the heart of the economic analysis of bribery. Payoffs induce agents to go against the interests of their principals, be they higher-level officials, politicians, or the citizenry in general. Bribery undermines the interests of principals by influencing electoral outcomes, lowering the benefits from public contracts, distorting the allocation of public benefits and costs, and introducing delay and red tape. The study of bribery thus highlights the conflict between the public interest and the market. Widespread bribery can transform government actions ostensibly based on democratic or meritocratic principles into ones based on willingness-to-pay.

The theory of perfect competition emphasizes the impersonality of all market dealings. A manufacturer will sell to all customers irrespective of their race, gender, or inherent charm. Similarly, the ideal official
makes decisions on the basis of objective, meritocratic criteria and is not influenced by personal, ethnic or family ties. Bribes can replace an impersonal meritocratic procedure with an impersonal willingness-to-pay procedure, or payoffs can support a system of personalized favours based on close personal relations. Alternatively, bribery can replace a personalized system based on family and ethnic ties with one based on financial capacity.

Early economic work on bribes concentrated on their role as prices and argued that they enhanced the efficiency of government (Leff, 1964). This perspective has been overtaken by both theoretical and empirical work arguing for and documenting the costs of systemic corruption. On the theory see, for example, Rose-Ackerman (1978), Shleifer and Vishny (1993), and the literature reviewed in Bardhan (1997) and Rose-Ackerman (1999). Cross-country empirical studies are reviewed in Graf Lambsdorff (2006) and Rose-Ackerman (2004, pp. 303–10). Kaufmann and Kraay (2002), part of a World Bank Institute governance team, deal with the issue of whether high corruption causes low growth or whether low growth generates corruption. They conclude that the causal arrow runs from high corruption to low growth, but the issue remains vexed and has led to a turn to history to seek independent causes. The problem with econometric studies that use historical data, however, is that they cannot be a guide to policy. If one is concerned with reform, it seems necessary to engage with the messy real world of feedback loops and multiple causes. History can then be put to different use as a source of case studies of successful and failed reform efforts (Glaeser and Goldin, 2006).

Corruption arises under many conditions in modern states. This article considers three variants: political corruption, kickbacks in major procurement and privatization contracts, and corruption in the allocation of benefits and burdens (for more details and references to the literature see Rose-Ackerman, 1978; 1999; 2004; 2006).

**Political corruption**

Non-democratic states tend to be more corrupt than democratic states, but democracies are clearly not immune from corruption. Obviously, corruption that arises from the competition for public office will be more prominent in democracies. The empirical results suggest that it is only long-established democracies that are less corrupt than other systems. As an example, the transition from socialism to market democracy in eastern Europe and central Asia has been fraught with corruption. During the transition, payoffs were a way to deal with an uncertain and rapidly changing environment just as, in the past, they had been a response to the excessive rigidities of a planned economy.

Furthermore, even within the universe of democracies, corruption levels vary with the constitutional structure of government. Kunicová and Rose-Ackerman (2005) find that presidential systems with legislatures selected by proportional representation are more subject to corruption than other democratic forms. Their explanation for this phenomenon is a bargaining situation in which a few strong party leaders negotiate with a powerful chief executive to share the spoils of office subject to relatively ineffective checks from voters, minority parties, and rank-and-file legislators.

At the individual level, the corruption of elected politicians depends upon the trade-off between their desire for re-election and their interest in monetary gain. Suppose voters are well-informed about politicians’ votes but cannot observe bribes directly. Assume that politicians run for re-election on their voting record and that no campaign spending is needed. Then a bribe designed to change a vote in the
legislature will cost the politician some constituency support. Bribes must be sufficient to compensate for the reduced chance of re-election. *Ceteris paribus*, politicians with the lowest reservation bribes are those who are either quite certain of being elected or quite sure of defeat; in each case a decline in electoral support has little impact on the ultimate outcome. The closer the race, the higher will be the politician's reservation bribe.

In this simple model there is no need for campaign contributions, so bribes are used only for personal gain, and there is a direct trade-off between bribes and the probability of re-election. If payoffs *can* be used either to support a re-election campaign or as personal income, then all politicians may be corruptible, depending on their moral scruples and the salience of the issues influenced by corruption (Rose-Ackerman, 1978, pp. 15–58). In electoral democracies, the control of corruption requires that re-election-seeking politicians feel insecure about their prospects but not too insecure. Too much security of tenure furthers corrupt arrangements. Too much insecurity can have the same effect.

**Procurement and privatization**

No bribes occur in a perfectly competitive market, where suppliers can sell and demanders can buy all they wish at the going price. If bribes are offered, there must be some prospective excess profits out of which to pay them, and, if bribes are accepted, it must be because the agent's superiors are either privy to the deal themselves or else cannot adequately monitor the agent's behaviour. Corruption requires market imperfections. These are widespread in government procurement, resource concessions, and the privatization of public firms. The government will often be a monopsony purchaser or a monopoly seller; and it may need products not available ‘off the shelf’ so that a negotiated contract is necessary. One might argue that corruption in procurement and the sale of assets furthers efficiency because the most efficient firm will have the highest prospective profits and so be willing to pay the highest bribe. This is simplistic. First, a winning firm in a procurement contract may gain advantage by lowering quality in subtle ways, not immediately obvious to government inspectors. Second, if managers of firms differ in respect for the law, the most unscrupulous have an advantage. Third, keeping payoffs secret both wastes resources and causes the market to operate poorly because of the low level of available information. Finally, the desire for payoffs may induce officials to contract for overly costly one-of-a-kind projects capable of hiding large kickbacks and to privatize firms on terms that favour corrupt bidders.

Mandating more effective competition is not always an option. In such situations one must consider the role of detection and punishment. Becker and Stigler (1974) first applied work on the economics of crime to corrupt payments. They stress the importance of giving each employee a stake in his or her job by, for example, providing non-vesting pensions. This will make workers less likely to take risks that could lead to their dismissal. More generally, the expected punishment for bribery should be tied to the marginal gain from marginal increases in the payoff (Rose-Ackerman, 1978, pp. 109–35; 1999, pp. 52–9). Otherwise only some bribes will be deterred. Thus the marginal expected penalty for the bribe-taker, that is, the probability of apprehension and conviction times the penalty if convicted, must rise by at least one dollar for every dollar increase in expected payoff. If it does not, then even if a large lump-sum penalty is levied, only relatively small bribes may be prevented. The bribe-payer's marginal penalty should be tied, not to the size of the bribe, but to the marginal increase in profit that a bribe makes
possible. Penalties set at a multiple of the bribe paid may have little deterrent effect on bribe-payers if the expected profits are many times larger.

Dispensers of benefits and burdens

Low-level officials frequently have considerable discretion to decide who should receive a scarce benefit such as a unit of public housing, expedited access to an important person, a liquor licence, or assignment to a particular judge. Others, such as health and safety inspectors, tax collectors, and the police, have the power to impose costs and the discretion to refuse to exercise that power. Although legal pricing systems can sometimes substitute for payoffs here, in many cases there is a strong public policy reason for opposing a market solution.

How then can corruption be controlled? There are many ways to limit the discretion of officials to extract payoffs (Rose-Ackerman, 1999, pp. 39–68). Consider just one option: the introduction of competitive pressures (Rose-Ackerman, 1978, pp. 137–66). If a bureaucracy dispenses a scarce benefit, competition can be introduced by permitting an applicant to reapply if he has been turned down by one official. Then if the cost of reapplication is small, the first official cannot demand a large bribe in return for approving the application; in fact the offered bribe may be forced down so low that the official may turn it down and instead behave honestly. A few honest officials in this system may produce honesty in the others. Notice, however, that unqualified applicants will still wish to make payoffs, and their willingness-to-pay increases if they expect that most other officials to whom they could apply are honest.

The case for competition among inspectors or police is somewhat different and depends upon the feasibility and cost of overlapping authority. Thus, the operator of a gambling parlour will not pay much to a corrupt policeman if a second independent policeman is expected to come along shortly. The whole precinct must be on the take, that is, monopolized, to make high bribes worthwhile.

In short, the role of competitive pressures in preventing corruption may be an important aspect of a strategy to deter the bribery of low-level officials, but it requires a broad-based exploration of the impact of both organizational and market structure on the incentives for corruption facing both bureaucrats and their clients.

John Bright, a Lancashire mill-owner, became a national figure in the campaign that repealed the Corn Laws in 1846 and that came to be known as the Manchester School. Elected to the House of Commons in 1843, he continued to represent industrial constituencies most of his life and worked tirelessly for radical reform which to him meant reducing the scope of government, making it more representative and keeping its foreign policy peaceful. He was a man of strong views but not doctrinaire or unwilling to change them. Believing in the market, he opposed factory legislation but not as it applied to children. At one time he supported John Stuart Mill's effort to give women the vote but later opposed the idea. He was against a state church, yet proposed its funds be distributed to all denominations as a once-and-never-again subsidy which recalls Smith's artful scheme. Although a Quaker, he never condemned war in principle and said that violence, while rarely called for, was sometimes necessary. In his day Bright was said to be the pacifist who could have been a pugilist if he had not been a Quaker. He does evoke truculence but what stands out a century later is his honesty and fierce independence. He combined them with an extraordinary speaking ability – in turns eloquent, persuasive, charming, brutally frank, cogent, and clever – all of which he could be because he had a first-rate mind. Never quite the equal of his intimate friend and ally, Richard Cobden, he nevertheless was one of the great figures in the reform movements of the century.

Britain, economics in (20th century)

K. Tribe
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The foundations of the modern discipline of economics were Marshallian, symbolized by acknowledgement of his *Principles of Economics* (1890) as the leading English-language exposition, and the creation of the very first undergraduate teaching course in economics in Cambridge in 1903. The work of Maynard Keynes made a similar, lasting international impression, although in the second half of the century a neoclassical synthesis became internationally predominant, a tendency that fostered an interest in technique rather than economic problems that would have been quite alien to Marshall and Keynes.

Article

During the early 1900s, economics in Britain completed its transformation from a science accessible to a literate public to an academic discipline that required specific training; to be a student of economics henceforth implied that one was a college or university student. The literature of economics matched this
transition. It moved out of the sphere of public argument into the closed world of an increasingly specialized academic discipline. Although there was never a perfect match between the general development of economic thinking and the pool of thinkers, these thinkers were henceforth overwhelmingly employees of universities, paid to teach and think about modern economics. Consequently, the story of British economics in the 20th century is closely related to the advance of university institutions, and within these institutions, the formation of new departments of economics. Well into the 1960s, universities, colleges and schools remained the principal employers of ‘trained economists’, for there were very few alternative openings for ‘economists’ in business or public administration. In turn, the extension of opportunities for British university economists to develop their interest in the subject was for most of the 20th century conditional upon their ability to recruit undergraduate students; for taught graduate programmes were likewise a feature of the last third of the century.

In the 1990s, with the reclassification of virtually all higher education as university education and the general deterioration of student–staff ratios, the relationship between teaching and research that had prevailed through the greater part of the century broke down. Given the late appearance of graduate programmes, ‘teaching’ had meant lectures and classes to undergraduates, shared between the staff; while from the 1950s to the 1980s a ‘class’ was no more than a dozen students, in Oxford and Cambridge individual supervision being the norm. It was also usual for the more senior members of the department to present the more elementary lectures, but they, like their junior colleagues, pursued research projects alongside their other duties, supplemented by spells of departmental research leave. This arrangement did not survive into the 1990s. Those economists seeking to pursue a research career (and hence retain their reputation as economists) required a succession of external research grants to sustain any ambition of career development; they sometimes no longer taught at undergraduate level at all. The incentive to deploy senior economists in undergraduate teaching, and hence stimulate an interest in the subject among a younger generation, was seriously compromised. Meanwhile, employers specifically interested in economics graduates usually only required a first degree of their recruits. A Master's qualification was overqualification for anything other than appointment to a technical economic job, while an economics Ph.D. was serious overqualification for anything other than university employment. Given the unattractiveness of university employment to gifted young people, the number of British students studying at this level slumped. This evolutionary development in university institutions coincided with an unrelated transition in the discipline, from a focus on economic problems to an emphasis upon the elaboration of technique. In Britain, as elsewhere, mainstream training in economics had become instruction in a set of mathematical or statistical techniques that might, or might not, illuminate the kind of economic issues with which a wider public outside the university was concerned. Early in the century economics had been propelled into British universities by widespread belief in its public purpose and utility. By the end of the century, the discipline had become dominated by technicians for whom such beliefs were less important. As we shall see, this evolutionary progression was also related to the post-war internationalization of economics, so that by the end of the century the idea of a specifically ‘British’ economics had become an empty one.

Systematic tuition in economic principles originated in Britain. The first three-year university course was the Cambridge tripos, founded in 1903. The London BSc (Econ.), centred on the newly formed London School of Economics, had preceded this in 1901, but was structured in such a way that specialization in economics was only one of a number of social science options; and economics was
taught only during the first year, at a very elementary level, in the commerce degree initiated by Ashley in Birmingham in 1902. The Oxford PPE, linking the study of Philosophy, Politics and Economics, and in this particular order because it had first been proposed by philosophers and opposed by economists, was initiated in 1920 (Chester, 1986, 34 ff.). Ultimately, the London degree had the greatest influence in advancing the study of modern economics – not simply because of the success of the LSE in attracting both students and funding, but because the external London degree offered students resident outside London, and in the wider Empire, the opportunity of studying economics. The new University Colleges of Leicester, Nottingham, Exeter, Southampton, Reading, Hull and Bristol offered to their students of economics the external London BSc (Econ.); and a succession of London Professors, from Cannan through Benham, Stonier and Hague to Lipsey, wrote popular undergraduate textbooks which remained widely used until late in the century.

Alfred Marshall, arguing for his new Tripos, had appealed to the growing need of business and public administration for young recruits conversant with the new science; a plausible enough argument, but one that in practice took many years to realise (Groenewegen, 1995, pp. 556–7). William Ashley, generally unenthused by modern economics, sought a parallel development with his Birmingham commerce degree, intended to place appropriately trained recruits in the middle levels of management. The ambitions of both men were thwarted by a general lack of interest on the part of British business and public administration in ‘new men’. Business remained dominated by small- and medium-size family firms until the interwar years at the very least, and here a professional training in law or accountancy remained a more useful general qualification than a degree in economics or commerce. In the mid-1930s having a first class degree in economics from the University of Cambridge led nowhere in particular: Terence Hutchison, appointed in the 1950s to Birmingham’s chair, worked as a Lektor at the University of Bonn before the war; Alexander Henderson, later Professor of Economic Theory at Manchester, took a year out but then replaced Kenneth Boulding as Assistant Lecturer in Edinburgh. Economics had become a university discipline, but a degree in economics was a qualification that had little cash value outside academia. Only with the general expansion of the university system in the 1950s did it become customary for bright undergraduates to become in turn graduate students and then junior members of staff – the path taken by Clive Granger at Nottingham, for example. This pattern of training and recruitment altered little until the 1970s when demand for trained economists on the part of financial institutions and public administration began to develop.

The institutions – Cambridge, Oxford, LSE and the provinces

The Cambridge Tripos was the first honours economics programme in the world because it was a key ambition of Alfred Marshall to establish the subject as a modern independent discipline, and he was in a position to realize this ambition. Appointed to the Cambridge Chair in 1884 in succession to Henry Fawcett, author of the Millian Manual of Political Economy (1863), Marshall published Principles of Economics in 1890, and in 1892 Elements of Economics of Industry, an abridged version of the Principles for use by students which proved extremely popular. Later in 1891, Marshall oversaw the founding of the British Economic Association (from 1902 the Royal Economic Society, RES) as a vehicle for the publication of the Economic Journal (EJ), the first number of which appeared in March 1891 (Tribe, 2001). In the United States, the Quarterly Journal of Economics had been founded in 1887
as the house journal of Harvard economists, while the *Journal of Political Economy*, founded in 1892, would be a house journal for Chicago economists. Marshall believed that the broad reception of new economics in Britain required a publication ‘open to all schools and parties’, and not therefore tied to any one institution. Following the publication of his textbook as a foundation for teaching, the *EJ* provided a platform for discussion among economic specialists while also keeping them informed of new publications, the current contents of foreign journals, and other relevant developments. The Tripos was the third of Marshall’s stones in the new edifice. *Principles* and *Elements* were a runaway success in the English-speaking world. The *EJ* in its early years indeed published a wide range of economic opinion – including, for example, the Erfurt Programme of the German Social Democratic Party, Vol. I September, 1891, pp. 531–3. But the Tripos remained merely a pedagogic monument for many years: during the 1930s, as many as 60 per cent of those taking the one-year Part I achieved modest Thirds (Tribe, 2000). Nonetheless, there were, during the 1930s, many graduates whose later reputation as economists began in Cambridge. In the 1880s and 1890s, economics had been taught as an option within the History and the Moral Sciences triposes at Cambridge; Marshall had made himself deeply unpopular among his colleagues with his persistence in seeking a separate existence for the teaching of economics, and having granted his wish in 1902 they proceeded to purge all economics from their own curricula. The tripos was certainly a model of a free-standing economics degree, but even in the boom years of the later 1940s the number of annual Firsts and Upper Seconds in Part II (the final examination) more or less matched the number of eminent economists in the faculty. The tripos, for the first 50 years of its existence, proved more successful in supporting the largest concentration of academic economists in Britain than teaching economics to receptive students.

On the other hand, many of Cambridge's economists turned to writing introductory textbooks under the auspices of the *Cambridge Economics Handbooks* series. The first of the handbooks was Hubert Henderson’s *Supply and Demand*, published in 1921, followed by Dennis Robertson on money (1922), Maurice Dobb on wages (1928), and Austin Robinson on the structure of industry (1931) among many others. Maynard Keynes took over the series in the mid-1920s, and drafted a general introduction printed in all editions arguing that economics was a method, not a body of doctrine, ‘an apparatus of the mind, a technique of thinking, which helps its possessor to draw correct conclusions’. Keynes was here reiterating his belief in the *organon* as the core of the Marshallian legacy, ‘a machinery that we build up in our minds, a method, an organon of enquiry that can be turned to particular problems as they arise …’ (Pigou, 1925, pp. 86–7); to which Keynes added the republican principle that the purpose of the *Handbooks* was to expound the elements of economics ‘in a lucid, accurate and illuminating way, so that the number of those who can begin to think for themselves may be increased. It is intended to convey to the ordinary reader and to the uninitiated student some conception of the general principles of thought which economists now apply to economic problems’. Published in the United States and widely circulated in the Empire, some of the handbooks were also translated, emphasising the general absence at this time of similar short works suitable for students of economics, as well as the manner in which Cambridge economics, generally unreceptive to the development of economic thinking elsewhere in Britain and abroad, was nonetheless projected into a wider world.

Oxford economics followed a different path. It had been the centre of British economics in the 1880s, pursuing the development of extension teaching in many provincial centres and graduating among others Edwin Cannan, W.J. Ashley, L.L. Price and W.A.S. Hewins (Kadish, 1982, ch. 2). But Francis
Edgeworth, appointed to the Drummond Chair in 1892, entirely lacked Marshall's institutional ambition, and in any case did not share Marshall's view that an understanding of economics required three years of systematic tuition. During the early 1900s teaching in Oxford remained broadly Millian (Young and Lee, 1993, p. 7), with Marshall being reserved for the more advanced students. The background of those who taught was primarily in history – when Roy Harrod was elected fellow of Christ Church in 1922, it was to a fellowship in history, but he immediately took himself off to Cambridge to study with Keynes, and then on his return arranged for Edgeworth to provide informal graduate supervision. By the later 1920s, with student numbers growing, new appointments were predominantly PPE graduates, among them Henry Phelps-Brown and James Meade in 1930. John Hicks had graduated in 1926 from the PPE, but with a second-class degree and was very fortunate to get taken on at the London School of Economics (LSE), since that institution too was beginning to recruit staff from among the ranks of its own graduates. Oxford lacked the organizational thread that the tripos gave Cambridge economics, and had no central figure to match Keynes, but it was perhaps as a consequence more open to external developments. In 1935 Jacob Marschak, an Oxford lecturer since he had been stripped of his Heidelberg post in 1933, was appointed to a readership in statistics and was made founding Director of the Institute of Statistics. Although, the institute was not the first of such research bodies established in Britain – Manchester's Research Section under John Jewkes preceded it – its foundation predated any plans for Cambridge's own Department of Applied Economics which, delayed by the war, eventually began work in 1945. Also significant is that fact that the Institute was funded externally, by the Rockefeller Foundation, together with a number of new posts in the social sciences. Similarly, Lord Nuffield's benefaction of the later 1930s – he had approached the university with the idea of funding a new engineering college and was persuaded by the then Vice-Chancellor, A.D. Lindsay, of the need for a social science foundation – also provided a focus for collaborative research in economics that Cambridge lacked. In 1941, the Nuffield College Committee established a social reconstruction survey, while the Institute conducted studies on full employment. This complemented work that had been initiated in the mid-1930s by the Oxford Economists' Research Group, again funded with Rockefeller money, which conducted studies of business decision-making and the role of interest rates, this work being published in the first issue of *Oxford Economic Papers* in 1938.

By this time, the *EJ* was being edited from Cambridge by Keynes and Austin Robinson and was widely, and disparagingly, referred to as the *Cambridge Economic Journal*, while the RES had also become closely associated with Cambridge. The LSE had also founded its own journal, *Economica*, in 1920, and with the launch of the ‘new series’ in 1933 this became a dedicated economics journal. This coincided with the maturation of a style of work distinct from Cambridge, by the mid-1930s condensed into a general scepticism of the significance of Keynes's *General Theory* and what today would be recognized as a strong leaning to neoliberalism. The School had been established in 1895 with a legacy linked to the Fabian Society (Kadish, 1993, p. 230), the common denominator being Sidney Webb and his involvement with commercial education in London. Before the First World War its teaching staff had been predominantly part-time – Cannan, its first professor of economics, retained his part-time status until his retirement in 1926 – but teaching was reorganized during the 1920s, adding a commerce degree to the BSc (Econ.) and replacing part-time with permanent staff recruited from among its own students. Lionel Robbins, appointed to the chair of economics in 1929, and Arnold Plant, who became professor of commerce the following year, were both examples of this trend, Plant gaining a First in economics in 1923 having also been awarded a First in commerce the previous year (Plant read for the commerce
degree as an external student alongside his full-time study of economics). The arrival of Friedrich von Hayek in 1931 as visiting professor confirmed the neoliberal profile that LSE economics assumed from the 1930s to the 1950s, but also the openness of the institution. Cannan's successor as professor had been the Harvard economist Allyn Young, and there was widespread dismay when his early death from pneumonia in 1929 terminated a direct connection to American economists that had been expected to endure for many years.

Likewise, LSE was more catholic in its teaching and reading materials than any other British institution of the time – Frank Knight's *Risk, Uncertainty and Profit* was used as a central text and re-issued in 1933 as No. 16 in the School's reprint series. As a first-year undergraduate in 1948, Bernard Corry recalled being first given sections of Samuelson's *Foundations* to work through, followed by Erich Schneider on the theory of production, and Pallander on location theory (Corry, 1997, pp. 179–80). In a 1937 survey of the School's work, Plant and Robbins noted that Frank Taussig's *Principles of Economics* was a 'good modern manual' which, besides specialized sections on public finance, railways and social reorganization, covered much the same ground as the LSE course in economics. Marshall's *Principles* headed the list of works on general economics (Plant and Robbins, 1937, pp. 67, 69). At least part of the differences between Cambridge and LSE economists during the 1930s can be traced to this contrast between an LSE aggressively open to the international development of economics, and a Cambridge which simply assumed that it was in the van of such development and did not therefore need to take account of work elsewhere. Acknowledging her debts on the opening page of *The Economics of Imperfect Competition*, Joan Robinson referred exclusively to Cambridge colleagues – Marshall, Pigou, Sraffa, Kahn, Austin Robinson and Gerald Shove. She did note the contributions to competition theory of Erich Schneider and Heinrich von Stackelberg, but considered that 'their work is marred by the use of unnecessarily complicated mathematical analysis where simple geometrical methods would serve' (Robinson, 1933, p. vii).

By the 1930s, Cambridge was graduating 50–60 students from its Part II every year, and well over 100 students left the LSE annually with a BSc (Econ.) containing an increasingly variable amount of economics. The new universities founded from the turn of the century – Birmingham, Manchester, Liverpool and Sheffield – made little direct headway in finding a constituency of students eager to learn the new economics, but they did find a ready market for teaching in commerce, which contained some economics. In most cases this teaching was quite practical, covering law, banking, economic geography, history and languages; and railway management was often an important component, given the size of the railway companies and the numbers of their employees. For many students approaching economics for the first time, it was taught as part of a vocational course that had the support of significant local employers. This was especially true in Scotland, where the four ancient universities – Glasgow, Edinburgh, St. Andrews and Aberdeen – were closer to the Continental European model, law and medicine being a part of the university. Chartered accountants in Scotland took university courses in elementary economics, highlighting a natural link between the professions and the university absent in England.

Ashley returned to Britain from Harvard's new chair in economic history to found Birmingham's Faculty of Commerce in 1902, but although this has become the single most well-known example of commerce teaching in Britain, it was atypical in many ways. Ashley had ambitions for commerce analogous to Marshall's for economics, seeking to educate future management leaders rather than the future line managers and college teachers turned out in Liverpool and Manchester. He established an advisory
board with local business in a deliberate effort to recruit the sons of business families. But instead of
drawing on the local business community for the teaching of accounts, commercial law and banking as
Liverpool or Manchester had done for many years, Ashley made accounting a professorial position and
in 1906 followed this with a chair in finance. These posts were not justified by the student numbers that
he recruited. There were never more than 36 students registered for the commerce degree before 1914,
and total registrations only averaged in the high fifties once the short-lived post-war boom had passed.
Birmingham's later reputation was based not on its early commitment to commerce, but on the
coincidence that Frank Hahn, Alan Walters and Terence Gorman all taught there in the mid-1950s.
Birmingham, together with Nottingham, was the first British institution to make a significant effort to
develop mathematical and statistical analysis in economics.
Manchester was another important centre: it was here that the first university-based research section was
established under Jewkes in the early 1930s, and Manchester economists predominated among those
recruited to government service during the Second World War. The Faculty of Commerce had been
established by Sydney Chapman (a former student of Alfred Marshall) in the late 1903, building upon a
solid foundation of teaching in political economy most recently developed by Alfred Flux, but reaching
back to Jevons's classes in the 1870s. Degrees were offered in both commerce and honours economics,
Chapman using part-time local professionals for the more specialized parts of the commercial
curriculum and appointing young economists to do the non-specialized teaching. This strategy enabled
him to develop the teaching of economics, and many of the pre-First World War junior staff went on to
chair their own departments: Hugh Meredith taught in Manchester 1905–8, and then was professor at
Queen's Belfast from 1911 to 1945; Robert Forrester taught in the Faculty 1910–13, went to Aberdeen,
then the LSE, and was Professor at Aberystwyth from 1931 to 1951; Harold Hallsworth taught in
Manchester during 1910, later becoming Professor at Newcastle; Douglas Knoop taught in 1909,
became a lecturer in Sheffield in 1910 and was then later Professor from 1920 to 1948; A.N. Shimmin
taught 1913–15, and was from 1945 professor of social science at Leeds. Clearly, Manchester became an
important staging post in the development of careers which imposed a clear pattern on the development
of the teaching of economics in provincial Britain, and hence by extension the propagation of economic
understanding to a diverse range of students.
This pattern in the academic life cycle had important consequences for the advancement of economics in
20th-century Britain. Those appointed to junior posts in this initial phase of pre-First World War
expansion quickly moved on to more senior posts as new departments were established, but they then
stayed in them for many years. This blocked mobility during the later 1920s and 1930s. But many senior
members in this first cohort retired together in mid-century, creating an opening for renewal in the
organization of academic economics, reinforced by increased demand for the teaching of economics in
the late 1940s. During the immediate post-war period departments expanded to meet this demand; new
posts were created, and a fresh wave of young candidates filled senior appointments. These in turn
dominated university departments during the 1950s and early 1960s, but reached retirement age at about
the same time that new universities were being founded and the number of senior positions extended
once more. The pace of development of research and teaching in economics that took place in Britain
during the 1960s rested to a considerable degree on the fluidity and openness that this academic life
cycle created.
But these two successive surges – in the 1940s and the 1960s – of mobility, expansion and disciplinary
development faltered with the uncertainties of the 1970s, and then broke on the university cutbacks of
the 1980s. The mobility and advancement of younger staff trained in the later 1960s and early 1970s was blocked; this cohort grew old together in the same posts while bright young economists looked elsewhere for employment, and for which in any case they did not require to spend several years on a Ph.D. that an academic career now dictated. The average age of departments increased year by year, hollowing out the institutional hierarchy. By the 1990s, the pool of potential young British economists was severely depleted, given the small number of doctoral and postdoctoral students in the system; and with the slow resumption of recruitment the cycle simply skipped a generation expanded the pool from which it drew. Shortlists came to be dominated by applicants from the EU and beyond, attracted by the openness of the UK labour market and the experience of working in the English language. Graduate programmes likewise became dominated by foreign students. As with recruitment to medical staff in the National Health Service, British universities made good the manifest deficiencies of the British educational structure by turning for graduate students and faculty to those trained elsewhere.

The interwar years

The foregoing is not intended to substitute for a more orthodox ‘history of economic thought’ story. It instead demonstrates how the building of a discipline required a financial and institutional framework as a condition for the development of ‘economic careers’, which careers in turn provided the basis for the elaboration of economic argument as spoken, written and published discourse. The first movers in this latter process are indeed generally to be found in Oxbridge and London; but, for a discipline to flourish, followers are also needed, who in turn have access to a secure institutional structure. Hence, the importance of a national perspective upon the development of economics in Britain.

Cambridge did occupy centre stage in the first half of the century, partly as a consequence of the employment opportunities the new tripos presented: students had to be supervised and courses of lectures delivered, and this all added up to a significant number of college fellows and University lecturers. Marshall was also an important spiritual and pedagogic presence – after retirement in 1908, he continued his practice of open hours at home for students, lending them the books that would later form the core of the Marshall Library. His young protégé Arthur Pigou had marked himself out early on with a number of articles in the *EJ* notable for their brevity and formal exposition – anticipations of a style that had not then become customary. His *Wealth and Welfare* broke new ground in seeking to determine what ‘welfare’ might be, and noting that however defined, if the ‘National Dividend’ (as he termed GNP) increased, then welfare also increased. Redistribution of welfare through the population could also be brought about, but given the regressive nature of the contemporary taxation system he thought of this chiefly in terms of access to health and education services. He noted that monopoly tended to distort the distribution of welfare, so that this book also involved an extended treatment of duopoly and imperfect markets. This and the work of Alfred Marshall had a considerable contemporary impact upon American discussion of price and competition, forming a natural background to the later work of Frank Knight and Edward Chamberlin, especially in respect of Pigou’s observations on the level of equilibrium output under monopolistic competition (Pigou, 1912, pp. 294, 356). The 1920 revision of this work into *Economics of Welfare* re-emphasized the social duties of the economist as outlined by Marshall in his inaugural lecture of 1887; and a new emphasis is laid upon the impact of taxation, commensurate with the consequences of the war for the post-war economy. The Marshallian cast of the work is highlighted by the following credo from the Preface:
The complicated analyses which economists endeavour to carry through are not mere gymnastic. They are instruments for the bettering of human life. The misery and squalor that surrounds us, the dying fire of hope in many millions of European homes, the injurious luxury of some wealthy families, the terrible uncertainty overshadowing many families of the poor – these evils are too plain to be ignored. By the knowledge that our science seeks it is possible that they may be restrained. Out of the darkness light! To search for it is the task, to find it, perhaps, the prize, which the ‘dismal science of Political Economy’ offers to those who face its discipline. (Pigou, 1920, p. vi)

Keynes certainly shared this credo, as his introductory comments to the Cambridge Handbooks show, but his later characterization of Pigou as a ‘classical’ that is, superseded, economist has subsequently been too easily subsequently accepted at face value. Pigou, being the professor, was debarred from supervising undergraduates, so that his involvement in teaching was limited to lecturing, and this he generally did at an elementary level only. As with many of his generation – D.H. MacGregor in Oxford, Alec Macfie in Glasgow – he had been badly affected by his experiences in the First World War, and played little further part in the shaping of teaching and research in Cambridge. He has consequently, and unjustly, been excluded from ‘Cambridge view’ of the history of economics, which has come to be dominated instead by Sraffa, Kahn and the Robinsons, amongst others (Collard, 1981).

The locus classicus of this Cambridge ‘insider story’ is George Shackle's *The Years of High Theory*, although curiously Shackle was never a ‘Cambridge man’: he went to school there, but was never connected with the university. *The Years of High Theory* takes its departure from Sraffa's 1926 *EJ* article, and ascribes to contemporary non-Cambridge economists a dogmatic and universal belief in ‘perfect competition’. Hence Sraffa's theoretical critique of perfect competition is presented as a radical, definitive, if unappreciated, settling of accounts, upon which new work can thereafter build. Here Shackle joins later neo-Ricardians, for whom likewise Sraffa is of decisive importance to the development of economic theory. ‘Perfect competition’ had however only just been systematically adumbrated, in Chapter 6 of Frank Knight's *Risk, Uncertainty and Profit* (1921), and by no means dogmatically; indeed, Shackle imputes to British economists of the 1920s views more common in the America of the later 1940s, and not before.

Dennis Robertson also fails to register in the Cambridge story, despite having Keynes as his Cambridge Director of Studies, and then spending almost his entire working life in Cambridge, retiring in 1957. This neglect can be attributed to his later criticism of Keynes, describing in 1948 the *General Theory* as ‘a step backwards’ which prematurely embraced ‘stagnationism’ ‘on the strength of one bad depression’ (Robertson, 1948, p. xvi). Remarks such as these make his relative neglect all too understandable, but this should not be allowed to obscure the larger significance of his early work. Hitherto studies of economic cycles had focused on the periodicity of price movements (Morgan, 1990, chs. 1, 2); the analysis of *Industrial Fluctuation* went behind price movements to the variations in output and employment that they represented. That bust follows boom was easily accepted; but why a slump should be followed by recovery was not so easy to explain. Robertson identified a number of causes, most important of which was invention and innovation, an emphasis which was new at the time in Britain, and which Robertson had arrived at without having read Joseph Schumpeter (Presley, 1981, pp.
Robertson's *Banking Policy and the Price Level* (1926) was likewise an influential work, extending his study of fluctuations to cover monetary phenomena (Laidler, 1999, 93 ff.). Robertson's mannered writing style did not make this book any easier to read, but as Laidler points out, Pigou took over large sections of the argument in his own *Industrial Fluctuations* (1927), disseminating Robertson's ideas in more readable English. As with his first book, Robertson took his departure from observable facts – that the British banking system balanced deposit liabilities against short-term loans. The banking system was therefore charged with coordinating the public's short-term saving with firms requirements for working capital, and although he noted the forced saving involved in this, he also saw its potential as a stabilizing factor, moderate forced saving being therefore the price paid for progress.

Cambridge in the 1930s is however dominated by the figure of Keynes, and not only intellectually. He had resigned his University Lectureship in 1920, after which his formal connection to the university was solely as a college fellow. Nonetheless, he made up for Pigou's disengagement through his editorial work on the *EJ* with Austin Robinson, in the Political Economy Club, to which promising students were invited and required to ask questions of visiting speakers, through his work for the college, and through his engagement in the arts. In Cambridge lectures could be offered by any college fellow, and were not confined to faculty members. Keynes developed a practice of lecturing from the proofs of his next book, the experience obviously leading him to substantial revisions (Rymes, 1989). He found jobs for some bright graduates – while other bright graduates of whom he was unaware found that their Cambridge First might not necessarily lead anywhere in particular (Tribe, 1997, pp. 77, 129).

Keynes's reputation has long been overlaid with 'Keynesianisms' of various kinds. That his memorial service in 1946 was held in Westminster Abbey is indication enough that, whatever the nature of his reputation, it was a very great one. Much of his work in the 1920s took the form of superior economic journalism – from *The Economic Consequences of the Peace* (1919) that made his public reputation, through 'The Economic Consequences of Mr. Churchill' (1925) to 'Can Lloyd George Do It?' (1929). His rise to become the single most influential British economist of the century began in the early 1930s. Peter Clarke has provided a lucid account of the early part of this story: the nature of contemporary government policy, Keynes's evidence to the Macmillan Committee in 1930, its relation to the two volumes of the *Treatise on Money* published that year, the impact of the abandonment of the gold standard in September 1931 and of free trade over the winter of 1931–32, and the consequent genesis of a new general theory of employment, interest and money – there is little dispute about the main lines of these developments (Clarke, 1988).

Argument breaks out however over the substance and intentions of the *General Theory*, published in February 1936. David Bensusan-Butt captures precisely the sense of confusion a modern reader experiences coming to this work for the first time:

> Never did a book fall more quickly and more completely into the hands of summarisers, simplifiers, boilers-down, pedagogues and propagandists. To get at what it seemed like at the time (and perhaps what it really was and is) one has to fight one's way through a cloud of commentators, and try to see it in a more empty landscape. (Quoted in Skidelsky, 1992, p. 537)
Notoriously, Keynes was one of the earliest such commentators, reflecting on his intentions in an article in the *QJE* in February 1937. Although few would seriously dispute that the *General Theory* marks the inauguration of an integrated macroeconomics, it was built out of existing elements – and some at least of the disagreements engendered by the book can be related to incompleteness in the integration of these elements. David Laidler has also shown, for example, that one of the most general statements that can be made about the *General Theory* – that it provides a clear role for government not in substituting for market activity, but by influencing the expectations of investors and businessmen – adopts arguments already made in Lavington's *The English Capital Market* (1921) (Laidler, 1999, pp. 87–8).

The translation of Keynes's fluent prose into the diagrams and algebra better suited to an increasingly formalized style of economic argument followed publication very rapidly. Brian Reddaway, reading a review copy of the book on the way to a post at Melbourne University arranged by Keynes, sketched four equations relating savings, income, investment, the rate of interest and the supply of money and published these in the June 1936 issue of *Economic Record* (Reddaway, 1936). On 26 September 1936, at a meeting of the Econometric Society in Oxford, a session was devoted to the *General Theory*. Here Roy Harrod, James Meade and John Hicks made graphical and algebraic presentations, Hicks writing this up in his article ‘Mr. Keynes and the Classics’ published the following year (1937). Thus was born the classroom IS–LM presentation of Keynes's ideas (Young, 1987).

The transformation of the *General Theory* into a blueprint for managing the mixed economy was, however, effected along two separate paths. In the United States Lawrence Klein, Alvin Hansen and finally Paul Samuelson systematized Keynes's insights and rendered them consistent with the new neoclassical economics (Klein, 1948; Hansen, 1953; Samuelson, 1955). In Britain, the outbreak of war in 1939 and the entry of British economists, including Keynes, into government service provided a unique opportunity to deploy Keynes's insights in managing the wartime economy (Cairncross and Watts, 1989, chs. 2–7).

The basic framework had been laid down by Keynes in his ‘How to Pay for the War’, reversing the assumptions upon which the *General Theory* had been built. The basic task now was to run an economy at its maximum potential output for war production without generating inflationary pressures. Such diverse characters as Lionel Robbins, Ronald Coase, Brian Reddaway, John Jewkes, Ely Devons and James Meade were recruited into government service to facilitate the wartime management of the UK economy. Whereas financing the First World War had been primarily a matter of managing international money markets – a task in which Keynes had played a part – ‘paying for the war’ now meant management of the domestic economy. Inflation was to be avoided as a means of suppressing private consumption in favour of war production. Excess purchasing power was instead to be absorbed through additional taxation, which implied estimation of the actual level of excess. A thorough system of rationing was devised, and financial planning increasingly gave way to manpower planning. Allowance had to be made for the subsidies necessary to stabilize the cost of living, and, on the assumption that this stabilized gross incomes, total volume of money demand needed to be established. By subtracting the amount of goods and services coming on the market an ‘inflationary gap’ could be identified, representing the amount of excess demand that had to be siphoned off. As early as the winter of 1940 government treated pressures in the economy in terms of an ‘output gap’ separating the level of demand from the capacity of factors of production to meet these demands (Sayers, 1983, p. 106). The 1941 Budget broke new ground, presented in a national accounting framework that would enable such
estimations to be made (Kaldor, 1941, p. 181). Moreover, this approach implied that the primary
economic aim of governments should be the stability and growth of national income, rather than the
more narrowly financial considerations traditionally associated with reviews of government income and
expenditure. This was underlined by the formulation of post-war plans such as William Beveridge's
Social Insurance and Allied Services (1942), followed by the Employment Policy White Paper of June
1944, the month of the Normandy landings (Coats, 1993a, p. 558). It was this framework that wartime
economists bequeathed to the peacetime civil servants who succeeded them, and which enabled them to
manage the economy in terms of Keynesian aggregates. The Economic Section, the central body of
economic advisors that had been led by Robbins for most of the war, survived the transition to
peacetime, but with a much reduced role. Coats notes that fewer than 20 professional economists were
employed by the government on matters relating to macroeconomic policy during the first two post-war
decades (Coats, 1993b, p. 523).

There have been many versions of Keynesianism since (Backhouse, 2006), but the most misleading
variant is that which links Keynes to the centralized management of peacetime mixed economies. Some
sort of Keynesian consensus did prevail in the British academic establishment from the later 1940s until
the early 1970s, but the overriding concern, which had brought its senior members into the discipline,
was a belief that the depression of the 1930s should not be allowed to recur. ‘Keynesianism’ offered a
route to a policy synthesis that could realize this, but this was not translated directly into the pursuit of
‘Keynesian’ economic policies on the part of post-war Labour and Conservative governments. The
Economic Section was not ineffective in its advice, but it was very small; while academics outside
Whitehall lacked direct influence on the formation and execution of policy, chiefly confined in their
expression of opinion to the letters’ column of The Times. Hugh Gaitskell had been an economics
lecturer at University College London and published on capital theory in the Zeitschrift für
Nationalökonomie, but the Labour Party was never in power during his period of leadership. Harold
Wilson likewise came from an Oxford economics background; his incoming Labour Government of
1964 did establish a Department of Economic Affairs, but its chief task was the drafting of a National
Plan on the French model. The drafting and execution of legislation right up to the early 1980s was
conducted by generalist civil servants with no special background in economics, directed for the most
part by Ministers likewise lacking in formal economic training. The ‘Keynesian’ nature of their
approach to government and the economy derived not from any particular theoretical beliefs, but chiefly
from a generalized public expectation that it was the job of government to counter downturns, stabilize
employment and promote growth. Until 1979, any party that denied its capacity to fulfil such electoral
expectations stood no chance of gaining office. Harold Wilson observed acutely that ‘Whichever party is
in office, the Treasury is in power’, but there is now an extensive literature which documents the
essentially pragmatic, rather than dogmatic, nature of Treasury decision-making during the 1950s and
1960s, supposedly the heyday of Keynesianism (Peden, 1988).

The post-war legacy

During the 1930s a number of British economists made theoretical innovations of lasting significance.
This was indeed the ‘decade of high theory’, to borrow from George Shackle, but it was certainly not, as
he suggests in his book, an exclusively Cambridge preserve. Ronald Coase, who graduated with a
commerce degree from LSE in 1932, went that same year to his first appointment in Dundee, where he
drafted his essay identifying a firm as a replacement for market transactions, eventually published in
1937. John Hicks, having published in 1934 an article in which consumer preferences displaced utility,
went on in Value and Capital (1939) to create a neoclassical microeconomic synthesis. James Meade
published in 1936 his Introduction to Economic Analysis and Policy, the first of many seminal works.
All later gained the Swedish Riksbank Prize in Economic Sciences (in 1991, 1972 and 1977,
respectively) for these and other works. But what is most notable about these annual awards, made since
1969 and beginning with Ragnar Frisch and Jan Tinbergen, is that they are dominated by American
economists who began their careers in the 1940s and 1950s. For in this period American economics
became international economics.
The war itself had turned out to be the apotheosis of British economics. US foreign policy sought to
block any prospect that post-war Britain would resume its former world role, and assumed Britain's
former international stance as model democracy and proponent of free trade and economic liberty.
Teaching of economics in American universities expanded, and during the 1950s graduate programmes
were developed on this foundation. There was a parallel expansion in demand for courses in
undergraduate economics in Britain, but neither the will nor the money to develop graduate education.
Increasingly, bright students and young economists looked to American connections to develop their
careers. Coase was already there; Alexander Henderson went from Manchester to Carnegie Mellon in
1950, and became joint author of the first textbook on linear programming; Clive Granger had by the
early 1970s gravitated to California. In turn, the teaching of economics in Britain became increasingly
modelled upon American programmes, increasingly making use of American books and articles
(Backhouse, 1996; 2000).

As already noted, with the end of the war the majority of economists had quickly left government
employment and moved back into the university. Economics was widely regarded as a ‘modern’ subject
in school and university (Coats, 1993c); educational opportunity was widely understood as the path to
social mobility, a belief underwritten by Lionel Robbins's report to the government which argued that
extension of university access would not compromise entry standards or teaching (Committee on Higher
Education, 1963). This finding coincided with the opening of a number of new universities in which
social sciences played a significant role. In 1964, Richard Lipsey moved from the chair at LSE to the
founding chair at Essex, primarily because he saw the opportunity to develop the graduate economics
programmes there that his colleagues at LSE had declined (Tribe, 1997, 217 ff.). Once established, this
model rapidly spread, but then ran into the uncertainties of the 1970s. As economics became more
technical, the capacity to train students in the new techniques remained very restricted. Generational
succession, as outlined above, also played a role as a new generation, born into the certainties of the
1950s and 1960s, found themselves in an uncertain world.

As Roger Middleton has argued, financial pressure on universities in the later 1970s and 1980s was
coupled with a collapse in the public authority of universities (Middleton, 1998, p. 312). Moreover,
throughout the 1980s academic economists were, with a few notable exceptions, generally hostile to
government policy. Notoriously, this was expressed in a letter to The Times in March 1981 where 364
economists signed up to the argument that government policy would deepen the current depression and
slow recovery. This polarized politicians and economists, to the lasting cost of the latter (Backhouse,
2000, p. 31). University economists were consequently shut out of government decision-making while at
the same time a broader public found the increasingly technical preoccupations of economists of little relevance to an understanding of economic problems. The broad consensus that had in the 1950s and 1960s made economics the ‘modern’ discipline broke upon widespread popular disillusion with both modern economics and the universities within which it was practised. The evolutionary development of the discipline was exacerbated by the process of research audit that began in the mid-1980s, ranking departments and their staff on the basis of research publications (the Research Assessment Exercise, RAE). Although this provides for a system of peer review and is not imposed by a separate educational bureaucracy, the resultant ranking was increasingly employed to determine the allocation of resources between and within universities. Furthermore, peer review has tended to sharpen the ‘scientization’ and public isolation of British economics, since ‘professional’ prestige and a high ranking comes only from publication in a very restricted number of international journals, not from an interest either in undergraduate education or in public issues (Middleton, 1998, 221 ff.). Each subject area draws up its own schedule of approved publication media, and in the case of economics this list has always been weighted towards ‘rigour’, which was what economists had come to pride themselves on as compared to the other social sciences. Since these other social sciences were less ‘rigorous’ in their judgement of what counted as worthwhile research outputs, median economics departments assessed in the 2001 RAE fared very badly within social science faculties, losing funding and strengthening the polarizing tendencies which concentrated ‘celebrity’ staff and resources in a handful of institutions.

The trend to internationalization in economics teaching and research was a general phenomenon during the last quarter of the century. The diversity, both between and within nations, with which the discipline had begun the century had, by the early post-war period, increasingly given way to homogenization of style and substance. This process accelerated in the 1980s as the personal computer offered every economist access to data and means for its processing without leaving the office. By contrast, most of Bill Phillips's work on inflation and unemployment in the 1950s had been done late at night on the National Physical Laboratory's computer in Teddington. Likewise, Richard Stone had during the 1940s done most of his own statistical work on a hand-cranked machine. The speed with which data could now be processed did away with the enforced lengthy periods during which one pondered the meaning of previous results and devised new strategies. But it also meant that such thinking was at a discount, given the range of data and software. The discipline of economics succumbed to a basic ‘law’ of markets: the larger the size, the less the diversity.

Nonetheless, public interest in economics survived, and economic careers developed that did not depend upon university status. This new trend originated in the 1980s. Nigel Lawson, Margaret Thatcher's Treasury minister, had a background in economic journalism, symbolizing the rise of a new source of authority independent of any academic institution. Many of the new breed of ‘City economist’ had no formal academic background in economics at all, but drew upon other technical skills. Independent ‘think tanks’ began making themselves heard, foremost among them the Institute for Fiscal Studies (IFS), which by the end of the century had grown into the leading non-government authority on domestic fiscal affairs. The rise of the IFS was accompanied by a number of similar organizations addressing the social, political and economic issues that university economics had for the most part left far behind. And finally, a new, non-academic popular literature of economics emerged, seeking to demonstrate the public utility of economic principles to an increasingly receptive readership.

British classical economics

Mark Blaug
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Classical economics is not just a period in the history of economic thought immediately prior to the marginal revolution but involves a distinct approach to economic problems. But endless controversy surrounds the definition of that approach. Indeed, the scope of the science of political economy as conceived in Smith's *The Wealth of Nations* was sharply contracted in Ricardo's *Principles of Political Economy*. Some modern commentators characterize classical economics as surplus theory; others as general equilibrium theory. Economists who are divided in their views will always try to find those views embodied in the writings of the past.

The label ‘classical economics’ is sometimes employed to refer quite simply to an era in the history of economic thought from, say, 1750 to 1870, in which a group of predominantly British economists used Adam Smith's *Wealth of Nations* as a springboard for analysing the production, distribution and exchange of goods and services in a capitalist economy. So broad a definition of classical economics must include such contemporary Continental writers as Cournot, Dupuit, Thünen and Gossen, not to mention such British writers as Bailey, Lloyd and Longfield, who at first glance seem to stand outside the tradition founded by Adam Smith. It is difficult to resist the implication, therefore, that classical economics is more than a period in the history of economic thought: it seems to involve a definite approach to economic problems. The difficulty, however, is how to characterize this approach.

Shrugging aside such tendentious definitions of classical economics as those of Marx and Keynes – for Marx (1867, pp. 174–5n) classical political economy begins with Petty in the 17th century and ends with Ricardo, and for Keynes (1936, p. 3n) the classical school begins with Ricardo and ends with Pigou – the first question is whether it was Adam Smith or David Ricardo who established the ‘essence’ or ‘core’ or classical economics. Of course, Adam Smith laid down the main issues that economists debated for a century after him, but there is also little doubt that the Smithian tradition was in some sense transformed with the appearance of Ricardo's *Principles of Political Economy and Taxation* in 1817. Some writers have nevertheless insisted that Smith and not Ricardo was the lasting influence on the character of classical economics, contending that the leading features of Ricardo's theoretical system were soon rejected even by his avowed followers in the decade after his death in 1823. Others, however, have insisted that, despite all the criticisms of Ricardo that no doubt appeared in the late 1820s and early 1830s, later writers like John Stuart Mill and John Elliott Cairnes continued to operate right up to the 1870s with the central Ricardian theorem that the rate of profit and hence the accumulation of capital depends critically on the marginal cost of production in agriculture; in that sense, they remained trapped in the Ricardian system. But even this assertion presupposes the notion that the Ricardian system is essentially characterized as a theory about the determination of the rate of profit, a proposition which is by no means accepted by all historians of economic thought.

It is only after clearing up this problem of the relative significance of Smith's and Ricardo's ideas in shaping the central current of classical economics that we can take up the question of where to place the utility theories of value put forward by such writers as Lloyd, Longfield, Senior, Dupuit and Gossen, the abstinence theories of interest of Bailey, Senior, Rae and John Stuart Mill, the use of both supply and demand forces in the determination of international prices by Mill, the theory of general gluts and the denial of Say's Law of Markets by Malthus, and the exploitation theory of profits by Marx – in short, all the elements of economic theorizing in the period 1770 to 1870 that so clearly do not belong to the corpus of doctrines bequeathed by Adam Smith and David Ricardo. Likewise, it is only then that we can start talking about the end of classical economics in the 1870s and the nature of the ‘marginal revolution’ that may or may not have marked a decisive break in the continuity of orthodox economics.
The endless debate on what was classical economics is neatly illustrated by the simultaneous appearance of three books on classical economics: Classical Economics Reconsidered by Thomas Sowell (1974), The Structure of Classical Economic Theory by Robert Eagly (1974) and The Classical Economists by Denis O'Brien (1975). Of the three, Eagly takes the widest view of the length of time over which something called ‘classical economic theory’ ruled the roost, beginning with the physiocrats in the 1750s and ending with the Walrasian theory of general equilibrium in the 1870s. His view is not only that the whole of classical economics can be defined in terms of a single conceptual framework but that this framework revolves essentially around a particular concept of capital as a stock of intermediate goods invested in staggered production periods, the question of the pricing of final goods always relegated to the next period after output has already been determined by the size of the labour force and the technology of the previous period; in short, the key to classical economics is to be found in the so-called ‘wages fund doctrine’. Whether this thesis is convincing or not, Eagly's book represents an extreme example of the tendency to define classical economics as one coherent body of ideas organised around a central unifying principle. The secondary literature is, of course, replete with other attempts to pin down once and for all the classical theory of economic growth (e.g. Lowe, 1954; Samuelson, 1978), but few allege, as Eagly does, that their modelling of classical economics captures all the essentials of the writings of Quesnay, Smith, Ricardo, Mill and Marx, as well as McCulloch, Torrens, Bailey, Jones, Senior, Longfield, Babbage, Tooke, Wakefield, etc.

Sowell, on the other hand, adopts the traditional definition of classical economics as in effect the School of Adam Smith, and he therefore excludes Marx and, more surprisingly, Malthus, Torrens and Senior at least in some respects from the mainstream of the tradition stemming from The Wealth of Nations. That tradition consisted, according to Sowell, of a common set of philosophical presuppositions, common methods of analysis and common conclusions regarding matters of substantive economic analysis: it comprised such major propositions as the labour theory of value, the Malthusian theory of population, Say's Law and the quantity theory of money and was predominantly oriented towards the issue of economic growth (although not in the modern sense of the term as a theory of the steady-state equilibrium growth path of an economy). However, Sowell admits that this picture has to be qualified after 1817 by such phrases as ‘classical economics in its Ricardian form’ because Ricardo worked a major change in Smith's eclectic mode of economic reasoning by adopting static equilibrium analysis as the only valid method of conducting an economic argument. At any rate, Sowell's treatment of classical economics leaves little doubt of the extensive and varied character of economics in the classical period, posing problems for anyone who seeks to define classical economics in one or two sentences.

Both Eagly's and Sowell's books are dwarfed by O'Brien's wide-ranging and comprehensive review of classical economics, which alone among the three begins with an incisive discussion of the extent to which the classical writers formed a ‘scientific community’. (O'Brien's book also contains excellent annotated bibliographical notes on classical economics; indeed, O'Brien, Blaug (1985) and Spiegel (1983) between them review the whole of the secondary literature.) O'Brien follows Schumpeter in arguing that the Ricardian system represented an analytical detour from the main line of advance running from Adam Smith to John Stuart Mill; it was not a fatal detour, however, because the full Ricardian apparatus attracted hardly any followers and in any case was more or less abandoned by the 1830s. As we noted earlier, this Schumpeter–O'Brien thesis has been questioned by some (e.g. Blaug, 1958; Hollander, 1977). The point is, however, that O'Brien's book perfectly illustrates our contention.
that any stand taken on the nature of classical economics as a whole depends critically on the attitude adopted towards the Ricardian metamorphosis of Smithian economics.

The Sraffa interpretation of Ricardo

Still more recently a new note has been struck in the old argument about the essential meaning of classical economics. Inspired by the publication of Sraffa's *Production of Commodities by Means of Commodities* (1960), a number of commentators have argued that classical economics is in effect a Sraffa-system, that is, an analysis of the manner in which a capitalist economy invests its surplus of net output over consumption, which is to say an output in excess of that required to reproduce that level of output, subject to the condition that goods and services are so priced as to maintain a uniform rate of wages and a uniform rate of profit on capital in all lines of investment. This approach, they contend, was buried in the 1870s when the central object of economic analysis became that of investigating the optimum allocation of resources whose quantities are given at the outset of the analysis; in reviving classical surplus analysis, Sraffa not only provides a promising new way of studying economic problems but also illuminates precisely what it was that united Smith, Ricardo and Marx, thus licensing the use of a single label such as ‘classical economics’ to cover them all (see Meek, 1973, 1977, the originator of the argument; and Dobb, 1973; Roncaglia, 1978; Walsh and Gram, 1980; Bradley and Howard, 1982; Eatwell, 1982; Garegnani, 1984; Howard and King, 1985).

As is well known, a Sraffa-system consists of a set of linear production equations, one for each commodity in the economy, and is intended to demonstrate that these equations are sufficient to determine all relative prices in long-run equilibrium irrespective of the pattern of demand, provided that (1) the output of each commodity is given; (2) rate of profit on capital is uniform throughout the economy and (3) the real wage or (alternatively the rate of profit on capital) is somehow determined exogenously. On the face of it, such a theory does indeed appear to be very much like ‘classical economics’. For example, after distinguishing between ‘natural’ and ‘market’ prices of commodities – or, as we would nowadays say, the long-run and short-run prices of commodities – Adam Smith focused much of his analysis on the determination of ‘natural’ prices, a tendency which became even stronger in the writings of Ricardo. Moreover, Smith and certainly Ricardo, not to mention Marx, always wrote as if demand played no role whatever in the determination of ‘natural’ price. We have all known ever since the work of Marshall that this neglect of demand can be justified if one assumes that commodities are produced under conditions of constant unit costs or constant returns to scale, the long-run supply curves of all industries being perfectly horizontal over the relevant range of output. Sraffa's production equations imply fixed coefficients of production and, again, we have known ever since the work of Leontief that fixed coefficients of production are sufficient (but not necessary) to produce constant costs. In short, Sraffa's demonstration that prices in his model are determined independently of demand is eminently ‘classical’.

Likewise, there is no doubt that the concept of a uniform rate of return on capital, or rather defining ‘natural’ prices to be those generated by a stationary equilibrium in which the rate of profit has become equalized by interindustry mobility of capital, is typical of all economic writing in the century between 1770 and 1870. Finally, the real wage rate in classical economics is determined by so-called ‘subsistence’ requirements and these were defined by Ricardo, Mill and Marx in historical rather than
physiological terms; in other words, it was assumed that the current ‘natural’ price of labour reflected the past history of the ‘market’ price of labour. The ‘natural’ price of labour was in effect determined by workers’ attitudes to the size of their families but since the classical economists did little to analyse these attitudes, it is not too much to say that the so-called ‘subsistence theory’ of wages’ actually amounts to taking ‘subsistence’ as a datum (Schumpeter, 1954, p. 665). Once again, it can be argued that the Sraffian assumption of an exogeneous real wage is ‘classical’ in spirit. There is no doubt that Sraffa's system captures many of the elements of ‘classical economics’. It provides a further bonus, however, in illuminating classical economics. Generations of critics have tried to make sense of Ricardo's lifelong quest for an ‘invariable measure of value’ and have given it up as a hopeless task. Ricardo was troubled by the fact that any change in money wages will alter the structure of relative prices owing to the fact that capital and labour are combined in different proportions in different industries. Thus, a rise in wages or a fall in the rate of profit raises the prices of labour-intensive goods relative to the price of capital-intensive goods. This violates the labour theory of value according to which relative prices are determined by the physical quantities of labour expended on production independently of the rate at which labour is rewarded. To remedy this difficulty, Ricardo struck upon the notion of expressing all prices in terms of a commodity produced by a ratio of capital to labour that is a weighted average of the entire spectrum of capital–labour ratios in the economy; such a commodity, he believed, constitutes an ‘invariable measure of value’ in the sense of providing a standard of measurement that is invariant to changes in the ratio of wages to profits. In the same way, Sraffa measures all prices in terms of a ‘standard composite commodity’ that consists only of outputs combined in the same proportions as the non-labour inputs that enter into all the successive layers of its manufacture. Moreover, in one of the many elegant demonstrations in his book, Sraffa succeeds in showing that such a ‘standard commodity’ is in fact embedded in any actual economic system and that the proportion of net output going to wages in that reduced-scale system determines the rate of profit in the economy as a whole. The explanation of this result depends on Sraffa's distinction between ‘basic’ commodities which enter directly or indirectly into the production of every commodity in the economy, including themselves, and ‘non-basic’ commodities which enter only into final consumption. If we treat labour itself as a produced ‘means of production’ then wage goods constitute examples of ‘basic’ commodities, that is, they are technically required to cause households to produce the flow of labour services. Ricardo clearly believed that wheaten bread was ‘basic’ in this sense but Sraffa parts company with Ricardo in rejecting any and all versions of the subsistence theory of wages; workers in Sraffa are primary, non–reproducible inputs. Nevertheless, there are plenty of other basics besides wage goods in an actual economy and the upshot of Sraffa's distinction between basics and non-basics is that the ‘standard composite commodity’ consists only of basics and indeed of all the basics in the economy; this collection of basics enters into the production of the invariant yardstick in a ‘standard ratio’, that is, in the same proportion as they enter into their own production. It turns out that relative prices and either the rate of profit or the rate of wages (depending on which one is given exogeneously) depend only on the technical condition of producing the ‘standard commodity’ and are in no way affected by what happens to nonbasic commodities. In a way this is obvious: a change in the cost of producing a nonbasic no doubts alters its own price but, by the definition of a nonbasic commodity, the effect stops there since the product in question never becomes an input into any other technical process. It is also obvious, at least intuitively, that an exogenous change in wages unconnected with a change in productive techniques alters the rate of profit
but has no effect on relative prices measured in terms of the standard commodity for the simple reason that the change alters the measuring rod in the same way as it alters the pattern of prices being measured. The ‘standard commodity’ therefore provides an ‘invariable measure of value’, and Ricardo’s old problem is at long last solved.

In developing his own ideas, Sraffa also advanced an entirely new interpretation of how Ricardo came to connect his theory of the determination of the rate of profit with the question of finding an invariable yardstick for measuring relative prices. In his early pamphlet *Essays on the Influence of a Low Price of Corn on the Profits of Stock* (1815), Ricardo wanted to show that the extension of cultivation to inferior soils depresses the rate of profit on capital throughout the economy by raising the marginal cost of producing ‘corn’, that is, wheat, the principal wage good consumed by workers. This is easy to demonstrate in a one-sector economy where the only output is wheat. However, from the beginning Ricardo operated with a two-sector economy in which an agricultural industry produces ‘corn’ and a manufacturing industry produces ‘cloth’. Of course, if wage goods consist entirely of corn and if cloth is always purchased out of profits and rents, it is still easy to show that the rate of profit on capital depends decisively on the action of diminishing returns in agriculture. In agriculture, wheat is the only output and it is also the input both in the form of wages ‘advanced’ to workers to tide them over the annual production cycle and seeds to plough back into the next agricultural cycle; hence, the ‘money’ rate of profit in agriculture cannot possibly diverge from the ‘wheat’ rate of profit because any change in the price of wheat affects inputs and output in the same degree. Manufacturing, however, only uses wheat as one of its inputs (namely, in the form of wage goods), and since the rate of profit earned on capital must be equal in between the two industries in equilibrium, the price of wheat determines a definite price for cloth. If, for example, the rate of profit in agriculture falls due to the operation of diminishing returns, the price of cloth in terms of wheat must likewise fall to prevent cloth from being more profitable to produce than wheat. To reiterate: measuring all prices in terms of wheat, the ‘money’ rate of profit in industry is governed by the ‘wheat’ rate of profit in agriculture, which, in turn, depends entirely on the technology of producing wheat, the unique wage good; in one of Ricardo’s famous catch phrases: ‘it is the profits of the farmer which regulate the profits of all other trades’.

This ingenious argument, which appears to explain the determination of the rate of profit in purely physical terms without the use of a theory of value, is known in the literature as the ‘corn model’. In the preface to his edition of *The Works of David Ricardo* (1951), Sraffa argued that the corn model is implicit in Ricardo’s 1815 Essay. To be sure, Ricardo never wrote it down in so many words because even in the Essay he could not swallow the assumption that wages are entirely spend on wheat, that all agricultural products are wage goods and that all manufactured products are luxuries which are never consumed by workers. Nevertheless, he did use wheat in the Essay as a measure for aggregating the heterogeneous inputs of agriculture on the assumption that all prices rise and fall with wheat prices, and he also employed arithmetical examples in which all inputs and outputs of both agriculture and manufacturing are expressed in terms of wheat. In the *Principles* he analysed an economy with many sectors in which a change in the terms of trade between wheat and cloth will alter real wages and hence the rate of profit on capital. Nevertheless, his preoccupation in this mature work with the ‘invariable measure of value’ may be read as an attempt to secure the same results obtained earlier with the aid of the corn model, that is, to tie the determination of the rate of profit directly to the production function of agriculture. Of course, if Ricardo could have ignored the varying proportions of labour and capital in different industries, he could have reached all his conclusions without the aid of an invariable yardstick.
of value. He had placed so much emphasis, however, on what Marx was to call the unequal ‘organic composition of capital’ that this route was closed to him. Hence, the quest for an ‘invariable measure’ with which to recapture the simple truth of the corn model. Here then is a rational reconstruction of Ricardo's arguments that accounts neatly for both the form and the drift of his reasoning.

A general equilibrium interpretation of Ricardo

Sraffa's interpretation of Ricardo has won wide assent even among those who otherwise remain sceptical about Sraffa's system in its own right. However, Samuel Hollander's recent reexamination of the whole of Ricardo's writings has taken sharp exception to Sraffa's reading (Hollander, 1979, pp. 123–90, 684–9). Ricardo, according to Hollander, never entertained the corn model even implicitly, never assumed that corn alone enters the wage basket, never argued that the rate of profit in agriculture determines the general profit rate and, above all, never assumed that real wages remain constant either because they are determined by the subsistence requirements of workers or because they are determined exogenously. What Hollander really objects to is the notion that ‘distribution’, that is, the rate of wages and the rate of profit, are determined in Ricardo as in Sraffa's own model independently of and indeed prior to the value of commodities, so that the former causally determines the latter. This is to be contrasted with the approach of Walrasian general equilibrium theory in which the pricing of factor services is determined simultaneously with the pricing of final consumption goods. It is simply not true, argues Hollander, that the history of economic thought can be neatly divided into two great branches, a general equilibrium branch leading down from Walras and Marshall to Samuelson, Arrow and Debreu today, in which all relevant economic variables are mutually and simultaneously determined, and a completely different branch leading down from Ricardo and Marx to Sraffa in which distribution takes priority over pricing because economic variables are causally determined in a sequential chain starting from a predetermined real wage (Pasinetti, 1974, pp. 42–4, even enlists Keynes into the ranks of the Ricardo–Marx–Sraffa school). Ricardo, Hollander insists, was essentially a general equilibrium theorist – and so were Adam Smith, John Stuart Mill and even Karl Marx (Hollander, 1973, 1981, 1982).

Before passing judgement on this dispute, it is worth noting that what has been called the ‘neo-Ricardian’ or ‘Cambridge’ interpretation of the history of economic thought claims superior merit for Ricardo because Ricardo divorced the question of distribution from the question of pricing. But this is precisely the grounds on which many pre-war historians of economic thought attacked Ricardo! Thus, Frank Knight in a famous essay on ‘The Ricardian Theory of Production and Distribution’ (1956) poured scorn on classical writers like Ricardo because they utterly failed to approach the problem of distribution as a problem of valuation and this despite the fact that the effective demand for any factor of production depends on the distribution of income, which in turn depends at least to some extent on the pricing of factor services; in short, ‘distribution theory has little meaning apart from a theory of general equilibrium’ (Knight, 1956, pp. 41, 63). Similarly, Schumpeter (1954, pp. 473, 568–9, 1171) spoke scathingly of the ‘Ricardian Vice’ whereby an already oversimplified economic model is further reduced by freezing one endogeneous variable after another by special ad hoc assumptions. First, rent in Ricardo is determined as an intra-marginal return to land treated as a factor in fixed supply; the location of the margin depends of course on the demand for agricultural produce, but this is in turn explained by the size of the population via the assumption of a perfectly inelastic demand for corn. Second, having
‘gotten rid of rent’ on the margins of cultivation, Ricardo then employed a subsistence theory of wages to determine the share of total-output-minus-rent that accrues to labour. Third, total profits in Ricardo are treated as a pure residual after the deduction of wages and rents, the rate of profit being determined as the quotient of total profits and the inherited stock of capital. In other words, the problem of distribution is explained by three totally different types of theories, which in turn are quite different from the principles employed to explain the pricing of goods and services, namely, the labour theory of value. How amazed Knight and Schumpeter would have been to see their critique stood on its head, so that what they regarded as vices are now viewed in certain quarters as virtues.

Ricardo versus Smith

Having expounded various interpretations of classical economics, it is time to attempt some sort of general assessment. To collect our thoughts, consider the number of problematic issues we have outlined above. Is the economics of Adam Smith something different from the economics of David Ricardo? Obviously there is no total break in the continuity of thinking, but nevertheless, is there a sufficient break to warrant the use of such dramatic language as the ‘Ricardian Revolution’? Was this ‘Ricardian Revolution’ the implicit resort to something like the ‘corn model’ to produce a clear-cut explanation of the determination of the rate of profit, or was it simply a change in the style of economic reasoning? Was Ricardo soon repudiated, so that the Smithian tradition survived right down to John Stuart Mill and beyond, or are the later phases of classical economics dominated by the ideas of Ricardo rather than those of Adam Smith? Is there sufficient coherence around a definite core of ideas to permit us to talk at all of ‘classical economics’? Is this core the notion of the origin and disposition of the ‘economic’ surplus and the proposition that distribution is independent of valuation? And, finally, is all of classical economics a primitive but prescient version of general equilibrium analysis?

We can deal quickly with the first question, the so-called ‘Ricardian Revolution’. With the exception of Hollander (1979, ch. 1), all modern commentators on classical economics agree that Ricardo altered the scope, method and focus of economics. Even if we take only *The Wealth of Nations* among Smith's books and essays, the scope of economics for Adam Smith is enormous and perhaps wider than that for any economist before or after him. The first two books of *The Wealth of Nations* consists largely of what later came to be regarded as the very hallmark of orthodox economics: the theory of value and the theory of production and distribution, employing in the main the method of comparative statics. But even the ‘Digression’ on the value of silver in chapter 11 of Book I takes up an unorthodox topic, namely, changes in the structure of prices over centuries with the aid of a method of analysis that might be called ‘inductive’ or ‘historical’. Moreover, here as elsewhere in *The Wealth of Nations* there is a remarkable emphasis on the notion of ‘increasing returns’ so widely defined as to include the effects of both increases in the scale of production and changes in the method of production or technical progress. Despite the flowering of a considerable literature in recent years purporting to model Smith's ‘theory of economic growth’, few have succeeded in capturing this vital element in Smith's thinking, which Kaldor (1972) has consistently emphasized (but see Eltis, 1984, ch. 3). Moreover, this notion of increasing returns soon dropped out of classical economics, coming back only ninety years later with the writings of Karl Marx.
Similarly, there is the famous distinction in Book III of *The Wealth of Nations* between productive and
unproductive labour which Ricardo and Mill accepted, which McCulloch and Senior denied, which Marx reinterpreted in a different way, but which nevertheless was never followed up and developed in any fruitful way. A simple explanation for this failure to elaborate Smith's distinction was that Smith made a mess of it, defining productive labour alternatively as labour which produces something tangible, produces a profit for its employer, and generates productive capacity that then creates a demand for additional employment. But another explanation is that the distinction between the employment of ‘manufacturers’ and ‘menial servants’, between wealth-creating and wealth-consuming activities, is only relevant in the context of long-run economic development, being partly a ‘positive’ account of different patterns of economic change in different nations and partly a ‘normative’ proposal for legislators seeking to maximize the rate of net investment in an economy. Although Mill was profoundly concerned with questions of economic development (see O'Brien, 1975, ch. 8), Ricardo had no real interest in the forces that govern the historical patterns of economic change, and for that reason alone the Smithian distinction between productive and unproductive labour, and the associated discussion of an optimum investment pattern between industries in chapter 5 of Book II of The Wealth of Nations, was effectively laid to rest all through the heyday of classical economics.

Smith's interest in ‘the different progress of opulence in different ages of nations’ totally dominates Book III of The Wealth of Nations and is at work even in Book IV on mercantilist theory and policy and Book V on public finance. In this latter half of The Wealth of Nations there is little appeal to the comparisons of steady-state equilibria, which was to figure so heavily in practically everything that Ricardo wrote. But there are two other elements in these pages that are totally missing in Ricardo and even in Mill, namely, a concern with the incentive effects of different institutional devices for rewarding self-employed professionals and individuals employed in the public sector (Rosenberg, 1960) and a keen sense of the role of pressure groups in the formulation of economic policies (Peacock, 1975; West, 1976; Winch, 1983). Thus, the modern theory of property rights as well as the economic theory of politics may properly claim Smith as a forerunner. At any rate, neither of these two aspects of The Wealth of Nations has any echoes in the writings of those that came immediately after Smith.

Consider next the theory of international trade. There is a static equilibrium theory of the gains of foreign trade in Smith based on the principle of absolute rather than comparative advantage, and here no doubt, Ricardo saw further than Smith. But there is also a dynamic theory of the gains of trade in Smith, the so-called ‘vent-for-surplus’ doctrine, according to which foreign trade widens the extent of the market and generates new wants; this view of foreign trade disappears in Ricardo and only comes back to classical economics with Mill (Bloomfield, 1975, 1978, 1981).

Smith's theory of money is also profoundly different from that of Ricardo, typically invoking the quantity theory of money in its dynamic 18th-century version in which the emphasis falls on the disequilibrium ‘transition period’ between an increase in the quantity of money and the rise in prices and not on the final equilibrium adjustment between money and prices (Laidler, 1981). In addition, Smith was an advocate of private, unregulated banking (qualified only by the prohibition of the issue of banknotes for small sums), reflecting the operation of Scottish banking, which was unregulated for over a century between 1716 and 1844. It was Henry Thornton who first rejected the Smithian tradition in his Paper Credit of Great Britain (1802), explicitly denying that the note issue in a free banking system would be self-regulating as Smith had argued. By the time of Ricardo it was orthodox to argue that the issue of banknotes was an obvious exception to the doctrine of laissez faire (White, 1984, ch. 3). Here
too, the gulf between Smith and Ricardo is almost total. There is no need to underline Ricardo's differences with Adam Smith over the labour theory of value, since Ricardo set out explicitly to criticize Smith's failure to apply the labour theory of value to a modern economy rather than a purely conjectural ‘early and rude state of society’. But what is not so obvious is the fact that even in respect of labour as a measure of the ‘real price’ of commodities – Smith's tortured language in Book I, chapter 5, for the problem of specifying an index number of economic welfare – Smith's view of labour is profoundly subjective, whereas Ricardo in his comparable chapter 20 of the Principles of Political Economy and Taxation on ‘value and riches’ consistently treats labour as an objective, physical expenditure of energy. In the masterly tenth chapter of Book I of The Wealth of Nations on ‘relative wages’, Smith demonstrated that competition in labour markets equalize the net advantages of different occupations, that is, the monetary returns to units of disutility of labour. In other words, to the extent that labour is a ‘measure of value’ in Smith, it is labour conceived as ‘toil and trouble’ and reflects the preferences of workers as much as those of their employers. Although Ricardo, and for that matter Marx, never disputed this analysis of Smith, they ignored its implications and blithely treated labour as fundamentally homogeneous in quality, its role in the production of commodities being conceived as a brute reflection of purely technological data; in short, they took as given something like Sraffa's production equations. It is this and not the famous debate over whether the value of commodities in Smith is determined by the labour ‘commanded’ by goods or the labour ‘embodied’ in their production that represents the real watershed in the history of the labour theory of value (Robertson and Taylor, 1957; Gordon, 1959; Blaug, 1985, pp. 49–53).

But the most profound departure in Ricardo from the Smithian tradition is the notion that rent is in a class by itself as a source of income: it is ‘unearned income’, being an intramarginal return to purely natural differences in the quality of land which have nothing whatever to do with the activity of landlords. Despite Smith's references to landlords who 'love to reap where they have never sowed' and the ‘conspiracy’ of merchants, the Smithian world is one in which all economic interests are essentially harmonious or, at any rate, capable of being made harmonious by wise legislators. The Ricardian world, however, is one which conflicting class interests are unavoidable. It is this unique element in the Ricardian system, which gave classical economics its sharp political edge, an edge that clearly worries so many of the minor classical economists, such as Jones, Senior and Longfield.

Finally, the central and indeed sole focus of the Ricardian system is the question: what determines the rate of profit on capital, or rather, what governs its changes over time? This is a question which never really troubled Adam Smith. He made it clear that profit is equalized among industries in the long run, but he had no explanation of how the level of the rate of profit is determined. To be sure, Smith believed that the rate of profit was eventually doomed to fall because of the exhaustion of profitable investment outlets. But he never emphasized this proposition and on balance he took an extremely optimistic view of the feature prospectus for economic growth. Ricardo too was essentially an optimist about the long-run growth potential of the British economy but only if the Corn Laws were repealed; he was thus motivated to argue the strongest possible connection between the rate of profit on capital and the real cost of producing wheat exclusively with domestic resources. In consequence, Ricardo viewed absolutely every aspect of economic activity, including monetary forces, currency arrangements, taxation, the financing of the public debt, and of course foreign trade, through the lenses of his theory of profits. Many readers of Ricardo have been deceived by the preface to his Principles – ‘To determine the laws which regulate this distribution (of rent, profit, and wages), is the principal problem in Political
Economy’ – into believing that the Ricardian system is largely devoted to an analysis of the
determination of the relative shares of land, capital and labour. But while Ricardo certainly had much to
say about the issue of relative shares, and indeed was responsible for introducing this theme into
economics, his analysis is in fact concentrated on rents per acre, the rate of the profit per unit of capital
and the rate of wages per man. It is, in a word, a book about the pricing of factor services and that is
(surely?) much less than the subject-matter of The Wealth of Nations.
There is little doubt, therefore, that the scope of the science of political economy as conceived in The
Wealth of Nations was sharply contracted in Ricardo's Principles of Political Economy. But, in addition,
Adam Smith wrote much besides The Wealth of Nations. Quite apart from The Theory of Moral
Sentiments and the remarkable essay on the History of Astronomy, the publication of the new University
of Glasgow edition of the complete Works and Correspondence of Adam Smith (1976–83) strongly
suggests that he intended to round off his contributions by a major work on the theory of jurisprudence
which he never lived to write; nevertheless, even in The Wealth of Nations he never lost sight of the fact
that political economy may be considered as ‘a branch of the science of a statesman or legislator’, the
latter being therefore something more comprehensive than the former. A number of recent
commentators (Cropsey, 1957; Lindgren, 1973; Winch, 1978; Skinner, 1979) have indeed insisted that
all of Adam Smith's writings are held together by a unified vision of an all-embracing social science,
which he unfortunately never succeeded in realizing to the full. Whether this thesis is persuasive or not,
it certainly strengthens the contention that the economics of Adam Smith is conceived on grander lines
than the economics of David Ricardo.

The corn model again

So there was what might be described in highly coloured language as a ‘Ricardian Revolution’: what
began as a criticism of some of ‘Professor Smith's opinions’ ended up as a wholesale revision of the
legacy of Adam Smith.
What was the cornerstone of this ‘Revolution’? Was it the ‘corn model’? It certainly was a denial of the
Smithian cost-of-production theory according to which a rise in money wages would raise all prices,
thus leaving the rate of profits unaffected. But that is not to say that Ricardo's fundamental theorem that
'profits vary inversely as wages' was based on an implicitly held corn model. It is true that the corn-
model interpretation neatly rationalizes Ricardo's arguments in the early Essay on Profits in which the
economy is conceived as consisting of two sectors but the rate of profit is determined exactly as it would
be in a one-sector economy. In other words, Ricardo should have held the corn model for without it the
Essay is simple logically inconsistent. Nevertheless, the corn-model version simply attributes far more
rigour and consistency to Ricardo's analysis than is warranted (Peach, 1984). What Ricardo later put in
place of the missing corn model was the ‘invariable measure of value’ which was designed to surmount
two of his unresolved difficulties at one and the same time: (1) that workers consume both manufactured
and agricultural goods, so that one can never be sure that the rising cost of producing wheat is directly
transmitted to the rate of profit; and (2) that capital and labour combine in different proportions in
different industries, so that a change in real wages for any reason whatsoever alters the structure of
prices and, thus, affects the rate of profit even if nothing has happened to the technology of agriculture.
We noted earlier that Sraffa's Production of Commodities by Means of Commodities may be said to have
vindicated Ricardo's belief in the existence of an ‘invariable measure of value’, capable of separating
and measuring the effects of changes in technology from those due to changes in the rate of wage and profits. But doubts remain about the validity of this claim. In Ricardo, the divining rod of the invariable measure is supposed to be invariant (as Ricardo kept saying) not just to changes in wages in profits but also to changes in its own methods of production. Sraffa's 'standard commodity' fills the bill on the first score but fails on the second score: it is not invariant to changes in its own techniques of production and therefore falls short of solving Ricardo's problem of linking the determination of the rate of profit directly and unambiguously to the action of diminishing returns in agriculture. The truth is that there is no such thing as an ‘invariable’ yardstick that will satisfy all the requirements that Ricardo placed upon it (Ong, 1983). All of which is to say that, despite the fact that Ricardo was the first truly rigorous analytical economist, it is impossible to exonerate him from all analytical errors: he was at times inclined to square a circle using only a ruler and a compass!

Classical economics as surplus theory

We turn next to the thesis that classical economics is the economics of the creation and disposition of surplus output over consumption – a theory of the reproducibility of economic systems in the making – in sharp contrast to the later neoclassical theme of the allocation of *given* resources between competing ends, subject to the constraints of technology and existing property rights. Now, there can be little doubt that this is precisely the nature of the economics of physiocracy (Eltis, 1984, ch. 2), and it is little wonder that those who argue the surplus interpretation include the physiocrats in classical economics (Walsh and Gram, 1980, ch. 2). There is also little doubt that it captures much of the drift of *The Wealth of Nations* and turns up again in Mill's *Principles* and in Marx's *Capital*. On the other hand, it does not begin to do justice to dominant features of the Ricardian system and leaves out almost as much as it manages to include in the writings of the classical economists.

What does it tell us, for example, about the jewel in the crown of classical economics: Ricardo's law of comparative advantage as the foundation of the belief in free trade, which served throughout the whole of the 19th century as the litmus-paper test of an economic liberal? Ricardo treated foreign trade as a matter of moving along a static world production-transformation curve, constructed on the basis of *given* resources and the *given* techniques of production of the trading countries; the gains of foreign trade in his celebrated cloth–wine example show up in a global increase in physical output from given labour resources in Portugal and England. There is no hint here of ‘surplus theory’ and perhaps that is why the surplus interpretation of classical economics studiously avoids discussion of the theory of international trade.

It might be argued, however, that the subject of foreign trade lies outside the mainstream of classical economics because it violates the assumption of a uniform rate of profit on capital – if capital were mobile between countries, international trade would be based like intranational trade on absolute cost advantages. As a matter of fact, Thweatt (1976) has argued that Ricardo's view of foreign trade never went beyond the conception of absolute advantage and this despite the three-paragraph illustration of comparative advantage in his *Principles*, which may well have been written by James Mill rather than Ricardo. After all, free trade for Ricardo meant a policy appropriate to an advanced manufacturing nation in its relation with agrarian nations supplying it with food; the point of the chapter on foreign trade in the *Principles* is not to explain the gains of trade but to demonstrate that foreign trade only...
affects the rate of profit insofar as it leads to the importation of cheaper wage goods.

Be that as it may, less than a decade after the death of Ricardo, the young Mill (1844, but written in 1829) completed Ricardo's argument by showing that the division of the overall gains from foreign trade in the two countries depends on 'reciprocal demand', thus putting another nail in the coffin of the labour theory of value: even when goods are produced by labour alone within countries, the barter terms of trade between countries depend on both demand and supply. Cairnes subsequently extended the reciprocal demand approach even to domestic trade at least in respect of exchange between 'non-competing groups'. None of this has anything to do with the creation, accumulation and allocation of an economic surplus, and so the surplus interpretation must leave to one side the classical theory of international prices, the classical theory of balance of payment adjustments and with it the classical theory of monetary management.

But the shortcomings of the surplus interpretation extend even to classical theorizing about the operations of a closed economy. It can throw no light on the care with which Adam Smith spelt out the effects of a public mourning on the price of black cloth in Book I, chapter 7, of *The Wealth of Nations*, so as to demonstrate that 'market' prices cannot permanently diverge from 'natural' prices because they imply profit opportunities for producers that will sooner or later be exploited; all this is to say that the surplus interpretation has little time for those short-run adjustments that formed the staple of much of the practical wisdom of classical economists grappling with day-to-day economic problems. Similarly, the surplus interpretation must pass over the doctrine of opportunity costs that was part and parcel of the legacy of Adam Smith, namely, that effective costs to producers are not expenditures incurred in the past but present opportunities foregone. As Buchanan (1929) showed many years ago, Ricardo's characteristic doctrine of 'getting rid of rent' by concentrating attention on the rentless margin of production implies that land has no uses alternative to the growing of wheat; while this may at a pinch be justified at a macroeconomic level, Smith's theory of rent, which recognizes the fact that land employed in cultivation must compete with land for grazing or urban use, is thus more truly in the tradition of analysing allocation with given resources than is Ricardo's. This Smithian emphasis on the competing uses for land, so that ground rent does enter into the price of agricultural goods, was never lost sight of by classical writers between Ricardo and Mill and comes back into its own in Mill's *Principles*, notably in Book II, chapter 16, on rent theory.

The surplus interpretation is thus a limited view of classical economics, but it is not a misrepresentation. In one sense it is only fancy language for the old view that classical economics is essentially the economics of development, which starts from a fundamental contrast between augmentable labour and non-augmentable land given in quantity and asks how, under these circumstances, growth in the sense of per capita income can be maximized (Myint, 1948). Indeed, the notion that growth of population and the accumulation of capital are the great themes of classical economics in contrast to the question of efficient allocation of given supplies of the factors of production in neoclassical economics after 1870 is endorsed in many, if not in all, textbooks on the history of economic thought (e.g. Blaug, 1985, pp. 295–6). So why all the fuss? Why all this insistence on the surplus interpretation in recent years?

A close reading of those who have advocated a reading of classical economics in terms of surplus analysis suggests two rather different motivations for the 'new' interpretation: one is to provide Marx with a respectable pedigree, or at least to display Marx as the true heir of bourgeois economics in its days of glory, solving the riddles that baffled Quesnay, Smith and Ricardo; the other is to reveal
Sraffa as the true heir of the classical tradition, demonstrating that there is an old and venerable tradition of explaining the determination of prices without resorting to the preferences and satisfactions of consumers and without relying on a market mechanism to price both capital and labour. Each of these two strands of the surplus interpretation produces its own special distortions of classical economics. It is certainly true that Marx was in many ways a direct descendant of Smith and Ricardo, and particularly of Ricardo. He took over from Smith the distinction between use value and exchange value (as well as the denial that the former had anything to do with the determination of the latter), the distinction between market and natural prices, together with the notion that the business of the economist is to explain natural prices as terminal states of long-run equilibrium outcomes, the distinction between productive and unproductive labour, the conception of historically increasing returns as a major force in the process of development, the tripartite division of national revenue into wages, profits and rents as the incomes of three distinct social classes – and much else. But he learned even more from Ricardo, and particularly Ricardo's discovery that all the problems of the labour theory of value are reducible to the undeniable fact that capital and labour combine in different proportions in different industries, difficulties which may be resolved however by measuring all prices in terms of the price of a commodity produced by the ‘average’ industry. This was the key to Marx's ‘transformation problem’, which demonstrated that ‘prices of production’ must systematically diverge from labour ‘values’ if the rate of profit is to be uniform between industries, an insight which, Marx thought, had always eluded Ricardo. Marx hardly noticed that in correcting Ricardo's answer, he also corrected his question. Ricardo's problem had been: what determines the rate of profit? Marx's problem, however, was: what determines the rate of profit if profit is in the nature of unpaid labour, a mark-up on the outlays of wages disguised as a mark-up on all cost-outlays? But the nature of profit as ‘earned’ or ‘unearned’ income did not interest Ricardo: he devoted one sentence to this subject in the *Principles* and even this sentence was a throw-away remark.

Marx also learned from Ricardo how to reduce skilled labour to common labour by simply taking the structure of relatives wages as given, thus missing the thrust of Smith's theory of relative wages, namely, that wages are not determined solely by the demand side in labour markets. Marx discarded the Malthusian theory of population but retained the subsistence theory of wages relying on the ‘reserve army’ of the unemployed to keep wages fluctuating around subsistence levels. He failed to notice, however, that this made wages a function of the play of demand and supply in labour markets and not the labour-costs of producing wage goods; in short, the pricing of wage goods in Marx does not conform to the labour theory of value. Like Ricardo, Marx conceded that the level of ‘subsistence’ is itself historically conditioned: it is a standard of living that workers have become accustomed to expect by past experience. Thus, even the ‘natural’ price of labour in Marx is not entirely cost-determined but depends on the preferences of workers. Once again, the ‘value of labour-power’ in Marx does not conform to the labour theory of value.

Marx never paid much attention to Ricardo's doctrine of comparative advantage and apparently failed to notice that it too violates the labour theory of value. It is also doubtful whether he ever truly grasped the import of Ricardo's theory of differential rent and particularly its central implication that prices everywhere, and not just in agriculture, are determined by marginal rather than average costs of production.

Nevertheless, despite all the obvious differences between Smith and Ricardo on the one hand and Ricardo and Marx on the other in both analytical constructs and social vision, there are so many striking
similarities between them that Marxian economics is simply unimaginable without Smith, Ricardo and (although Marx did not like to admit it) John Stuart Mill. Marx went further than any of them in his grasp of business cycles, his treatment of technical change and the so-called ‘reproduction schema’ – the true starting point of the modern theory of steady-state growth – but he never emancipated himself from his starting point in classical economics with all its strengths and all its weaknesses.

There can be little quarrel, therefore, with a surplus interpretation of classical economics that treats Marx squarely as one of the last classical economists. However, it is when this Marxian strand in the surplus interpretation is combined with the Sraffian strand that we begin to encounter a mythical classical economics that never existed. We are told that the data for the analysis of prices in classical economics are the same as those for Sraffa, namely, (1) the size and composition of output, (2) the techniques of production in use, and (3) the real wage rate; these are contrasted with the data of neoclassical economics, namely, the preferences of individuals, the initial endowment of the factors of production among individuals and the existing techniques of production (e.g. Eatwell, 1977, p. 62). We are even told that long-run prices in classical theory are not the outcome of the opposing forces of demand and supply and that classical ‘natural’ prices are not what (ever since Marshall) are called long-run ‘normal’ prices (Harcourt, 1982, p. 265) or that, although classical ‘natural’ prices are indeed the same as neoclassical long-run ‘normal’ prices, the theories advanced by classical and neoclassical economists for the determination of these long-run equilibrium prices are quite different (Garegnani, 1976, pp. 28–9).

But there is actually no warrant for any of these assertions. The size and composition of output is certainly not treated as given in Smith and to say so is to make nonsense of Smith's emphasis on secular economic development and the optimum balance of manufacturing and agriculture in the course of secular growth. Ricardo, on the other hand, frequently but not invariably treats the output of agricultural produce as determined by the size of population via a perfectly inelastic demand for wheat (Barkai, 1965; Stigler, 1965). Thus, he does not assume the output of wheat (or any other product) to be a datum but to be an endogeneously determined variable, a function of population growth, which in turn is treated as an endogeneous variable. He never squarely faced up to all the difficulties created for his argument by commodity-substitution as the price of ‘corn’ rises relative to ‘cloth’, but he certainly recognized the problem. There is no support, therefore, for the contention that he took the composition of output to be a datum, except provisionally at certain points in his argument for the sake of producing what he called ‘strong results’. What we have said about Smith and Ricardo follows with double force for both Mill and Marx. So much then for this part of the attempt to bring the classical economists fully into the Sraffian fold.

We can agree that the classical economists took for granted an existing state of techniques – has there ever been an economist, apart possibly from Marx, who has not? – but the real question is whether they conceived of this state of techniques à la Sraffa as ruling out factor substitution. On balance, as we noted earlier, the answer to this question must be yes. Ricardo of course recognized the problem the moment he introduced the chapter on machinery in the third edition of the *Principles* (1821), but by then he was thoroughly committed to his invariable standard of value, which necessarily rules out factor substitution. On the other hand, a special kind of factor substitution was built into his theory of differential rent in which variable doses of capital-and-labour combined in fixed proportions are applied in increasing amounts to a fixed quantity of heterogeneous land; it is this idea which of course led John Bates Clark and Philip Wicksteed in later years to hail Ricardo as the ‘father’ of marginal productivity theory. When we consider that the theory of differential rent was the very cornerstone of the Ricardian system, we can
only gasp at Sraffa's bold declaration in the preface to his *Production of Commodities by Means of Commodities* (1960) that his own system, concerned as it is ‘exclusively with such properties of an economic system as do not depend on changes in the analysis of value production or in the proportions of “factors” is identical to the “standpoint … of the old classical economists from Adam Smith to Ricardo”.

Next, can it be argued that the classical economists took the real wage rate as a datum for their analysis of value and distribution? It is perfectly true that the much-maligned theory of subsistence wages in factor amounts to saying that the subsistence wage is whatever has been the real wage for a long time. How long is long? About a generation, Malthus said, and Ricardo agreed. But such assertions did not help much in specifying the subsistence wage, since annual population growth had been positive for as long as anyone could remember, and a positive rate of population growth implied that market wages exceeded the natural subsistence wage rate. So, in effect, the classical economists regarded real wages as data but that is not what they thought they were doing; after all, the only reason that the Malthusian theory of population was so quickly incorporated into the mainstream of classical economics was that it appeared to provide a truly endogeneous explanation of the determination of real wages. The long-run equilibrium wage rate, Malthus had taught, was that wage rate, which, given the historically conditioned habits and customs of the working class, encouraged them to reproduce a family of given size. Some classical economists, like Senior and McCulloch, came to doubt the validity of the Malthusian theory but never managed to put any other theory of determination of long-run wages in its place. John Stuart Mill, on the other hand, found the Malthusian theory so suitable for his purpose of alleviating poverty through the self-help of the poor – birth control, education and the formation of consumer and producer cooperatives – that he espoused it more vehemently than even Malthus himself. All in all, there is simply no warrant for arguing that any classical economist (including Marx) intended to explain real wages by forces outside the purview of economic analysis.

Lastly, we come to the most grotesque distortion of all: the idea that any appeal to the forces of demand and supply in determining prices is necessarily alien to classical economics and that classical ‘natural’ prices have nothing whatsoever in common with Marshall’s long-run ‘normal’ prices. Now, it is true that Ricardo (and Marx after him) propagated the misleading idea that demand-and-supply explanations only pertain to ‘market’ prices, whereas ‘natural’ prices are to be explained solely in terms of costs of production, as if costs can influence prices without acting through supply. Ricardo lacked the analytical apparatus to appreciate the fact that supply-side explanations of prices hold only if goods are produced under conditions of constant costs; this might well justify the neglect of demand in the case of the pricing of ‘cloth’ but certainly not on his own grounds in the case of the pricing of ‘corn’. This marvellous confusion of language, encouraged by Ricardo’s tendency to think of demand and supply as quantities actually bought and sold and not as schedules of demand and supply prices, was almost entirely cleared up by Mill in his masterful treatment of value in Book III of his *Principles* in which he noted that an equilibrium price is one which equates demand and supply in the sense of a mathematical equation and concluded that ‘the law of demand and supply… is controlled but not set aside by the law of cost of production, since cost of production would have no effect on value if it could have none on supply’. In fact, this is not very different from what Ricardo (1952, Vol. IX, p. 172) once said in private to Jean Baptiste Say: ‘You say demand and supply regulates the price of bread; that is true, but what regulates supply? The cost of production.’

Marshall’s schema of market-period, short-period and long-period prices, of constant-cost, increasing-
cost and decreasing-cost industries, and their accompanying diagrams of demand and supply, are
indispensable aids to clear thinking about the determination of prices and imply nothing whatsoever
about the truth or falsity of any particular theory of prices. To treat demand and supply as dirty words
that classical economists would never have employed in the explanation of natural prices is to take their
outmoded language at its face value and, indeed, to deny any analytical progress in the history of
economics.
To reject Sraffian interpretations of classical economics is not to reject Sraffa’s system on its own
grounds. Whether or not it is faithful to both the spirit and the letter of classical economics, it is
undeniably true that, like all advances in economic theory, it casts a new light on the ideas of the past. It
has certainly made us think again about Ricardo’s invariable measure of value and its intimate
connection with Marx’s transformation problem; it has illuminated the problem of joint production and
the difficulties which this creates for the labour theory of value, however formulated; and it has
highlighted the fact that any theory of prices necessarily involves some proposition about how total
output is divided between wages and profits. Its impact on the ongoing debate about the great ideas of
the past is perhaps best illustrated by the furore which it has created among Marxian economists,
suggesting for example, that the labour theory of value in Marx is both unnecessary and incapable of
producing Marx’s results (Steedman, 1977, 1981). But to endorse Sraffa’s system as a tool for historical
exegesis is not to say that it successfully models the essence of classical economics. Smith, Ricardo,
Mill and Marx are simply richer than anything captured in Production of Commodities by Means of
Commodities.

Classical economics as general equilibrium theory

Every extreme reaction produces a counter-reaction. The surplus interpretation of classical economics is
a reaction against Marshallian interpretation of classical economics in which Ricardo and Mill are
viewed as neoclassical theorists in embryo; for Marshall there was one and only one thread of
continuous thought from Adam Smith to his own times (e.g. Marshall, 1890, App. I). In reaction to the
surplus interpretation, Hollander has argued that from Ricardo onwards, classical economics was, for all
practical purposes, general equilibrium theory; there never was any ‘marginal revolution’. Since this
assertion is, to say the least, surprising, let us quote his own words:

Ricardian economics – the economics of Ricardo and J.S. Mill – in fact comprises in its
essentials an exchange system fully consistent with the marginalist elaborations. In
particular, their cost–price analysis is pre-eminently an analysis of the allocation of scarce
resources, proceeding in terms of general equilibrium, with allowance for final demand,
and the interdependence of factor and commodity markets. (Hollander, 1982, p. 590)

It is evident that by ‘general equilibrium theory’, Hollander means a number of interconnected
propositions, such as efficient allocation of given resources among alternative uses subject to the
principle of diminishing marginal returns, the simultaneous determination of both quantities and relative
prices with the aid of the principle of equality between demand and supply, and the consequent
interdependence between equilibrium in product and factor markets. Perhaps we have already said
enough to suggest that if this what is meant by general equilibrium theory, there is no sense in which we can subscribe to Hollander's interpretation of classical economics. Hollander has spelled out his meaning in great detail in a major work on *The Economics of David Ricardo* (1979). In interpreting Ricardo as a general equilibrium theorist, Hollander found himself revising more or less the entire body of Ricardian scholarship, implying that absolutely everybody else before him had radically misinterpreted Ricardo. To convey the flavour of his iconoclasm, consider the following small sample of the extraordinary conclusions of this book (for a complete list, see O'Brien, 1981, pp. 354–5): (1) Ricardo's method of analysis was identical to that of Adam Smith; (2) Ricardo's theory of money was not very different from that of Smith; (3) Ricardo treated the pricing or products and the pricing of factors as fully interdependent; (4) Ricardo's profit theory did not originate in a concern over the Corn Laws, and Ricardo never believed, even in his early writings, that profits in agriculture determine the general rate of profit in the economy; (5) Ricardo's value theory was essentially the same as that of Marshall in that it paid as much attention to demand as to supply, and Ricardo never regarded the invariable measure of value as an important element in his theory; (6) Ricardo could have established his fundamental theorem of the inverse wage–profit relationship without his invariable yardstick and he frequently took the short-cut of assuming identical capital–labour ratios in all industries to give the answers he looked for; (7) wages in Ricardo are never conceived at any time as constant or fixed at subsistence levels; (8) Ricardo never assumed a zero price-elasticity of demand for corn, making the demand for agricultural produce a simple function of the size of population; (9) Ricardo did not predict a falling rate of profit or a rising rental share and never committed himself to any clear-cut predictions about any economic variable; and (10) Ricardo was never seriously concerned about the possibility of class conflict between landowners and everybody else or between workers and capitalists.

There must be something wrong with an interpretation of Ricardo that produces so many conclusions diametrically opposed to what every commentator has found in Ricardo, not only since his death but even while he was still alive. The distortions produced by the surplus interpretation of classical economics are therefore as nothing compared to those generated by Hollander's general equilibrium interpretation. Walsh and Gram (1980) provide a more reasonable version of the general equilibrium characterization of classical economics: they take the view that general equilibrium analysis embraces more or less the whole of the history of economic thought, but they distinguish between pre-Walrasian general equilibrium analysis of the allocation of the economic surplus over successive time periods and post-Walrasian general equilibrium analysis of the allocation of given resources within the same time period. One difficulty with their argument is that they never inform the reader what precisely is meant by 'general equilibrium analysis'. If we mean a discussion of the determination of both product and factor prices which proceeds in terms of an explicit or implicit set of simultaneous equations in order to ensure that the number of unknowns to be determined are equal to the number of equations written down, then obviously classical economics is not general equilibrium analysis: factor pricing in classical economics is invariably explained on different principles from those governing the pricing of products. If we go further and demand that such a discussion must include not just a demonstration of the existence of a unique equilibrium solution for the vector of factor and product prices but also an analysis of the stability and determinacy of the set of equilibrium prices, such as Walras himself struggled to provide, then even more obviously classical economics is not general equilibrium analysis. But what Walsh and
Gram seem to mean by general equilibrium analysis is simply any analysis that involves the simultaneous determination of prices and one distribution variable on the assumption that other factor prices are given; in short, they define general equilibrium analysis to be nothing more nor less than Sraffian economics. Their book therefore collapses the general equilibrium interpretation of classical economics into the surplus interpretation, sharing the deficiencies of both in equal proportions. Finally, Arrow and Hahn (1971, pp. 1–3) join the fray in the introduction to their textbook on general equilibrium theory. In contrast to Walsh and Gram, they are perfectly explicit about what is meant by general equilibrium theory: if it means anything it implies some notion of both determinateness and stability, that is, the relations describing the economic system are sufficient to determine the equilibrium values of its variables, and a violation of any one of these relations sets in motion forces to restore it. They go on to introduce a new note into the argument: general equilibrium theory is typically associated with the doctrine of unintended consequences – equilibrium outcomes may be and usually are different from those intended by individual actors – and the doctrine that competition is a social mechanism that is capable of achieving a determinate and stable set of equilibrium prices. In all these senses of the term, they count Adam Smith as a ‘creator’ of general equilibrium theory and Ricardo, Mill and Marx as early expositors. They add, however, that there is another sense in which none of the classical economists had a ‘true general equilibrium theory’: no classical economist gave explicit attention to demand as a coordinate element with supply in determining prices, and hence classical economics determined the prices but not the quantities of commodities, the only exception to this statement being their treatment of agricultural output; on the other hand, Mill’s theory of foreign trade was ‘a genuine general equilibrium theory’.

To this brief but incisive discussion of the sense in which classical economics is or is not general equilibrium theory, one must add one word of caution: it is the subtle but nevertheless unmistakable difference in the conception of ‘competition’ before and after the ‘marginal revolution’. The modern concept of perfect competition, conceived as a market structure in which all producers are price-takers and face perfectly elastic sales curves for their outputs, was born with Cournot in 1838 and is foreign to the classical conception of competition as a process of rivalry in the search for unrealized profit opportunities, whose outcome is uniformity in both the rate of return on capital invested and the prices of identical goods and services but not because producers are incapable of making prices. In other words, despite a steady tendency throughout the history of economic thought to place the accent on the end-state of competitive equilibrium rather than the process of disequilibrium adjustments leading up to it, this emphasis became remorseless after 1870 or thereabouts, whereas the much looser conception of ‘free competition’ with free but not instantaneous entry to industries is in evidence in the work of Smith, Ricardo, Mill, Marx and of course Marshall and modern Austrians (Stigler, 1957; McNulty, 1967; Littlechild, 1982). For that reason, if for no other, it can be misleading to label classical economics as a species of general equilibrium theory except in the innocuous sense of an awareness that ‘everything depends on everything else’.

Summing up

We have reviewed the recent upswell of new and startling interpretations of classical economics in the light of developments in modern economics, such as the economics of development, growth theory, general equilibrium theory, and Sraffian analysis. In itself there is nothing surprising about this, nor is it
a new phenomenon: every turn and twist in the history of economic thought has always been attended by a fresh look at the past. Marx in propounding his own treatment of the ‘laws of motion’ of capitalism felt impelled to re-examine the ideas of his predecessors over more than a thousand pages. Jevons, Menger and Walras, the triumvirate that is said to have launched the ‘marginal revolution’, accompanied the exposition of their ‘new’ economics by scathing denunciations of the fallacies of classical political economy. Marshall, in seeking unsuccessfully to reconcile a static with a dynamic treatment of economic problems, naturally looked with sympathy at the work of his classical forebears and struggled to depict them as slightly exaggerating one side of the truth in contrast to Jevons, who exaggerated the other. Perhaps therefore the recent proliferation of definitely new but conflicting interpretations of the essential meaning of classical economics is simply an expression of the fact that modern economists are divided in their views and hence quite naturally seek comfort by finding (or pretending that they can find) these same views embodied in the writings of the past.

Karl Brunner's scholarly contributions are in three areas, namely, monetary and macroeconomics, methodology and its application to cognitive science, and social, political, and institutional analysis. Brunner founded three major journals and organized many conferences, including the Konstanz Seminar in Germany and the Carnegie-Rochester Conference in the United States, which remain current in 2007. Laidler (1991) contains a more complete discussion of Brunner's contributions, and I have relied heavily on his paper. Brunner's own discussion of his intellectual and personal odyssey is in Brunner (1988). I was involved as co-author in much of the work on monetary economics, but I choose to use the pronouns 'he' and 'his' for this article.

Brunner was born in Zurich, Switzerland, in February 1916. His mother was from the French-speaking region, his father from the German-speaking. They met when both were in Russia working with Russian children. Later his father became the director of the Swiss Observatory. Karl received his doctorate in economics from the University of Zurich in 1943 after spending 1937–38 studying modern economics at the London School of Economics. He travelled to the United States as a Rockefeller Foundation Scholar at Harvard and the University of Chicago from 1949 to 1951. He served on the UCLA faculty from 1951 to 1966 when he left on visiting appointments at Wisconsin and Michigan State before becoming the Everett D. Reese Professor of Economics at Ohio State University. In 1966, he moved to the University of Rochester, where he remained until his death in 1989. From 1979 to 1989, he was the Fred H. Gowen Professor of Economics. During his years at Rochester he served also as Permanent Guest Professor at the University of Konstanz (Germany) from 1968 to 1973 and Professor Ordinarius at the University of Bern (Switzerland) from 1974 to 1985. He arranged for many of his doctoral students at Bern to study at the University of Rochester. This had a lasting influence on economics and finance in Switzerland and
Europe.
Brunner often commented on the gap, often a wide one, between economic policy and economic theory. Much of his research, his efforts to influence policy, his journals and conferences reflected his belief that this gap could be closed by substantive research. Much of his analysis of institutions and the policy process considered the incentives that produced these outcomes and the uncertainty under which policies are made. To properly analyse issues of this kind, he proposed (1987) replacing the ‘economic man’ of the textbooks with the more dynamic and uncertain REMM – resourceful, evaluating, maximizing man. He used REMM also to compare economists’, sociologists’, political scientists’ and psychologists’ ability to understand society's processes.

Macroeconomic theory and monetary theory were his major interests. His earliest work (1951) was a lasting contribution to the early post-war concern with the purely analytic issues raised by Don Patinkin and others as to the determinacy of equilibrium in classical macroeconomics. Brunner developed a stock–flow analysis and devised equilibrium conditions.

Purely formal analysis did not fit well with his developing ideas about methods and the means to scientific development and knowledge in economics. He saw economics as an empirical science that produced refutable hypotheses. He did not reject formal analysis; he no longer did it.

After a few years, he turned to money supply theory. The central idea was to go beyond the standard IS–LM framework in which typically bonds and real capital are perfect substitutes, so that a single interest rate could represent the panoply of relative prices that transmit monetary and other impulses through the economic system. Brunner began by making the interest rate and the money supply endogenous variables. This generation of models was used to reject reverse causation and to critique Federal Reserve policymaking in a study for the US Congress. He proposed an alternative (Brunner and Meltzer, 1964).

Subsequent work (Brunner and Meltzer, 1989) introduced an output sector with endogenous prices and output. The complete static model had two endogenous relative prices, base money, bonds and real capital. Adding some institutional detail brought in the money stock and bank credit.

Although anticipated prices appear in these models, price expectations have a minimal role. Responding to the heightened emphasis in the 1970s on expectations and many discussions of stagflation, Brunner, Cukierman and Meltzer (1980; 1983) introduced transitory and persistent shocks into the analysis. This offered an explanation of asset markets requiring at least two relative prices to account for uncertainty of beliefs about the persistence of various impulses. It also offered an explanation of gradual adjustment of wages and employment in response to shocks of uncertain duration. The extended (1983) model introduced price setting and allowed inventories to absorb short-run shocks to aggregate demand.

The role of uncertainty and information was recognized early but took a central position in his monetary theory in ‘The Uses of Money’ (Brunner and Meltzer, 1971). The paper develops the reason that society adopts money, treats money's central role as a medium of exchange and explains why societies converge to a small number, often a single, money. The medium of exchange reduces transaction and information costs, thereby saving resources.

Karl Brunner is known as one of the founders of monetarism, a name he coined for the counter-revolution against Keynesian economics of the 1950s and 1960s.

Article

Michael Bruno was born in Germany in 1932 and emigrated with his family to Israel in 1933. After military service he studied mathematics and economics at the Hebrew University of Jerusalem and at King's College, Cambridge. On returning to Israel, he worked at the research department of the Bank of Israel. In 1961 he was brought to Stanford University by Hollis Chenery and Kenneth Arrow, where he received his Ph.D. in 1962. He then returned to Israel and in 1963 joined the faculty of the Department of Economics at the Hebrew University of Jerusalem. Over the years he visited MIT, Harvard, the University of Stockholm, and the LSE. Many times during his academic career Michael Bruno was involved in economic policymaking. In the mid-1970s he participated in a tax reform in Israel and advised the government on economic policy. In 1985 he was chief advisor to the Israeli disinflation programme. From 1986 to 1991 he was Governor of the Bank of Israel, and between 1993 and 1996 he served as a Senior Vice-President and Chief Economist of the World Bank.

Michael Bruno's research covered many areas in macroeconomics, was both theoretical and empirical, but was always strongly related to the economic problems of the time. In the 1960s, living in a rapidly developing country, he studied economic growth and development, focusing on input–output analysis and on duality in growth theory. In the 1970s, following the oil shocks, he began to study the macroeconomics of open economies, especially their reaction to shocks. One outcome of this research contains a pioneering discussion of the important ‘intertemporal approach to the balance of payments’ (1976). Another outcome is the research conducted with Jeffrey Sachs on stagflation and supply shocks, which culminated in their important book on stagflation (1985). In the 1980s, influenced by high inflation in Israel and by his role in the Israeli stabilization programme of 1985, Bruno's attention turned to inflation and stabilization. His research then reflected his deep interest in issues of disinflation and of reform in general. He promoted the idea that creating consensus is important for the
success of reforms, and applied it also to the analysis of the post-Communist transition in eastern Europe. In the 1990s Michael Bruno served in the World Bank and there his focus returned to issues of development, which he had studied in the beginning of his career. Actually, he combined it with his deep understanding of inflation and studied how inflation affects economic growth. His main finding appears in a paper with Easterly (1998) that shows that high inflation has a strong negative effect on growth. Thus, his last period of life and of economic research saw a closing of a circle, where he synthesized knowledge that he had accumulated throughout his scientific career, to analyse this important issue.

In addition to his general research and to his effect on policymaking, Michael Bruno also contributed significantly to research on the Israeli economy, both through his research and through his roles as director of the research department in the Bank of Israel, as director of the Falk Institute for Economic Research in Israel, and as Governor of the Bank of Israel.

A bubble may be defined loosely as a sharp rise in price of an asset or a range of assets in a continuous process, with the initial rise generating expectations of further rises and attracting new buyers – generally speculators interested in profits from trading in the asset rather than its use or earning capacity. The rise is usually followed by a reversal of expectations and a sharp decline in price often resulting in financial crisis. A boom is a more extended and gentler rise in prices, production and profits than a bubble, and may be followed by crisis, sometimes taking the form of a crash (or panic) or alternatively by a gentle subsidence of the boom without crisis.

Bubbles have existed historically, at least in the eyes of contemporary observers, as well as booms so intense and excited that they have been called ‘manias’. The most notable bubbles were the Mississippi bubble in Paris in 1719–20, set in motion by John Law, founder of the Banque Générale and the Banque Royale, and the contemporaneous and related South Sea bubble in London. Most famous of the manias were the Tulip mania in Holland in 1636, and the Railway mania in England in 1846–7. It is sometimes debated whether a particular sharp rise and fall in prices, such as the German hyperinflation from 1920 to 1923, or the rise and fall in commodity and share prices in London and New York in 1919–21, the rise of gold of $850 an ounce in 1982 and its subsequent fall to the $350 level, were or were not bubbles. Some theorists go further and question whether bubbles are possible with rational markets, which they assume exist (see e.g. Flood and Garber, 1980).

Rational expectations theory holds that prices are formed within the limits of available information by market participants using standard economic models appropriate to the circumstances. As such, it is claimed, market prices cannot diverge from fundamental values unless the information proves to have been widely wrong. The theoretical literature uses the assumption of the market having one mind and
one purpose, whereas it is observed historically that market participants are often moved by different purposes, operate with different wealth and information and calculate within different time horizons. In early railway investment, for example, initial investors were persons doing business along the rights of way who sought benefits from the railroad for their other concerns. They were followed by a second group of investors interested in the profits the railroad would earn, and by a third group, made up of speculators who, seeing the rise in the railroad’s shares, borrowed money or paid for the initial instalments with no intention of completing the purchase, to make a profit on resale.

The objects of speculation resulting in bubbles or booms and ending in numerous cases, but not all, in financial crisis, change from time to time and include commodities, domestic bonds, domestic shares, foreign bonds, foreign shares, urban and suburban real estate, rural land, leisure homes, shopping centres, Real Estate Investment Trusts, 747 aircraft, supertankers, so-called ‘collectibles’ such as paintings, jewellery, stamps, coins, antiques etc. and, most recently, syndicated bank loans to developing countries. Within these relatively broad categories, speculation may fix on particular objects – insurance shares, South American mining stocks, cotton-growing land, Paris real estate, Post-Impressionist art, and the like.

At the time of writing, the theoretical literature has yet to converge on an agreed definition of bubbles, and on whether they are possible. Virtually the same authors who could not reject the no-bubbles hypothesis in the German inflation of 1923 one year, managed to do so a year later (Flood and Garber, 1980). Another pair of theorists has demonstrated mathematically that rational bubbles can exist after putting aside ‘irrational bubbles’ on the grounds not of their non-existence but of the difficulty of the mathematics involved (Blanchard and Watson, 1982).

Short of bubbles, manias and irrationality are periods of euphoria which produce positive feedback, price increases greater than justified by market fundamentals, and booms of such dimensions as to threaten financial crisis, with possibilities of a crash or panic. Minsky (1982a, 1982b) has discussed how after an exogenous change in economic circumstances has altered profit opportunities and expectations, bank lending can become increasingly lax by rigorous standards. Critical exception has been taken to his taxonomy dividing bank lending into hedge finance, to be repaid out of anticipated cash flows; speculative finance, requiring later refinancing because the term of the loan is less than the project’s payoff; and Ponzi finance, in which the borrower expects to pay off his loan with the proceeds of sale of an asset. It is objected especially that Carlo Ponzi was a swindler and that many loans of the third type, for example those to finance construction, are entirely legitimate (Flemming, Goldsmith and Melitz, 1982). Nonetheless, the suggestion that lending standards grow more lax during a boom and that the banking system on that account becomes more fragile has strong historical support. It is attested, and the contrary rational-expectations view of financial markets is falsified, by the experience of such a money and capital market as London having successive booms, followed by crisis, the latter in 1810, 1819, 1825, 1836, 1847, 1857, 1866, 1890, 1900, 1921 – a powerful record of failing to learn from experience (Kindleberger, 1978).

Bubbles refer to asset prices that exceed an asset's fundamental value because current owners believe they can resell the asset at an even higher price. There are four main strands of models: (i) all investors have rational expectations and identical information, (ii) investors are asymmetrically informed and bubbles can emerge because their existence need not be commonly known, (iii) rational traders interact with behavioural traders and bubbles persist since limits to arbitrage prevent rational investors from eradicating the price impact of behavioural traders, (iv) investors hold heterogeneous beliefs, potentially due to psychological biases, and agree to disagree about the fundamental value.

Article

Bubbles are typically associated with dramatic asset price increases followed by a collapse. Bubbles arise if the price exceeds the asset's fundamental value. This can occur if investors hold the asset because they believe that they can sell it at a higher price than some other investor even though the asset's price exceeds its fundamental value. Famous historical examples are the Dutch tulip mania (1634–7), the Mississippi Bubble (1719–20), the South Sea Bubble (1720), and the ‘Roaring ‘20s’ that preceded the 1929 crash. More recently, up to March 2000 Internet share prices (CBOE Internet Index) surged to astronomical heights before plummeting by more than 75 per cent by the end of 2000. Since asset prices affect the real allocation of an economy, it is important to understand the circumstances under which these prices can deviate from their fundamental value. Bubbles have long...
bubbles: The New Palgrave Dictionary of Economics

intrigued economists and led to several strands of models, empirical tests and experimental studies. We can broadly divide the literature into four groups. The first two groups of models analyse bubbles within the rational expectations paradigm, but differ in their assumption as to whether all investors have the same information or are asymmetrically informed. A third group of models focuses on the interaction between rational and non-rational (behavioural) investors. In the final group of models traders’ prior beliefs are heterogeneous, possibly due to psychological biases, and consequently they agree to disagree about the fundamental value of the asset.

Rational bubbles under symmetric information

Rational bubbles under symmetric information are studied in settings in which all agents have rational expectations and share the same information. There are several theoretical arguments that allow us to rule out rational bubbles under certain conditions. Tirole (1982) uses a general equilibrium reasoning to argue that bubbles cannot exist if it is commonly known that the initial allocation is interim Pareto efficient. A bubble would make the seller of the ‘bubble asset’ better off, which – due to interim Pareto efficiency of the initial allocation – has to make the buyer of the asset worse off. Hence, no individual would be willing to buy the asset. Partial equilibrium arguments alone are also useful in ruling out bubbles. Simply rearranging the definition of (net) return, $r_{t+1,s} = \frac{(p_{t+1,s} + d_{t+1,s})}{p_t - 1}$, where $p_{t,s}$ is the price and $d_{t,s}$ is the dividend payment at time $t$ and state $s$, and taking rational expectations yields

$$p_t = E_t \left[ \frac{p_{t+1} + d_{t+1}}{1 + r_{t+1}} \right].$$

That is, the current price is just the discounted expected future price and dividend payment in the next period. For tractability assume that the expected return that the marginal rational trader requires in order to hold the asset is constant over time, $E_t[r_{t+1}] = r$, for all $t$. In solving the above difference equation forward, that is, in replacing $p_{t+1}$ with $E_{t+1} \left[ \frac{p_{t+2} + d_{t+2}}{(1 + r)} \right]$ in eq. (1) versus Equation (2) below and then $p_{t+2}$ and so on, and using the law of iterated expectations, one obtains after $T - t - 1$ iterations

$$p_t = E_t \left[ \sum_{\tau=1}^{T-t} \frac{1}{(1 + r)^\tau} d_{t+\tau} \right] + E_t \left[ \frac{1}{(1 + r)^{T-t}} p_T \right].$$
The equilibrium price is given by the expected discounted value of the future dividend stream paid from \( t+1 \) to \( T \) plus the expected discounted value of the price at \( T \). For securities with finite maturity, the price after maturity, say \( T \), is zero, \( p_T = 0 \). Hence, the price of the asset, \( p_t \), is unique and simply coincides with the expected future discounted dividend stream until maturity. Put differently, finite horizon bubbles cannot arise as long as rational investors are unconstrained from selling the desired number of shares in all future contingencies. For securities with infinite maturity, \( T \to \infty \), the price \( p_t \) only coincides with the expected discounted value of the future dividend stream, call it fundamental value, \( v_t \), if the so-called transversality condition,

\[
\lim_{T \to \infty} E_t \left[ \frac{1}{(1+r)^{T-t}} p_T \right] = 0
\]

holds. Without imposing the transversality condition, \( p_t = v_t \) is only one of many possible prices that solve the above expectational difference equation. Any price \( p_t = v_t + b_t \), decomposed in the fundamental value, \( v_t \), and a bubble component, \( b_t \), such that

\[
b_t = E_t \left[ \frac{1}{(1+r)} b_{t+1} \right]
\]

(2)

is also a solution. Equation (2) versus eq. (1) needs to be made consistent. Equation (2) highlights that the bubble component \( b_t \) has to ‘grow’ in expectations exactly at a rate of \( r \). A nice example of these ‘rational bubbles’ is provided in Blanchard and Watson (1982), where the bubble persists in each period only with probability \( \pi \) and bursts with probability \( (1-\pi) \). If the bubble continues, it has to grow in expectation by a factor \( (1+r)/\pi \). This faster bubble growth rate (conditional on not bursting) is necessary to achieve an expected growth rate of \( r \). In general, the bubble component may be stochastic. A specific example of a stochastic bubble is an intrinsic bubble, where the bubble component is assumed to be deterministically related to a stochastic dividend process.

The fact that any bubble has to grow at an expected rate of \( r \) allows one to eliminate many potential rational bubbles. For example, a positive bubble cannot emerge if there is an upper limit on the size of the bubble. That is, for example, the case with potential bubbles on commodities with close substitutes. An ever-growing ‘commodity bubble’ would make the commodity so expensive that it would be substituted with some other good. Similarly, a bubble on a non-zero net supply asset cannot arise if the required return \( r \) exceeds the growth rate of the economy, since the bubble would outgrow the aggregate wealth in the economy. Hence, bubbles can only exist in a world in which the required return is lower than or equal to the growth rate of the economy. In addition, rational bubbles can persist if the pure existence of the bubble enables trading opportunities that lead to a different equilibrium allocation. Fiat money in an overlapping generations (OLG) model is probably the most famous example of such a bubble. The intrinsic value of fiat money is zero, yet it has a positive price. Moreover, only when the price is positive, does it allow wealth transfers across generations (that might not even be born yet). A negative bubble, \( b_t < 0 \), on a limited-liability asset cannot arise since the bubble would imply that the asset price has to become negative in expectation at some point in time. This result, together with eq.
bubbles: The New Palgrave Dictionary of Economics

(2), implies that if the bubble vanishes at any point it has to remain zero from that point onwards. That is, rational bubbles can never emerge within an asset-pricing model; they must already be present when the asset starts trading.

**Empirically testing** for rational bubbles under symmetric information is a challenging task. The literature has developed three types of tests: regression analysis, variance bounds tests and experimental tests. Initial tests proposed by Flood and Garber (1980) exploit the fact that bubbles cannot start within a rational asset-pricing model and hence at any point in time the price must have a non-zero part that grows at an expected rate of $r$. However using this approach, inference is difficult due to an exploding regressor problem. That is, as time $t$ increases, the regressor explodes and the coefficient estimate relies primarily on the most recent data points. More precisely, the ratio of the information content of the most recent data point to the information content of all previous observations never goes to zero. This implies that as time $t$ increases, the time series sample remains essentially small and the central limit theorem does not apply. Diba and Grossman (1988) test for bubbles by checking whether the stock price is more explosive than the dividend process. Note that if the dividend process follows a linear unit-root process (for example, a random walk), then the price process has a unit root as well. However the change in price, $\Delta p_t$, and the spread between the price and the discounted expected dividend stream, $p_t - d_t/r$, are stationary under the no-bubbles hypothesis. That is, $p_t$ and $d_t/r$ are co-integrated. Diba and Grossman test this hypothesis using a series of unit root tests, autocorrelation patterns, and co-integration tests. They conclude that the no-bubble hypothesis cannot be rejected. However, Evans (1991) shows that these standard linear econometric methods may fail to detect the explosive nonlinear patterns of periodically collapsing bubbles. West (1987) proposes a different test that exploits the fact that one can estimate the parameters needed to calculate the expected discounted value of dividends in two different ways. One way of estimating them is not affected by the bubble, the other is. Note that the accounting identity (1) can be rewritten as

$$p_t = \frac{1}{1+r} (p_{t+1} + d_{t+1}) - \frac{1}{1+r} (p_{t+1} + d_{t+1} - E_t[p_{t+1} + d_{t+1}]).$$

Hence, in an instrumental variables regression of $p_t$ on $(p_{t+1} + d_{t+1})$ – using for example $d_t$ as an instrument – one obtains an estimate for $r$ that is independent of the existence of a rational bubble. Second, if, for example, the dividend process follows a stationary AR(1) process, $d_{t+1} = \varphi d_t + \eta_{t+1}$, with independent noise $\eta_{t+1}$, one can easily estimate $\varphi$. Furthermore, the expected discounted value of future dividends is $v_t = (\varphi / (1 + r - \varphi)) d_t$. Hence, under the null-hypothesis of no bubble, that is $p_t = v_t$, the coefficient estimate of the regression of $p_t$ on $d_t$ provides a second estimate of $\varphi / (1 + r - \varphi)$. In a final step, West uses a Hausman specification test to test whether both estimates coincide. He finds that the US stock market data usually reject the null hypothesis of no bubble.

Excessive volatility in the stock market seems to provide further evidence in favour of stock market bubbles. LeRoy and Porter (1981) and Shiller (1981) introduced variance bounds that indicate that the stock market is too volatile to be justified by the volatility of the discounted dividend stream. However, the variance bounds test is controversial (see, for example, Kleidon, 1986). Also, this test, as well as all the aforementioned bubble tests, assumes that the required expected returns, $r$, are constant over time. In a setting in which the required expected returns can be time-varying, the empirical evidence favouring excess volatility is less clear-cut. Furthermore, time-varying expected returns can also rationalize the
long-horizon predictability of stock returns. For example, a high price–dividend ratio predicts low subsequent stock returns with a high $R^2$ (Campbell and Shiller, 1988).

Finally, it is important to recall that the theoretical arguments that rule out rational bubbles as well as several empirical bubble tests rely heavily on backward induction. Since a bubble cannot grow from time $T$ onwards, there cannot be a bubble of this size at time $T - 1$, which rules out this bubble at $T - 2$, and so on. However, there is ample experimental evidence that individuals violate the backward induction principle. Most convincing are experiments on the centipede game (Rosenthal, 1981). In this simple game, two players alternatively decide whether to continue or stop the game for a finite number of periods. On any move, a player is better off stopping the game than continuing if the other player stops immediately afterwards, but is worse off stopping than continuing if the other player continues afterwards. This game has only a single subgame perfect equilibrium that follows directly from backward induction reasoning. Each player's strategy is to stop the game whenever it is his or her turn to move. Hence, the first player should immediately stop the game and the game should never get off the ground. However, in experiments players initially continue to play the game – a violation of the backward induction principle (see for example, McKelvey and Palfrey, 1992). These experimental findings question the theoretical reasoning used to rule out rational bubbles under symmetric information. More experimental evidence on bubbles in general is provided in the final section.

In a rational bubble setting an investor only holds a bubble asset if the bubble grows in expectations ad infinitum. In contrast, in the following models an investor might hold an overpriced asset if he thinks he can resell it in the future to a less informed trader or someone who holds biased beliefs. In Kindleberger's (2000) terms, the investor thinks he can sell the asset to a greater fool.

**Asymmetric information bubbles**

Asymmetric information bubbles can occur in a setting in which investors have different information, but still share a common prior distribution. In these models prices have a dual role: they are an index of scarcity and informative signals, since they aggregate and partially reveal other traders’ aggregate information (see for example Brunnermeier, 2001 for an overview). In contrast to the symmetric information case, the presence of a bubble need not be commonly known. For example, it might be the case that everybody knows the price exceeds the value of any possible dividend stream, but it is not the case that everybody knows that all the other investors also know this fact. It is this lack of higher-order mutual knowledge that makes it possible for finite bubbles to exist under certain necessary conditions (Allen, Morris and Postlewaite, 1993). First, it is crucial that investors remain asymmetrically informed even after inferring information from prices and net trades. This implies that prices cannot be fully revealing. Second, investors must be constrained from (short) selling their desired number of shares in at least one future contingency for finite bubbles to persist. Third, it cannot be common knowledge that the initial allocation is interim Pareto efficient, since then it would be commonly known that there are no gains from trade and hence the buyer of an overpriced ‘bubble asset’ would be aware that the rational seller gains at his expense (Tirole, 1982). In other words, there have to be gains from trade or at least some investors have to think that there might be gains from trade. There are various mechanisms that lead to these. For example, fund managers who invest on behalf of their clients can gain from buying overpriced bubble assets, since trading allows them to fool their clients into believing that they have
superior trading information. A fund manager who does not trade would reveal that he does not have private information. Consequently, bad fund managers churn bubbles at the expense of their uninformed client investors (Allen and Gorton, 1993). Furthermore, fund managers with limited liability might trade bubble assets due to classic risk-shifting incentives, since they participate on the potential upside of a trade but not on the downside risk.

**Bubbles due to limited arbitrage**

Bubbles due to limited arbitrage arise in models in which rational, well-informed and sophisticated investors interact with behavioural market participants whose trading motives are influenced by psychological biases. Proponents of the ‘efficient markets hypothesis’ argue that bubbles cannot persist since well-informed sophisticated investors will undo the price impact of behavioural non-rational traders. Thus, rational investors should go against the bubble even before it emerges. The literature on limits to arbitrage challenges this view. It argues that bubbles can persist, and provides three channels that prevent rational arbitrageurs from fully correcting the mispricing. First, *fundamental risk* makes it risky to short a bubble asset since a subsequent positive shift in fundamentals might *ex post* undo the initial overpricing. Risk aversion limits the aggressiveness of rational traders if close substitutes and close hedges are unavailable. Second, rational traders also face *noise trader risk* (DeLong et al., 1990). Leaning against the bubble is risky even without fundamental risk, since irrational noise traders might push up the price even further in the future and temporarily widen the mispricing. Rational traders with short horizons care about prices in the near future in addition to the long-run fundamental value and only partially correct the mispricing. For example, in a world with delegated portfolio management, fund managers are often concerned about short-run price movements, because temporary losses instigate fund outflows (Shleifer and Vishny, 1997). A temporary widening of the mispricing and the subsequent outflow of funds force fund managers to unwind their positions exactly when the mispricing is the largest. Anticipating this possible scenario, mutual fund managers trade less aggressively against the mispricing. Similarly, hedge funds face a high flow-performance sensitivity, despite some arrangements designed to prevent outflows (for example, lock-up provisions). Third, rational traders face *synchronization risk* (Abreu and Brunnermeier, 2002, 2003). Since a single trader alone cannot typically bring the market down by himself, coordination among rational traders is required and a synchronization problem arises. Each rational trader faces the following trade-off: if he attacks the bubble too early, he forgoes profits from the subsequent run-up caused by behavioural momentum traders; if he attacks too late and remains invested in the bubble asset, he will suffer from the subsequent crash. Each trader tries to forecast when other rational traders will go against the bubble. Timing other traders’ moves is difficult because traders become sequentially aware of the bubble, and they do not know where in the queue they are. Because of this ‘sequential awareness’, it is never common knowledge that a bubble has emerged. It is precisely this lack of common knowledge that removes the bite of the standard backward induction argument. Since there is no commonly known point in time from which one could start backward induction, even finite horizon bubbles can persist. The other important message of the theoretical work on synchronization risk is that relatively insignificant news events can trigger large price movements, because even unimportant news events allow traders to synchronize their sell strategies. Unlike the earlier limits to arbitrage models, in which rational traders do not trade...
aggressively enough to completely eradicate the bubble but still short an overpriced bubble asset, in Abreu and Brunnermeier (2003) rational traders prefer to ride the bubble rather than attack it. The incentive to ride the bubble stems from a predictable ‘sentiment’ in the form of continuing bubble growth. Empirically, there is supportive evidence in favour of the ‘bubble-riding hypothesis’. For example, between 1998 and 2000 hedge funds were heavily tilted towards highly priced technology stocks (Brunnermeier and Nagel, 2004). Contrary to the efficient markets hypothesis, hedge funds were not a price-correcting force even though they are among the most sophisticated investors and are arguably closer to the ideal of ‘rational arbitrageurs’ than any other class of investors. Similarly, Temin and Voth (2004) document that Hoares Bank was profitably riding the South Sea bubble in 1719–20, despite giving numerous indications that it believed the stock to be overvalued. Many other investors, including Isaac Newton, also tried to ride the South Sea bubble but with less success. Frustrated with his trading experience, Isaac Newton concluded ‘I can calculate the motions of the heavenly bodies, but not the madness of people’ (Kindleberger, 2005, p. 41).

Heterogeneous beliefs bubbles

Bubbles can also emerge when investors have heterogeneous beliefs and face short-sale constraints. Investors’ beliefs are heterogeneous if they start with different prior belief distributions that can be due to psychological biases. For example, if investors are overconfident about their own signals, they have a different prior distribution (with lower variance) about the signals’ noise term. Investors with non-common priors can agree to disagree even after they share all their information. Also, in contrast to an asymmetric information setting, investors do not try to infer other traders’ information from prices. Combining heterogeneous beliefs with short-sale constraints can result in overpricing since optimists push up the asset price, while pessimists cannot counterbalance it since they face short-sale constraints (Miller, 1977). Ofek and Richardson (2003) link this argument to the Internet bubble of the late 1990s. In a dynamic model, the asset price can even exceed the valuation of the most optimistic investor in the economy. This is possible, since the currently optimistic investors – the current owners of the asset – have the option to resell the asset in the future at a high price whenever they become less optimistic. At that point other traders will be more optimistic, and hence be willing to buy the asset since optimism is assumed to oscillate across different investor groups (Harrison and Kreps, 1978). It is essential that less optimistic investors, who would like to short the asset, are prevented from doing so by the short-sale constraint. Heterogeneous belief bubbles are accompanied by large trading volume and high price volatility (Scheinkman and Xiong, 2003).

Experimental evidence

Many theoretical arguments in favour of or against bubbles are difficult to test with (confounded) field data. Laboratory experiments have the advantage that they allow the researcher to isolate and test specific mechanisms and theoretical arguments. For example, the aforementioned experimental evidence on centipede games questions the validity of backward induction. There is a large and growing literature that examines bubbles in a laboratory setting. For example, Smith, Suchanek and Williams (1988) study
a double-auction setting, in which a risky asset pays a uniformly distributed random dividend of \( d \in \{0, d_1, d_2, d_3\} \) in each of the 15 periods. Hence, the fundamental value for a risk-neutral trader is initially \( 15 \sum \frac{1}{4} d_i \) and declines by \( \sum \frac{1}{4} d_i \) in each period. Even though there is no asymmetric information and the probability distribution is commonly known, there is vigorous trading, and prices initially rise despite the fact that the fundamental value steadily declines. More specifically, the time-series of asset prices in the experiments are characterized by three phases. An initial boom phase is followed by a period during which the price exceeds the fundamental value, before the price collapses towards the end. These findings are in sharp contrast to any theoretical prediction and seem very robust across various treatments. A string of subsequent articles show that bubbles still emerge after allowing for short sales, after introducing trading fees, and when using professional business people as subjects. Only the introduction of futures markets and the repeated experience of a bubble reduce the size of the bubble. Researchers have speculated that bubbles emerge because each trader hopes to outwit others and to pass the asset on to some less rational trader in the final trading rounds. However, more recent research has revealed that the lack of common knowledge of rationality is not the cause of bubbles. Even when investors have no resale option and are forced to hold the asset until the end, bubbles still emerge (Lei, Noussair and Plott, 2001).

In summary, the literature on bubbles has taken giant strides since the 1970s that led to several classes of models with distinct empirical tests. However, many questions remain unresolved. For example, we do not have many convincing models that explain when and why bubbles start. Also, in most models bubbles burst, while in reality bubbles seem to deflate over several weeks or even months. While we have a much better idea of why rational traders are unable to eradicate the mispricing introduced by behavioural traders, our understanding of behavioural biases and belief distortions is less advanced. From a policy perspective, it is interesting to answer the question whether central banks actively try to burst bubbles. I suspect that future research will place greater emphasis on these open issues.

Buchanan, David (1779–1848)

Andrew Skinner

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Buchanan, David; Smith, Adam; taxation

Article

Buchanan was born in Montrose, the eldest son of David Buchanan, the renowned printer, publisher and amateur literary scholar. Unlike his father, David the younger did not attend university, but entered the family business. Primarily interested in economics, geography and statistics, Buchanan is generally regarded as a journalist and writer, but also as a ‘Scottish economist’ (*Encyclopedia of the Social Sciences*, 1935, iii. 27). Buchanan's career amply justifies all of these claims.

Invited by Francis Horner and Francis Jeffrey to act as editor for the short-lived *Weekly Register* in 1808, Buchanan moved to the *Caledonian Mercury* two years later and remained in this post until 1827. In the same year he became editor of the *Edinburgh Courant*, a position he held until his sudden death in 1848.

In 1835 Buchanan helped to compile the *Edinburgh Geographical Atlas*, and made a number of contributions to the *Edinburgh Gazetteer*. He also contributed pieces on geography and statistics to the seventh edition of the *Encyclopaedia Britannica* (1842), which were acknowledged in the preface. But the bulk of Buchanan's output was on economics, with numerous articles appearing in Cobbett's *Political Register* and in the *Edinburgh Review*. The latter in particular carried pieces on ‘Lord Henry Petty's plan of Finance’ (1807), ‘Wheatley on money and finance’ (1807), ‘Spence on agriculture and commerce’ (with Francis Jeffrey, 1809), the Corn Laws (1815), and ‘Corn and money’ (1816).

This growing interest in economic subjects prepared Buchanan for his critical, annotated edition of the *Wealth of Nations* (1814), which in turn paved the way for his *Observations on the Subjects Treated of in Dr. Smith's Inquiry* published in the same year. In the Introduction to the latter work Buchanan set Smith's achievement in the context of the work done by Sir James Steuart and the physiocrats. While expressing qualified admiration for both, Buchanan noted that the *Wealth of Nations* ‘is a great display of reason on the business of the world; touching society in all its essential relations, containing lessons for government as well as for common life, and embracing subjects formerly placed without the limits of...
Yet Dr Smith had ‘not published a perfect work’. The critical ‘dissertations’ which follow supplement the notes with the intention of correcting ‘what is amiss’ (p. xv).

Less successful in his treatment of Ricardo, Buchanan elaborated on the determinants of price and criticized Smith's theory of rent. Other subjects covered included metallic money and paper currency, wages, stock, productive and unproductive labour, the progress of opulence, the Corn Laws, commercial treaties, defence, public debt and the East India Company. Buchanan included a section on taxation and went on to publish an Inquiry into the Taxation and Commercial Policy of Great Britain (1844) which subsequently attracted some critical acclaim.

In 1852 Buchanan was described as a man of ‘unobtrusive habits, mild and gentle in his demeanour, and held in high respect by all who had an opportunity of forming an estimate of his character’ (Anderson, 1863, p. 481).

Buchanan, James M. (born 1919)

Richard E. Wagner
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The customary Anglo-Saxon approach to public finance treats the state as exogenous to the economic process, which restricts public finance to the study of market-based reactions to exogenous fiscal impositions. In contrast, Buchanan has cultivated an approach to public finance that incorporates the state into the economic process. The domain of fiscal analysis is thus expanded in two directions. One direction, public choice, involves the study of the effect of political institutions on collective choices. The other direction, constitutional political economy, involves the emergence of and changes in political institutions.

Article

James M. Buchanan was awarded the 1986 Nobel Memorial Prize in Economic Science for his seminal role in developing ‘the contractual and constitutional bases for the theory of economic and political decision-making’.
Buchanan spent his boyhood in rural Tennessee near Murfreesboro. After receiving Bachelor's and Master's degrees from Middle Tennessee State College and the University of Tennessee respectively, he entered the US Navy in 1941. After completing his naval service in the Pacific, Buchanan enrolled at the University of Chicago in 1946, receiving his Ph.D. in 1948. He has spent the preponderance of his academic career at three Virginia universities: the University of Virginia (1956–68), Virginia Polytechnic Institute (1969–83), and George Mason University (since 1983). Buchanan has been a truly
prolific scholar throughout this period, as shown by the 20 volumes of his collected works published by Liberty Fund; moreover, he has continued his scholarly work at full speed since the completion of that collection in 2001.

The Nobel citation referred to above identifies two predominant strains within Buchanan's scholarly oeuvre. One of these is the theory of public choice, which entails the application of economic theorizing to politics. The other is constitutional political economy, which explores the relationship between constitutional rules and political outcomes. While Buchanan's body of work also contains numerous contributions to economic theory and methodology, which by themselves would have constituted a significant scholarly career, this short article focuses exclusively on Buchanan's approach to public choice and constitutional political economy.

Precursory influences

While Buchanan has been creative as well as prolific, he has nonetheless been inspired by, and has built upon, the contributions of others. Buchanan has acknowledged these precursory influences numerous times, particularly in his autobiographical Better than Plowing, where he identifies three sources of primary influence on his work.

The primary precursors to Buchanan's public choice theorizing were a set of Italian scholars, among them Antonio De Viti De Marco, Maffeo Pantaleoni, and Luigi Einaudi, who developed a unique orientation towards public finance between the 1880s and the 1930s. Where Anglo-Saxon scholars treated the state as outside the economy, the Italians sought to incorporate political outcomes into the economic process. For instance, much Anglo-Saxon fiscal scholarship sought to develop norms regarding the desirable degree of tax progressivity, as illustrated by various sacrifice theories of taxation. By contrast, the Italians sought to explain the actual structure of taxation independently of normative concern, and to do so with reference to the same categories of utility and cost as they invoked to explain market outcomes. This Italian orientation of sober realism towards political processes was central to the later development of public choice theorizing. For instance, in his foreword to the German translation of Amilcare Puviani's 1903 treatise on fiscal illusion, Teoria della illusione finanziaria, Gunter Schmölders observed that ‘over the last century Italian public finance has had an essentially political science character…. This work [Puviani] is a typical product of Italian public finance…. Above all, it is the science of public finance combined with fiscal politics, in many places giving a good fit with reality’ (Puviani, 1960). The Italians were thoroughgoing realists and not romantic idealists, and it was a short distance from their initial formulations to what subsequently became known as public choice.

The sober realism of the Italians implied, in keeping with the general equilibrium theorizing of the time, that actual fiscal outcomes were to be explained as equilibrium outcomes. If so, it might seem as though fiscal theorizing offered no coherent vantage point from which to pursue any programme of fiscal reform. Yet Buchanan has always sought to use fiscal knowledge as an instrument of fiscal reform. It was Knut Wicksell who provided Buchanan with the vehicle for combining his sober realism with his interest in reform. Buchanan's constitutional emphasis can be traced to the second of Wicksell's three essays in Finanztheoretische Untersuchungen, which Buchanan translated as ‘A New Theory of Just Taxation’, in Classics in the Theory of Public Finance, edited by Richard Musgrave and Alan Peacock. From Wicksell, Buchanan derived two themes that informed his work thereafter. One theme was the treatment of unanimous consent and not majority approval as the normative benchmark for appraising...
Buchanan, James M. (born 1919) : The New Palgrave Dictionary of Economics

political outcomes. The other theme was a distinction between constitutional politics, where institutional rules are selected, and post-constitutional politics, where particular outcomes emerge. Wicksell's treatment of two distinct levels of political activity led to Buchanan's articulation of a constitutional political economy, wherein political reform was a matter of changing the rules that govern the game, as distinct from changing the strategies of play within a game.

While Wicksell and the Italians cover the two themes mentioned in Buchanan's Nobel citation, any mention of precursory influences would be remiss without including Frank Knight, whom Buchanan initially encountered during his student days at the University of Chicago. Knight's influence on Buchanan is not so much one of particular ideas as of general attitude and orientation towards a scholar's life and work. From Knight, Buchanan carried forward the belief that no doctrine or authority should be treated as sacrosanct and above challenge. Everyone else may say that something is true, but this doesn't mean they are right; there may be many pretentious emperors walking around naked. Buchanan's work has also demonstrated the same multidisciplinary character that was prominent in Knight's work. For Buchanan, as for Knight, economic theorizing was not self-contained, but had points of contact throughout the humane studies, which led to a style of theorizing wherein Buchanan, like Knight, continually makes contact with such related fields of inquiry as law, ethics, history, philosophy, and politics.

From Italian public finance to public choice

The Italian approach to public finance treated the state as an entity whose actions conformed to the same principles of marginal utility as the actions of other economic participants. The Italians did not seek to advance statements concerning how large the state should be in order to promote some vision of social welfare. They sought instead to offer coherent explanations about the actual size of the state. At the level of formal analysis, this meant that the state would expand until the marginal utility from state-provided services equalled the marginal utility from market-supplied services. To be sure, the Italians recognized the numerous problems of aggregation that were involved in making such statements. In response, they developed a variety of models regarding just whose utility was driving the equilibrium. Where some models treated the state as a cooperative enterprise that worked to the benefit of all, others treated the state as an entity that promoted the advantage of ruling classes. In any case, it was a small step from the Italian fiscal theorizing to the public choice theorizing that began to take shape in the 1960s, as elaborated in Richard Wagner (2003).

Perhaps the best place to see the Italian influence on public choice is Buchanan's 1967 treatise Public Finance in Democratic Process, which was written at a time when 'public choice' was not yet a term of scholarly identification. Buchanan starts that book by noting the narrow and limited scope of Anglo-Saxon approaches to public finance, wherein public finance is concerned only with explaining market-based reactions to exogenously imposed taxes and expenditures. On the tax side of the budget, for instance, a progressive income tax with several brackets of rising marginal rates might be replaced by a regressive tax where a single marginal rate is imposed above some initial exemption. The task of the fiscal scholar would be to explain the impact of such an exogenous tax shift on such things as the amount of labour people supply, the amount of underground economic activity they undertake, and the amount of taxable income they earn. Alternatively, on the expenditure side of the budget, an appropriation might be made to finance a highway. The task of fiscal analysis would be to analyse the
market-based reactions to the highway. For instance, land rents near highway exits might rise due to the reduction in travel time that resulted. Whatever the particular topic examined, the analytical task of Anglo-Saxon public finance has everything to do with explaining market-based reactions to exogenously imposed fiscal measures and has nothing to do with explaining state budgets and fiscal institutions.

In treating state budgets as exogenous to fiscal inquiry, the Anglo-Saxon orientation towards public finance ignored two large areas of possible inquiry, both of which Buchanan explores in *Public Finance in Democratic Process*. One ignored area is the ability of fiscal institutions to influence budgetary outcomes and not just market outcomes. This topic occupies the first part of *Public Finance in Democratic Process*, and the analyses presented there were early illustrations of public choice theorizing. The second ignored area is the choice or emergence of fiscal institutions. This topic occupies the second part of *Public Finance in Democratic Process*, and the analyses presented there were harbingers of subsequent work in constitutional political economy.

Buchanan gives several illustrations in *Public Finance in Democratic Process* of how fiscal institutions and arrangements might influence fiscal outcomes, of which I mention three. First, Buchanan examines the possible budgetary consequences of a choice between general-fund financing and tax earmarking. Under the former practice, tax revenues accrue to a general fund from which various appropriations are made; under the latter practice, specific taxes are earmarked to finance particular services. Buchanan suggests that general-fund financing is a form of tie-in sale that might bring about a budgetary shift in favour of services in relatively elastic demand.

Second, Buchanan examines the possible budgetary consequences of the withholding of income taxes. His analysis in this case is related to claims about fiscal illusion or perception. Buchanan argues that individual perceptions about the costliness of public output depend on the manner in which tax extractions are made. Perhaps the most open and direct manner of paying for public output would be for people to write monthly checks to government, just as they pay their utility bills. Buchanan explores the possibility that withholding may create some tendency for individuals to perceive the cost of government to be less than it would otherwise be, which should in turn lead to some increase in the size of government.

Third, Buchanan examines the effect of public debt on budgetary outcomes, a topic that he initially explored in *Public Principles of Public Debt* and to which he returned in *Democracy in Deficit* (co-authored with Richard Wagner). The principle of Ricardian equivalence holds that tax finance and debt finance are identical. In the aggregate, this is true as a simple matter of double-entry accounting. If $1 million of tax revenue is replaced by public borrowing, the present value of the future payments necessary to service the debt will equal the tax reduction. However, the collectivity does not act as a unit, so a statement about aggregate equivalence is irrelevant to any effort to explain fiscal conduct. What matters for collective action is the direction of individual desires as these are mediated through political and fiscal institutions. For instance, people in higher age ranges will find debt to be less costly than taxation, increasingly so with age. Compare a tax of $1,000 now with a perpetual debt that entails payments of $100 when the appropriate discount rate is ten per cent. In terms of perpetuity, the debt and the tax are equivalent. For a younger person who might look forward to 50 taxpaying years, the present value of the debt is $991. For an older person who might only have ten years of tax-paying life expectancy left, the present value of the debt is but $614.

To be sure, it could be claimed that the older person has some bequest motivation towards heirs. If so, that older person would treat the debt obligation as continuing beyond his life. But not all older people
have heirs. And of those that do, not all of them seem to have the types of bequest motives that generate Ricardian equivalence. This point gets to another significant feature of Buchanan's thought: his unwillingness to make statements based on aggregates without exploring the underlying structural patterns to which those aggregates pertain. After all, aggregates are not entities that act, and in Buchanan's approach collective action must be generated out of choices by discernible, acting individuals, as these choices are mediated through institutional frameworks for making collective choices.

The literature on public choice has, of course, exploded since 1967, with entrées to this literature provided by such compendia as Mueller (1997), Rowley and Schneider (2004), and Shughart and Razzolini (2001). A good deal of that literature has carried forward the effort of Buchanan and his Italian forebears to articulate the impact of political institutions on collective outcomes.

**From Wicksell to constitutional political economy**

Where public choice examines the impact of political and fiscal institutions on collective outcomes, constitutional political economy examines the impact of constitutional rules on post-constitutional outcomes. The seminal statement of constitutional political economy is the *Calculus of Consent* (co-authored with Gordon Tullock), which the authors described as simply an elaboration with economic logic of the American constitutional framework of 1789. According to that framework, government is established by the consent of the governed, which provides unanimity as the conceptual starting point, just as it did for Wicksell (Wagner, 1988, explores the relationship between Wicksell and the *Calculus of Consent*). While unanimity is the conceptual starting point, any effort actually to implement unanimity will confront free riders and strategic hold-outs. If everyone's consent is required to undertake collective action, some people will be tempted to withhold their consent, not because they object to the action but because they are acting strategically to shift the fiscal terms of the action in their favour. Such strategic efforts at securing distributional gain can sabotage projects that are genuinely beneficial to all. Consequently, people may reasonably agree to be bound by something less than unanimous consent.

Buchanan and Tullock conceptualized a trade-off between decision costs and external costs, as these are viewed from the perspective of participants in collective choice. Decision costs are the costs people bear in trying to reach a collective decision. The greater the degree of consent required, the higher will be those costs due to such things as free riding and strategic bargaining. External costs are the costs that individuals bear when collective choices run contrary to their desires. These costs will fall with increases in the degree of consent required to take to collective action, and will vanish when unanimity is required. An optimal voting rule, formally speaking, will result when the sum of those costs is minimized. With this analytical construction, Buchanan and Tullock provided a rationalization for Knut Wicksell's support for some super-majority rule within a parliamentary assembly, as illustrated by references to three-quarters and four-fifths consent.

A voting rule is a simple scalar. Actual constitutional frameworks for collective choice contain a vector of characteristics, and to some extent those other characteristics can substitute for greater inclusivity in the degree of consent required. For instance, a representative assembly that is bicameral can achieve a greater degree of consensus with a less inclusive voting rule than would be possible within a unicameral assembly. Legislative action, moreover, can be filtered in various fashions through different
parliamentary rules. There are many margins along which political and fiscal institutions can be modified, and with post-constitutional politics adapting to whatever constitutional framework is in place. There are two levels of analysis in Buchanan's analytical schema: constitutional and post-constitutional. Post-constitutional politics, public choice, represents the working out of interactions among political participants within the context of some particular institutional arrangement. Constitutional politics concerns the selection among possible institutional arrangements. Buchanan's distinction between constitutional and post-constitutional politics calls forth the distinction between choosing the rules of a game and choosing strategies by which to play a game. For Buchanan, reform is a constitutional and not a post-constitutional matter.

Consider, for instance, his approach to progressive income taxation. Where the Anglo-Saxon sacrifice theorists sought to specify the degree of progressivity that some exogenous authority should impose on a society, Buchanan sought to probe the circumstances under which people might choose to employ progressivity in taxing themselves. In several places, he explores the conditions under which people might support progressive income taxation as a form of income insurance. Progressive taxation, as compared with proportional taxation, allows people to achieve some smoothing of consumption in the presence of fluctuating income. The purchase of insurance, after all, is a constitutional and not a post-constitutional activity: people purchase insurance before they have had accidents and not after. To the extent that such formulations have merit, what appears to be redistribution when seen from an ex post perspective might represent mutual gains from trade when viewed from an ex ante, constitutional perspective.

Alternatively, consider the treatment of broad-based taxation in Buchanan and Congleton (1998). Without a constitutional requirement of uniformity in taxation, post-constitutional politics will generate increasingly complex revenue systems as tax favours are granted or removed within the political marketplace. While the resulting narrowing of the tax base imposes excess burdens on market participants, it also warps processes of collective choice. For instance, those who are favoured by the resulting fiscal discrimination will support more collective activity than they would otherwise. With the continual churning of the tax code that results, however, most participants may end up worse off than they would have been under a simple system of tax uniformity.

**Buchanan's legacy**

Until the late 1930s there was a flourishing Continental orientation towards public finance that stood in contrast to the Anglo-Saxon orientation, and pretty much along the lines articulated by Buchanan in *Public Finance in Democratic Process* (this thesis is elaborated in Backhaus and Wagner, 2005). Within this orientation, public finance was a multidisciplinary field of study, with a home in economics but with tentacles that reached out into such fields as politics, law, and public administration. Buchanan has carried forward the Continental approach to public finance, and has given it new life through his many creative works.

budget deficits

William G. Gale
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article describes alternative measures of the federal budget deficit, discusses traditional and non-traditional channels through which deficits can affect the economy, and summarizes research on the effects of deficits on national saving and interest rates.

Keywords

aggregate consumption; budget deficits; consumption function; crowding out; Euler equations; financial market expectations; fiscal policy; generational accounting; interest rates; labour supply; national income; national saving; public debt; Ricardian equivalence theorem; Ricardo, D.; small open economy view

Article

Federal budget deficits reflect the extent to which current federal spending policies are not being financed with current federal tax policies, and can have significant effects on national saving and interest rates. Economists have explored the effects of budget deficits extensively, and analysis of the aggregate effects of fiscal policy dates back at least to the work of David Ricardo. Modern academic interest was reinvigorated by the work of Barro (1974) and others, and by the large US federal budget deficits in the 1980s and early 1990s. These factors led to a substantial amount of research that is summarized in several excellent surveys (Barro, 1989; Barth et al., 1991; Bernheim, 1987; 1989; Elmendorf and Mankiw, 1999; Seater, 1993). The rapid but short-lived transition to unified budget surpluses in the late 1990s, followed by the sharp reversal in budget outcomes since 2000, has raised interest in this question again.

The budget deficit can be defined in many different ways, and the most appropriate measure is likely to depend on the particular model or application of interest. For any measure of the deficit, which is a flow...
During a given time period, there is an analogous measure of the public debt, which is a stock at a given point in time and which represents the net accumulation of the associated deficits over all previous time periods.

The most widely used measure of the US federal deficit – the unified budget balance – is fundamentally (but not exactly) a cash-flow metric that includes both the Social Security and non-Social Security components of the federal budget. In a first approximation, the unified deficit shows the extent to which the government borrows or lends in credit markets. For some purposes, it is more informative to examine the primary budget, which excludes interest payments on the public debt (that is, it is equal to the unified budget balance minus net interest payments). The standardized budget balance adjusts the unified budget for the business cycle and special items. All these measures share a basic focus on cash flow.

Broader measures of the budget deficit look beyond cash flow and take into account the implicit or explicit promises embedded in current government policies, even if such promises do not result in current-period cash flow. Generational accounting, for example, aims to tally the net debt that each generation or birth cohort faces (see Auerbach, Gokhale, and Kotlikoff, 1991 for discussion of generational accounting and Auerbach et al., 2003 for discussion of alternative measures of the deficit). However, it is unclear how the market and households value implicit debts relative to the government's explicit debt. Thus, while the importance of the broader measures is clear conceptually, this article focuses mostly on the cash-flow related measures of the deficit.

In the fiscal year 2005, the unified US federal deficit was about 2.6 per cent of the GDP, and the standardized deficit was about 1.8 per cent (Congressional Budget Office, 2006). The current budget situation would largely not be a concern if future fiscal prospects were auspicious. Unfortunately, the longer-term budget outlook is dismal, primarily because of projected rising expenditures on health care and programmes for the elderly (Congressional Budget Office, 2005).

**Economic effects of budget deficits: traditional channels**

Economists tend to view the aggregate effects of tax cuts from one of three perspectives. To sharpen the distinctions, consider deficits induced by changes in the timing of lump-sum taxes, with the path of government purchases and marginal tax rates held constant. Under the Ricardian equivalence hypothesis, such deficits are fully offset by increases in private saving and have no effect on national saving, interest rates, exchange rates, future domestic production, or future national income. A second model, the small open economy view, suggests that budget deficits reduce national saving, but induce increased international capital inflows that finance the entire reduction in national saving. As a result, domestic production does not decline and interest rates do not rise, but future national income falls because of the burden of repaying the increased borrowing from abroad. A third model, which we call the conventional view, suggests that deficits reduce national saving and that the reduction in national saving is at least partly reflected in lower domestic investment. In this model, budget deficits partly crowd out private investment and partly increase borrowing from abroad; the combined effect reduces future national income and future domestic production. The reduction in domestic investment in this model is facilitated by an increase in interest rates, establishing a connection between deficits and interest rates.
It is worth emphasizing that the relationship between deficits and national saving is central to analysis of the economic effects of fiscal policy. National saving, which is the sum of private and government saving, finances national investment, which is the sum of domestic investment and net foreign investment. Higher national saving raises the capital stock owned by the nation's citizens and thus raises future national income. An increase in the budget deficit reduces national saving unless it is fully offset by an increase in private saving. If national saving falls, national investment and future national income must fall as well, if all else remains equal. Therefore, to the extent that budget deficits reduce national saving, they reduce future national income. This reduction in future national income occurs even if there is no increase in domestic interest rates. In the case where there is no rise in domestic interest rates, the reduction in national saving associated with budget deficits would manifest itself solely in increased borrowing from abroad (as under the small open economy view). This is the sense in which the effect of deficits on interest rates and exchange rates (the distinction between the small open economy view and the conventional one) is subsidiary to the question of the effects on national saving (the Ricardian view versus the other two).

A key consideration is that the results above consider only the effects of increased budget deficits or debt per se. A full analysis of the effects of public policies on economic growth should take into account not only the effects of increased deficits and debt but also the direct effects of the spending programmes or tax reductions that cause them. The effects of fiscal policies on both economic performance and interest rates depend not only on the deficit but also on the specific elements of the policies generating that deficit. For example, spending one dollar on public investment projects would increase the unified budget deficit by one dollar, but the net effect on future income would depend on whether the return on the public investment project exceeded the return on the private capital that would have instead been financed by the national saving crowded out by the deficit. Similarly, a deficit of one per cent of GDP caused by reducing marginal tax rates will generally have different implications for both national income and interest rates from a deficit of one per cent of GDP caused by increasing government purchases of goods and services.

**Economic effects of budget deficits: non-traditional channels**

Beyond their direct effect on national saving, future national income and interest rates, deficits can affect the economy in other ways. For example, increased deficits may cause investors gradually to lose confidence in national economic stability and leadership. As Truman (2001) emphasizes, a substantial fiscal deterioration over the longer term may cause ‘a loss of confidence in the orientation of US economic policies’. Such a loss in confidence could then put upward pressure on domestic interest rates, as investors demand a higher risk premium on dollar-denominated assets. The costs of current account deficits – which are in part induced by large budget deficits – may even extend beyond narrow economic ones. More broadly, Friedman (1988, p, 76) notes that ‘World power and influence have historically accrued to creditor countries. It is not coincidental that America emerged as a world power simultaneously with our transition from a debtor nation … to a creditor supplying investment capital to the rest of the world.’

Both the traditional models and the non-traditional effects noted above focus on gradual negative effects from reduced national saving. This focus may be too limited, however, in that it ignores the possibility
of much more sudden and severe adverse consequences. In particular, the traditional analysis of budget deficits in advanced economies does not seriously entertain the possibility of explicit default or implicit default through high inflation. If market expectations regarding the probability of default were to change and investors had difficulty seeing how the policy process could avoid extreme steps, the consequences could be much more sudden and severe than traditional estimates suggest. The role of financial market expectations in this type of scenario is central. One of the key triggers would occur if investors begin to doubt whether the strong historical commitment to avoiding substantial inflation would be weakened in order to reduce the real value of the public debt (Ball and Mankiw, 1995; Rubin, Orszag and Sinai, 2004).

Although this article does not explicitly incorporate non-traditional effects into the discussion below, such effects serve as an important reminder of why budget deficits, especially chronic deficits, could exert large adverse effects on US economic performance. The focus on traditional effects is certainly justifiable in the context of historical analysis of post-war data from the United States. That does not imply, however, that to ignore such issues is appropriate when examining the likely impacts of future deficits. The nation has never before faced substantial deficits that are projected to be sustained and indeed to grow over many decades.

**Deficits and consumption**

Testing the effect of deficits on aggregate consumption, with government spending held constant, is an important focus of analysis for several reasons. First, these analyses provide a direct test of whether the timing of tax collections affects the economy, with other factors controlled for. Second, the aggregate time series tests measure the magnitude of the effects in question. This is particularly important because virtually no one claims that Ricardian equivalence is literally true. Rather, the controversy is over the extent to which Ricardian equivalence is a good approximation of the aggregate impact of fiscal policies. There is a wide variety of research findings from studies of aggregate consumption and fiscal policy, in part because of a variety of difficult econometric issues. Barro (1989) and Elmendorf and Mankiw (1999) conclude that the literature is inconclusive. Seater (1993) concludes that, once the studies are corrected for econometric problems, Ricardian equivalence is corroborated – or at least that it is not possible to reject Ricardian equivalence. Bernheim (1989) concludes that, once the studies are normalized appropriately, Ricardian equivalence should be rejected.

One strand of the literature specifies consumption functions and then tests for the effects of fiscal policy. Perhaps the best-known study in this area is Kormendi (1983), who finds no evidence of non-Ricardian effects. This work has spawned significant research, including three sets of exchanges in the *American Economic Review*. Recent research, however, has extended the Kormendi results in three ways: using more recent data, which captures significant variation in budget outcomes; controlling for measures of marginal tax rates; and (in the United States) allowing federal and state fiscal variables to have different effects on consumption. The last issue is particularly relevant because the states collect a significant share of their revenue through consumption taxes, which would be expected to vary positively with consumption, whereas other taxes would be expected, at least in non-Ricardian theory, to vary negatively. With these extensions, the results suggest that about 30 to 46 cents of every dollar in federal tax cuts is spent in the same year (Gale and Orszag, 2004). This is a rejection of the Ricardian view.
Another strand of the literature focuses on Euler equation tests (relating to the growth rate of consumption, as opposed to the tests above, which examine consumption levels), with mixed results. As Bernheim (1987) points out, Ricardian equivalence can fail even if the Euler equation does not, and vice versa. Nevertheless, some studies have found substantial effects of fiscal policy on consumption using the Euler framework, most recently Gale and Orszag (2004), who find that about 50 to 85 cents of every dollar in tax cuts is spent in the first year, with most of the effects measured precisely. This range is consistent with some previous assessments, but it is inconsistent with the Ricardian prediction of a full offset from private saving.

**Deficits and interest rates**

The effects of fiscal policy on interest rates have also proven difficult to pin down statistically. The issues include the appropriate definition of deficits and debt, whether deficits or debt should be the variable of interest, the difficulty of distinguishing expected and unexpected changes, and the potential endogeneity of many of the key explanatory variables (see Bernheim, 1987; Elmendorf and Mankiw, 1999; Seater, 1993).

In part because of these statistical issues, the evidence from the empirical literature as a whole is mixed. However, the key role of expected deficits rather than current deficits is sometimes overlooked. As Feldstein (1986, p. 14) has written, ‘it is wrong to relate the rate of interest to the concurrent budget deficit without taking into account the anticipated future deficits. It is significant that almost none of the past empirical analyses of the effect of deficits on interest rates makes any attempt to include a measure of expected future deficits.’ Since financial markets are forward-looking, to exclude expectations could bias the analysis towards finding no relationship between interest rates and deficits. In fact, studies that incorporate more accurate information on expectations of future sustained deficits tend to find economically and statistically significant connections between anticipated deficits and current interest rates. Gale and Orszag (2004) show that, of the 19 papers incorporating timely information on projected deficits, 13 find predominantly positive, significant effects between anticipated deficits and current interest rates, five find mixed effects, and only one finds no effects. The other studies in the literature that find no significant effect are disproportionately those that do not take expectations into account at all or do so only indirectly through a vector autoregression. Thus, while the literature as a whole, taken at face value, generates mixed results, analyses that focus on the effects of anticipated deficits tend to find a positive and significant impact on interest rates.

The challenge in incorporating market expectations about future deficits is that such expectations are not directly observable. An important caveat to the whole literature, then, is that, to the extent that proxies for expected deficits are imperfect reflections of current expectations, the coefficient on the projected deficit will tend to be biased towards zero because of classical measurement error, and the studies would tend to underestimate the effects of deficits on interest rates.

Even among studies that use expected deficits, one potential concern is that the business cycle could be affecting current yields. Laubach (2003) suggests a novel way to resolve this issue: he examines the relationship between projected deficits (or debt) and the level of real forward (five-year ahead) long-term interest rates. The underlying notion is that current business cycle conditions should not influence the long-term rates expected to prevail beginning five years ahead. Laubach uses projections of the US
Congressional Budget Office and Office of Management and Budget, and finds that a one percentage point increase in the five-year-ahead projected deficit-to-GDP ratio raises the five-year-ahead ten-year interest rate by between 24 and 40 basis points, and that a one percentage point in the projected debt-to-GDP ratio raises the long-term forward rate by between 3.5 and 5.5 basis points. The deficit-based results are not dissimilar from the debt-based results. Consider, for example, an increase in the budget deficit equal to one per cent of GDP in each year over the next ten years. After ten years, that would raise government debt by roughly ten per cent of GDP. The deficit-based results in Laubach would suggest about a 30 basis point increase in interest rates, whereas the debt-based results would suggest about a 45 basis point increase.

Using a similar framework, Engen and Hubbard (2004) obtain somewhat smaller effects while Gale and Orszag (2004) obtain somewhat larger effects. Indeed, despite a rancorous public debate, there appears to be a surprising degree of convergence in recent estimates of the effects of fiscal policy on interest rates, with a variety of econometric studies implying that a sustained one per cent of GDP increase in unified deficits over ten years would raise interest rates by 30 to 60 basis points. The relationship between deficits and interest rates not only provides further evidence against the Ricardian view, but also implies that the conventional view is a better description of reality for the United States than the small open economy view. Ardagna, Caselli and Lane (2004) find even stronger results in a panel of 16 Organisation for Economic Co-operation and Development (OECD) countries over several decades.

Conclusion

Sustained federal budget deficits have two sets of effects. The direct effect of the increase in government borrowing is to reduce national saving and raise long-term interest rates, often by empirically sizable amounts. The other set of effects depends on the specific tax or spending policies that were chosen to create the deficits. These findings have significant implications. First, both the consumption and the interest rate results reject the Ricardian view of the world. Second, the interest rate results reject the small open economy view, at least as it applies to the US economy. Third, the results suggest that the sustained deficits facing the nation will impose significant economic costs. Fourth, some tax-cut policies that have traditionally been considered growth-enhancing may actually backfire, because the generally positive effect of the tax rate cut on labour supply and investment, if interest rates are held constant, can be offset by the impact of the deficit on interest rates and on national saving. While it would be wrong to conclude that all these issues are decisively resolved in the economics literature, there is more than strong enough evidence to raise concerns about sustained projected future deficits.

budget projections

Douglas Holtz-Eakin

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article surveys different approaches to the construction of government budget projections, illustrated with procedures from the United States Office of Management and Budget (OMB) and Congressional Budget Office (CBO). It sets out the several distinct steps that are required in budget projections, from macroeconomic forecasting to comparing projections with outcomes and analysing the sources of deviations.

Keywords

aggregate demand; budget projections; budget window; business cycles; forecasting; intertemporal incentives; scoring; uncertainty

Article

Budget projections are central to governmental policymaking. In general, budgeting is the practice of devoting economic resources to policy objectives and providing specific means for raising these resources. A typical budget process includes budget proposals, review, adoption, and execution. Budget projections inform the process by providing estimated values for government revenues, government spending, and other budgetary concepts over a specific planning horizon (often referred to as the ‘budget window’). Budgetary projections are made under specific assumptions, for differing government programmes, using alternative approaches as part of the budgetary process. We discuss each in turn, with examples drawn from the United States federal government.

Threshold assumptions for budget projections fall along two dimensions: economic and policy.

Economic assumptions

One approach to developing a budget projection is based on a comprehensive economic forecast,
budget projections: The New Palgrave Dictionary of Economics

inclusive of any possible future business cycle fluctuations. In this instance, the result is a projection of the potential future outlays, receipts, and budget deficit or surplus. In the United States, both the White House Office of Management and Budget (OMB) and the Congressional Budget Office (CBO) adopt a variant of this approach in which the near-term forecast incorporates the state of the business cycle, while projections beyond the first two years assume an average of full employment. Alternatively, it is sometimes assumed that the economy operates continuously at full resource utilization with no cyclical fluctuations. In this instance, the budget projections are often referred to as ‘cyclically adjusted’ or ‘full-employment’ projections of the budget and its balance.

Each approach serves distinct purposes. Budget projections are necessary, for example, to anticipate the cash-flow borrowing needs of the government on a year-by-year basis. In contrast, cyclically adjusted budget projections are useful for judging whether current deficits or surpluses are reflective of the state of the economy, and thus the degree to which fiscal policies are sustainable over the longer term.

Policy assumptions

The future path of the budget also depends on the evolution of tax and spending policies. In constructing the budget projection, one possible assumption is that current policies (or current laws) remain unchanged. Such a projection – known alternatively as a budget baseline projection or current services projection – provides a means by which to judge the future implications of current policies and a benchmark (or baseline) against which to measure the impact of policy changes.

Two issues arise in constructing and interpreting baseline budget projections. The first is the rules for anticipating any necessary future policy actions. For example, in the US federal budget a large fraction (roughly two-thirds in 2007) of spending results from ‘mandatory’ (or ‘direct’) spending programmes in which laws authorize automatic expenditures to eligible parties. Common examples are Social Security, Medicare, and farm support programmes. In these instances, projections of spending rely on combining rules of the programmes with projections of eligible populations and their relevant characteristics. An issue arises when the legal authorization for a programme expires during the projection period, requiring an assumption regarding whether spending will stop entirely or continue as if the current programme remains in place. (In the United States, ‘large’ programmes – spending in excess of $50 million – are assumed to continue.)

The remainder of spending (over one-third in 2007) is ‘discretionary’ and determined by the annual decisions of Congress. Consistent with the spirit of projecting current policy, baseline projections typically assume that this type of spending continues (in real, inflation-adjusted terms) exactly as in the most recently completed budget. An implication of this procedure is that baseline projections of discretionary spending may be heavily influenced by transitory policy events such as emergency spending.

These types of swings in projected spending are illustrative of the second key feature of baseline or current services projections. These projections are not forecasts of actual budget outcomes, but rather tools to inform the budgetary process.

A second approach is to embed in the budget projections a specific path for future policies, that is, to construct a policy-based budget projection. For example, the annual Presidential budget submitted to the US Congress is constructed under the assumption that all the proposed policies are adopted as requested. As with baseline budget projections, policy projections are not forecasts of actual budgetary outcomes.
Scoring

A topic closely related to budget projections is ‘scoring’ – the evaluation of the budgetary implications of policy proposals. Mechanically, scoring represents the difference between a policy-based projection and a baseline projection, thereby revealing the budgetary difference as a result of the specific policies. Scoring budgetary proposals permits comparisons of alternative proposals on a consistent basis. Traditionally, scores have been constructed under the assumption that overall macroeconomic performance is unchanged by the policy proposal (‘static scoring’). There are some proposals, however, of sufficient magnitude and impact on incentives (for example, tax reform) that it would be desirable to incorporate not only the direct budgetary impacts but also the budgetary feedbacks from changes in the overall levels of economic output and incomes (‘dynamic scoring’). Incorporating economic impacts, however, raises issues in maintaining consistency in scoring across proposals and details of executing the analysis (see Congressional Budget Office, 2002; Joint Committee on Taxation, 2006).

Steps for budgetary projections

Official governmental budget projections from, for example, the OMB and the CBO, are sophisticated, detailed exercises that require several distinct steps.

1. *Project macroeconomic performance*. The budget projection is built upon a macroeconomic forecast, including the path for real and nominal gross domestic product (GDP), the future rates of unemployment, the path for prices and inflation, and the path of future interest rates and exchange rates. As part of anticipating the near-term position in the business cycle, it is necessary to forecast the components of aggregate demand – consumption, residential and business investment, government spending, and net exports – as well as the determinants of the potential for overall output, such as capital stocks, labour force, and technological progress. Because of the importance of tax revenues to the budgetary projections, the projection of national income is more important than in other settings, imposing the requirement for projecting labour compensation, taxable versus non-taxable compensation, corporate profits, dividends, interest payments, and non-corporate business income.

2. *Impute a distribution to macroeconomic aggregates*. In the United States, personal income tax is progressive and heavily skewed towards the upper part of the income distribution (with the top one-half of households paying nearly all the income tax). Accordingly, the distribution of wage and salary earnings (as well as other components of household income) among households has a large impact on the overall level of tax receipts. In these circumstances, the macroeconomic forecast must be combined with microeconomic data drawn from tax returns and population surveys to provide accurate projections.

3. *Impose programme rules on the macroeconomic and microeconomic data to project spending and revenues*. For example, the projections for population, labour force, and the unemployment rate yield forecasts of the number of unemployed individuals. When combined with unemployment insurance programme rules, the unemployment forecast yields a projection of outlays for the unemployment insurance programme. Similarly, the projection of wage income, dividend payments, interest payments, and capital gains, along with distributional information on each, may be combined with parameters of the tax code to produce projections of individual income tax receipts.

An important aspect of this step is the sophistication of incorporating responses to incentives in the
projections. For example, if current law indicates that tax rates will rise in the next several years, it is likely that intertemporal incentives may shift forward some economic activity (for example, labour supply) and some tax-based planning behaviours (for example, realization of capital gains to obtain lower tax rates). It is desirable to incorporate these responses in the projection.

4. **Check for internal consistency.** In some circumstances, budget projections involve an element of simultaneity. For example, fiscal projections (spending and taxes) are necessary to forecast near-term aggregate demand, while actual outlays and tax receipts depend upon the employment and incomes generated by economic activity. Accordingly, it is desirable to check whether the budget totals are consistent with the economic projection.

5. **Compare projections with actual outcomes to improve projections.** The accuracy of budget projections is an obvious concern. Hence it is desirable to do a comparison of actual outcomes with past projections to identify systematic sources of error and opportunities for improvement. In addition, a second desirable attribute of projections is their credibility, which is aided by a transparent process for revealing differences between actual and projected outcomes, and a systematic analysis of the sources of deviation.

### Uncertainty and valuation in budget projections

#### Uncertainty

Budgetary projections are fraught with uncertainty. At the most basic level, the future is literally unknowable, and budgetary projections will be affected by the future course of macroeconomic fluctuations, variations in inflation, the path of interest rates, and so forth. The degree to which projections are uncertain is important information to policymakers. One approach to revealing the scale of uncertainty is to undertake the budget projections in a series of scenarios (for example, ‘base case’, ‘faster growth and higher inflation’, and ‘slower growth and lower inflation’). The difficulty then becomes choosing scenarios that are representative of the likely fluctuations to be experienced.

A more complete and formal approach is to conduct the entire projection in the context of a stochastic simulation methodology. In this approach, historical joint distributions are constructed for the key inputs to the projection (GDP growth, inflation, interest rates, wages, and so forth). Undertaking a large number of projections, each based on a ‘draw’ from the joint distribution, permits policymakers to be presented with the full distribution of potential outcomes over the budget horizon.

A second type of uncertainty is important for individual programmes. In some cases, government budget flows are contingent upon uncertain outcomes. A prominent example is agriculture programmes that provide funds only in the event of poor harvests due to drought or other adverse events. How should budget projections be constructed for such programmes? Choosing a single scenario will probably yield a projection in which the programmes either have a budget impact every year or in no year – neither of which is a sensible projection. A simple solution is to use the average (perhaps over a historical period) as the projected value of the budget impact of the programme, with the logic being that the projection is never precisely correct, but on average informative. As above, however, an alternative is to undertake formal stochastic simulations of the programme in question and use the expected value of the programme as the budget projection.
Valuation

The practice of budgetary projections (and scoring) raises issues in the correct valuation of budgetary transactions. In the main, the goal is to value government purchases using market prices (and thereby adhering as closely as possible to private-sector measure of marginal cost and marginal benefit). Similarly, tax collections and transfers to individuals and governments are measured in dollar values. However, difficulties can arise in the consistent application of these principles. A notable example is the provision of insurance and insurance-like programmes by the government. Adhering to the principles of taxes and transfers, the projections of these programmes consist of the future tax receipts by the government and payments to individuals. Put differently, the budget projection consists of the future cash flows, perhaps summarized in an expected value form. Note, however, that this budgetary treatment may complicate comparisons with an equivalent programme – the direct purchase of an equivalent private-sector insurance product, where the private-sector entity will charge a risk premium.

Article

Karl Bücher was born in Kirberg (Germany) into a poor family. He studied history and classical philology in Bonn and Göttingen. Bücher first worked as a journalist for the liberal Frankfurter Zeitung, and from 1881 taught political economy in Dorpat, Basle, Karlsruhe and Leipzig, where he retired in 1917.

Bücher is counted among the outstanding economists of the German ‘younger’ historical school. He remained, however, independent in his economic thinking. He did not adhere to the inductive method and in the Methodenstreit he sided with Menger against Schmoller. Although he advocated the adoption of social policy measures by the state, he confessed to being a liberal and did not follow the protectionist and state interventionist line of the ‘Kathedersozialisten’ (socialists of the chair). An important contribution to economics was Bücher’s ‘law of mass production’, which described the relationship between production costs and output in industrial manufacturing. Moreover, Bücher carefully analysed the organization of the labour process and the division of labour (1893, pp. 261–334). His study on the importance of rhythm for the working process in pre-industrial societies is extremely interesting and may be regarded as his most original work (1896). He described how workers transformed monotonous physical labour through the adoption of rhythmic repetitions of their movements. By adjusting the work speed to this rhythm, the working process was both eased and intensified. Such a rhythm could be generated, for example, by singing. Bücher gave vivid examples of typical work songs and particularly described the role played by work songs in combining large masses of workers to carry out large-scale works. However, a precondition for all this was the worker controlling his individual work speed and dominating his working instruments. The fact that in modern industry this was no more the case led Bücher to interesting reflections on man and work in our industrial environment (1896, pp. 112–117).

Bücher's historical research focused on primitive people, antiquity and the Middle Ages. His analysis of
primitive people (1893, pp. 1–82; 1918, pp. 1–26) was too generalized and did not grasp fully the extreme complexity of economic relations among these peoples. However, in his elaborate research on the distinction between exchange and gift he anticipated some of the problems which modern ethnology would later discuss. His studies on the economies of ancient Rome and Greece were important because they contributed to the refutation of authors who described these economies as simply capitalistic. Among his contributions on the Middle Ages were studies on the social situation of women and journeymen, and a demographic study on medieval Frankfurt, where Bücher applied statistical methods (1886; 1922).

Bücher developed a theory of stages of economic development (1893, esp. pp. 83–160), where he distinguished between the household economy (Hauswirtschaft) of classical antiquity (in accordance with J.K. Rodbertus’ notion of the oikos economy), the town economy (Stadtwirtschaft) of the Middle Ages, and the national economy (Volkswirtschaft), that is, the extensive exchange economy of modern times. The role of exchange served as the central distinctive criterion: exchange was supposed to be virtually absent in the household economy, which is the reason why the characterization of antiquity (where trade had been more important than Bücher thought) as a household economy was inaccurate. Exchange was confined to locally produced commodities and local markets in the medieval town economy, and dominating every sphere of economic life in the ‘national economy’.

Bücher may also be regarded as one of the founders of journalism as an academic discipline. He especially focused on the role of the press for public opinion and the problems raised by the capitalist and profit-oriented structure of the press.

Bukharin, Nikolai Ivanovitch (1888–1938)

Donald J. Harris

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Austrian economics; Bukharin, N. I.; capitalism; falling rate of profit; imperialism; Lenin, V. I.; Luxemburg, R.; marginal revolution; Marx, K. H.; monopoly; period of production; planning; socialism; underdevelopment; uneven development

Article

Nikolai Bukharin is commonly acknowledged to have been one of the most brilliant theoreticians in the Bolshevik movement and an outstanding figure in the history of Marxism. Born in Russia, he studied economics at Moscow University and (during four years of exile in Europe and America) at the Universities of Vienna and Lausanne (Switzerland), in Sweden and Norway and in the New York Public Library. While still a student, he joined the Bolshevik movement. Upon returning to Russia in April 1917, he worked closely with Lenin and participated in planning and carrying out the October Revolution. After the victory of the Bolsheviks he proceeded to assume many high offices in the Party (becoming a member of the Politbureau in 1919) and in other important organizations. In these various capacities he came to exercise great influence within both the Party and the Comintern. Under Stalin's regime, however, he lost most of his important positions. Eventually, he was among those who were arrested and brought to trial under charges of treason and was executed on 15 March 1938.

At the peak of his career Bukharin was regarded as the foremost authority on Marxism in the Party. He was a prolific writer: there are more than five hundred items of published work in his name, most of them written in the hectic 12-year period 1916–1928 (for a comprehensive bibliography, see Heitman, 1969). Only a few of these works have been translated into English and these are the works for which he is now most widely known. A brief description of the major items gives an indication of the scope and range of his intellectual interests.

*The Economic Theory of the Leisure Class* (1917) is a detailed and comprehensive critique of the ideas of the Austrian school of economic theory, as represented by the work of its chief spokesman Eugen von Böhm-Bawerk, but situated in the broader context of marginal theory as it had appeared up to that time. In *Imperialism and World Economy* (1918) he formulated a revision of Marx's theory of capitalist

devision and set out his own theory of imperialism as an advanced stage of capitalism. This was
written in 1914–15, a year before Lenin's *Imperialism*, and is credited with having been a major
influence on Lenin's formulation. The theoretical structure of the argument is further elaborated in
*Imperialism and the Accumulation of Capital* (1924) by way of a critique of the ideas of Rosa
Luxemburg, another leading Marxist writer of that time. *The ABC of Communism* (1919), written jointly
with Evgenii Preobrazhensky and used as a standard textbook in the 1920s, is a comprehensive
restatement of the principles of Marxism as applied to analysis of the development of capitalism, the
conditions for revolution, and the nature of the tasks of building socialism in the specific context of the
Soviet experience. This book, taken with his *Economics of the Transition Period* (1920), constitutes a
contribution to both the Marxist theory of capitalist breakdown and world revolution on the one hand
and the theory of socialist construction on the other. *Historical Materialism: A System of Sociology*
(1921), another popular textbook, combines a special interpretation of the philosophical basis of
Marxism with what is perhaps the first systematic theoretical statement of Marxism as a system of
sociological analysis. In style much of this work is highly polemical and geared to immediate political
goals. But it reveals also a versatility of intellect, serious theoretical concern, and scholarly inclination.
Arguably, his works represent in their entirety ‘a comprehensive reformulation of the classical Marxian
theory of proletarian revolution’ (Heitman, 1962, p. 79). Viewed from the standpoint of their
significance in terms of economic analysis, three major components stand out.

There is, first, the critique of ‘bourgeois economic theory’ in its Austrian version. Bukharin's approach
follows that which Marx had adopted in *Theories of Surplus Value*, which is to give an ‘exhaustive
criticism’ not only of the methodology and internal logic of the theory but also of the sociological and
class basis which it reflects. He scores familiar points against particular elements of the theory, for
instance, that utility is not measurable, that Böhm-Bawerk's concept of an ‘average period of production’
is ‘nonsensical’, that the theory is static. Such criticisms of the technical apparatus of the theory have
since been developed in more refined and sophisticated form (see Harris, 1978; 1981; Dobb, 1969).
Moreover, certain weaknesses in Bukharin's presentation, such as an apparent confusion between
marginal and total utility and misconception of the meaning of interdependent markets, can now be
readily recognized. But these are matters that were not well understood at the time, even by exponents of
the theory. Bukharin views them as matters of lesser importance. What is crucial for him is ‘the point of
departure of the … theory, its ignoring the social-historical character of economic phenomena’ (1917, p.
73). This criticism is applied with particular force to the treatment of the problem of capital, the nature
of consumer demand, and the process of economic evolution. As to the sociological criticism, his central
thesis is that the theory is the ideological expression of the rentier class eliminated from the process of
production and interested solely in disposing of their income through consumption. This thesis can be
faulted for giving too mechanical and simplistic an interpretation of the relation between economic
theory and ideology where a dialectical interpretation is called for (compare, for instance, Dobb, 1973,
ch. 1, and Meek, 1967). But the issue of the social-ideological roots of the marginal revolution remains a
problematic one, as yet unresolved, with direct relevance to current interest in the nature of scientific
revolutions in the social sciences (see Kuhn, 1970; Latsis, 1976).

Secondly, Bukharin's work clearly articulates a conception of the development of capitalism as a world
system to a more advanced stage than that of industrial capitalism which Marx had earlier analysed. This
new stage is characterized by the rise of monopoly or ‘state trusts’ within advanced capitalist states,
intensified international competition among different national monopolies leading to a quest for economic, political and military control over ‘spheres of influence’, and breaking out into destructive wars between states. These conditions are seen as inevitable results deriving from inherent tendencies in the capitalist accumulation process, at the heart of which is a supposed falling tendency in the overall average rate of profit. Altogether they are viewed as an expression of the anarchic and contradictory character of capitalism. The formation of monopolies is supposed to take place through reorganization of production by finance capitalists as a way of finding new sources of profitable investment and of exercising centralized regulation and control of the national economy. This transformation succeeds for a time at the national level but only to raise the contradictions to the level of the world economy where they can be resolved only through revolutions breaking out at different ‘weak links’ of the world-capitalist system. The idea of a necessary long-term decline in the rate of profit, and also the specific role assigned to financial enterprises as such, can be disputed. A crucial ingredient of the argument is the idea of oligopolistic rivalry and international mobility of capital as essential factors governing international relations. In this respect the argument anticipates ideas that are only now being recognized and absorbed into the orthodox theory of international trade and which, in his own time, were conspicuously neglected within the entire corpus of existing economic theory. Much of the analysis as regards a necessary tendency to uneven development between an advanced centre and underdeveloped periphery of the world economy has also been absorbed into contemporary theories of underdevelopment. Underpinning the whole argument is a curious theory of ‘social equilibrium’ and of ‘crisis’ originating from a loss of equilibrium. ‘To find the law of this equilibrium’, he suggests (1920, p. 149), ‘is the basic problem of theoretical economics and theoretical economics as a scientific system is the result of an examination of the entire capitalist system in its state of equilibrium’.

The third component is a comprehensive conception of the process of socialist construction in a backward country. These ideas came out of the practical concerns and rich intellectual ferment associated with the early period of Soviet development but have a generality and relevance extending down to current debates both in the development literature and on problems of socialist planning. The overall framework is one that conceives of socialist development as a long-drawn-out process ‘embracing a whole enormous epoch’ and going through four revolutionary phases: ideological, political, economic and technical. The process is seen as occurring in the context of a kind of war economy involving highly centralized state control, though there is an optimistic prediction of an ultimate ‘dying off of the state power’. Room is allowed for preserving and maintaining small-scale private enterprise. The agricultural sector is seen as posing special problems, due to the assumed character of peasant production, which can only be overcome through transformation by stages to collectivized large-scale production. Even so, it is firmly held (in 1919) that ‘for a long time to come small-scale peasant farming will be the predominant form of Russian agriculture’, a view which Bukharin later abandoned in support of Stalin's collectivization drive. In industry, too, small-scale industry, handicraft, and home industry are to be supported, so that the all-round strategy is one that seems quite similar to that of ‘walking on two legs’ later propounded by Mao for China. An extensive discussion is presented of almost every detail of the economic programme, from technology to public health, but little or no attention is given to issues of incentives and organizational problems of centralization/decentralization which have emerged as crucial considerations in later work. Cohen (1973) remains a classic biography; his widow's memoirs, Larina (1993) are also of interest.

bullionist controversies (empirical evidence)

Lawrence H. Officer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

There are three historical episodes in which bullionist–anti-bullionist macroeconomic debates occurred: Sweden (1745–76), England (1797–1821), and Ireland (1797–1821). Expressing the bullionist and anti-bullionist models as chains of causation facilitates presentation of empirical studies of the experiences. As a group, the studies suggest that the anti-bullionist position is more supported by the empirical evidence.

Article

The bullionist periods of Sweden, England, and Ireland involved bullionist–anti-bullionist macroeconomic debates, with empirical studies vindicating largely the anti-bullionist side.

History of bullionist periods

The bullionist controversy is a debate that can occur in monetary history when a paper currency and floating exchange rate interrupt a metallic standard. The three famous bullionist periods pertain to Sweden, England and Ireland. In 1745, the Riksbank made its notes inconvertible into copper bullion, resulting in the paper daler. It was not until 1776 that the Swedish bullionist period ended, with conversion to a new currency unit (the riksdaler) on a silver standard. The English, followed by the Irish, bullionist period began in 1797, each by government order requiring the Bank of England and Bank of Ireland to cease making gold payments for its notes. Legislation, periodically renewed, solidified the orders. In 1821 the Bank of England, followed by the Bank of Ireland, resumed payment in gold, and the countries were back on a gold standard. The English episode is called the ‘Bank Restriction Period’.

The three bullionist periods involved common elements: a prior metallic standard replaced by a paper standard, a fixed exchange rate (constrained within a band around an effective mint parity) giving way to a floating rate, unusually high inflation, depreciation of the currency in the foreign-exchange and bullion markets, a sub-period of deflation, and eventual return to a specie standard and fixed exchange rate. Also, periods of war occurred both before and during the bullionist periods. Some characteristics were shared by only two of the periods. First, the proximate cause of the Swedish and English Restrictions was a tremendous loss of reserves on the part of the Riksbank and Bank of England. This was not the case for the Bank of Ireland; British pressure induced the Irish government to suspend convertibility of Bank of Ireland notes. Second, for Sweden and England, their main trading partners remained on a metallic standard. This was not so for Ireland, with England also on paper. Third, England and Ireland returned to a gold standard at the old parity; Sweden switched from an effective copper to an effective silver standard, and banknotes were depreciated by 50 per cent in terms of silver.
Two additional features characterize all three periods. First, the macroeconomic debate centred on determination of the exchange rate and price level, and their relationship to the balance of payments and note issues of the central bank. The bullionists adopted a monetarist approach, and the anti-bullionists a non-monetarist position. Second, Parliament played a key role in the controversy. In the case of Sweden, two political parties vied for control of Parliament. The ‘Caps’ had a bullionist agenda, and the ‘Hats’ an anti-bullionist policy. Both had intellectual supporters on the outside. The British House of Commons appointed committees, in 1804 and 1810, to investigate the depreciated Irish and English currencies. Each committee produced a highly bullionist report, important in the literature; but in neither case was the report favourably received by Parliament.

Bullionist, anti-bullionist, and country-bank models

To examine the empirical literature on the bullionist controversies, each side is represented by its mainstream model of chains of causality, sequential hypotheses. Notation is $X \rightarrow Y$ (‘$X$ causes $Y$, with $\partial Y / \partial X > 0$’). Multiple hypotheses are $W, X \rightarrow Y$ (‘$W \rightarrow Y$ and $X \rightarrow Y$’) and $X \rightarrow Y, Z$ (‘$X \rightarrow Y$ and $X \rightarrow Z$’). The subscript $f$ designates a foreign variable. Variables are:

- BN: central-bank notes in circulation
- BP: balance-of-payments deficit
- CN: country banknotes in circulation
- ER: exchange rate, price of foreign currency
- FR: remittances to foreign countries
- HQ: quantity and quality of harvest
- MS: money supply (M1)
- PG: price of gold
- PL: price level
- PM: price of imports
- PW: price of wheat
- TR: foreign trade restrictions

The bullionist model is decidedly monetarist: only monetary variables affect only monetary variables. The English-bullionist chain of causation is: $BN \rightarrow MS \rightarrow PL \rightarrow ER, PG$.

$BN \rightarrow MS$ reflects the bullionist, and correct, perception that Bank of England notes constituted the monetary base during the Restriction Period. There was a hierarchy of banks: the Bank of England (central bank), London private banks, and country banks. Bank of England notes (held as reserves by the country banks and London private banks) were non-redeemable; deposits at the Bank (held as reserves only by the London private banks) were cashable only in Bank of England notes. The country banks – but not the London private banks – issued notes. There were no legal reserve requirements for any bank; but, like all companies, banks had to settle their debts (note and deposit liabilities) in cash. Reserves of the country banks were principally deposits at the London private banks, with Bank of England notes (and, in principle, gold) for vault cash. Bank of England notes circulated in and around London, as well as in Lancashire and Norwich; country banknotes circulated elsewhere in England and Wales. During the Bank Restriction Period, the English country banks and Scottish banks ‘redeemed’ their notes in Bank of England notes rather than gold. This was a matter of practice rather than law.

Strictly speaking, gold coin was a component of the monetary base, but the premium on gold bullion did not have a counterpart in the premium of gold coin over Bank of England notes. There was no legal market for domestic coin in terms of paper money, and an overwhelming proportion of the gold coin nominally in circulation or newly minted was in fact hoarded or exported.

For the bullionists (and anti-bullionists), the money supply had as components Bank of England notes, country banknotes, and coin. In excluding deposits from M1, the writers of the Restriction Period were not far off the mark. First, except in London, ‘deposits’ generally meant time or savings deposits rather than demand deposits. Second, if interbank transactions are excluded, demand deposits typically were exchanged for cash rather than transferred to another account.

$BN \rightarrow MS$ was also asserted by the Irish bullionists, even though the banking system was looser. In and around Dublin, notes of the Dublin private banks circulated along with notes of the Bank of Ireland. Gold did not circulate, except in the north until 1808-9, when it was replaced by the notes of newly established Belfast banks. Elsewhere, local private banknotes generally dominated, but in competition with Bank of Ireland notes and, to a lesser extent, Dublin private-bankers’ notes. The private banks kept their reserves in Bank of Ireland notes (and gold), and by convention their notes were redeemed in Bank of Ireland notes.

In the Swedish bullionist period, $BN=MS$. With little coin circulating, no commercial banks in existence, and deposits at the Riksbank representing merely the right to make withdrawals in notes, Riksbank notes essentially equalled the money supply.

$MS \rightarrow PL$ pertains to the quantity theory of money. Underlying this theory is the bullionist view that the Bank of England effectively pegged the market interest rate at five per cent, by
standing ready to discount all ‘good’ commercial bills at that rate. Thus the monetary base is perfectly elastic at the constant discount rate of five per cent, a powerful impetus to the quantity theory.

There is good reason for this view: the usury laws set a five per cent limit on annual interest on bills of exchange, and the discount rate of the Bank of England was fixed at this rate. While bill brokers could charge a commission and private banks could require a minimum balance, the Bank did not use such devices. The market discount rate (for good bills) did not exceed five per cent during the Restriction. In fact, only for about a year (beginning July 1817) did the market rate even fall below five per cent. The situation was yet stronger regarding the Bank of Ireland. Its discount rate was limited to five per cent by charter.

However, the English and Irish bullionists were wrong in inferring that the monetary base (essentially BN) could rise without limit. First, there is evidence that in historical fact the monetary base was not perfectly elastic. Only ‘good’ bills—a minority of bills—were acceptable by the Banks. Also, the Bank of England effectively regulated discounts via a rationing system. These facts act against the quantity theory but support the concept of BN as an autonomous policy variable. Second, even if the supply of the monetary base (essentially BN) is perfectly elastic at the pegged market interest rate, BN is limited by the demand for the monetary base. The Bank of England and Bank of Ireland could not induce the private sector to hold more BN than demanded. BN was viewed by the bullionists as the first link in the causal chain; but it is an endogenous variable. A low level of economic activity could hold down the demand for BN.

PL → ER is the purchasing-power-parity theory (given PLf), the causal nature of which is generally ignored in the modern literature. PL → PG involves a relatively unchanged PGf, for, under perfect markets, PG is the product of ER and PGf. PG was not as interesting to the Swedish and Irish bullionists as it was to the English. Sweden had been on a copper standard; the concern in Ireland was depreciation of the Irish currency against the British. For the Swedish and English protagonists, foreign exchange was Continental currencies. For most Swedish and Irish bullionists, the latter part of the chain is merely MS → PL, ER. The price level and exchange rate are co-determined by the money stock. Some Irish bullionists allowed for a changing foreign (English) price level, so the hypothesis becomes MS/MSf (or BN/BNf) → ER.

The English anti-bullionist model involves a balance-of-payments theory of the exchange rate, with demand for and supply of bills of exchange represented by the payments deficit (BP), yielding ER and PG. The state of the harvest, a real factor, determines the domestic price of grain, represented by the price of wheat (PW). The exchange rate is an ingredient in the price of imports, which, together with PW, determines PL. These anti-bullionists saw three principal determinants of BP, that is, of shifts in the demand for or supply of foreign exchange: PW, foreign trade restrictions (wartime restraints: the Continental System and the American embargo), and foreign remittances (external government payments: direct military expenditure and subsidies to allied countries).

In emphasizing the price of wheat, the anti-bullionists recognized the highly agrarian state of the British economy, notwithstanding the industrial revolution in progress. The emphasis on wartime interference with trade and on external military expenditure reflected the French Revolutionary and Napoleonic Wars, in which Britain was engaged for much of the Bank Restriction Period.

For the Irish anti-bullionists, concerned with the English exchange, TR and PG were unimportant. They did not make explicit the connection of PW and PM to PL, and FR took the form of payments to absentee landlords in England. Some consolidated the trade balance, interest payments, net capital exports, and FR, to compose (and presumably shift) BP in the causal chain. They left unclear the mechanism from BP to PL. The Swedish anti-bullionists had the chain: BP → ER → PM → PL allowing real shocks to operate on BP. The anti-bullionists used the ‘real-bills’ doctrine to reverse the bullionist BN → PL causation. They accepted that the Bank behaved passively in its note issuance, but used the real-bills theory to demonstrate that excess issue (beyond the ‘needs of trade’) would be returned to the Bank instead of acting to increase the price level monetarily. Only non-monetary forces could cause real income and then the price level to increase, and would underlie the demand for discounting to finance a higher volume of transactions, whence PL → BN. The Irish bullionists also propounded the real-bills doctrine (for the Bank of Ireland), although some saw ER playing the role of PL.
Bullionists in all three periods essentially inverted the real-bills theory by offering the policy rule that central-bank note issuance should be oriented to the exchange rate and (for the English bullionists) gold price: \( \text{ER, PG} \rightarrow 1 / \text{BN} \).

Extension to country banks

A subsidiary part of the English and Irish bullionist controversies was the extent to which the country banks (in Ireland, including Dublin private banks) could affect the money supply independent of the central bank. Should the first hypothesis in the bullionist chain, \( \text{BN} \rightarrow \text{MS} \), incorporate CN naturally as \( \text{BN} \rightarrow \text{CN} \rightarrow \text{MS} \) (country banks unable to vary their note issues independent of the central bank)? Or should the hypothesis be \( (\text{BN} + \text{CN}) \rightarrow \text{MS} \) (the central bank and country banks able either jointly or separately to change their issues)? Or should the hypothesis be \( \text{CN} \rightarrow \text{MS} \) (only the country banks, not the central bank, having the power to change the money supply)? The question was answered differently by groups that cut across the bullionist–anti-bullionist line.

The correct hypothesis is not clear, because of the environment in which banks operated. Among the complicating, and largely unknown, elements are the extents to which (a) one-time replacement of gold by central-bank notes in reserves altered country-bank policy regarding reserve ratios, (b) country-bank reserve ratios varied over time, (c) public preference for central-bank over country-bank notes changed in particular geographic areas and over time, (d) circulation of counterfeit notes and unlicensed-bank notes affected the demand for and supply of country-bank and central-bank notes, and (e) London private banks were prepared to run down their reserve ratios to accommodate country-bank demand for additional reserves.

Empirical studies: visual comparison of movements of variables

The empirical studies examined here make use of quantitative information to test one or more component hypotheses of the bullionist or anti-bullionist models. It is logical to begin with contemporary studies, as it is the hypotheses of contemporary authors that are delineated in the previous sections.

All contemporary investigations use a simple technique: visual inspection of sets of figures, formal tables, or charts. The earliest such studies pertain to the Ireland bullionist period, with BN and BN_c the note circulations of the Bank of Ireland and Bank of England. Parnell (1804), Foster (1804) and the 1804 Currency Report (in Fetter, 1955) find that BN \( \rightarrow \) ER is confirmed. Ó Gráda (1993) and Fetter (1955) criticize the Report for its small number of observations and selective observations. These criticisms can be extended to Parnell, but not to Foster. The report of 1804 and Parnell also claim successful testing of \( \text{BN} / \text{BN}_c \rightarrow \text{ER} \). Ó Gráda (1991) finds this part of the Report misleading in several respects; but the Report is to be commended for making specific allowance for the replacement of gold coin by notes. The Report also claims to disprove BP \( \rightarrow \) ER, via computation of a net balance-of-payments surplus. However, this proves little, because there is no representation of shifts in the demand for or supply of bills on London.

Contemporary empirical work on the English bullionist period begins with Ricardo (1811), whose positive finding of \( \text{BN} \rightarrow \text{ER} \) (Hamburg exchange) is reinforced by observation of a lagged effect and by accounting for replacement of gold coin by Bank of England notes. Galton (1813) confirms that BN \( \rightarrow \) ER, PG. Anonymous (1819) sees mixed evidence for that hypothesis, but observes that grain imports and FR (not precisely defined) affect the exchange rate – the first results in favour of anti-bullionism.

There is a hiatus of more than a century, but three groupings of subsequent work do not merit review. First is any investigation, such as Silberling (1924), involving the London price of the Spanish dollar to represent the exchange rate. That choice is methodologically unsound. Britain was on a suspended gold (not silver) standard, and the Spanish silver dollar was not a circulating coin in Hamburg, the main foreign-exchange market. Second are tests making use of Silberling-developed series of Bank of England total advances and their private and public components. These series have been shown to be seriously inconsistent with the Bank's published data. Third, and most unfortunate, are all studies using 'data' on country banknote circulation. There exist no true data on country banknote circulation in England, or private banknote circulation in Ireland, during the bullionist period. Further, with no legal or fixed reserve ratio of note liabilities to cash, the circulation of the Bank of England, or Bank of Ireland, cannot be used to infer that of the private banks. Private banks were required to register at the Stamp Office and pay a stamp tax on notes prior to issuance. Some have used stamp-tax data to develop proxy CN series for England, based on the value of country banknotes stamped; but the series are based on assumptions so tenuous as to make the series unusable.

Silberling (1924) develops an annual series for FR ('extraordinary foreign payments'), consisting of grain imports over a normal amount, Continental British war expenditures, and subsidies to foreign states. Using various definitions of FR, based largely on Silberling, Angell (1926) shows that FR \( \rightarrow \) ER, but can find no causal relationship between PL and ER. This result, favourable to anti-bullionism, is supported by Morgan (1939; 1943) and Viner (1937). Morgan rejects BN \( \rightarrow \) PL, but accepts PL \( \rightarrow \) BN. His only finding not supportive of anti-bullionism is the lack of a relationship between PW and PL or BN.

Gayer, Rostow, and Schwartz (1953, p. 932) support BP \( \rightarrow \) ER; but they represent BP by the balance of trade, the data of which are crude. For the Swedish period, Eagly (1971) and Bernholz (1982; 2003) support BN \( \rightarrow \) ER, favourable to bullionism.

This entire body of literature must be viewed with caution. First, interpretation of relationships among variables is subjective when data are merely tabulated or plotted. Second, macroeconomic variables are generally non-stationary, leading to the possible outcome of 'spurious regression'.
Empirical studies: time-series analysis

Myhrman (1976) computes annual growth rates of BN and PL, for Sweden and England, and argues that BN → PL. Jonung (1976) does the same for Sweden alone. Transforming data to growth rates could yield stationarity. In a joint test of bullionist and anti-bullionist hypotheses, Arnon (1990) regresses PL on PW, BN, and a trend. He finds that BN contributes more to the regression than PW. The variables are transformed to correct for serial correlation, which could correct spurious regression. Formal time-series analysis in the bullionist literature begins with Ó Gráda (1989; 1993). For England, he cannot reject a cointegration relationship between logPL and logBN. This means that there is no long-term equilibrium between the variables, a failure of support for either bullionism or anti-bullionism. The same negative result holds for Ireland, with BN/BN_f used in place of BN.

Nachane and Hatekar (1995) use Granger causality and cointegration techniques for England. Their variables are PL, ER, PG, BP, and BN/Y (transformed to logarithms except for BP, the only non-stationary variable), where Y is real output. Their results are ER → PL, PL → BN / Y (with PL and BN/Y the only cointegrated pair of variables), and BP → ER, PG. The findings are strongly supportive of anti-bullionism; but measuring the money supply in relation to output is outside the mainstream controversy.

The analyses of Ó Gráda and Nachane–Hatekar are restricted to bivariate econometrics. Officer (2000) applies multivariate testing to PL, ER, BN, FR, and PW, for England. Non-stationarity cannot be rejected, but cointegration is rejected. The logarithmic variables are first-differenced (to achieve stationarity), and Granger causality testing along with innovation analysis is applied. Results are mixed for bullionism, but unambiguously favourable to anti-bullionism. For example, the real-bills doctrine, PL → BN, receives stronger support than does the quantity theory, BN → PL.

It is logical that the time period for testing hypotheses be strictly within the pertinent bullionist period, because the alternative (bullionist versus anti-bullionist) models are geared to a paper standard and floating exchange rate. As his sample, Officer uses the 96 quarters encompassed by the Bank Restriction Period (1797–2 to 1821–1). Nachane and Hatekar employ annual data, and extend the time period to 1838. Ó Gráda has quarterly observations, but begins his time periods prior to 1797.

Nachane and Hatekar can also be criticized for using the exchange rate on Paris rather than Hamburg to represent ER. There are no quotations on Paris until 1802 (whence they lose observations), and historians agree that the Hamburg exchange was more representative during wartime.

To conclude: certainly, at least for England, the anti-bullionist position receives greater support (or less contradiction) than the bullionist side of the controversy. This result is inconsistent with modern macroeconomics. The anti-bullionist approach to the exchange rate (a flow theory) and monetary policy (passive, accommodating the price level) has been superseded in modern theory. Also, modern monetarism emanates from bullionism.

bundling and tying

Barry Nalebuff
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Bundling can be thought of as akin to a volume discount, but one where the volume is based on aggregate sales across products. Instead of offering a discount for buying two apples rather than one, the customer is given a better price for buying an apple and an orange together. Bundling may be used to reduce cost and improve quality, and for price discrimination. While the Chicago School has argued that a monopolist cannot gain by bundling its monopoly good with a competitive product, recent work suggests that in a dynamic game bundling can help protect and leverage market power.

antitrust policy; bundle discounting; bundling; Chicago School; complementarities; consumer surplus; Cournot, A.; envelope theorem; market power; Markup; metering; mixed bundling; one-monopoly profit argument; price discrimination; pure bundling; two-part tariffs; tying

Article

Bundling is a prevalent feature of pricing. It is akin to a volume discount, but where the volume is based on aggregate sales across products. Instead of offering a discount for buying two apples rather than one, the customer is given a better price for buying an apple and an orange together.

Under pure bundling, two goods A and B are sold together only as a package. Under mixed bundling, customers can also buy each good. Typically, the bundle is offered at a discount to the individual prices. Mixed bundling is the most general case. A pure bundle can be thought of as a case where the individual prices exceed the bundle price, so that no one has an incentive to purchase anything but the bundle. Tying can also be viewed as a special case of mixed bundling; customers are offered prices for A and B together or for B alone, but not A without B.

The first to study bundling was Cournot (1838), who showed how it solves a double markup problem for complementary products. Bundling may increase efficiency more directly by improving quality and
reducing cost (see Evans and Salinger, 2004; 2005). Manufacturers gain scale economies by standardizing the combination of goods and guaranteeing that the components work together. The early bundling literature debated whether it was used to leverage market power or price discriminate. This debate was stimulated by a series of cases in which the courts viewed bundling (and tying) as anti-competitive. Director and Levi's (1956) and Stigler's (1963) influential Chicago School argument claimed that a monopolist cannot gain by leveraging its power from one market to another. Starting with Whinston (1990), the current literature suggests that, in a dynamic setting, bundling can profitably leverage market power by deterring entry, excluding one-good rivals, and amplifying existing market power. Three review articles provide a guide to the literature and antitrust cases: Kaplow (1985), Nalebuff (2003a), and Kobayashi (2005).

The Chicago School argument

In response to United States v. Loew's (1962), Stigler (1963) argued that block booking (selling movies bundled rather than individually) was best viewed as price discrimination. He argued that a monopolist in product A could not make more money by requiring buyers to take a product B that was competitively available – the alternative strategy of selling A alone for a price of \( p - c \), where \( p \) is the bundle price and \( c \) the marginal cost of B, is more profitable. Any sale of A at price \( p - c \) would be just as profitable as selling the bundle at \( p \). Yet anyone willing to buy the bundle at \( p \) would also be willing to buy A alone at \( p - c \), as, by assumption, B is available at the competitive price of \( c \). Bundling is weakly worse as it might cause the firm to lose sales to customers who value A at \( p - c \) but do not value B at \( c \) and thus do not buy the bundle. This has become known as the ‘one-monopoly profit’ or ‘Chicago School’ argument (see Director and Levi, 1956; Bork, 1978).

If leverage does not explain bundling, something else must. Stigler suggested price discrimination.

Price discrimination

The idea of bundling (and tying) as price discrimination dates from Bowman (1957) and Burstein (1960). As Burstein noted, a monopolist would generally like to employ a two-part tariff in pricing. Requiring customers to buy an overpriced B is an indirect way to charge a lump-sum fee. If the monopolist starts from a profit-maximizing price, then (by the envelope theorem) profits lost from cutting price will be very small. In contrast, existing consumers will gain a great deal, and so will be willing to buy B at an inflated price in return for a lower-priced A.

The problem is that other producers of B end up excluded. Customers of A won't switch to lower-priced B goods because they don't want to lose the discount on A. While the monopolist could have used a two-part tariff directly, such pricing schedules seem rare in practice. Bundle pricing as a two-part tariff is explored in Mathewson and Winter (1997) and Nalebuff (2004b).

Two-part pricing becomes even more effective when B's demand is correlated with A's value. This leads to metering. For example, a firm selling printers would like to charge high-value customers more. But customer valuation may be unobservable. However, if value is correlated with usage, then a per-page charge would allow the seller to charge high-value customers more. A per-page charge could be levied
directly, although that would require monitoring usage. In practice, sellers patent the shape of their toner cartridge, thus requiring users to buy toner at a premium price. These results rely on B’s demand being either elastic or heterogeneous. Bundling permits price discrimination even when A and B are consumed in fixed amounts. Consider movies. If regional variation in the valuation of two movies is negatively correlated, a distributor can profit more by pricing the movies as a package than by selling them à la carte. Bundling reduces demand heterogeneity and thus captures more of consumer surplus (see Adams and Yellen, 1976).

The advantages of the bundle discount strategy are remarkably general. McAfee, McMillan and Whinston (1989) show that, for any two goods independent in value, a firm with market power will find an advantage offering them at a bundle discount (holding individual prices constant) – an impressive result, given the near endless opportunities for bundling products with independent values. One intuition for their argument is that discounting via bundling leads to twice the demand expansion for the same price reduction. Consider the offer to lower A’s price by one dollar if you buy B. The cost of the offer is one dollar to all customers who would have bought both A and B at the previous prices. The gain is the new demand from customers who were buying B but not A, as they now have an opportunity to get A at a dollar off. If A was priced optimally to begin with, then the incremental profit from increased demand should just offset the lost revenue on existing customers. (Here demand independence is critical, as it implies that customers buying B are representative of the entire A market.) So far, everything is a wash. However, the dollar off A if you buy B is the same as a dollar off B if you buy A. Thus there is a second set of incremental customers: those already buying A but on the margin on B. Demand for B expands without imposing any further cost in terms of lost revenue. The ability of the bundle to expand demand on two fronts for one discount is the ‘special sauce’ behind bundling.

**Bundling to leverage monopoly**

The recent re-examination of bundling as leveraging market power and foreclosing rivals uses dynamic reasoning, which is absent in the Chicago argument. For example, a monopolist in A might bundle A with B to drive rivals out of the B market. The motivation could be to monopolize what was previously a competitive B market, or to protect the A monopoly. Eliminating firms in the B market protects A if being in the B market facilitates entry into A. The US Department of Justice (1998) argued thus in explaining Microsoft’s motivation to bundle Explorer with Windows – defeating Netscape would prevent it from threatening Microsoft’s operating system monopoly.

The first dynamic model appears in Whinston (1990), where the bundler has market power in both A and B and uses the bundle to deter potential entrants. The monopolist is concerned that there may be a rival who can produce B at a lower cost. In defence, it commits itself to sell A only along with B. Thus, if a rival were to create a lower-cost B, the monopolist would not concede, as that would cost it its profits in A sales. Since the monopolist is committed to selling A only along with B, it would have to subsidize B in order to sell A. Even more efficient B good rivals won’t enter, realizing that they won’t win; this preserves monopoly profits in B. Nalebuff (2004a) offers a second perspective. Absent entry, the dual monopolist gains via price discrimination. With entry (and heterogeneous consumer preferences), the firm would rather respond
bundling and tying: The New Palgrave Dictionary of Economics

with a bundle than with head-to-head competition (and thereby lose all profits in the B market). The incumbent's bundling reduces the potential market available to the entrant. The entrant is mostly limited to those customers who like B but not A. This market may not be large enough to cover costs of entry or to achieve a minimum efficient scale (Carlton and Waldman, 2002).

The bundling models illustrate the challenge for anyone contemplating entry against Microsoft Office. Given the large discount for buying the Office bundle, a firm that developed a better word-processing program (and nothing else) would find its market limited to those who value word processing, but not spreadsheets or presentations. The entrant could try to sell to those who already have Word, but that would limit the price to its product's incremental value over Word, which is much less than what it can charge customers who don't already have Word.

A firm could always develop a rival bundle of products. But this also discourages entry, as it is much harder to develop two better products than one. Furthermore, it turns out that bundle-against-bundle competition is particularly fierce (see Matutes and Regibeau, 1992).

These examples of bundling emphasized the use of pure bundles as a way of protecting and leveraging market power. Even with mixed bundling, firms can achieve similar results by keeping the component prices artificially high.

A bundle discount may be large due to a low bundle price or high individual prices, prices that might exceed monopoly levels. Although entry is blocked in both cases, the welfare implications are different, as discussed in Greenlee, Reitman and Sibley (2004). Bundling can be used to create a horizontal price squeeze, an issue considered by the Supreme Court in Ortho Diagnostic v. Abbott Lab (1996) and developed in Nalebuff (2005).

A bundle discount leads to foreclosure if even the monopolist could not afford to sell B at a large enough discount to offset the loss of the bundle discount. Exclusionary bundling arises when the incremental price for an A–B bundle over A alone is less than the long-run average variable costs of B.

Bundling complements

An incentive to bundle arises when two products are perfect complements, so that customers care only about their combined price. Cournot (1838) considered copper and zinc, which combine to produce brass; a more modern example would be hardware and software.

Two monopolists selling A and B independently will charge inefficiently high prices. Were the two firms to merge or coordinate their pricing, they can lower prices and raise profits. The gain from bundling complements is the horizontal equivalent of vertical integration to avoid double marginalization. As consumers and firms are both better off, this is a Pareto improvement.

The situation is more complicated if there are multiple producers of A and B. Nalebuff (2000) and Choi (2001) consider the case where two firms are able to solve the coordination problem while their rivals are not. This issue arose in 2001 when the European Commission blocked the proposed US$42 billion merger between General Electric and Honeywell. The Commission was concerned that the merger would allow the combined firm to better coordinate the pricing of airplane engines and avionics, and give it an advantage over engine-only rivals such as Rolls Royce or avionics-only rivals such as Thales or Rockwell Collins (see Nalebuff, 2003b, for a cautionary note).

Bundling can change competition in two ways. When a bundle competes against components, the
bundled seller is better able to coordinate pricing and gains share against his rivals. Profits may not rise as rivals respond to their reduced market share with lower prices. When there is bundle-against-bundle competition, as shown by Matutes and Regibeau (1992), prices are the lowest of all, and profits fall substantially. Customers benefit from the lower prices but lose the ability to mix and match and thereby buy their ideal mix of product.

There may also be a combination of these two effects. With an imbalance between A and B producers, only some firms are able to offer bundles, and these firms compete aggressively. The left-out firms have only one good and end up disadvantaged; see Gans and King’s (2004) analysis of bundle discounts offered by supermarket and gasoline retailers in Australia.

Conclusions

There is no grand unification theory of bundling. The decision to bundle is connected both to product design and to pricing. While price discounts are typically pro-competitive, in some cases bundling creates a cause for antitrust concern as it can be used to protect and leverage market power.

bureaucracy

Mancur Olson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Bureaucracy in both businesses and governments continues to grow despite its unpopularity. Falling transport and communication costs have created global markets. The rising relative importance of firms with new technologies and methods often unsuited to market transfer via licensing of patents has given rise to multinational corporations with transnational bureaucracies. Government bureaucracies typically produce indivisible goods contributions to which by individual bureaucrats cannot be measured, giving rise to red tape and enabling bureaucracies to exploit society's demand for their products. Bureaucracies may not be highly efficient, but market failures that give rise to them also make them inevitable.

Article

The study of bureaucracy has to deal with an elemental paradox. The role of bureaucracy has obviously increased dramatically in modern times. This is true not only of government bureaucracies but business bureaucracies as well. Though there were a few bureaucracies of significant size in pre-industrial times, such as the hierarchy of the Roman Catholic Church and the civil services of various Chinese empires, they were clearly exceptional. By contrast, a very large proportion of the total resources in the developed nations are controlled by either governmental or private bureaucracies. The role of governmental bureaucracies, at least, has increased with some rapidity within the last few decades. The increase in the use of bureaucracies has occurred in so many countries that it could hardly be due entirely to chance,
and thus must be due to what are, in some sense, social choices to use more bureaucracy. Normally, when there are great increases in the demand for or use of some product or instrumentality, this is accompanied by independent evidence of enthusiasm for the product or instrumentality in question. When a society experiences a great increase in the demand for automobiles or for personal computers, there is at the same time a considerable amount of favourable commentary about whatever product is experiencing the boom in demand. There is pride in automobile ownership or awe at the power or compactness of personal computers. Nothing is more natural than that people's choices should be influenced by enthusiasms.

But where is the enthusiasm for bureaucracy that might have been expected to accompany the dramatic increase in the use of bureaucratic mechanisms? Any such enthusiasm is difficult to discern, and there are many conspicuous examples of dislike (or even contempt) of bureaucracy. Some of this negativism may be traced to particular ideological traditions, but this is not sufficient to explain the negativism; the problem is not only that the prevalence of the relevant ideology needs to be explained, but also that the lack of enthusiasm for bureaucracy prevails in a wide variety of ideological and cultural contexts and tends to apply (at least to some extent) to business as well as to governmental bureaucracies. There is no doubt that ‘red tape’ is viewed negatively by almost everyone, and that it is associated with bureaucracy, and especially governmental bureaucracy; the phrase is derived from the colour of the ribbons that were once used to tie folders of papers in the British government.

Some strands of the literature on bureaucracy are called into question by the paradox. Much of the admiring literature on bureaucracy is difficult to reconcile with the negative popular image of bureaucracy, whereas much of the negative literature suffers from the lack of any explanation of why virtually all societies, at least implicitly, keep choosing to use the instrumentality that is alleged to be so faulty. Perhaps the most influential scholarly analysis of bureaucracy is not by an economist, but rather by the sociologist and historian, Max Weber. According to Weber:

… the fully developed bureaucratic mechanism compares with other organizations exactly as does the machine with the non-mechanical modes of production …

Precision, speed, unambiguity, knowledge of the files, continuity, discretion, unity, strict subordination, reduction of friction and of material and personal costs – these are raised to the optimum point in the strictly bureaucratic administration (1946, p. 214).

Although also critical of ‘bureaucratic domination’, Weber's more positive view of bureaucracy has been influential in sociology and political science. Yet it does not appear to have generated systematic or quantitative empirical studies that have tended to provide any confirmation for it, and it surely is not in accord with the popular image of bureaucracy. Weber himself fails to identify any strong incentives in bureaucracies that would lead to efficient allocations of resources or to high levels of innovation. Similarly, the popular pejorative view of bureaucracy is inadequate to the extent that it offers no explanation why modern societies choose or accept an increasing degree of bureaucratization. There is, admittedly, a rapidly growing economic literature on the growth of government that attempts to identify incentives that lead to a supra-optimal size of government. Examining this large literature would take us a long way from bureaucracy, and it has not in any case yet advanced to the point of generating a professional consensus on any incentive that would systematically bring about the overuse of...
government and thus of governmental bureaucracy, though some contributions (e.g. Mueller and Murrell, 1985) are extremely promising. But even dramatic success in the literature on the growth of government would not be sufficient to solve the problem, as it would leave us with no explanation of the growth in modern times of business and other private bureaucracies. Since an explanation of the growth of private bureaucracies is needed, and since an inquiry which begins with the growth of private bureaucracies may obtain some modest degree of detachment from the ideological controversies about the appropriate role of government, it may be best to consider private bureaucracies first. Here the basic question that must be answered is, ‘Why do firms with hierarchies of employees exist?’ Familiar economic theory explains that markets can under the appropriate conditions allocate resources efficiently, so we must ask why individuals in the business hierarchy, and owners of the buildings and equipment that a typical corporation uses, do not use the price signals of the market to coordinate their everyday interaction. As Ronald Coase pointed out in somewhat different language in his seminal article on ‘The Nature of the Firm’ (1937), the survival of firms with hierarchies of long-run employees and long-term ownership of complementary fixed capital can only be explained by a kind of market failure. The type of market failure that Coase, and Williamson (1964, 1975 and 1985) and the other economists that have developed the very important literature on private hierarchies have emphasized is ‘transactions costs’. It would cost too much to contract out each day each of the very many separate tasks that are usually needed in any complex productive process, so in many cases it pays to forego the use of the market and to make long-term deals with employees who will perform such tasks each day as their superiors instruct them to do and receive in turn a regular salary. Though most of the literature in this tradition emphasizes only transactions costs, it is important to note that any market failure, such as that arising from an externality, could provide the incentive for the establishment of a firm that would internalize the externality, and all but the smallest firms have bureaucracies. Though the foregoing argument also applies to small firms of the kind that predominated in pre-industrial times, there have been some changes since the industrial revolution that, within this Coasian–Williamson framework, can provide important insights into the growth of business bureaucracies. One factor that made for larger and more bureaucratic firms was the discovery of technologies subject to indivisibilities that only a large enterprise can profitably exploit. But the extraordinary improvement in the technologies of transportation and communication was probably far more important. Reductions in transportation and communication costs make it economic for firms to draw factors of production from farther away and also make it profitable for a firm to sell its output over a wider area. When transportation and communication technologies make it profitable for many firms to operate at a global rather than a village level, some very large firms can emerge. The improved transportation and communication also make it possible to coordinate the activities of a firm over a larger area. Superficial observers of the emergence of large firms have supposed that this growth of firm size entails a reduction in competition and a growth of monopoly. In fact, the dramatic reductions in transportation and communication costs have, of course, also increased the opportunities for market transactions over great distances, so the size of the market and the number of firms to which the typical consumer has access has (in the absence of extra trade barriers) also increased. At least in the Common Market or the United States, the average consumer, even if purchasing a product such as an automobile that is produced under greater-than-average economies of scale, has more firms competing for his business than did the average consumer in the typical rural village before the industrial revolution. Thus we see that the growth of business bureaucracy and the expansion of competitive
markets are by no means necessarily obverse tendencies, but rather the kinds of things that often happen together. The technologies that facilitated larger markets and larger firms also gradually led to the discovery of better methods of governing large-scale business organizations, as the historian Alfred D. Chandler has shown in some seminal historical studies of what he has called The Visible Hand (1977; see also 1962 and 1980). Several of these innovations occurred in the unprecedentedly large and geographically scattered railroads in the 19th-century United States, and many involved the creation of separate ‘profit centres’ and other devices that enabled larger firms to use market mechanisms to fulfill some functions within the firm (Williamson, 1985). This suggests that the costs and control losses in bureaucracies are still very considerable, so that business bureaucracy can only be explained in terms of rather substantial costs of using markets. The same conclusion emerges from the observation that activities that are highly space-intensive, such as most types of agricultural production, are quite resistant to bureaucratization, even after the development of modern technologies of transportation and administration; the firms that succeed in surviving in most types of farming are normally too small to have bureaucracies (Olson, 1985).

By contrast, in activities in which the transfer of new technologies and other information is especially important, market failure is likely to be fairly extensive, mainly because new information would only be rationally purchased by those who did not already have this information, and from this it follows that the market for new information is particularly handicapped by the asymmetrical information of the parties to any transaction. Thus, as J.C. McManus (1972), Buckley and Casson (1976) and, especially, Hennart (1982) have shown, the emergence of the multinational firms with bureaucracies that transcend national borders can be explained in this framework; capital can cross national borders through portfolio investment (almost all British and other foreign investment in the 19th century was portfolio investment), but the rise in the relative importance of firms with new technologies and methods that were often not well suited to market transfer via licensing of patents, gave rise to the multinational corporation.

The foregoing emphasis on the business bureaucracies that are generally neglected in discussions of bureaucracy makes possible a brief and unified explanation of governmental bureaucracy as well. Governmental bureaucracies are similarly necessary only because markets fail, at least to some degree; the theory of market failure is readily capable of being generalized to include all functions for which governmental are an efficient response (Olson, 1986). Since governmental as well as market mechanisms are obviously imperfect, it does not follow from the presence of market failure that government intervention is normatively appropriate, since the government might fail even worse than the market, but market failures are nonetheless often important and always a necessary condition for optimal governmental intervention. Of course, it would be absurd to suppose that actual government intervention is always optimal or that governments always intervene when it is Pareto-efficient for them to do so. It is nonetheless instructive to look at the existence of government bureaucracy, as of business bureaucracy, in terms of market failure.

Among other reasons, it is instructive because the very conditions that give rise to market failure inevitably generate, in governments, and to a considerable degree also in firms, exactly those inefficiencies and rigidities that are popularly and correctly attributed to bureaucracies. Some of these inefficiencies also occur when either governmental or business bureaucracy is used inappropriately, but
the problem is most easily evident, and most serious, in precisely those cases where market failure makes bureaucratic mechanisms indispensable. The reasons why the same conditions that make markets fail also generate difficulties and inefficiencies in bureaucracies unfortunately do not lend themselves to brief exposition. But perhaps a faint and intuitive sense of the matter will be evident from a moment’s reflection about what could make a bureaucracy necessary. If, say, the fruits or vegetables grown on a farm are best picked by hand and the best way to pay each worker is by the number of bushels picked, there is no need to have any bureaucratic mechanism for getting the work done. When piece-rate or commission systems of reward work well, the market gives each worker a more or less optimal incentive to work and to be as efficient as the worker knows how to be. In essence, the reason is that the output is highly divisible into more or less homogeneous units or the revenue attributable to each worker is known, and so the output of different workers can be measured with reasonable accuracy.

Let us now shift to an opposite extreme. Consider a typical civil servant in the foreign ministry of a government. Even supposing that the only purpose of the foreign ministry in question was peacefully to maintain the country's independence, there would still be a stupendous difficulty in rewarding the civil servant on a piece-rate or commission basis, or in any way that is proportional to his productivity. The security of the country in question would normally depend in large part on what might loosely be described as the state of the international system – on world-wide indivisible or public good for which no one country could be entirely responsible. But even if the country in question were the only producer of this indivisible good, the foreign ministry would not be the only part of the government or the country that was relevant. Even in the foreign ministry, the typical civil servant is only one among thousands. How is his individual output to be measured, or even distinguished from that of his co-workers? The civil servant obviously cannot be paid in proportion to the revenue he generates, because if there really is market failure, the output cannot be sold in a market in the first place. Thus in practice, the remuneration of civil servants involved in producing public goods is not even a close approximation to each civil servant's true output; rewards in civil services will depend dramatically on proxy variables for performance such as seniority, education, and the fidelity of the employee to the interests of his superior and to the ‘culture’ or ideology of that bureaucracy. The peculiarities of civil service personnel systems, competitive bidding rules, and red tape are mainly explained by this logic (Olson, 1973, 1974).

The knowledge of the ‘social production function’ of a government bureaucracy producing public goods will also be limited by the same indivisibility that has been described; there are fewer countries, or even airsheds for pollution abatement, than there are farms (or experimental plots at agricultural experiment stations), so in general less is known about how to run countries or control pollution than about agriculture or about production processes in other competitive industries (Olson, 1982). The same indivisibility that obscures the social production function and the productivity of individual civil servants and other public inputs also insures that there cannot be even an imperfectly competitive market, so there is also no direct information on what an alternative bureaucracy could have achieved in the same circumstances.

In large part, it is the lack of information due to the indivisibilities described above that allows some of the bureaucratic pathologies described in Niskanen (1971) and Tullock (1965) to occur. In Niskanen's widely cited formal model, it is assumed that only the government bureaucrats know how many resources are required to produce a given public output. These bureaucrats are assumed to gain from growth of the bureaucracy, because an official's power, opportunities for promotion and other perquisites
are assumed to be an increasing function of the budget the bureaucrat administers. An agency faces the constraint, however, that the electorate will not sustain any government programme whose total costs exceed the total value of its output. The optimization of government bureaucrats therefore leads to a bureaucracy far larger than is Pareto-efficient; in essence the bureaucracy takes all of the surplus under the society's demand curve for the government output at issue. Critics of Niskanen's model have pointed out that it neglects the subordination of bureaucrats to politicians, and that politicians whose opportunities for re-election are positively correlated with the government's performance will endeavour to prevent bureaucracies from taking all of the surplus (see, for example, Breton and Wintrobe, 1975). These criticisms have substantial empirical support, but it is also true that there are many known cases where officials who fear a lower budget allocation than anticipated for their agency will eliminate or threaten to eliminate their politically most cherished activity rather than a marginal activity; this is precisely what Niskanen's model predicts. Though any final conclusion must await further research, the evidence available so far appears to suggest that the lack of information due to the indivisibilities described above does often allow bureaucracies to appropriate some of the surplus that consumers might otherwise be expected to receive, but that the incentives faced by politicians tends to keep bureaucracies from getting anything resembling the whole of this surplus.

Bureaucracies operating in a market environment share some of the information problems that confront government agencies providing public goods, but not others. The divisions of a large corporation that handle personnel, accounting, finance or public relations for the entire corporation provide collective goods to the corporation as a whole. They are in many ways in a situation analogous to the foreign ministry described above when deciding how much of the total profits of the firm to attribute to a given corporate employee; this accounts for the many similarities of large corporate and civil-service bureaucracies. But the corporation as a whole, and even the nationalized firm producing private goods in a market, does not, when it sells its output, have as great a difficulty as the government agency that produces a collective of public output that is indivisible and unmarketable. The firm produces a good or service that is divisible in that it may be provided to purchasers and denied to non-purchasers. This means that the output is directly measurable in some physical units or at least that the revenue obtained from this output is measurable. Since consumers, even in the absence of any high degree of competition, will have alternative uses for their money, the private corporation or nationalized firm in a market economy will get some feedback about how much value it is providing. If there is no legal barrier to the operation of a competitive enterprise and the market is contestable, the society will also have at least potential information about what value an alternative organization could provide. An enterprise in the market produces an output from which non-purchasers may be excluded, and this also means there is normally better knowledge of the production functions for private goods than of production functions for public goods. All this implies that the problems of bureaucracy are less severe in private business than in government agencies producing public goods. Interestingly, they are also less severe in government enterprises that unnecessarily produce private goods that private firms would readily provide than they are in agencies that produce public goods that would not have been provided by the market. The more flexible personnel policies in some nationalized firms than in classical civil service contexts thus provides support for the conception offered here.

The paradox of a vast growth of both public and private bureaucracy at the same time that there is almost a consensus that bureaucracies are not very efficient or flexible, thus appears to have a resolution. There are fundamental reasons, arising from the inherent conditions causing market failure that make
both public and private bureaucracies inevitable. These same reasons also explain why bureaucracies lack the information needed for high levels of efficiency. But these same market failures show that (though the existing degree of bureaucracy may of course be far from optimal), it should not be surprising that societies choose to use more private and public bureaucracy even as they condemn such bureaucracy.

Burns, A. F.; business cycle measurement; business cycles; Council of Economic Advisers (USA); Economic Policy Advisory Board (USA); Federal Reserve System; Mitchell, W. C.; National Bureau of Economic Research

Article

Burns was born in Stanislau, Austria, on 27 April 1904. In 1914 his family emigrated to the United States, settling in Bayonne, New Jersey. Burns became a member of the economics faculty at Rutgers University in 1927, leaving in 1941 to accept an appointment at Columbia University, where he taught for many years and became John Bates Clark Professor of Economics Emeritus. He joined the staff of the National Bureau of Economic Research in New York in 1930, was director of research, 1945–53, and president 1957–67. In Washington Burns served as chairman of the Council of Economic Advisers, 1953–6; Counsellor to the President, 1969–70; chairman of the Federal Reserve System, 1970–78; and member of the President's Economic Policy Advisory Board since 1981. From 1981 to 1985 he was US Ambassador to the Federal Republic of Germany. In 1978–80 and again after 1985 he was distinguished scholar in residence at the American Enterprise Institute.

Burns's economic studies have been primarily concerned with economic growth, business cycles, inflation, and economic policies bearing upon these phenomena. In *Production Trends in the United States since 1870*, published in 1934, he examined growth rates in individual industries, noting the nearly universal tendency towards retardation. An initial stage of rapid growth in a new industry is usually followed by slower growth as it loses part of its market or its resources to still newer industries. Despite the tendency towards slower growth and eventual decline of most industries, Burns noted that this did not imply that growth in total output would slow. The underlying cause, that is the rise of new industries, would itself help to maintain rapid growth in total output.

Burns's collaboration with Wesley Mitchell in the study of business cycles led to many innovations in measurement technique and to a vast accumulation of knowledge about the characteristics of cycles and the economic interactions that generated them. It also led to a more realistic view of what business cycle
theory had to explain and what economic policy could be expected to accomplish. This in turn was
useful to Burns in his later role as an economic policymaker, that is as a presidential adviser and as
chairman of the Federal Reserve. Before taking on these responsibilities he wrote prophetically (1953):
‘It is reasonable to expect that contracyclical policy will moderate the amplitude and abbreviate the
duration of business contractions in the future … But there are no adequate grounds, as yet, for believing
that business cycles will soon disappear, or that the government will resist inflation with as much
tenacity as depression …’ Burns's subsequent efforts were largely directed to improving the anti-
recession, anti-inflation, and growth promoting policies of government.

Burns, Arthur R.; Burns, Eveline M.; competition theory

Article

A native of London, Burns was educated at the London School of Economics, where he was a pupil of Edwin Cannan. His doctoral dissertation, *Money and Monetary Policy in Early Times*, appeared in a prestigious series in 1927 and is still a standard work on the subject. After the completion of his studies Burns moved to the United States and taught at Columbia University from 1928 to 1963. His service there overlapped with that of his wife Eveline M. Burns, with whom he published an introductory economics text in 1928, and with that of Arthur F. Burns, another noted economist.

In 1936 Burns, still an assistant professor, published *The Decline of Competition*, the bulk of which consisted of chapters on trade associations, price leadership, market sharing, price stabilization, price discrimination, non-price competition and integration. The work formed part of a discussion that had been set in motion by the writings of Sraffa, Joan Robinson and Chamberlin and which explored the no man's-land between competition and monopoly. It was to serve as a bridge that linked the abstractions of the theories of imperfect or monopolistic competition with the world of reality. Standing between abstraction and description, Burns' work was in the main an attempt at classification. It holds middle ground between the soaring abstractions of pure theory and the industry studies published by Walton Hamilton and Associates under the title *Price and Price Policies* in 1938. Hamilton was a follower of Veblen. Burns shared a friendly disposition toward institutional economics with other Columbia economists.

*The Decline of Competition* constitutes Burns's main claim to fame. In later years he directed a Twentieth Century Fund study of electric power and government policy, and in 1955 he published *Comparative Economic Organization*. The former work was overtaken by the rise of atomic power as a source of electric energy, and the latter compared in isolation various factors affecting the national income.

We describe different ways of measuring the business cycle. Institutions such as the NBER, OECD and IMF do this by locating the turning points in series taken to represent the aggregate level of economic activity. The turning points are determined according to rules that either come from a parametric model or are nonparametric. Once located, information can be extracted on cycle characteristics. We also distinguish between cases where single and multiple series are used to represent the level of activity.

Article
Measurement of business cycles provides a reference point against which macroeconomic theories and policy discussion can be assessed. The process requires an operational definition of a cycle, criteria to distinguish business cycles from other forms of fluctuation, procedures to detect the presence of a business cycle, and methods to measure its features. A central theme of this entry is that good measurement should not prejudge the nature of the phenomena under investigation. Moreover, it should produce statistics which are informative about features of interest and which can be formally analysed.

Defining and detecting cycles
In their classic work *Measuring Business Cycles*, Burns and Mitchell (BM) (1946) define specific cycles in a series $y_t$ in terms of turning points in its sample path. This tradition has been central to work at the NBER and other institutions such as the IMF (2002) and the OECD (leading indicators). When it came to discussing the business cycle, BM simply referred to $y_t$ as the level of aggregate economic activity, although in this article we will regard it as the log of economic activity, as the turning points in the level and the log of economic activity are the same. When Mintz (1969; 1972) had trouble finding turning points in the level of activity in surging economies such as West Germany's, this led her to first extract a permanent component $p_t$ from $y_t$ and to then study turning points in $Z_t = y_t - P_t$. The resulting growth cycle in $z_t$ has many forms depending on the method used to extract the permanent component. Others, such as the Economic Cycle Research Institute (ECRI) (growth rate cycle), have studied turning points in the differenced data $\Delta y_t$. A generalization of this, explored by Kedem (1980; 1994) and Harding (2003), is to study turning points in $\Delta \gamma_t$. At the time Mitchell began his work, the alternative way of thinking about cycles (or oscillations) was to view $y_t$ as composed of periodic components represented by sine and cosine waves, that is
\[ y_t = \sum_{j=1}^{m} \alpha_j \cos \lambda_j t + \beta_j \sin \lambda_j t, \]  

(1)

where \( \lambda_j \) is the frequency of the \( j \)th oscillation. If \( m = 1 \) there would be a single periodic cycle. The problem with this way of looking at cycles was that few economic time series showed evidence of periodicity. To overcome that problem \( \alpha_j \) and \( \beta_j \) were allowed to vary stochastically over time. Specifically, they were treated as uncorrelated random variables with zero mean and variance \( \sigma_j^2 \). This formulation meant that \( y_t \) had to be a stationary random variable and so could not be applied to the levels of variables such as GDP (unlike turning point analysis). However, in this form one can measure the importance of the \( j \)th periodic cycle by looking at the ratio of \( \sigma_j^2 \) to the variance of \( y_t \), and it is the basis of spectral analysis. Such a perspective has increasingly been referred to as studying fluctuations rather than cycles, since the focus of attention is upon the variance of \( y_t \).

To understand the difference between these alternative ways of measuring cycles, take the special case where \( \lambda_1 = 0 \) and there is another frequency \( \lambda_2 \). Then

\[ y_t = \alpha_2 \cos \lambda_2 t + \beta_2 \sin \lambda_2 t + \alpha_{1t} = y'_t + \alpha_{1t}. \]  

(2)

Now there are certainly turning points in the series \( y'_t \) and the period between them is determined by \( \lambda_2 \). In contrast, the turning points in \( y_t \) will also be affected by the random variable \( \alpha_{1t} \), and thus may be very different to those in \( y'_t \). Information about cycles gathered from spectral analysis concerns the nature of turning points in \( y'_t \) and not \( y_t \). To give a more concrete illustration of this point, suppose that the model for \( y_t \) is of the form

\[ y_t = 1.4 y_{t-1} - 0.53 y_{t-2} + \varepsilon_t. \]

Then the periodic cycle in \( y_t \) can be isolated by setting \( \varepsilon_t = 0 \) to get \( y'_t \). To use the dating methods of an institution like NBER, the turning points in \( y'_t \) are 22 quarters apart, as could also be discovered by computing the roots of \( (1 - 1.44 + 0.53 \lambda^2) = 0 \). However, applying the same methods to \( y_t \), one finds that the turning points in \( y_t \) will be on average 12 quarters apart. A further disadvantage of the periodic cycle approach is that the data needs to be filtered to render it stationary before analysis proceeds and, as Cogley observes elsewhere in this dictionary (data filters), the filters most commonly used by macroeconomists can introduce spurious periodic cycles, thereby blurring the picture.

**Locating turning points**

To locate turning points in a series it is necessary to define what these are and to provide some way of recognizing them in a given data-set. An obvious solution is to use the idea that peaks (troughs) are local maxima (minima) in the series \( y_t \). Hence, if \( \forall t(\wedge i) \) are binary variables taking the value of unity where there is a peak (trough) at \( t \) and zero otherwise, applying the proposed definition gives

\[ \forall T = 1(y_t < y_{t \pm j}, \ 1 \leq j \leq k) \]
In eqs. (3) and (4) \( I(A) \) is the indicator function taking the value 1 if the event \( A \) is true and zero otherwise. Of course, this still leaves one with the need to describe the interval over which the local maxima or minima are said to occur, that is, a choice needs to be made regarding \( k \). To replicate the main features of Burns and Mitchell’s specific cycle dating procedures, it is necessary to set \( k = 5 \) for monthly data or \( k = 2 \) for quarterly data.

This is not the last of the choices that need to be made when locating turning points, but the others do not relate to the location of local maxima and minima. Rather, they concern the question of whether one should eliminate some of the local turns in deciding on a final set of turning points. Mostly these extra restrictions are imposed as phase length constraints, where phases are the periods of expansions and contractions between turning points. Thus, NBER dating procedures require that completed phase and complete cycles durations last longer than 5 and 15 months respectively. These are generally referred to as censoring operations. Whether turning points should be censored depends on the objectives of the research. If the objective is to match NBER business cycle dates, then censoring is essential. But if the researcher is pursuing other objectives such censoring may not be necessary. Censoring turning points makes it much harder to formally analyse the statistics produced and this may provide an important reason for not imposing them.

BM acknowledged that the final set of dates they selected for turning points reflected considerable amounts of judgement and incorporated specific information about economic activity at particular dates. Today, academic economists are primarily interested in the average characteristics of the cycle, and so it may well be that automated methods of turning point detection become attractive. In the early post-Second World War period many of the procedures used by BM were codified, producing an expert system for locating turning points. Ultimately, Bry and Boschan (1971) produced an algorithm and FORTRAN program (called BB here) that largely replicated this expert system. Subsequently Mark Watson (1994) implemented this algorithm in the language GAUSS, and that code is available at (http://www.princeton.edu/~mwatson).

There were three key components to the BB algorithm. The first was to engage in some smoothing of the series and to find an initial set of turning points using eqs. (3) and (4) with \( k = 5 \). The second was to eliminate enough of these turning points so as to ensure that expansion and contraction phases exceeded 5 months in duration, while completed cycles exceed 15 months in duration. The third component was to ensure that peaks and troughs alternated by deleting multiple sequential occurrences of these. That was done through the application of various rules, such as choosing between two peaks based on which had the higher value of \( y_t \).

Although BB were interested in analysing monthly data, they suggested a method for working with quarterly data that involved treating the observations on each of the months in a quarter as one-third of the quarterly value. A variant of BB has been developed by Harding and Pagan (2002) and called BBQ. It omits the smoothing in the BB algorithm but retains the three key principles of the BB algorithm. It also sets \( k = 2 \) and makes the minimum phase and cycle lengths two and five quarters respectively. Faster recursive algorithms for locating turning points have been developed by Artis, Marcellino and Proietti (2004) and James Engel. Engel’s computer programs are called MBBQ. They are written in MATLAB and GAUSS and are available at the National Centre for Econometric Research (MBBQ Code).

Model-based procedures for defining and locating turning points

The procedures above do not require any knowledge of the data-generating process for \( y_t \). An alternative approach is to adopt a model of \( \Delta y_t \) and use this to locate turning points. To date the models used are parametric and generally feature two regimes. Perhaps the best known parametric model is that of Hamilton (1989), where the growth rate is treated as a Markov switching (MS) process of the form

\[
\Delta y_t = \mu_0 (1 - \xi_t) + \mu_1 \xi_t + \epsilon_t
\]

Here \( \mu_j \) are the growth rates in the two regimes, and these are indexed by a latent binary state, \( \xi_t \), while \( \epsilon_t \) is a normally distributed zero mean error term. Here \( \mu_0 \) is the growth rate of the low growth state and \( \mu_1 \) is the high growth rate. Sometimes the restriction \( \mu_0 < 0 \) is also imposed. The model is completed by specifying the transition probabilities of moving from \( \xi_{t-1} = 0 \) or 1 to \( \xi_t = 1 \) or 0. The model can be made more complex with extra dynamics, different variances in each regime, allowing the transition probabilities to depend on some observable data, and so on. This parametric model is used to compute the conditional
probability, \( \Pr[\xi_t = 1|\mathcal{A}_t] \), where \( \mathcal{A}_t \) is either all or a subset of the growth rates \( \{\Delta y_j\}_j^T \). Thus the estimate of \( \Pr[\xi_t = 1|\mathcal{A}_t] \) is a function of whatever growth rates are in \( \mathcal{A}_t \). Generally this probability will be a nonlinear function of the elements in \( \mathcal{A}_t \) although a linear function can be quite a good approximation – see Harding and Pagan (2003) for an example.

The cycle is then associated with a binary variable \( S_t \) that takes the value 1 in expansion and zero in contraction. A rule is used to construct \( S_t \) by comparing the estimated probability of being in the high growth state with some critical value. Hamilton chose .5, and most of those using the technique have followed suit. Consequently, if \( \Pr[\xi_t = 1|\mathcal{A}_t] > .5 \), an expansion is signified and \( S_t \) is set to unity. If the criterion is not satisfied \( S_t \) is set to zero. Notice that the \( \xi_t \) are not the phase states; the latter are \( S_t \). They are simply a device for producing some nonlinear structure in \( \Delta y_t \), although often one can think of the outcomes for \( \xi_t \) as signifying a low or high growth period. The correlation between \( S_t \) and \( \xi_t \) may be very low. Many applications of this methodology have now been made and the MS model that one chooses seems to vary a lot with the series it is being applied to. The simple one described above rarely works satisfactorily.

In most instances a decision about the utility of the method is made by comparing the business cycle states produced by the rule based on the magnitude of \( \Pr[\xi_t = 1|\mathcal{A}_t] \) with those found by turning point methods. Because of the latter comparison one has to ask what the advantages there are in using a model to locate turning points. Chauvet and Piger (2003) claim that an advantage of the model-based approach is that it allows an investigator to forecast turning points in real time. There is some truth to this but it is exaggerated. Since forecasts can be found for any such model, they could be passed through any chosen dating algorithm to determine the predicted phases.

### Measuring cycle features

Turning points segment time series into phases. An expansion phase runs from the trough to the next peak. A contraction runs from a peak to the next trough. In what follows it is easiest to just describe the derivation of information on expansions.

The two most basic statistics related to phases are duration and amplitude. The **duration** of an expansion is the number of periods of time between the trough and next peak. The **amplitude** of an expansion measures the change in \( y_t \) from trough to the next peak. In many cases \( y_t \) is the log of some variable such as GDP or industrial production, that is, \( y_t = \ln(Y_t) \), and the amplitude has a natural interpretation as the approximate percentage change in \( Y_t \) between trough and peak.

Duration and amplitude form two sides of a triangle. Connecting the trough and peak produces the hypotenuse. If \( Y_t = \ln(Y_t) \), then the hypotenuse represents the path followed by a variable that exhibits a constant growth rate during an expansion. With this in mind it is instructive to inspect the actual path followed by the data, and to compare that path with the constant growth path represented by the hypotenuse. Figure 1 shows how US expansion paths have deviated from the constant growth rate path in the post-Second World War period. The important feature evident in this figure is that the growth rate of GDP is not constant over the expansion phase and typically is highest in the first half of an expansion.

While comparisons such as that in Figure 1 are visually informative, there is also a need for statistics that summarize the average shape of phases. Sichel (1994) divides expansions into three stages, computes the average growth rate for each stage, and shows graphs of these, as well as providing formal statistical tests of equality of the growth rates in each stage. Harding and Pagan (2002) compare the cumulated gain in an expansion with what it would have been if growth had been constant throughout the phase. This comparison was motivated by the idea mentioned above, that a plot of $y_t$ against $t$ during an expansion would look like a triangle if growth had been constant. The area of such a triangle would be one-half the product of the amplitude and duration. If growth was not constant the area under the path actually followed by activity during the expansion would differ from the triangle. Thus, a comparison of the two areas provides a measure of the extent of departure from a constant growth scenario. The evidence seems to be that expansions do not feature constant growth in some countries like Australia, the United States and the UK, but do so in many Continental European countries. The shape analysis is interesting since a linear process for $\Delta y_t$ will produce phases that, on average, have constant growth rates. So a failure to see this signals the need for a nonlinear process for $\Delta y_t$. The shape analysis also provides a useful tool for testing whether nonlinear models produce realistic business cycles.

All of the methods for summarizing business cycle information can be applied to growth cycles and to data that have undergone higher-order differencing. In addition, Sichel (1993) suggested tests for ‘deepness’ and ‘steepness’ in the growth cycle that were effectively tests for symmetry in the densities of $z_t$ and $\Delta z_t$. 
Using multivariate information in defining and detecting business cycles

Burns and Mitchell's famous definition of a business cycle – 'Business cycles are a type of fluctuation found in the aggregate economic activity of nations...a cycle consists of expansions occurring at about the same time in many economic activities, followed by similarly general ... contractions...' (1946, p. 1) – has two aspects. One points to the need to identify aggregate economic activity, and the other to the fact that there should be synchronization across many series during the phases of a business cycle. Burns and Mitchell commented that GDP was a suitable index of economic activity, although others, such as Moore and Zarnowitz (1986), have preferred a weighted average of several series rather than a single one. However, since data on GDP was not available to Burns and Mitchell, for either the time period or the frequency in which they were interested, it is natural that they placed more emphasis upon the second component of their definition when discussing the business cycle. This second component emphasizes synchronization of the cycles in the specific series taken to represent economic activity. Burns and Mitchell took the turning points in many series and then extracted a reference cycle by determining those dates which peaks and troughs 'clustered around'. So a primary task is to be able to measure the tightness of the clusters. At the end of the process one also wishes to know how synchronized each of the specific cycles is with the cycle in the aggregate. Harding and Pagan (2006) develop procedures to measure the tightness of clusters of turning points and the degree of synchronization of cycles through concordance indices that measure the fraction of time spent in the same phase. They apply those procedures to the series referred to by the NBER when dating the business cycle, and find that the turning points in those series are tightly clustered together. Harding (2003) finds that between March 1949 and September 2001 there is a concordance of 0.96 between the NBER business cycle states and the cycle obtained by locating turning points in US GDP.

Automated construction of the reference cycle

To automate the calculation of the reference cycle requires some rules which will distill the specific cycle turning points into a single set of turning points. To determine what these rules might be, one could look at the NBER Business Cycle Dating Committee procedure. It has a similar modus operandi to that of Burns and Mitchell, as seen in its discussion about dating the 2001 recession (NBER, 2003). However, one rarely gets a precise description either of how its decisions are made or of the series used in that process. In addition, it seems as if the series which have been most influential in decisions may have been different at different periods in time. The clearest description of the procedures for aggregating turning points in a set of series to create a reference cycle is in Boehm and Moore (1984), who explain how NBER methods were used when establishing a reference cycle for Australia. Their description can be taken as authoritative because Moore was a pivotal figure in the NBER Business Cycle Dating Committee for many years. Moore and Zarnowitz (1986) also provide information on methods used by NBER in dating the business cycle. Given that the process for establishing the reference cycle is a little vague, it should not be surprising that there have been few attempts at producing automated dating algorithms to establish it from multivariate series. Harding and Pagan (2006) construct an algorithm to replicate the NBER procedures described by Boehm and Moore (1984). They obtain the 'clustering parameter' which is essential to measuring the tightness of turning point clusters by looking at Boehm and Moore's spreadsheets. The resulting algorithm has produced a reference cycle that matches the Australian version established by Boehm and Moore quite well. Subsequently, it has been tested on US data, and is able to produce quite a good replication of the reference cycle for the United States, even though the clustering parameter had been calibrated with Australian data.

Model-based procedures for defining detecting and extracting a reference cycle

Recently, academic economists have used parametric models to construct a coincident index and the reference cycle from multivariate series $\Delta y_{jt}$, $\Delta \gamma_{kt}$. A common element to all approaches is to write $\Delta y_{jt}$ as a function of a common component $\Delta f_{j}$ and idiosyncratic components $\tilde{u}_{jt}(j = 1, \ldots, m)$. Hence a simple representation would be

$$\Delta y_{jt} = \alpha_{j} \Delta f_{j} + \tilde{u}_{jt}.$$ 

The $f_{j}$ is often thought of as the coincident index of the business cycle. Of course, there may be more than one $f_{j}$ but, ultimately, we can think of combining them to form a single variable. There are then many ways that models for $\Delta f_{j}$ and $\tilde{u}_{jt}$ might be specified, depending upon how strong the assumptions are that one wishes to make about the nature of $f_{j}$ and $\tilde{u}_{jt}$. Often $\Delta f_{j}$ is given an MS form (for example, Chauvet and Piger, 2003). Depending on what these assumptions are, they will determine how an estimate of $f_{j}$ is to be made. Stock and Watson (1991) and Chauvet (1998) represent different approaches. In some instances one can avoid specifying precise parametric models for $f_{j}$ and $\tilde{u}_{jt}$, restricting them only to be in a general class. Forni et al. (2001)'s dynamic factor approach is the main representative of this latter technique. The main issue with these approaches is that the coincident index and reference cycle obtained are conditioned on the assumptions made about the data-generating process. For that reason these approaches cannot provide a neutral measurement of the reference cycle.

Conclusion

Although widely used in official circles, Burns and Mitchell's methods of measuring cycles through turning points have been less popular in academia. But this has changed in recent years. There are a number of reasons why the methods have become increasingly attractive. First, information about the nature of the cycle phases can be generated, and this shape information proves important when one tries to construct models of economic activity. Second, the literature now contains expert systems for locating turning points, and these have been coded into various computer languages, thereby eliminating the judgmental aspect of the method. Nevertheless, the automatically generated turning points have been quite good approximations to those found via judgment. Third, the ability to produce simulated data from parametric models means that such information can be passed through the algorithms for locating turning points to produce simulated distributions for the statistics that summarize the features of the cycle. Fourth, the emerging mathematics literature on crossing points provides a natural foundation on which to build a distribution theory for Burns and Mitchell's methods. Fifth, there is now a large literature on parametric methods for locating turning points and measuring cycles. This latter literature can readily be linked to the nonparametric turning point approach of investigators such as Burns and Mitchell, as seen in Harding and Pagan (2003).

business networks

Francis Bloch
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Informal and formal business networks play an increasing role in economic activities. Business networks have been studied both by sociologists and economists in order to answer three questions: What is the influence of business networks on economic activities? What are the determinants of business networks? When and how are business networks alternatives to organized markets?

Keywords

business networks; class; commitment; corporate governance; credit markets in developing countries; diffusion of innovations; economic geography; enforceable international contracts; interlocking directorates; intermediate goods; international trade; knowledge spillovers; labour market search; market sharing; matching; spatial concentration; strategic alliances

Article

Informal and formal business networks play an increasing role in economic activities. A large literature in economics and sociology has focused attention on these business networks. Three sets of questions have been raised: What is the influence of business networks on economic activities? What are the determinants of business networks? When and how are business networks alternatives to organized markets?

The importance of social networks has been stressed in three spheres of economic activities: the job market, where personal referrals play an essential role; international trade, where the existence of networks helps explain the volume of trade across borders; and urban economics, where business relations are an important determinant of the degree of local knowledge spillovers.

Empirical studies show that as many as half of the jobs are found through personal contacts. Granovetter's landmark study (1974) of the importance of networks in the managerial and professional job market in a Boston suburb stresses the difference between ‘strong’ and ‘weak’ ties. According to his
study, weak ties – distant acquaintances to individuals who belong to different communities – play a much stronger role than ‘strong ties’ – close relations to individuals belonging to the same group – in helping business executives finding or changing jobs. Recent economic models of job networks emphasize the dynamic effect of networks on unemployment and inequality (Calvo-Armengol and Jackson, 2004).

In international trade, informal co-ethnic networks formed by migrants – like the Chinese trading network – and formal business networks like the Japanese keiretsu have a significant impact on the volume of trade across borders. Rauch's survey (2001) summarizes the empirical evidence and outlines different theoretical explanations of the effect of business networks on international trade. The existence of personal links allows traders to match opportunities better as the network provides an informational link across agents from different countries. Networks also allow traders to solve the problems of enforcement of international contracts – agents who do not meet their obligations may be expelled from the network.

Informal networks also play a fundamental role in the diffusion of innovations and the emergence of new ideas in local areas. In her celebrated comparison of business models in the Silicon Valley and on Route 128, Saxenian (1994) argues that the success of the Silicon Valley is in large part due to the flexible, informal organization of business relations in California. Economic geographers have long noted that these informal networks generate important knowledge spillovers, which help explain the concentration of industrial activities over space and justify the emergence of industrial districts. The architecture of business networks has been extensively studied in two areas where precise data can be obtained: interlocking directorates and strategic alliances. Empirical studies of interlocking directorates – the exchange of directors across company boards – first show that networks of intercorporate relations are highly asymmetric: a small number of firms occupy a central position on the network, concentrating a large number of interlocks. Second, intercorporate links tend to be local, and interlocking occurs among firms in the same geographical area. Third, the number of interlocks increases with the firm's size.

To explain this pattern of interrelations, two competing theories have been proposed, resulting in a lively controversy in the sociological literature, reviewed by Mizruchi (1996). Proponents of the social class theory argue that interlocking reflects the dominance of the upper class, and that relations among firms are mostly explained by individual friendships and the desire to maintain hegemony over the corporate world. The resource dependence theory explains the existence of interlocks by the firms’ desire to access resources detained by other firms. According to this theory, industrial companies exchange directors with financial institutions in order to obtain easier access to credit and with their suppliers in order to guarantee access to intermediate goods needed in production.

Strategic alliances are bilateral agreements among firms in the same industry. Agreements to launch joint R&D projects have received special attention in the literature. On the empirical side, a large database of bilateral research agreements has been developed by the MERIT center in Maastricht (Hagedoorn, 2002). These data show a large increase in the number of partnerships in the 1990s, and demonstrate that firms increasingly use flexible contractual arrangements rather than joint-equity subsidiaries to launch new research programmes. Research partnerships are very unevenly distributed across industrial sectors, with high-tech industries (in particular information technology and the pharmaceutical industry) accounting for a very large share of agreements.
Goyal and Joshi (2003) propose a theoretical model to explain the formation of these collaborative networks. Their analysis explains the high density of the networks by showing that, in the absence of linking costs, firms always have an incentive to form strategic alliances. In the presence of linking costs, stable networks become asymmetric, with a small number of isolated firms facing a large group of interrelated firms. When firms choose their research investments after the network is formed, inefficiencies arise as firms have a tendency to fragment their investments over too many links.

Belleflamme and Bloch (2004) study a different type of strategic alliance: reciprocal market-sharing agreements whereby firms divide markets geographically. They show that stable networks are typically asymmetric and contain complete components of different sizes.

Trade networks can provide a viable alternative to organized, anonymous, markets. Buyers and sellers establish personal links, and conduct trade on a bilateral basis rather than through a centralized market. Historically, business networks have played a fundamental role in the development of trade. Greif’s celebrated study (1993) of the Maghribi network, formed by Jews in the western Mediterranean in early medieval Europe, points out that business networks were able to solve commitment problems in the absence of institutions enforcing contracts. Still in the western Mediterranean, but in modern times, Kirman’s detailed study (2001) of the fish market in Marseille also shows that a larger volume of trade is conducted on a bilateral basis, with buyers and sellers linked through durable relations.

Casella and Rauch (2002) and Kranton (1996) propose alternative theoretical models to investigate the difference between anonymous markets and personalized networks. In Casella and Rauch (2002), business networks enable traders to overcome informational trade barriers, and to learn about matching opportunities in international markets. They show that agents who continue to conduct trade through organized markets suffer from the presence of the business network. Kranton's model (1996) is built around the issue of enforcement of contracts: agents can either choose to trade on the market at the risk of being cheated but benefiting from a wide variety of goods, or to use a personal network. Kranton shows that there exists a strong interaction between the two modes of exchange: the more people use networks, the lower their incentives to use markets; the larger the fraction of the population which uses markets, the lower are their incentives to engage in personal transactions.

In summary, the importance of business networks in economic activities, which has long been recognized by sociologists, is attracting increasing attention from economists. New theoretical and empirical methods enable researchers to revisit business networks. In this relatively new field of study, a number of problems remain open. For example, the theoretical corporate governance literature is still silent on the issue of interlocking directorates. The interaction between formal insurance and credit markets and informal network arrangements in developing countries also awaits further study.

Noel George Butlin, one of Australia's leading historical economists, was born in Singleton, New South Wales on 19 December 1921. He was the sixth child and third son of Thomas Lyon Butlin, a railway porter, and Sara Mary Butlin (née Chantler). Butlin attended Maitland Boys High and studied economics at Sydney University. During his undergraduate years, Sydney had the nation's best economics department in terms of the professional qualifications of its teaching staff. Even so, Butlin claimed that, while his lecturers taught him how to deconstruct aspects of the economy, they were unable to show him how it all worked. He wanted to become a scholar to understand real-world economic processes.

Like many others of his generation, Butlin's career was disrupted by war. While he wanted to enter academia, the only avenue available on graduation was the Australian public service. Between 1942 and 1945 Butlin was mainly seconded to posts in the UK and USA. There he met J.M. Keynes, L. Robbins, A. Robertson, R. Stone, and H.J. Habakkuk. Back in Australia he participated in 1945 in making plans for Australia's post-war reconstruction, and in 1946 finally took up a lectureship at Sydney University. To further his research ambitions, Butlin accepted a Rockefeller Fellowship in 1949 to study for a Ph.D. at Harvard under Joseph Schumpeter. Unfortunately, the great man died a few months after Butlin's arrival, and he found himself in Harvard's Centre for Entrepreneurial Studies. He had little sympathy with their growing sociological interests and, after initial research on Canadian railways, decided in 1951 to return to Australia to work at the Australian National University (ANU). In 1963 he became Professor and Head of the Department of Economic History. Butlin's 40-year association with the ANU ended only with his death on 2 April 1991.

Back in Australia, Butlin was swept up in the post-war concern with economic development. On the theoretical side, the old influence of Schumpeter was joined by the new influences of Harrod and Solow–Swan, and, on the measurement side, the great statistician Coghlan was joined by Kuznets.
absorbed ideas from them all. He borrowed the ‘structural disequilibrium’ concept from Schumpeter, but ignored technological change in favour of the investment focus of the neoclassical growth model. Economic development in Butlin's analysis proceeded via long investment booms that created structural disequilibria and required depressions to reattain structural balance. The outcome of these influences, together with much hard work during the 1950s, was the publication of his two-volume magnum opus on Australian development (Butlin, 1962; 1964). This set the pattern for subsequent analysis by historians and economists in the 1970s and 1980s, and was only challenged in the 1990s (Snooks, 1994). Despite being an active researcher until his death, Butlin never surpassed this early work. His most interesting subsequent research focused on pushing his GDP estimates back to 1788 (Butlin, 1986), and on analysing the Aboriginal economy (Butlin, 1983; 1994).

What was the nature and importance of Butlin's contribution to economics and history? First and foremost, Butlin focused our attention on the process of Australian economic development, and showed that it was endogenously generated. This was an essential counterpoint to the traditional view that development was exogenously driven. Second, he demonstrated that real-world growth processes could not be encompassed by the simple neoclassical growth models that were fashionable among orthodox economists at the time. Unfortunately he was unable to fulfil his intention of writing a ‘strictly analytical’ volume to complete the 1960s trilogy. He failed, therefore, to develop a general dynamic theory that could displace these totally unrealistic growth models. That was left to others (Snooks, 1998). Third, while his hybrid national accounting techniques have been criticized, they have weathered the storm reasonably well. More than most Australian national accountants, Butlin had an impressive understanding of the history that generated the data he employed. When used for long-run rather than year-to-year analysis, the differences in alternative estimates are not significant (Snooks, 2007). In any case, it is Butlin's overarching interpretation, his realist vision, and his important example of what can be done with the available data that constitute his enduring contribution.

Cairnes was born at Castlebellingham, County Louth, Ireland. At the height of his career he was probably the best-known political economist in England after John Stuart Mill, whose friend and associate he was from 1859 onwards; but his interest in economic questions developed relatively late, after periods spent working in his family's brewing business and in journalism. In 1856 he competed in the examination by which the Whately professorship of political economy at Trinity College, Dublin, was then filled, and was appointed for a five-year term. In 1859 he was also appointed Professor of Political Economy and Jurisprudence at Queen's College, Galway, a post which he held until 1870. However, he employed a deputy to perform his duties in Galway after he himself moved to London in 1865. In 1866 he became Professor of Political Economy at University College, London, but was forced to resign in 1872 by the progress of the rheumatic disease which left him almost completely paralysed before his death in 1875.

Cairnes has often been described as ‘the last of the classical economists’. He always worked within the framework of the Ricardo–Mill tradition, devoting himself to refining and strengthening it and seeing no necessity for any radical reform or reconstruction. Within these self-imposed limits and in a career of less than 20 years as a professional economist, he succeeded in making contributions to both theoretical and applied economics which earned him a high reputation among his contemporaries and a definite place in the history of economic thought.

Cairnes's first work in economics proved to be one of his most enduring contributions to the subject. This was *The Character and Logical Method of Political Economy* (1857; 2nd edition, 1875) which is still regarded as one of the best statements of the verificationist methodology of the English classical school. Following the lines laid down by Senior and Mill, Cairnes stressed the neutrality of economic
science, emphasized the value of the deductive method and characterized the subject as a hypothetical science ‘asserting, not what will take place, but what would or what tends to take place’ ([1857] 1875, p. 55).

It was in the use of the deductive method to develop the central areas of economic theory that Cairnes's main interest came to lie. Yet it was through his work on applied economics and current issues of policy that he first came to be nationally and internationally known. In September 1859 Cairnes published the first of a series of ‘Essays towards a solution of the Gold Question’ in which he sought to ‘apply the principles of economic science’ in an attempt to ‘forecast the directions in which the course [of trade and prices] would be modified by the increased supplies of gold’. This a priori approach was almost precisely the opposite of that used by Jevons to deal with the same problem, but their results coincided remarkably.

It was another application of this approach which first made Cairnes's work known to a much wider audience. In The Slave Power (1862) he sought to explain on economic grounds the appearance of slavery in the southern parts of the United States, tracing out both the conditions for and the consequences of the operation of a slave economy. As an indictment of the political economy of the Confederate States it strongly influenced public opinion in Britain towards support of the Northern states in the American Civil War.

Between 1864 and 1870 Cairnes wrote a number of articles on the problems of land tenure in Ireland, in which he argued in favour of proposals to fix rent by law and contended that this was not inconsistent with classical rent theory. There is evidence that his views on this and other questions of the day, such as Irish university education, exerted considerable influence on (and through) Mill and Fawcett.

Cairnes's most important contribution to economic analysis, Some Leading Principles of Political Economy Newly Expounded (1874), was also to be his last work and that by which he came to be most widely known and judged. In it he restated, but with significant modifications, the essentials of classical doctrine on the central questions of value, distribution and international trade. His most important innovation was to show that the existence of ‘non-competing groups’ in labour markets implied that the cost of production theory must be supplemented by the analysis of reciprocal demand in the theory of domestic as well as international values.

Nevertheless his unsympathetic review of Jevons's Theory of Political Economy (Fortnightly Review, N. S., vol. 11, 1872) showed that he lacked interest in and understanding of the subjective approach to value theory which was then developing. Cairnes's treatment of distribution in the Leading Principles echoed Mill in showing sympathy for the position of the labourer combined with pessimism based on acceptance of Malthusian population theory; but it was chiefly notable for an elaborate but ultimately unsuccessful attempt to rehabilitate the wages-fund doctrine abandoned by Mill himself in 1869. The verdict of Schumpeter (1954, p. 533) still seems appropriate: Cairnes ‘expounded the old analytical economics and explicitly distanced himself from the new’.

calculus of variations

Morton I. Kamien
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

The development of the calculus of variations is attributed to Euler and Lagrange, although some of it can be traced back to the Bernoullis. A history of the calculus of variations is provided by Goldstine (1980). The calculus of variations deals with the problem of determining a function that optimizes some criterion that is usually expressed as an integral. This problem is analogous to the differential calculus problem of finding a point at which a function is optimized, except that the point in the calculus of variations is a function rather than a number. The function over which the optimum is sought is usually restricted to the class of continuous and at least piecewise differentiable functions.

A typical calculus of variations problem is of the form

$$\max_{x(t)} \int_{t_0}^{t_1} F[t, x(t), x'(t)] dt \quad \text{s.t.} \quad x(t_0) = x_0,$$

where $x'(t) = dx/dt$, and $t$, $x(t)$, and $x'(t)$ are regarded as independent arguments of the function $F$. The necessary conditions for $x^*(t)$ to maximize (1) are the Euler equation

$$F_x = dF_{x'}/dt,$$

(2)

$F$ the Legendre condition
\[ F_{x'x'} \leq 0 \]  
(3)

and the transversality conditions

\[ F_{x'} = 0 \text{ at } t_1, \text{ if } x(t_1) \text{ is free}, \]  
(4a)

\[ F - x'F_{x'} = 0 \text{ at } t_1, \text{ if } t_1 \text{ is free}, \]  
(4b)

where \( F_x \) and \( F_{x'} \) refer to the partial derivatives of \( F \) with respect to \( x \) and \( x' \), respectively, and \( F_{x'x'} \) is the second partial derivative of \( F \) with respect to \( x' \). The Euler equation (2) is in general a nonlinear second order differential equation. The initial condition \( x(t_0) = x_0 \) and the transversality condition (4a) provide the means for determining the two constants of integration that arise in solving the Euler equation. The optimal value of the upper limit of integration, \( t_1 \), if it can be chosen, is determined by the transversality condition (4b). The problem posed in (1) can be extended to include additional arguments of the function \( F \), to include a variety of additional constraints, and to involve double integrals (see Kamien and Schwartz, 1981). Concavity of \( F \) with respect to \( x(t) \) and \( x'(t) \) assures that the necessary conditions are also sufficient.

The earliest application of the calculus of variations to the analysis of an economic problem appears to have been attempted by Edgeworth (1881), who seems to have been greatly impressed by its successful employment in deriving some of the basic laws of physics. He sought to employ it to find a function for distributing income and assigning work among the members of society so as to maximize total social welfare. Many applications of the calculus of variations to economic problems have been conducted since then, a few of which will be described.

As the calculus of variations deals with the problem of finding a function or a path that maximizes some criterion, its major application in economics has been to problems involving optimal decision making through time where an entire course of actions is sought rather than a single action. One of the earliest and most influential applications along these lines is by Ramsey (1928). The question he addressed is how much should a nation save out of its national income through time so as to maximize its overall welfare over time. Ramsey argued that the discounting of future utilities was ‘ethically indefensible’ as
it means that we give less weight to the utility of future generations than to our own. He posited, 
therefore, a maximum level of net utility, the utility of consumption minus the disutility of work, that he 
called bliss. This bliss level of utility is the asymptotic limit of the achievable level of net utility.
Ramsey then sought the savings rate through time that would minimize the integral over the indefinite 
future of the difference between the bliss level of utility and the actual net utility level at each point in 
time, subject to the constraint that savings plus consumption equal total output at each instant of time. 
The rule he derived for the optimal savings rate, through the Euler equations, is that the ‘rate of saving 
multiplied by the marginal utility of consumption should always equal bliss minus actual rate of utility 
enjoyed’. This is essentially a marginal sacrifice today equals marginal benefit tomorrow rule. The 
rationale for taking the upper limit of integration to be infinite in the objective function is that while 
individuals have finite lives, society as a whole goes on forever. Ramsey also took up the case where 
future utilities are discounted at a constant positive rate and derived what may be regarded as the 
fundamental equation of optimal consumption through time, namely that the proportionate rate of 
change of marginal utility of consumption should equal the difference between the marginal productivity 
of capital and the rate at which future utility is discounted. The Ramsey model became the basis for 
optimal growth theory that was intensely investigated in the late 1950s and 1960s.
Strotz (1956) addressed the question of the circumstances under which an individual would continue 
today to follow the optimal consumption plan through time that he had determined at an earlier date. In 
other words, he asked for the conditions under which an optimal consumption plan through time would 
be consistent. He found the necessary and sufficient conditions for consistency to be that ‘the 
logarithmic rate of change in the discount function must be constant’. Exponential discounting at a 
constant rate satisfies this criterion.
Yaari (1965) addressed the question of an individual's optimal consumption plan through time when his 
lifetime is uncertain. He also allowed for the possibility that the individual derives utility from a bequest 
to his heirs. Yaari found that a major effect of the presence of uncertainty about one's lifetime is the 
same as an increase in the rate at which future utilities are discounted. Thus, the ‘effective’ rate at which 
future utilities are discounted has a risk premium term added to the discount rate in the absence of 
uncertainty about one's lifetime. The risk premium term is the instantaneous conditional probability of 
dying in the next instant given survival to the present. The presence of the risk premium means that the 
rate of consumption at any point in time is higher than it is in its absence. Uncertainty about one's 
lifetime increases one's rate of current spending, if there is no bequest motive.
While Ramsey applied the calculus of variations to the problem of optimal savings through time, Evans 
(1924) appears to have been the first to have employed it for determining the optimal rate of output 
through time. Evans used, as his vehicle for making the problem of choosing the level of output so as to 
maximize a monopolist's profit over an interval of time nontrivial, i.e. just simple maximization of profit 
at each instant of time, the assumption that the demand function for a good depended both on its current 
price and the rate of change of price. In particular, he assumed that the demand function was linear in 
price and its first derivative, and that the cost of production was a quadratic function of the level of 
output. Under these assumptions Evans sought the level of production that would maximize the integral 
of profits over a finite horizon. He was able to characterize this path and to show that a particular 
solution to the second order differential equation stemming from the Euler equation was the static 
monopoly profit maximizing level of output. Indeed, it is not difficult to show that when the problem is 
posed as one of maximizing the present value of an infinite horizon profit stream that the static
monopoly profit maximizing level of output and the corresponding monopoly price constitute a steady-state towards which the output and price paths converge through time. This, of course, is intuitively plausible, as in the steady-state the rate of change of price with respect to time is zero, and so the demand function depends only on the current price level. Evans's work was extended by Roos (1925) to the case of duopolistic producers of a homogeneous product seeking to maximize their individual profits through time. The Roos paper may be regarded as the earliest analysis of what has come to be known as a differential game (see Fershtman and Kamien, 1987).

The last paper that deserves special mention because of its important application of the calculus of variations is Hotelling's (1931), dealing with the rate at which a mineral resource such as coal, copper or oil should be extracted from a mine and sold so as to maximize the present value of its profits. Hotelling derived the fundamental equation for optimal extraction, under competitive production of the resource, namely that the extraction rate be such as to equate the percent change in price through time with the rate of interest at each instant in time. The intuitive reason for this is that if the percent change in the price of the resource exceeds the interest rate then it pays to extract and sell more today, because the alternative of extracting less and earning the interest on the revenue from that level of extraction yields less. The increase in the current rate of extraction, however, causes price to decline until the percent change in the price through time is equalized with the rate of interest. A similar analysis yields that current extraction will decline if the percent change in price is below the interest rate, which in turn will cause price to rise until equality is achieved. Along the optimal extraction path the mine owner is just indifferent between extracting an extra unit of resource today and extracting it tomorrow. A similar analysis can be carried out for a monopolistic mine owner, with the percent change in marginal revenue through time being equated with the interest rate.

There have been a very large number of applications of the calculus of variations since these early ones. Many have employed optimal control methods and dynamic programming methods, both of which constitute generalizations of the calculus of variations. As long as decision making though time is regarded as an important subject of economic analysis, the calculus of variations will continue to find use in economics.

calibration

Edward C. Prescott and Graham V. Candler
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The methodologies used in aerospace engineering and macroeconomics to make quantitative predictions are remarkably similar now that macroeconomics has developed into a hard science. Theory provides engineers with the equations, with many constants that are not well measured. Theory provides macroeconomists with the structure of preference and technology and many parameters that are not well measured. The procedures that are used to select the parameters of the agreed upon structures are what have come to be called ‘calibration’ in macroeconomics.

Keywords

calibration; elasticity of intertemporal substitution; equity premium; impatience; Lucas critique; measurement; neoclassical growth theory; risk aversion; total factor productivity

Article

What is calibration? In the dictionary definition, calibration is the act of calibrating a measurement instrument so that it gives the correct measurement for some known conditions. When calibrating a thermometer that will be used to measure the air temperature, calibration would involve setting it to read 100 degrees Celsius when submerged in boiling water at sea level and zero degrees when submerged in ice water. Because the boiling point of water varies with altitude, the calibration would be different in Mexico City, which is more than a mile above sea level.

Sometimes macroeconomists calibrate a measurement instrument – that is, a model – in this narrow sense. But calibration has gained a broader meaning in economics and is what macroeconomists do when using theory to derive quantitative theoretical inference. Prescott emphasizes that calibration is not estimation. Calibration is a process that uses theory to construct a model – that is, an instrument – which will be used to provide a quantitative answer to a question.

Clearly, instruments are not measured; rather, they are calibrated so that they can be used to accurately answer quantitative questions. The nature of questions varies. Examples of questions are as follows:
what is the welfare benefit or cost of changing the currently employed policy arrangement to another one? What will happen to a spacecraft when it enters the atmosphere of Mars? To predict the quantitative consequences of a particular policy, theory and observations are used to select a model economy, and the equilibrium behaviour of that economy is determined for the proposed policy. Theory provides a set of instructions for selecting the model economy. This selection process is what calibration in economics has come to mean. Needless to say, the nature of the application of theory and the availability of economic statistics dictate which model economy is selected. Before proceeding, a little history of the development of macroeconomics is needed. The modern national accounts were developed by the NBER staff in the 1920s, with Simon Kuznets playing the leading role. In the 1950s and 1960s, macroeconomists searched for the dynamic system governing the behaviour of these accounts. The controls for this dynamic system were policy actions. Not having much theory, this activity was largely empirical. Macroeconomists would write down a parametric set of models and find the one that best fitted the national accounts, augmented with other statistics. This search for the dynamic system failed because, as established in the Lucas critique, the existence of such a policy invariant dynamic system is inconsistent with dynamic economic theory. The failure of this search led to a vacuum in quantitative macroeconomics. The profession did not want to go back to conjecturing and story-telling that characterized pre-war business cycle theory. As a result, the 1970s was a frustrating decade for quantitative macroeconomists given the failure of the empirical approach and the lack of needed tools and theory to quantitatively study macroeconomic behaviour. This vacuum was filled in the early 1980s when the extended neoclassical growth model was used to study business cycles. The national accounts had to be modified to be consistent with the model. The most important modification in the study of business cycles is treating consumer durable expenditures as an investment and imputing consumption services to the stock of consumer durables as is done for owner-occupied housing. The secular growth observations with constancy in shares of output led to a constant elasticity structure with share and elasticity parameters. The fact that capital share of income displayed no trend even though the relative price of labour increased secularly led to a unit elasticity of substitution aggregate production function with share parameters equal to income shares. The depreciation rate, for example, was calibrated to average depreciation share of product. The national accounts use prices of used capital goods to estimate depreciation. This methodology is used in virtually all quantitative theoretical aggregate studies. We emphasize that quantitative theoretical research and empirical research are fundamentally different activities and fundamentally different tools are needed. If the objective of the research is to derive the quantitative implications of the neoclassical growth theory for business cycle fluctuations, the use of statistical tools to select the parameters that best fit the business cycle observations is not sound scientific practice. In this short article macroeconomist Prescott will describe what he does when addressing macroeconomic issues and aerospace engineer Candler will describe what he does when addressing the problem of making predictions of what will happen when a capsule enters the atmosphere of Mars. These predictions are relevant to the design of the capsule. Prescott will conclude by comparing the approaches and argue that these scientific approaches are essentially the same. We begin with what aerospace engineers do so that comparison can be made with what they do and what macroeconomists do.
I work in the field of aerodynamics, and specifically I try to predict what happens when a spacecraft enters the atmosphere of a planet. For example, one of my current projects involves predicting how the Mars Science Laboratory capsule will fly as it enters the Martian atmosphere. What is the peak heat transfer rate to the spacecraft? How much heat shield is required to protect it from the extremely high temperature gas that surrounds it during atmospheric entry? Will it produce enough lift so that it will fly along the planned trajectory? Will the uncertain state of the atmosphere cause the capsule to veer off course? These questions must be answered to a known level of accuracy before the spacecraft can be designed. Failure to predict heating levels or aerodynamic performance can result in a well-publicized and expensive loss of the mission. At the same time, excessive conservatism in the design reduces the useful payload of the spacecraft and increases the cost of the mission.

How do we go about modelling this complex problem? We cannot fly a statistical ensemble of missions and empirically extrapolate to the flight conditions of interest. Instead, we must rely on ground-based wind-tunnel testing and theory-based simulations. However, experiments have a number of limitations: it is impossible to test the full-scale capsule; it is usually impossible to produce the actual flight conditions; and we cannot produce the actual intense heating levels for realistic periods of time. On the other hand, we can use numerical simulations to predict the flow field around the full-scale spacecraft at critical points in the entry trajectory. In principle, these calculations can predict the heat transfer rates and aerodynamic forces, and provide accurate data for the spacecraft designers. Of course, these simulations are only as accurate as the underlying equations being solved, and herein lies the problem. We cannot rely on purely empirical measurements to test a spacecraft design, yet simulations require a set of governing equations that must be validated by realistic flight experiments.

Interestingly, the basic set of governing equations that describes the flow over a spacecraft entering a planetary atmosphere is well established. However, there are many parameters in these equations that are the subject of intense debate within my field. We do not have an accurate understanding of the chemical reaction rates in the flow field; we do not know how to model transition to turbulence in the flow near the surface; we cannot predict how much turbulent flow enhances the heat transfer rate; and we do not understand how the high-temperature gas interacts with the spacecraft surface. A complete model of the flow over a spacecraft entering the atmosphere of Mars has well over 100 model constants that must be determined before the equations are fully specified. Clearly, with our limited experience base and with the limitations of the ground-based testing facilities, it is fundamentally impossible to determine these model constants with the available data. Rather, we must impose a rigorous theoretical basis for the choice of these model parameters. Also, we must understand the sensitivity of the critical results (heat transfer rate and aerodynamic forces) to the choice of the parameters. For example, there is no sense in investing a lot of time and money to accurately determine a model parameter that has a one per cent effect on the lift at relevant conditions.

So what do we do? We attack the problem from two sides. First, we break the full problem into well-defined parts and use theory and experiment to determine specific parameters under controlled conditions. For example, we might be concerned with how high-temperature oxygen molecules attack a particular heat-shield material. We would commission experiments to address this specific issue at conditions that are as close as possible to the flight conditions. Typically, it is impossible to exactly reproduce the conditions, and we would then perform experiments in different test facilities to help bound the parameters. Theory would then be used to extrapolate from the test conditions to those
encountered in flight. We always try to use a theoretical basis to provide discipline to this process. We never perform atheoretic variations of parameters to try to match the data – if it is necessary to break the laws of physics, there is usually something wrong!

The second approach to modelling the flow field is to determine what parameters really matter to the design. A very useful approach is to use theory and experience to bound the range of all parameters in the model. Then a large number of simulations are performed, sampling from the distribution of each parameter. With enough simulations, it is possible to determine the sensitivity of the spacecraft design to each of the modelling parameters. Usually with this parametric uncertainty analysis it is possible to isolate several critical parameters that require particular attention. For example, Wright, Bose and Chen (2007) determined that eight modelling parameters out of several hundred were responsible for 90 per cent of the uncertainty in the design of a proposed spacecraft. New experiments were then designed and carried out to reduce the uncertainty in these critical parameters.

Another engineering perspective is worth noting. We fully recognize that our representation of the world will never be 100 per cent accurate. Rather, we must quantify the level of accuracy of a given model and determine if we can fly a mission with that implied level of risk. We must quantify levels of uncertainty in a design and recognize that a spacecraft that will never fail will be excessively expensive or will carry so little payload as to be worthless. Thus, there is a calculated risk associated with the uncertainty in our modelling parameters. Of course, we try to reduce this uncertainty, but ultimately we are always forced to live with some level of risk if we want to fly an interesting mission.

**Prescott: the macroeconomist**

The selection of parameters in quantitative theory is not measurement. However, quantitative theory is often useful in measurement. It is also useful in making predictions and in accounting for observations. Some examples of successful application are as follows.

The Lucas (1978) asset pricing model with the Markov process on the growth rate of endowments places restrictions on the joint behaviour of asset returns and consumption given two parameters that specify the stand-in household's preference ordering. The first parameter is the degree of risk aversion and the second parameter is the degree of impatience. These restrictions hold in worlds in which there are no transaction costs, no taxes, and no intermediation costs. Whether abstracting from certain factors is reasonable or not depends upon the question.

Mehra and Prescott (1985) used this asset-pricing model economy to estimate how much of the historical equity premium is a premium for bearing aggregate risk. We selected a Markov aggregate endowment growth-rate process whose first two moments matched the historical experience. We used observations and theory to restrict the values of the two preference parameters, including numerous observations on household behaviour. This process of restricting these parameters is part of the calibration process. We found that only a small part of the historical equity premium was a premium for bearing aggregate risk for any value of the parameters in the restricted range. This model economy is ill suited for measuring the curvature and impatience parameter of the stand-in household, but it was well suited for determining how much of the historical equity premium is for bearing aggregate risk.

I turn now to a case where a key economic parameter was estimated accurately using a calibrated set of model economies. The neoclassical growth model used to study business cycles was used to estimate the
leisure intertemporal elasticity of substitution parameter. This parameter is crucial for evaluating tax policies. Because the income and substitution effects roughly offset secularly, balanced growth observations say nothing about the magnitude of this elasticity parameter. If the neoclassical growth model is accepted as a good abstraction for studying business cycles, business cycle observations tie down this parameter. But the profession was reluctant to accept this theory as a useful one for studying business cycles and therefore did not accept the business cycle-based estimate of this elasticity. This important parameter was tied down by cross-country and cross-time observations on tax rates and labour supply. Tax rates, broadly defined to be those features of policy that affect the households' budget constraint, account for virtually all the large differences in labour supply across the large advanced industrial countries and across time for France, Italy and Germany. That this estimate is the same one found in the study of business cycles gave confidence to the view that business cycles are in major part optimal responses to real shocks including productivity, taxes, and terms of trade. As established theory and measurement were used in this study, this is calibration.

I turn now to a specific application of the neoclassical growth model to the study of the aggregate value of the stock market, which also entailed calibration. The study that began in late 1999 was motivated by the question of whether the stock market was overvalued and about to crash. At that time people did not know how to use this theory to obtain an accurate answer to this question and relied on historical relations such as price–earnings ratios to answer the question.

To address this issue neoclassical growth theory as developed in the study of business cycles was used. The model economy had to be modified in three important ways. First, there had to be at least two production sectors, a corporate and a non-corporate sector. To have a reason for having two producing sectors, the outputs of the sectors must be different and must be aggregated in some way. McGrattan and Prescott (2005) use the standard procedure of introducing an aggregator of the sector outputs that produces a composite final output good. This aggregator has a share parameter that must be calibrated to some observation. The observation selected is the average relative outputs of these two sectors. This is a crucial dimension for the model to mimic reality, given the issue being addressed. The conclusion turned out to be insensitive to the elasticity of substitution between these inputs, which was fortunate given there is not good information on this elasticity. Second, the tax and regulatory system had to be modelled explicitly. For example, we set the model's tax rate on corporate distributions equal to the average marginal tax rates on distributions. This is calibration because in the model world this tax rate is the same for all individuals when in fact it is not. Third, we deal with the fact that corporations have large stocks of unmeasured productive assets and that these assets are an important part of the value of corporations, being stocks of knowledge resulting from investment in research and development, organization capital and brand capital. We figure out how to estimate this stock of unmeasured capital using national account data and the equilibrium conditions that the after-tax return on measured and unmeasured capital are equal.

A theory is tested through successful use. The theory correctly predicts the great variation in the value of the stock market in relation to GDP, which varied by a factor of 2.5 in the United States and by a factor of three in the United Kingdom in the 1960–2000 period. Little of this variation is accounted for by the obvious factors, namely after-tax earnings in relation to GDP and the debt–equity ratio, which varied little over time. The secular behaviour of the stock market value, with its large variation in relation to gross national income, turned out to be as predicted by theory and is not due to animal spirits.

Another example of successful calibration is Hayashi and Prescott (2002), who examined why Japan lost...
a decade of growth. The neoclassical growth model used in their study is the one used in the study of business cycles. The exogenous parameter paths were working-age populations, capital income tax rates, and total factor productivity parameters (TFP). The TFP parameters were determined residually from the production function given the quantities of the factor inputs and the output. Given these exogenous elements the equilibrium path was computed. The finding is that the Japanese economy behaved as predicted by the theory. The reason for the lost decade of growth was the failure of TFP to grow. This led to the important question of why Japanese TFP failed to grow as it did in western Europe and North America in this period.

Similarities and differences between aerospace engineering and macroeconomics

Both Candler and Prescott study and model aggregate phenomena. Neither can find the answers empirically through trial and error and both must rely on theoretical computer simulations restricted by measurement. We both test for the robustness of our predictions when making predictions as to what will happen in situations never experienced. In one case the prediction is what will happen to a spacecraft that will be sent to Mars. In the other case it is what will be the consequences of implementing a proposed policy arrangement. Both rely on established theory and measurement to draw quantitative inference.

A difference is that the engineers have the equations, while macroeconomists have statements about preferences and technology. A consequence of this is that macroeconomists have the added step of determining the equilibrium equations of their model. Another minor difference is that computational intensity is much greater in aerospace engineering than in macroeconomics.

Cameralism is the specific version of mercantilism taught and practised in the German principalities (Kleinstaaten) in the 17th and 18th centuries. Becher (1635–82), von Justi (1717–71) and von Sonnenfels (1732–1817) are the principal figures who contributed to a vast cameralist literature of about 14,000 titles (Humpert, 1935). The subject matter of Kameralismus reflected the political and economic phenomena and problems in the German territorial states. As a branch of ‘science’ it is a fiscal Kunstlehre, that is, the practical art of how to govern an autonomous territory efficiently and justly via financial measures designed to fill the state's treasury. Its subject matter includes economic policy, legislation, administration and public finance. While there is no unifying analytical foundation of cameralism, it did develop in two distinct phases (a younger and an older branch) with varied emphasis on its different elements, and since the rising state was, in theory and reality, the focus and ultima ratio of political, economic and ethical (occasionally promotive) speculation, cameralism takes on a unitary form (Gestalt) only when viewed in retrospect.

The term ‘cameralism’ itself originates in the management of the state's or prince's treasure (Kammer, caisse, camera principis), seen as the principal instrument of economic and political power. In the age of enlightened absolutism, German–Austrian cameralism, based on a somewhat obscure natural-law philosophy, emphasized the paternalistic character of the governments' centralized fiscal policy (not, as is sometimes mistakenly thought, a Keynesian short-run instrument but rather a regulator for development which was to serve the general happiness of the subjects (Untertanen), that is, an eudaemonistic utilitarianism). English and French mercantilism, on the other hand, stressed much more the wealth or ‘riches’ of the sovereign as an end.

The princely bureaucrats had been trained in their own universities (for example, Halle, Frankfurt/Oder, Vienna) in ‘fiscal jurisprudence’ (von Stein) – a mixture of both formal budget and tax ‘principles’ – and
A highly pedantic and descriptive systematization of facts and definitions. Analytical economics, insights into the laws of the market and the study of the interaction between market and state (or even of the bureaucratic and political mechanism) are relatively unknown in the simple textbooks of the cameralists, which show otherwise sound common sense. Statistics, important for census and grasping foreign trade, became a new discipline of the cameral curriculum.

The practical policy of cameralism concentrated on the development of a country which had been devastated and depopulated in the Thirty Years' War and impoverished by the discovery of the sea route to India and the fall of Constantinople. Under these abnormal circumstances a political and bureaucratic monopoly attempted to reconstruct the economic foundations of the country by an active population policy, the establishment of state manufactures and banks, the extension of infrastructure (canals, bridges, harbours and roads) and the promotion of modernization. It strictly regulated the still important agricultural sector, as well as trade and commerce.

The state protected the trades (Gewerbe) by means of high tariffs to restrict imports of unnecessary raw materials and it facilitated exports of manufactures and import substitution. On the other hand, the government removed internal trade barriers by abolishing the medieval guild organization and by unifying the law for municipalities. Mercantilist efforts to augment the state treasure via trade surplus and money policy were, of course, another main cameralistic aim. Finally, it is notable that its monetary policy was inconsistent, in so far as the hoarding of precious metals as opposed to their circulating function was not clearly distinguished.

To set cameralism in secular perspective, the famous arguments of Smith and the Physiocrats against the 'mercantile system' seem to be mutatis mutandis valid for neo-mercantilism, which also justifies both state intervention in the market and a greater GNP government share and often reverts to the regulatory rules and the principles of planning in this former epoch. However, neo-mercantilism fails to prove seriously both the state's competence to ensure efficiency and equity in the public sector and its ability to regulate the market reasonably. Some writers tend to overlook that in our times the basic conditions in the state and the economy are radically different from those of three centuries ago. For example, economic, political and administrative conditions in the German principalities differed strikingly from Ludwig Erhard's situation after the Second World War. And the wide gap between the Great Depression of the 1930s and the technologically influenced stagflation of the 1980s was obviously so fundamental that the regulatory Keynesian budget and employment theory, with its then unrealistic assumptions, became rather obsolete. Thus any attempt to revive the strict regulating prescriptions of all-embracing cameralism, which lacks sufficient analysis and empirical testing, would apparently be a violation of both reason and experience. In this case we would use analytically poor (and old) tools to repair the wrong (and modern) machine.

This article surveys recent work aimed at evaluating the welfare effects of campaign finance reform. The theoretical literature distinguishes two types of contributor: those who desire ideological policies and those who want personal favours. A series of models shows that these different types of contributor have different implications for campaign finance regulation. The models also give some suggestions about the sort of empirical evidence that would argue for or against certain campaign finance regulations. These suggestions have been followed up by recent empirical work.

advertising; campaign finance reform; campaign finance, economics of; election; incumbency; matching funds; multiple equilibria; probabilistic voting; voting

Article

Campaign finance is a contentious issue in American politics. Reformers charge that a system in which interest groups provide the funds for campaigns creates opportunities for corruption, while others argue that restrictions on donations would limit the provision of information to voters. For an economist, the natural way to evaluate such arguments is to construct a model that explicitly treats the preferences and beliefs of the voters, to deduce the conditions under which the model predicts welfare improvements from regulation, and to check empirically if these conditions hold in actual elections. This article surveys a recent body of literature that does just that.

1 First-generation models

Early work on campaign finance took a reduced-form approach to the link between campaign activity and votes (Austen-Smith, 1987; Baron, 1989; 1994; Grossman and Helpman, 1996; Snyder, 1990). This
literature identified two ideal types of contributor: position-induced contributors, who help ideologically compatible candidates win office, and service-induced contributors, whose contributions are analogous to purchasing contingent claims on favours provided to the buyer at the expense of citizens in general. This literature yielded several important insights. For example, Baron (1989) finds that trades of contributions for promises of favours have interesting implications for the incumbency advantage (see, for example, Gelman and King, 1990, and Ansolabehere and Snyder, 2002, for empirical work on the incumbency advantage in US elections). A candidate with an exogenous advantage is more likely to be able to deliver the promised favours, making the promise more valuable. Thus an advantaged candidate can raise funds on more favourable terms, reinforcing the advantage. Morton and Myerson (1992) show that this mechanism can even lead to multiple equilibria, where predictions that one candidate will win become self-fulfilling because contributions flow to the presumptive winner.

As the comprehensive survey of this literature by Morton and Cameron (1992) emphasizes, this approach cannot address the welfare qsts raised by proposals for campaign finance reform. We now turn to more recent research that ‘opens up the black box’ and provides some welfare analysis.

2 Microfounded models

A bare-bones model illustrates the main points of the literature. The game has four players: two candidates, a voter, and an interest group.

Each candidate has some level of ‘quality’, which could be either ability or ideological similarity to the voter. The key is that quality is valued by the voter. Candidate $i$'s ability is $\theta_i$. It is common knowledge that $\theta_1 = 1$, and that $\theta_2$ is equally likely to be 0 or 2. Each candidate maximizes his probability of winning.

At the start of the game, the candidates learn $\hat{\theta}_2$, but the voter does not. At cost $c \in (0, 1)$, candidate 2 can truthfully reveal $\theta_2$. Candidates have no funds of their own. The interest group has sufficient funds to pay for the information transmission, if it wants to.

Even without specifying the group’s payoffs, we can derive two benchmarks.

The no-campaign solution. First, assume the interest group is prohibited from funding candidate 2's campaign. Then the voter goes to the polls not knowing $\theta_2$. Thus she is indifferent between the two candidates, and gets expected payoff 1 no matter how she votes. The natural voting rule is to have her toss a fair coin. (This would be the outcome if there were a mean-zero popularity shock prior to the election.) In this case, each candidate gets payoff 1/2.

The voter's optimum. Second, assume there is a planner who can observe the true $\theta_2$ and communicate it to the voter, paying for the communication with a lump-sum tax on the voter. Announcing the true $\theta_2$ in only one of the states suffices for complete communication, and allows for a cost savings compared with always announcing the state. So the planner announces $\hat{\theta}_2$ if and only if $\theta_2 = 2$, and the voter votes for 2 if there is an announcement and for 1 if not. Her payoff is

$$\frac{1}{2} + \frac{1}{2}(2 - c) = \frac{3}{2} - \frac{1}{2}c > 1.$$
Thus the voter is better off than in the no-campaign solution. Furthermore, each candidate still wins with *ex ante* probability 1/2, so the policy represents an *ex ante* Pareto improvement over the no campaign solution.

This scheme would be hard to implement, because it is vulnerable to collusion between the regulator and candidate 1. Thus we are interested in whether or not interest-group finance can improve on the no-campaign benchmark.

### 2.1 Position-induced contributors

Now assume the interest group wants candidate 2 to win independent of \( \theta \), perhaps because it shares the candidate's ideology. Formally, the group's payoff is

\[
\hat{b}w - k,
\]

where \( b > 0 \) is the payoff to the group from having 2 win, \( w \) is an indicator variable equalling 1 if and only if candidate 2 wins, and \( k \) is the contribution to candidate 2.

The timing is:

1. 1. The candidates and the group learn \( \theta \).
2. 2. The group chooses a contribution \( k > 0 \).
3. 3. If \( k \geq \zeta \), the candidate decides whether or not to advertise \( \theta \).
4. 4. The voter sees any ads purchased, and then selects the winner.

**Proposition 1:** If \( b > \zeta \), then there is a perfect Bayesian equilibrium (PBE) in which

- the group contributes \( c \) if and only if \( \theta = 2 \) and
- the voter chooses candidate 2 if and only if she sees an ad certifying that \( \theta = 2 \).

The idea is simple. The group is better off if 2 wins. If \( \hat{b} = 2 \), the group can ensure that 2 wins by funding a campaign informing the voter of her true preference for 2. And if the benefit from having 2 win (\( b \)) exceeds the cost (\( c \)), the group wants to do this. Finally, the group does not contribute to a low type of candidate 2 – this cannot help the group because the candidate cannot lie.

If there are contributions in equilibrium, then the voter gains over the no-campaign solution, having a payoff of \( \frac{3}{2} > 1 \). Thus banning contributions reduces the voter's welfare. Furthermore, the equilibrium without contributions is Pareto dominated by the following matching fund policy. Fix \( \gamma \) strictly between 0 and \( b \). If the group donates \( \gamma \) to candidate 2, then the regulator kicks in \( \zeta - \gamma \), paid for by a lump-sum tax on the voter. The group's *ex ante* payoff increases from 0 to \( \frac{(b - \gamma)}{2} \) and the voter's payoff increases from 1 to \( \frac{3}{2} - \frac{(\zeta - \gamma)}{2} > 1 \). The candidates are indifferent at the *ex ante*
Coate (2003) elaborates on this story in two ways. First, the voter is uncertain about both ideologies, and both candidates can receive contributions. Second, and more importantly, candidates are selected by the party's median member, who has different preferences from the median in the electorate. (Here quality is the inverse of distance from the median.) The interest group prefers less moderate candidates. However, the groups prefer to fund more moderate candidates – campaign ads are effective only when the ad reveals that the candidate is more moderate than a non-advertising candidate. This gives the party an additional incentive to choose moderate candidates, because moderate candidates can raise funds and thus do well in the election. In equilibrium, the party mixes between moderate and extremist candidates. In this environment, simply banning contributions creates both winners and losers. Moderate voters lose. First, they must make their choices with worse information, as in the bare-bones model above. Second, candidates are less likely to be moderate. Members of the interest groups, on the other hand, are better off. They save the cost of the contributions, and policy is no worse in expectation – the extra probability that policy is extreme in the wrong direction is exactly offset by the increased probability that policy is close to the group.

2.2 Service-induced contributors

Now assume the group does not care directly who wins the election. Instead, the group values transfers from the winner. The group and candidate 2 can sign a contract specifying that candidate 2 receives \( c \) from the group, and, if he wins, he transfers the amount \( t \) to the group. This transfer if financed by a tax on the voter of \((1 + \lambda) t\), where \( \lambda \) represents the deadweight loss of the transfer.

The timing is:

1. 1. The candidates and the group learn \( \theta_2 \).
2. 2. Candidate 2 makes a take it or leave it offer of a contract \( t \) to the group.
3. 3. The group accepts or not.
4. 4. If the contract is accepted, the candidate decides whether or not to advertise \( \theta \).
5. 5. The voter sees any ads purchased, and then selects the winner.

**Proposition 2:** If \((1 + \lambda) c \leq 1\), then there is a PBE in which the group funds the campaign if and only if \( \theta_2 = 2 \) and the voter selects candidate 2 if and only if she sees an ad certifying \( \theta_2 = 2 \).

Again, the basic idea is simple. If the voter sees an ad, she learns two things. First, she learns that \( \theta_2 = 2 \), which improves her evaluation of candidate 2. Second, she learns that the group and the candidate have made a deal, so electing candidate 2 costs her \((1 + \lambda) c\). This tradeoff is acceptable if \((1 + \lambda) c \leq 1\).

In such an equilibrium, the voter's payoff is

\[
\frac{1}{2} + \frac{1}{2} (2 - (1 + \lambda) c) = \frac{3}{2} - \frac{(1 + \lambda) c}{2}.
\]
This payoff is lower than the voter-optimal benchmark payoff by $\frac{\lambda \alpha}{2}$.
Again, matching funds can help. Assume again that the regulator pays $\epsilon - \nu$ of the cost. This policy reduces the welfare loss compared with the benchmark to $\frac{\lambda \nu}{2} < \frac{\lambda \alpha}{2}$.
Most papers in the literature introduce some uncertainty in the voting stage. With this addition, Prat (2002), Coate (2004) and Ashworth (2006) show that the candidate might promise so much that the voter actually loses from the campaign. To see the intuition, consider the candidate’s incentive to advertise. Without probabilistic voting, the incentive to expand transfers is limited – once the voter's cost of transfers passes 1, the probability of election changes discontinuously from 1 to 0. With probabilistic voting, by contrast, small changes in transfers have similarly small effects on the reelection probability. In this case, candidates have an incentive to expand transfers all the way to the point where the voter is indifferent between a high-quality candidate with transfers and a low-quality candidate with no transfers. In such a case, the voter actually loses from the possibility of a campaign, and would be better off if contributions were banned outright – the likelihood of getting a high-quality winner is no lower, and the voter escapes the cost of favours.
The key to the inefficiency here is that the voter’s knowledge that ads imply favours to interest groups makes the ads less effective at ensuring a high-quality candidate is elected.
Again, matching funds might be a better solution. In Coate (2004), the scale of the campaign can vary continuously. Greater spending increases the fraction of the (large) electorate that is informed. Matching funds come into play if the benefit from winning is low enough that ads are not rendered totally ineffective. In that case, a limit on contributions reduces the amount of favours, preserving the effectiveness of the ads. And the matching funds allow the scale of the campaign to be unchanged from the unregulated case.
So far, matching funds have seemed like a great policy. But they have a cost in asymmetric contests. In Ashworth (2006), the scale of campaigns is fixed (as in the bare-bones model above), but candidate 2 has an advantage independent of advertising. For moderate levels of the advantage, the advantaged candidate mounts a costly campaign even though the value of the information to the voter is less than the cost the voter pays ex post. For greater values of the advantage, no campaign takes place in equilibrium – the possible increase in the voter's evaluation is too small to outweigh the promised favours. Matching funds can increase the likelihood of an active campaign in such cases, even though reducing their likelihood would be efficient.

2.3 Hard vs. soft information

The literature focuses on two mechanisms that make advertisements informative. The first is the one we have relied on above, namely, the candidate may have verifiable information, information that cannot be falsified. The second, studied by Gerber (1996), Prat (2002), and Potters, Slooof and van Winden (1997), is indirectly informative campaigns. Interest groups observe the quality of the candidates, but voters do not. If groups condition their contributions on quality, then voters can learn about quality by inverting the contribution schedule. Gerber and Prat show that equilibria with informative advertising exist, even though the ads have no direct informational content. As in the case with hard information, service-induced contributions imply that a ban on contributions can benefit the median voter. On the
other hand, public financing would have no value with indirectly informative advertising – there's no signal if the election regulator hands out funds to everyone. Thus a non-trivial policy problem of public financing arises only with directly informative advertising.

3 Empirics

3.1 Do contributions buy favours?

Contributors' motivations played a key role in the welfare conclusions above. What do the data say about these motivations? The most direct approach to this question looks at correlations between donations from interest groups and votes that those groups care about. For example, we could regress votes in favour of increasing the minimum wage on contributions from unions. Of course, a positive correlation on its own does not discriminate between the theories – are the union contributions changing votes or do unions just contribute to exogenously union-friendly candidates? The many studies that try to disentangle these forces affecting roll-call votes find only weak evidence that contributions buy votes (Ansolabehere, de Figueiedo and Snyder, 2003). One interpretation is that contributions are position-induced rather than service-induced.

However, focusing on roll calls misses much Congressional activity (Hall, 1996). Thus researchers have also looked to more indirect evidence. For example, Gordon and Hafer (2005) find that firms making large donations are less monitored by agencies, suggesting that donations induce members of Congress to interfere in regulatory oversight. Many papers have shown that political action committees (PACs) direct their contributions in ways more consistent with service-induced motivations than with position-induced motivations (Kroszner and Stratmann, 1998; Romer and Snyder, 1994; Snyder, 1990). Perhaps the most convincing is McCarty and Rothenberg (1996), who document that individual PACs made significant shifts in donations from Democrats to Republicans after the Republicans took control of Congress in 1994, suggesting that the contributions were not ideological.

Attempts to directly estimate the impact of contributions on policy have not reached a consensus, except that the effects are smaller than public outcry might suggest (Ansolabehere, de Figueiedo and Snyder, 2003). The next subsection turns to a more theory-driven approach to evaluating the potential for welfare gains from regulation.

3.2 Spending and election outcomes

A substantial empirical literature has tried to estimate the effect of campaign spending on electoral outcomes. Cross-sectional analyses that do not condition on incumbent quality show that challenger spending is associated with better electoral performance, but incumbent spending is unrelated to success. (See the discussion in Jacobson, 2001, ch. 3, which summarizes the extensive empirical work initiated by Jacobson, 1978.) Of course, interpreting these correlations is difficult because of an endogeneity problem – candidates spend more when they expect the race to be competitive. Several researchers have tried to deal with this endogeneity issue (Green and Kranso, 1988; Levitt, 1994; Gerber, 1998; Erikson and Palfrey, 1998; 2000). These papers all find that spending is roughly equally effective for both
incumbents and challengers, but there is no consensus about the size of the effects. (Looking across several of the most prominent estimates, Gerber, 2004, calculates an implied cost for a House incumbent to get one additional vote ranging from $15 to $367.) Prat (2000) points out that, even when one controls for candidate quality, there is an identification problem in these regressions. Simply put, the functional relationship between spending and election outcomes (with quality held fixed) depends on the way funds are raised. To see this, consider the models of service-induced contributions discussed previously. In all of the models, an exogenous increase in quality has two effects. First, the candidate raises more funds and informs the voters of his high quality, which helps his electoral chances. Second, the voter infers that the funds were given in exchange for promises of favours, which hurts his electoral chances. Thus the regressions estimate ‘the effect on electoral outcomes of an extra dollar of campaign spending net of the political cost of persuading lobbies to donate the extra dollar’ (Prat, 2006, p. 60).

In addition to providing an important critique of the standard inputs of the empirical evidence, the prediction that the effectiveness of advertising is decreasing in the degree of service-induced contributing provides a way to test empirically for the possibility of welfare-improving policy. In particular, the theoretical models suggest that limits on contributions and (perhaps) matching funds can improve welfare precisely when campaign spending is ineffective. Thus the prediction of reduced effectiveness speaks directly to the welfare implications of the models.

Stratmann and colleagues have been leaders in testing these implications. Houser and Stratmann (2006) carry out laboratory experiments modelled after the theoretical set-up of Coate (2004) and Ashworth (2006). High-quality candidates are more likely to win in a public financing treatment than in a privately financed treatment. They also find that margins of victory are greater in the public financing treatment. In a treatment with caps on contributions, they find that voter welfare goes up, but the probability of electing a high-quality incumbent does not. These experiments support the theoretical predictions, suggesting that voters are capable of inferring that interest-group financed ads imply that the candidate has promised favours.

Stratmann (2006) exploits state-level variation in campaign finance laws to see whether the theoretical predictions hold up in field data. He first estimates standard vote-share/spending regressions for each state’s House elections. He then examines the relationship between the effectiveness of spending and the existence of limits on contributions. As predicted by the theory, he finds that effectiveness is lower when campaign finance regulations are more liberal. These results hold for all of incumbents, challengers, and open-seat candidates. Stratmann and Aparicio-Castillo (2006) show that states that limit giving subsequently have lower incumbent vote shares. This finding is consistent with Baron’s (1989) and Ashworth’s (2006) theoretical finding that the financing process can exaggerate incumbency advantages.

Canada, economics in

Robert W. Dimand and Robin F. Neill
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In the first half of the 20th century, economics in Canada was primarily economic history, and its contribution was the staple theory of Canadian economic development. After the Second World War Keynesian macroeconomics swept the nation and, despite its British origin, it indigenized into a theory of primary product export-based growth, and a Western Marxist theory of the staple trap. In the last quarter of the century, positivism, monetarism, and neoconservative new classical economics swept north from the United States, leaving only the specific domestic circumstances to which it was applied as the distinctive thing about economics in Canada.

Article

Beginnings

The pre-history of economics in Canada begins with the description of the society and products of New France by Pierre Boucher (1664), a former governor at Trois Rivières and the founding seigneur of Boucherville, writing in the political arithmetic tradition of Boisguilbert and Vauban. The most notable of such descriptive works was, after the British conquest, the vast, disorganized, but often incisive
Statistical Account of Upper Canada by the political dissident Robert Gourlay (1822), whose criticism of unrepresentative and corrupt government led to his exile as an undesirable alien – on the grounds of his birth in Scotland rather than England (Dimand, 1992). Although, apart from Boucher and Gourlay, early descriptive writings about settlement and economic conditions in Canada tended to have little economic analysis, Boucher displayed an intuitive sense of economies of scale, urging that policy should encourage concentration of settlement in small areas, where mutually beneficial exchange would lead to a surplus product. Independently, Gourlay later formulated a linear relationship between land values and the number of inhabitants per acre. He urged the government to borrow to fund increased immigration and settlement, paying off the loan by taxing the resulting increase in land value. The influence of Gourlay's theorizing about the appropriate structure of property rights to promote population density in a newly settled colony (such as limiting the size of land grants to avoid dispersion of settlers) was acknowledged by Edward Gibbon Wakefield, the English theorist of colonization who wrote Appendix B on land policy for Lord Durham's report on Canada after the 1837 rebellion and then served in the Canadian legislature before taking a leading role in the settlement of New Zealand (Wakefield, 1968; Goodwin, 1961, ch. 1; Neill, 1991, ch. 1). One Canadian topic, the playing card currency of New France, so often cited by later economic historians (for example, Shortt, 1987), attracted the attention of one of the great early economists, the philosopher David Hume, as British chargé d'affaires in Paris after the Seven Years War and then as Under-Secretary of State; Hume negotiated the settlement of the outstanding paper money of New France after the British Conquest (Dimand, 2005).

John Rae was an outstanding 19th-century economic theorist who wrote his New Principles of Political Economy (1834) while headmaster of the Gore District Grammar School in Upper Canada (now Ontario). Rae, although born and educated in medicine in Scotland, eventually became a district judge in the Kingdom of Hawaii before dying in Staten Island. For decades, he was known primarily through John Stuart Mill's citation of his statement of the infant industry argument for protection: although Sir John A. MacDonald, Canada's first prime minister, cited Rae in support of his national policy of tariff protection for manufacturing, he seems to have known of Rae only through Mill (MacDonald, quoted in Neill, 1991, pp. 85–91). C.W. Mixter's new, rearranged edition of Rae's book in 1905 revealed Rae's analysis of 'effective desire of accumulation' as a pioneering capital theory, and two years later Irving Fisher dedicated The Rate of Interest ‘to the memory of John Rae who laid the foundations upon which I have endeavored to build’, acknowledging Rae for foreshadowing both time preference and internal rate of return over costs. Rae has since been celebrated for his discussions of conspicuous consumption, more than six decades before Thorstein Veblen, and of endogenous technical change (James, 1965; Hamouda, Lee and Mair, 1998). University of Toronto mathematics professor John Bradford Cherriman (educated at St John's College, Cambridge, a few years before Alfred Marshall) made another striking, but isolated, contribution to economic theory: a ten-page review article and exposition of Cournot's essay in mathematical economics of 19 years before, endorsing the mathematical approach to political economy, hailing Cournot's work as more important than Ricardo, and long antedating Joseph Bertrand's 1883 article that was long thought to be the first review of Cournot's 1838 volume (Cherriman, 1857; Dimand, 1988; 1995). More characteristic of this period than the theorizing of Rae and Cherriman were the numerous practical and descriptive discussions of economic affairs, economics in the context of action (see Goodwin, 1961; Neill, 1991; Neill and Paquet, 1993).
The rise of academic economics in Canada

Although a few courses had been offered previously, economics in Canadian universities began in 1888 with the appointment of the English historical economist W.J. (later Sir William) Ashley as professor of political economy and constitutional history at the University of Toronto and of Adam Shortt (previously tutor in philosophy, instructor in botany, and demonstrator in chemistry) as lecturer in political economy at Queen's University, Kingston (promoted to Sir John A. Macdonald Professor of Political Science in 1891). Professorial appointments at the university were then made by Order in Council by the provincial government, and candidates were interviewed by the Premier of Ontario and by the chancellor of the University. No classical or neoclassical theorist would have been appointed, lest they promote free trade in their lectures, but the English Historical School was acceptable (Drummond, 1983). When Ashley departed in 1892 to become professor of economic history at Harvard (and later dean of commerce in Birmingham), he was succeeded by James Mavor, Scottish economic historian of Russia and friend to Tolstoy, Kropotkin, and the Doukhobors (see Mavor, 1923), and until 1970 the Department of Political Economy was led by a succession of distinguished economic historians (apart from one sociologist), notably Harold Innis and William Easterbrook, and the historian of economic thought Vincent Bladen (see Drummond, 1983; Bladen, 1978). Under Ashley's sponsorship, the University of Toronto published the first academic economic writing by a Canadian woman, Jean Scott Thomas (1889), 'The conditions of female labour in Ontario'. As in other disciplines and elsewhere in the Dominions and the British Empire, several early professors of economics in English-speaking Canadian universities, notably Ashley and C.R. Fay in Toronto and A.W. Flux at McGill, were British scholars who had finished their careers in Britain, as was James Bonar, Deputy Master of the Mint in Ottawa and authority on Malthus. The British Association for the Advancement of Science met in Montreal in 1884; in other years it met in Dublin, Cape Town, or Sydney. The following year, the association commemorated its meeting with Canadian Economics, a volume of 27 papers by Canadian and American authors that, according to Goodwin (1961, p. 116), 'marked the end of an era when description and analysis were carried out by interested persons in all walks of life and before there were any professional economists in government and the universities'. The Canadian Political Science Association met in September 1913, with Adam Shortt as president, and published a volume of proceedings, but the September 1914 meeting was cancelled when the First World War broke out, and the association lapsed until 1929.

Long after the social sciences separated in Britain and the United States, they remained institutionally linked in Canada, sharing a single Department of Political Economy at the University of Toronto until 1982 (the equivalent term at McGill and the University of Saskatchewan was Department of Economics and Political Science), a single Canadian Political Science Association and the Canadian Journal of Economics and Political Science (first published in 1935) until 1966 (the sociologists and anthropologists seceded in 1963), with the economists departing only much later from the joint annual conferences of the Learned Societies (now the Humanities and Social Science Congress). As Taylor (1960, p. 8) remarks, 'Shortt, Skelton, Mavor, and Leacock throughout their careers could almost equally well be described as historians or political scientists.' While the economic historian Harold Innis headed Toronto's Department of Political Economy during the 1930s and 1940s, scholars in the various disciplines there, not all of them within the department, were linked by their historical approach and by
Innis's influence, in historical sociology (S.D. Clark), history of political thought (C.B. Macpherson), history of economic thought (Vincent Bladen), economic history (John Dales, William Easterbrook), historical geography (Andrew Hill Clark), history of communications (Marshall McLuhan), Canadian history (Donald Creighton, Innis's biographer). Formal economic theory, in contrast, was conspicuously absent, except that A.F.W. Plumptre, before joining the public service, taught Keynes's *Treatise on Money*, having studied in Cambridge while that book was being written. When the University of Saskatchewan opened in 1910, economics was taught by the professor of history, using texts by Richard T. Ely, an American economist influenced by the German Historical School, and by Ashley, Archdeacon William Cunningham, and J. Kell Ingram of the English Historical School, but not Marshall or Jevons (Spafford, 2000). One consequence of multidisciplinary sharing of departments, association, and journal was that after the humorist Stephen Leacock, trained in political science and author of a successful textbook in that field, succeeded Flux as Dow Professor of Economics and Political Science at McGill in 1908, he acquired public credibility for his economic pronouncements, such as advocating a tariff union for the British Empire to end the Great Depression. Growing numbers of academics, and the gains from division of labour in scholarly research and publication as in other activities, led the social sciences in Canada to become increasingly separate after the Second World War, well in advance of formal institutional separation. The British connection and the emphasis on a historical approach also faded in the same decades, as Canadian economics became more grounded in formal theory and quantitative methods and more attuned to intellectual developments in the United States. The teaching of economics emerged later in French Canada. The journalist Etienne Parent (1846), an admirer of Adam Smith and Jean-Baptiste Say, was unusual in declaring political economy a science and urging the enlightened publication of the principles it taught, notably free trade and the respectability of commerce and industry as occupations. Although Parent became Under-Secretary of State when the Dominion of Canada was created in 1867, his views on the study of economics had little influence. Political economy was widely identified with doctrinaire free traders (such as Parent) and with the secular pursuit of material gain, and did not often find a place in the curriculum of the Jesuit classical colleges in Quebec, which steered promising students towards law, medicine and the Church. Attitudes toward social and economic research in Quebec changed following papal social encyclicals such as *Rerum Novarum* in 1891 (an influence that ceased to dominate intellectual life in Quebec after the 1960s). The École des Hautes Études Commerciales (HEC) was established in Montreal in 1911, and its journal *Actualité •conomique* began publication in 1925. Such HEC professors as Esdras Minville (1979), Edouard Montpetit (1939–42), and François-Albert Angers were concerned with the economic independence and distinctive cultural values of French Canadian society, beyond the technical aspects of the economics that Montpetit had studied under Charles Gide at the Sciences-Po in Paris, and the concerns of French Canadian economists were shaped by the uneasy relationship of their intellectual milieu and society with the rest of Canada and North America (see Falardeau, 1944; Angers, 1961; Parizeau 1968; and the extensive oral history in Paquet, 1989 on the emergence and evolution of francophone economics in Canada).
The two outstanding figures of inter-war Canadian economics, William A. Mackintosh (1923; 1939), of Queen's University, and Harold A. Innis (1930; 1940; 1956), of the University of Toronto, developed a distinctive approach to understanding Canada's economic development, the staples thesis (see also Mary Quayle Innis, 1935; Creighton, 1937; Neill, 1972). Rejecting the universal applicability of neoclassical analysis of the market determination of relative prices, the staples thesis drew on a wide range of influences (including American institutionalists, notably Veblen) to argue that a newly settled, peripheral economy could not be studied in the same way as the core economies of the world economy. The keys to analysing Canadian economic development were the geographical setting (especially regional differences and the transport routes such as the St Lawrence Valley/Great Lakes) and the characteristics of the staple commodities such as cod, fur and wheat that successively dominated an export-oriented peripheral economy. The core–periphery distinction in the staples thesis was mirrored in the structure of interwar Canadian economics discipline: Mackintosh and Innis at the leading universities in the industrial and commercial heartland of Ontario developed the dominant interpretation of Canadian development as whole, while George Britnell (1939) and Vernon Fowke (1946) at the University of Saskatchewan focused on the locally dominant staple, wheat, and maritime economists such as Stanley Saunders (1939) were concerned with the maritime provinces as an economically backward region within Confederation. This historical and institutional approach, which had parallels in later Latin American dependency theory, received considerable attention beyond Canada: at the time of his death in 1952, Innis had been elected president of the American Economic Association, the only foreigner or non-resident ever so honoured. Except for Creighton on the merchant class, the staple literature paid little attention to class until H. Clare Pentland's Toronto dissertation on the emergence of Canada's industrial working class, finished in 1961 and published posthumously 20 years later, but largely written at the University of Toronto before Innis's death (Pentland, 1950; 1981). Canadian political economy influenced by Innis and Pentland continues to flourish in the disciplines of political science and sociology (and Innis, 1951, is influential in communications studies in Canada), but has largely disappeared from economics departments, as Canadian economics has become part of an international mainstream in which the old (or original) institutional economics, widespread in the interwar United States, has been marginalized.

Economists in and on government in Canada

The Dominion Bureau of Statistics (now Statistics Canada) became a leading centre of quantitative research under Robert Coats, for 25 years the first Dominion Statistician, an achievement recognized internationally by the election of Coats as president of the American Statistical Association in 1938 (see Coats, 1932; Keyfritz and Greenway, 1961). Economists at Queen's and McMaster Universities produced two volumes of Statistical Contributions to Canadian Economic History in 1931. Economists became deeply involved in other areas of government, more so than in many other countries. After exploring Canada's monetary and banking history in a long series of articles in the Journal of the Canadian Bankers Association (reprinted as Shortt, 1987), Adam Shortt, the first economics professor at Queen's University, came to Ottawa to head the Civil Service Commission and then to superintend the publication of numerous documents on monetary history (see Shortt, 1976). His student and successor at Queen's, Oscar D. Skelton, winner of the Hart Shaffner & Marx Prize for a study of socialism (Skelton,
Canada, economics in: The New Palgrave Dictionary of Economics

1911), was Under-Secretary of State for External Affairs from 1925 until his death in 1941, an especially important position because the External Affairs portfolio was held by the prime minister, so that Skelton was the prime minister's deputy minister. Skelton in turn recruited another Queen's economics professor, W. Clifford Clark, as Deputy Minister of Finance from 1932 until Clark's death in 1952. Noteworthy anniversary surveys of the progress of economic scholarship in Canada were written by the Under-Secretary of State for External Affairs (Skelton, 1932) and the Deputy Minister of Finance (Taylor, 1960), rather than by academics, and economic research in Quebec was surveyed by a future separatist Finance Minister and Premier of Quebec (Parizeau, 1968).

The Great Depression of the 1930s, which was especially severe in the Prairie provinces, and the Second World War expanded the role of the government in the economy, and of economists in government, notably with the creation of the Bank of Canada in 1934 and of a system of national accounts during the war. The extent of popular dissatisfaction with existing economic arrangements was shown in 1935 when Alberta gave 56 of the 63 seats in its provincial legislature (and, later that year, all 15 of its seats in the federal House of Commons) to Social Credit, a movement devoted to the heterodox monetary doctrines of Major C.H. Douglas (Ascah, 1999). Keynesian macroeconomic policy offered a way to stabilize the economy and avoid depressions without recourse to central planning or inflationary Social Credit (see Brecher, 1957, on interwar monetary and fiscal discussions in Canada). William A. Mackintosh of Queen's, nominally only a wartime special assistant to Clifford Clark but de facto head of the Economic Advisory Committee, drafted the federal government's 1945 White Paper on post-war employment policy. The White Paper made a commitment to macroeconomic demand management to maintain full employment that lasted in one form or another for three decades, until in 1975 Bank of Canada Governor, Gerald Bouey, announced the bank's conversion to targeting monetary aggregates to control inflation.

Keynesian ideas reached Canada through Keynes's wartime visits to Ottawa en route to and from the United States, and especially through a group of leading civil servants including some of his former students at Cambridge (Granatstein, 1982; Owram, 1986). A.F. Wynne Plumptre, who had studied with Keynes in the late 1920s, headed the economics division of the Department of External Affairs and then was Assistant Deputy Minister of Finance (1954–65) before returning to the University of Toronto. Robert Bryce, after attending Keynes's lectures for three years while Keynes was writing *The General Theory*, was secretary to the Economic Advisory Committee during the war, Secretary to the Cabinet and Clerk of the Privy Council (1954–63), and Deputy Minister of Finance (1963–70). Keynesian macroeconomics reached Canadian academic economists through Mabel Timlin's *Keynesian Economics* (1942). Timlin, a secretary at the University of Saskatchewan, began writing that remarkable book as a Ph.D. dissertation for the University of Washington as early as 1935, before the publication of Keynes's *General Theory*, when Benjamin Higgins arrived in Saskatoon with a copy of Robert Bryce's summary of Keynes's lectures, which Bryce had presented to Hayek's seminar at the London School of Economics, where Higgins was studying. Timlin's book, her first publication at the age of 50, led to a distinguished academic career at the University of Saskatchewan, the presidency of the Canadian Political Science Association, the executive committee of the American Economic Association, and being the first woman in the humanities or social sciences elected to the Royal Society of Canada (see Alexander, 1995, on the history of women in economics in Canada). After the war, Timlin wrote a series of review articles in the *Canadian Journal of Economics and Political Science* on welfare economics.
and the applicability of general equilibrium methods to public policy analysis, helping introduce
Canadian economists to advances in economic theory elsewhere.
Mabel Timlin was also an early academic critic of the Bank of Canada for permitting inflation during the
Korean War by failing to pursue Keynesian stabilization policy. A few years later, many Canadian
economists denounced the Bank of Canada Governor, James Coyne, for being more concerned about
inflation than with expansionary Keynesian policy to end a recession (Gordon, 1961). Economists at the
University of Western Ontario, notably David Laidler, Michael Parkin, and Thomas Courchene, later
brought to Canada monetarist arguments that the Bank of Canada should adopt a monetary policy rule
designed to combat inflation rather than pursuing Keynesian discretionary stabilization policy
(Courchene, 1975–80).

After the Second World War

The Canadian economics profession expanded along with the great expansion of Canadian universities
that began in the 1960s and also with the growing employment of economists in the business community
(Parish, 1997). Along with the growth of numbers came specialization, first between the different
Canadian social sciences (previously sharing departments, conferences and a journal), then between
fields within economics. Canadian economics became increasingly theoretical and econometric, and
decreasingly historical, in line with changes elsewhere, especially in the United States. Since the rise of
academic economics in Canada, Canadian economists had studied in the United States (for example,
Innis had taken his Ph.D. at the University of Chicago, with a thesis on the Canadian Pacific Railway)
and taken part in American associations, but increasingly Canadian economics, like the rest of Canadian
intellectual life, became more oriented towards the United States than to Britain (except that Quebec
academics were very conscious of intellectual developments in France). Post-war Canadian economists
made noteworthy contributions to economics, particularly the economics of natural resources (Gordon,
1954; Scott, 1955; Easterbrook, 1959; George, 1989) and international economics (for example, the
effects of trade liberalization), but while Canada's position as a resource-based, small open economy
guided the choice of topics, the analytical approaches taken were shared with the international
community of economists. Many outstanding economics graduates of Canadian universities pursued
careers outside the country, mostly in the United States, but among these, Jacob Viner, John Kenneth
Galbraith, Harry Johnson, and Robert Mundell retained close ties to Canada, paid attention to Canada's
distinctive economic experience (very large capital inflows relative to GDP before 1914, a floating
exchange rate from 1950 to 1962), and took part both in Canadian policy debates and in influencing the
development of the Canadian economics profession (for example, Viner, 1924; Johnson, 1963; 1968).

Article

French mathematician and economist, Canard was born in Moulins, near Vichy, around 1750, and died there in 1833. Little is known about his life other than the fact that he taught mathematics at the Ecole Centrale de Moulins. His other interests included economics, jurisprudence and meteorology. Canard's reputation as an economist rests on his *Principes d'économie politique* (1801), a study of the incidence of taxes, which, however, has drawn more attention for its use of mathematics in economic analysis. Written in the year of Cournot's birth, the *Principes* was honoured by the French Institute, the same body that refused to recognize the later efforts of Cournot and Walras. Cournot (1877, p. i) reviled Canard's work as 'false', even as he admitted that it provided him an important starting point for his own researches. Other harsh critics were Francis Horner, J.B. Say, Joseph Bertrand, W.S. Jevons, and Léon Walras. Despite this rejection by French and English economists, Canard had considerable influence in Italy, where a group of writers, led most conspicuously by Francesco Fuoco, defended his method and adopted some of his ideas. In the present century, Seligman (1927, pp. 159–62) has credited Canard with the diffusion theory of taxation, Schumpeter (1954) has discounted his contribution completely, while Theocharis (1983) has defended him.

The *Principes* was influenced by Cantillon and to a lesser extent by the Physiocrats, whose doctrine Canard sought to refute. Cantillon's influence is obvious in two major areas. First, without using the terms, Canard advanced both an 'intrinsic' and a 'market' conception of price. He held that everything derives its value from the quantity of labour bestowed upon it. Different (unmeasurable) qualities of labour, however, render labour quantity an unsatisfactory measure. Therefore, one must look to the market to discover the determinants of price. Canard developed an equilibrium theory based on the
relative bargaining power of buyer and seller, which he related to need and competition. (Clearly recognizing the forces of monopoly and monopsony, he nevertheless failed to develop a bilateral monopoly model.) Second, Canard revived Cantillon's ‘three rents’, and wove them into a general equilibrium conception of the economy, which he used to trace the effects of taxation (in the process, adumbrating the Ricardian theory of land rent).

Canard argued that the imposition of a new tax produces disequilibrium and sets in motion certain equilibrating adjustments which take time to work themselves through the economy. Each person who initially pays the new tax will attempt to pass it on to the purchaser of the good, but his success in doing so depends upon the ‘forces’ encountered; or as we would say today, the tax is shifted in proportion to the elasticities of demand and supply. Canard's maxim that ‘every old tax is good, every new tax is bad’, must be judged in this context.

One Richard Cantillon, son of Philip Cantillon of Ballyheigue, County Kerry, was born in Ireland. Joseph Hone argued convincingly that this was the economist, on the ground that this Richard married Mary Ann Mahony, daughter of Lady Clare, and had with her a daughter Henrietta, who married Lord Farnham (after the death of her first husband, the Earl of Stafford). Earlier writers had estimated Cantillon’s birth to have been as many as 17 years earlier, but subsequent scholars have tended to accept Hone’s evidence; for example, Joseph J. Spengler (1954, p. 283) and Anita Page (1952, p. xxiv).

Richard Cantillon’s close association with France has often been noted, but certain facts about his family go far to explaining this connection. An Anglo-Irish county family whose establishment in Ireland was Elizabethan or later would of course be Protestant, and the term ‘Anglo-Irish Protestant ascendancy’ would then apply strictly. But those families which came to Ireland in Norman times were Catholics, and some of these remained so for hundreds of years, in spite of dungeon, fire and sword (to use an old phrase). They often became Jacobites, and in that case Europe was for them a place of refuge and support. These were the ‘Wild Geese’, who joined foreign flags after one or other Irish rebellion failed. Often educated in Europe, their ideas were cosmopolitan, their eyes on Paris and on Rome.

The Cantillons were established in Ireland in Norman times and remained Catholics, although not always very good ones. And in later centuries they became, and long remained, devoted to the Stuart cause. Roger Cantillon of Ballyheigue married Elizabeth Stuart in 1556, and his grandson Valentine fought for Charles I at Naseby, while his great-grandson Richard was wounded at the Boyne, went to France with James II and was made a chevalier for his pains. The chevalier, clearly more notable for gallantry than for worldliness, is said to have become banker to the Stuart Pretender in Paris (Spengler,
Cantillon, Richard (1697–1734) : The New Palgrave Dictionary of Economics (1954, p. 284) and died insolvent, a not unpredictable fate, in 1717. Our Richard appears to have come to the rescue of his uncle's honour, paying off most of the poor old Jacobite soldier's debts, many of which, indeed, were to him. This was not the end of the family's Stuart involvement; a James Cantillon, believed by Hone to be the young future economist's brother, followed King James to France and was decorated for valour, while a nephew, Thomas, mentioned in the economist's will, was with the Irish Brigade at Lauffelt. Migration to France and beyond was in the blood of these wild geese. It should cause no surprise that our Cantillon had houses in seven European cities, or that he lived much in Paris. He was there, active in banking, between 1716 and 1720. Brilliantly anticipating the fate of John Law's scheme, he was also daring enough to profit immensely by it and, if the sources consulted by W. Stanley Jevons can be believed, ‘made a fortune of several millions in a few days, but still, distrusting Law, prudently retired to Holland’ (Jevons, 1881, p. 336). He appears again in Paris between 1729 and 1732, and seems to have had to engage in litigation with people who had lost through the collapse of Law's scheme, and blamed Cantillon for his part in this. Henry Higgs, after surveying the evidence, commented that Cantillon appeared ‘to have triumphed in the Courts over all his opponents' (Higgs, 1931, p. 373). One gets the feeling as one reads of rather ordinary people playing a game for stakes they could not afford with a master they could not match. Bankers fell like autumn leaves in Paris between 1717 and 1720, and as Higgs remarks, ‘Their losses were probably very heavy in 1720 and much of them went into Cantillon's pocket’ (1931, p. 370).

Back in London in 1734, Cantillon's luck ran out. At the height of his success and his brilliance, he was robbed and murdered, left in the flames of his townhouse in Albermarle Street, Mayfair, during the early morning of 14 May. His precious manuscripts, the Marquis de Mirabeau tells us, perished with him (Higgs, 1931, p. 382). Lady Penelope Compton, who lived opposite, tells us that ‘it burnt very feirce two houses intirely down before they could get any water’ (1931, p. 374). Given this furious blaze, the really remarkable thing to the modern reader is that even despite the primitive state of the forensic science of the day, evidence of foul play was nevertheless found. Higgs, who read the account of the subsequent trial at the Old Bailey, observes that

it was soon evident that he had been murdered before the house was set on fire. His body was burned to ashes. The Journals for 6 June 1734 say ‘Yesterday the refiners finished their search into the ashes of the late Mr Cantillon's house, when no plate, money, or jewels had been found; an undeniable circumstance of a robbery previous to the burning of the house’. (1931, p. 374)

Cantillon's servants were tried for murder, but quickly acquitted. Suspicion then fell on a Frenchman, Joseph Denier, alias Lebane, who, we are told by Higgs, had been Cantillon's cook for 11 years, but apparently had been dismissed a little more than a week before the murder. The French chef, whether in fact guilty or not, fled to Holland and thus evaded arrest.

So it came about that we possess only one work of Cantillon's, and that in what it has been claimed is a rough French translation. Even now its early publishing history is shrouded in mystery. The Essay on the Nature of Trade in General (1755) is thought to have been written between 1730 and Cantillon's death, but it was not published in a complete version until 1755, and then in the French translation, claiming on the title page to have been printed in London by Fletcher Gyles, a claim reasonably disputed by Jevons.
Cantillon, Richard (1697–1734) : The New Palgrave Dictionary of Economics (1881, p. 341). The Marquis de Mirabeau, who revealed that the French translation was in his possession for 16 years, insisted that Cantillon ‘never intended that the work should appear in French and only translated it for a friend’ (Higgs, 1931, p. 383).

Yet, as we have seen, there would be nothing odd in someone of Cantillon's family background and personal habits writing a book in French and publishing it in Paris. It would appear, however, that an English original must have existed, and had been in the hands of Malachy Postlethwayt, since the latter incorporated large parts of Cantillon's Essay in publications beginning in 1749. The first complete English translation from the French text, which was printed alongside it, was that of Higgs in 1931. Higgs, incidentally, collated his English translation with parallel passages from Postlethwayt. In addition we now have the scholarly French edition, edited by Alfred Sauvy (1952) with a number of studies and commentaries.

Since the ‘discovery’ of Cantillon by the English-speaking world following Jevons's enthusiastic article (1881), no less than justice has been done to the merits of the Essay on those topics treated by Cantillon whose significance can be expressed satisfactorily in broadly neoclassical terms. Over these topics we may pass quickly. Jevons himself noted that Cantillon had presented a treatment of currency, foreign exchanges, banking and credit which, judged against the work of its period, he felt to be ‘almost beyond praise’ (Jevons, 1881, p. 342). This enthusiasm has proved infectious, and we find Joseph Spengler, 73 years later, writing that Hume, assuming he knew Cantillon's work, missed ‘the import of Cantillon's brilliant analysis (which compares favourably with Keynes's) of the response of the price structure to changes in the quantity of money’ (Spengler, 1954, p. 283). Spengler was not quite as impressed by Cantillon's treatment of the international specie flow mechanism, but Joseph A. Schumpeter found it a brilliant performance and insisted that ‘the automatic mechanism that distributes the monetary metals internationally is … almost faultlessly described’ (1954, p. 223).

It was likewise recognized as early as Jevons that Cantillon had set out the leading ideas of Adam Smith's ‘important doctrine concerning wages in different employments’ (Jevons, 1881, p. 343), and that the Essay contained what Jevons (somewhat exaggeratedly) called ‘an almost complete anticipation of the Malthusian theory of population’ (p. 347). Jevons, with remarkable objectivity considering his own views on the formation of value, also singled out Cantillon's treatment of ‘the whole doctrine of market value as contrasted to cost value’ (1881, p. 345). It was also customarily recognized by neoclassical scholars later than Jevons that Cantillon made important contributions to the founding of allocation theory.

To intellectual historians approaching the Essay in terms of the neo-Walrasian class of models for general equilibrium theory, it became natural to construe Cantillon's land and labour as given resources. In the Essay, however, while land is a given non-produced input, labour is a produced commodity available in return for subsistence. A reproduction structure thus exists, and surplus may be defined. Cantillon is largely concerned with the allocation of surplus output. This was understood by the first classical theorist to read Cantillon, François Quesnay. For all his one-sided preoccupation with agricultural surplus, Cantillon's French successor picked up the importance of the role of surplus, embodied it in a formal model and passed it on to later classical economists.

From a modern classical point of view Cantillon made several important contributions, which are not always stressed by traditional scholars. For one thing, he offered an early analysis of the respective roles of produced and non-produced inputs in a more than minimally viable commodity reproduction structure. Developing Sir William Petty's concept of a ‘par’ between land and labour, Cantillon
Cantillon investigated the assumptions upon which a reduction of labour to land is legitimate. But, of course, Cantillon was reducing labour to the *produce* of land; that is, to corn. He noted that ‘as those who labour must subsist on the produce of the Land it seems that some relation might be found between the value of labour and that of the produce of the Land’ (Cantillon 1755b, p. 31; emphasis added). Cantillon had entered an area which even today bristles with problems, which would nowadays be described as concerning the aggregation of heterogeneous objects. Cantillon was well aware of some of them. He used a concept of subsistence, that of the ‘meanest Peasant’ (p. 39), as his unit of labour, but he was well aware that this differed all over Europe, and had apparently offered statistical material on this in the lost supplement. It is then necessary to be able to express units of more skilled labour in terms of common labour. He argues that ‘it is easily seen that the difference of price paid for daily work is based upon natural and obvious reasons’ (p. 23). Even today not much progress has been made on this problem, and highly sophisticated models blithely assume it out of existence by using a single homogeneous labour input. Land is also heterogeneous, as Cantillon was well aware; furthermore, any given kind of land can be used to grow different crops. But the analysis of heterogeneous land in the case of a single crop was not developed until Ricardo's period, and the formal analysis of the case where different crops are grown had to wait for Piero Sraffa (1960, pp. 74–8), and more recent work on the relations between produced and non-produced means of production, such as that of Alberto Quadrio Curzio (1980, pp. 218–40).

Leaving aside the difficulties of heterogeneous labour and heterogeneous land with multiple uses, the par is the quantity of corn needed for the subsistence of a labourer and his family during a given period. To get a consistent model, corn must be treated as the only commodity strictly necessary to the reproduction system (the only ‘basic’ in the Sraffian sense). Other outputs have to be treated as luxury goods (non-basics), so that one can accommodate the changing modes and fashions of Cantillon's prince and landowners. Cantillon in fact allowed even his meanest peasant a number of commodities: ‘the married Labourer will content himself with Bread, Cheese, Vegetables, etc., will rarely eat meat, will drink little wine or beer’ (Cantillon, 1755b, p. 37).

To accept this and retain the par, only two options seem open. The poor peasant's commodities other than bread (or other things made in the household from corn, labour, and any free ingredients) could be regarded as non-basic. Or one could construct a composite commodity, containing bread, cheese, vegetables, and so on, in fixed proportions, and use this as the unit of measurement for the par. Then, if one is to avoid the problems of different crops, one must assume that any parcel of the uniform land can produce these commodities in the standard proportions. Cantillon stressed how much even peasant consumption varied from country to country in Europe in his day. But it was not absurd to suppose, as he did, that consumption habits were fixed and traditional among the peasants of a particular area. None of this is meant to deny the justice of Marian Bowley's claim that ‘the “par” between land and labour could only be found under special and unrealistic assumptions’ (1973, p. 105).

In a model where corn is the only basic, or where a unit of composite commodity is always consumed in fixed proportions, one can express the surplus as corn output minus necessary corn input (seed, subsistence, feed for animals), or alternatively one can express surplus as net output of the composite commodity. Passages such as the following are then consistent with the measurement of the surplus in terms of corn (or units of the composite commodity) as required for the par:

> The Farmers have generally two thirds of the Produce of the Land, one for their costs and the support of their Assistants the other for the Profit of their Undertaking … The
Procurator has usually one third of the produce of his Land and on this third he maintains all the Mechanicks and others whom he employs in the City as well, frequently, as the Carriers who bring the Produce of the Country to the City. (Cantillon, 1755b, pp. 43–5)

Cantillon's treatment of surplus strongly implies that it arises only in agriculture. All those in a state, we are told more than once, subsist at the expense of the proprietors of land. There are isolated passages where he seems to be recognizing that profits (in the sense in which these reflect the existence of surplus) can arise in manufacturing. Perhaps the classic case is the description of the master hatter, who, we are told, besides his upkeep, ought also to find 'a profit like that of the Farmer who has his third part for himself' (1755b, p. 203). Certainly Cantillon believed (unlike the Physiocrats) that farmers kept two-thirds of the total produce, one-third representing their profit. But Cantillon used his term 'undertaker' (entrepreneur) to cover chimney sweeps and water-carriers, and Samuel Hollander is probably correct in saying that, in Cantillon, 'profits and wages were said to have a common source in, or to be dependent upon, the property of landowners' (1973, p. 40, n. 48). The concept of surplus throughout industry, and the dual concept of a rate of profit tending to equality across all sectors, including industrial sectors, would not be clearly and systematically expressed until the mature work of Adam Smith (see Walsh and Gram, 1980, pp. 40–77).

Cantillon, however, did pioneering work in developing the theory of the allocation of surplus. His model is remarkably sophisticated. It is an isolated economy – one might think of it as an island – ruled by a prince or landowner. Cantillon is perfectly clear that the prince's significant freedom of choice concerns only that part of output which constitutes the surplus he receives after providing for necessary inputs. He remarks that the prince, deciding on the use of the estate, 'will necessarily use part of it for corn to feed the Labourers, Mechanicks, and Overseers who work for him, another part to feed the Cattle, Sheep and other Animals' (Cantillon, 1755b, p. 59). The consumption pattern of workers is fixed, just like fodder for the animals: 'Labourers and Mechanicks who live from day to day change their mode of living only from necessity' (p. 63).

Cantillon is far from assuming, however, that the composition of surplus output is unchanging. Indeed, changes in the allocation of surplus, dictated by changes in the demands of the prince and any other landowners, are his explanation of deviations of current market prices from natural prices, or intrinsic values. In the original classics, and indeed as late as Alfred Marshall (as Pierangelo Garegnani has noted), natural prices are centres of gravitation towards which market prices tend (Garegnani, 1976). This idea is clearly present in Cantillon. The prince or landlord, who is assumed to have a third of the produce of each of the farms he owns, and is mainly responsible for luxury consumption, is 'the principal Agent in the changes which may occur in demand' (Cantillon, 1755b, p. 63). If a few prosperous farmers engage in some luxury consumption, they will imitate the tastes of the prince. Thus changes in fashion were the leading cause of 'the variations of demand which cause the variations of Market prices' (p. 65). Cantillon is well aware that good or bad harvests, extraordinary consumption resulting from foreign troops, and so on, can disturb the gravitation of market prices towards natural prices, but he eliminates such accidents 'so as not to complicate my subject, considering only a State in its natural and uniform condition' (p. 65). This is precisely the concept of a long-period position common to all the great classical economists.

Even more surprisingly, Cantillon shows that he is quite aware that a planned economy directed by the prince, and a system of prices, can each achieve the identical allocation of surplus output – a result
whose formal proof had to wait until the 20th century, and which lay fallow after Cantillon as classical political economy developed in other respects.

Cantillon, of course, was by no means the first to make some kind of distinction between market and natural prices. The Schoolmen had distinguished between the price ruling at a given moment on a market and the just price, sometimes relating the latter to costs. But in Cantillon the distinction between market and natural price is an integral part of a whole economic model. The natural price, or intrinsic value of a commodity ‘is the measure of the quantity of Land and of Labour entering into its production’ (1755b, p. 29). Labour is then reduced, through the par, to subsistence units, which, as we have seen, can either be measured in corn or in quantities of a composite commodity. These intrinsic values are assumed to be invariant (p. 31). Market prices may deviate from intrinsic values following a change in demand, as we have seen, but the actions of profit-maximizing capitalist farmers will then lead to supply changes, initiating the gravitation process. If the farmers ‘have too much Wool and too little Corn for the demand, they will not fail to change from year to year the use of the land till they arrive at proportioning their production pretty well to the consumption of Inhabitants’ (pp. 61–3).

Notice that since we are considering a change in demand for corn and wool, these goods are here being used for luxury consumption. Corn can be fed to servants and musicians, and wool makes fine garments. What is more, Cantillon can allow for the existence of a number of agricultural sectors producing only luxuries: fine wines, silks, blood horses, and so on. His model clearly implies that there is a tendency towards a long-period position in which capitalist farmers in each of these sectors would receive profits at the uniform rate of one-third of the intrinsic value of their total output. Thus the extraction of surplus, and its reflection in a uniform intersectorial rate of profit, is certainly understood by Cantillon for those sectors where capitalist production relations were firmly established in his period. It remained for Adam Smith to extend this analysis to the newly widespread phenomenon of his time, capitalist production throughout industry.

capital asset pricing model

M.J. Brennan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Two general approaches to the problem of valuing assets under uncertainty may be distinguished. The first approach relies on arbitrage arguments of one kind or another, while under the second approach equilibrium asset prices are obtained by equating endogenously determined asset demands to asset supplies, which are typically taken as exogenous. The capital asset pricing model (CAPM) is an example of an equilibrium model in which asset prices are related to the exogenous data, the tastes and endowments of investors, although the CAPM is often presented as a relative pricing model.

Keywords
arbitrage pricing theory; asset price anomalies; capital asset pricing model; consumption capital asset pricing model; international asset pricing model; intertemporal capital asset pricing model; mean-variance analysis; portfolio theory; pricing kernels; probability distributions; relative pricing models; risk aversion; separation; Tobin separation theorem; von Neumann and Morgenstern

Article

If they are to be of practical use, equilibrium asset pricing models must be parsimonious in their parameterization of asset demands. To date this parsimony has been achieved only by a choice of assumptions which leads to universal portfolio separation: this is the property that the asset demand vector of every agent can be expressed as a linear combination of a set of basis vectors which may be thought of as portfolios or mutual funds. The distinguishing feature of the set of models which is collectively known as the capital asset pricing model (CAPM) is that each of these basis portfolios can be interpreted as the solution to a particular constrained portfolio variance minimization problem.

Historical perspective

The assumption that uncertainty about future asset returns can be described in terms of a probability distribution is at least as old as Irving Fisher (1906), although Hicks (1934b) appears to have been the first to suggest that preferences for investments could be represented as preferences for the moments of the probability distributions of their returns, and to propose that, as a first approximation, preferences could be represented by indifference curves in mean-variance space. Von Neumann and Morgenstern (1947) were the first to place the theory of choice under uncertainty on a rigorous axiomatic basis.

The story of modern portfolio theory really begins, however, with Markowitz (1952; 1958) who assumed explicitly that investor preferences were defined over the mean and variance of the aggregate portfolio return, related these parameters to the portfolio composition and the parameters of the joint distribution of security returns, and for the first time applied the principles of marginal analysis to the choice of optimal portfolios.

Both Markowitz and Tobin (1958) showed that mean-variance preferences can be reconciled with the von Neumann–Morgenstern axioms if the utility function is quadratic in return or wealth. This assumption is objectionable since it implies negative marginal utility at high wealth levels. Tobin also showed, however, that mean-variance preferences could be
derived by restricting the probability distributions over which choices are made to a two-parameter family. After some initial confusion it was recognized that, since portfolio returns are weighted sums of security returns, the two-parameter family must be stable under addition, and the only member of the stable class with a finite variance is the normal distribution. Subsequently Merton (1969) and Samuelson (1970) showed that mean-variance analysis is applicable for a broad class of continuous asset price processes if the trading interval is infinitesimal.

The major part of Tobin’s analysis deals with the choice between a single risky asset and cash, but he demonstrated that nothing essential is changed if there are many risky assets, for they will always be held in the same proportions and can be treated as a single composite asset. This, the first separation theorem in portfolio theory, is illustrated in Figure 1, which plots mean returns, $\mu$, against the standard deviation, $\sigma$. In this figure the curved locus AMOVB corresponds to the set of portfolios offering the lowest standard deviation for each level of mean return: the positively sloped segment is referred to as the efficient frontier, for points along it offer the highest $\mu$ for a given $\sigma$. In the absence of any riskless investment opportunities, risk-averse mean-variance investors will select portfolios corresponding to the points at which their indifference curves in $(\mu, \sigma)$ space are tangent to the efficient frontier (Tobin shows that the indifference curves of risk averters will have the requisite curvature). Point C represents cash which has zero risk and return. By combining cash with the portfolio of risky assets corresponding to the tangency portfolio O, investors are able to attain the $(\mu, \sigma)$ combinations along the line segment CO, and all investors who find it optimal to hold cash will find it optimal to combine their cash with the same risky portfolio O: their portfolio decisions can be separated into the choice of the optimal combination of risky asset (O) and the choice of the cash–risky asset ratio.

Figure 1
The efficient frontier and the CAPM
Six years elapsed before the equilibrium implications of the Tobin separation theorem were exploited by Sharpe (1964) and Lintner (1965). The reason for delay was undoubtedly the boldness of the assumption required for progress, namely, that all investors hold the same beliefs about the joint distribution of security returns. Nevertheless, this assumption of homogeneous beliefs, combined with the further assumption that all investors can borrow as well as lend at the riskless rate, \( r \), leads to the powerful conclusion that all investors hold the same portfolio of risky assets, denoted by \( M \) in the figure. Then the only risky assets that will be held by investors in equilibrium are those contained in portfolio \( M \), and \( M \) must be the market portfolio of all risky assets in the economy. This identification of the tangency portfolio \( M \) with the aggregate market portfolio is the essence of the Sharpe–Lintner CAPM.

The interest of this result derives from the restriction that it imposes on expected asset returns: the excess of \( \mu_j \), the expected return on any security \( j \), over the risk-free rate \( r \), must be proportional to the covariance of the security return with the return on the market portfolio, \( \sigma_{jM} \):

\[
\mu_j - r = \theta_M \sigma_{jM} \quad \text{for all } j
\]  

(1)

where \( \theta_M \) is a measure of aggregate risk aversion. The intuition behind this important result is that if investors are content to hold portfolio \( M \), the marginal rate of transformation between risk and return obtained by borrowing to invest in a risky security must be the same for all risky securities. Frequently the unknown risk aversion parameter, \( \theta_M \), is eliminated and the relative pricing result is obtained:

\[
\mu_j - r = \beta_j (\mu_M - r) \quad \text{for all } j
\]  

(2)

where \( \mu_M \) is the expected return on the market portfolio and \( \beta_j \equiv \sigma_{jM} / \sigma_{MM} \) is the ‘beta’ coefficient, which corresponds to the slope of the regression line relating the return on the security to the return on the market portfolio.

During the first half of the 1970s extensive progress was made in relaxing the strong assumptions underlying the original model, and new separation theorems and models were obtained. At the same time, extensive empirical investigations made possible by the development of new stock-price databases found results which were interpreted as favourable to the model. The model also has an influence on practical investment management and corporate finance.

A turning point was reached with the publication of a paper by Roll (1977); this argued that the market portfolio of the theory, which includes all assets, could never be empirically
identified, and that therefore the CAPM, which simply asserts the efficiency properties of this portfolio, could never be empirically tested. This argument had substantial influence, and for some time played a major role in shifting attention away from the CAPM to the newly emerging arbitrage pricing theory (APT) of Ross (1976). However, since the early 1990s growing acceptance of the empirical importance of time variation in investment opportunities has led to a resurgence of interest in Merton’s (1973) intertemporal version of the CAPM which is formally similar to the APT but is able to provide an economic interpretation of the return factors that are priced in equilibrium.

The CAPM is of great historical significance, not only because it was the first equilibrium model of asset pricing under uncertainty, but also because it showed the importance of portfolio separation for tractable equilibrium models; and, being derivable from assumptions of either quadratic utility or normal distributions, it revealed that the requisite separation properties could be obtained by restrictions either on preferences or on distributions. Cass and Stiglitz (1970) clarified the rather restrictive assumptions necessary for preference-based separation, and equilibrium models based on this have been constructed, for example, by Rubinstein (1976). Ross (1978) has identified the distributional assumptions required for separation in the absence of restrictions on preferences, and the arbitrage pricing theory is based on a generalization of his separating distributions. Chamberlain (1983) discusses spherical distributions, the subclass of separating distributions for which the expected utility is a function of the portfolio mean and variance. Both preference-based and distribution-based models of capital market equilibrium are lineal descendants of the CAPM.

A pricing kernel is a non-negative weighting function for asset returns under which the expected returns on all assets are equal to the risk-free interest rate; the kernel corresponds roughly to the marginal utility of a representative investor and the existence of a pricing kernel is a necessary and sufficient condition for arbitrage free security markets. Modern treatments of asset pricing such as Cochrane (2005) treat the general problem of asset pricing as that of specifying an appropriate pricing kernel: the CAPM specifies a class of pricing kernels that are linear in the aggregate market return.

An unfortunate consequence of the one-period nature of the CAPM was a concentration of attention on equilibrium rates of return, rather than on prices, which are the fundamental variables of interest. However, Merton (1973) placed the CAPM in an intertemporal context, and his necessary condition for equilibrium rates of return forms one cornerstone (the other being an assumption of rational expectations) for partial differential equations for asset prices which, following Cox, Ingersoll and Ross (1985), has tended to unify the pricing theories for bond and equity markets.

**Formal models**

While a complete asset pricing model endogenizes the riskless interest rate as well as the prices of risky securities, the CAPM adds nothing new to the theory of interest rate determination, and we shall simplify by taking the interest rate and current consumption decisions as given, concentrating our attention on portfolio decisions and the pricing of risky securities.

In considering the various versions of the CAPM we shall pay particular attention to the implied demands of investors. It will be seen that in all cases in which risks are freely traded asset demands exhibit the separation property, and even when there are restrictions on trading as in the Mayers (1972) asset pricing model, an approximate separation property obtains.

**The Sharpe–Lintner model**

Consider a setting in which each investor \(i (i=1,\ldots,m)\) is endowed with a fraction \(z_{ij} \) of security \(j (j=1,\ldots,n)\) and (a) investor utility is defined over the mean and variance of end of period wealth; (b) securities are traded in a competitive market with no taxes or transactions costs; (c) investors share homogeneous beliefs or assessments of the joint distribution of payoffs on the securities; there are no dividends; (d) there is an exogenously determined interest rate \(r = R - 1\) at which investors may borrow or lend without default; (e) there are no restrictions on short sales.

Then define:

- \( \bar{p}_j / \) expected end of period value of security \( j \);
- \( p_{j0} \) initial value of security \( j \);
- \( \omega_{jk} \) covariance between end of period value of \( j \) and \( k \);
- \( \bar{w}_i, \bar{s}_i^2 \) expectation and variance of end of period wealth of investor \( i \);
- \( v_i(\bar{w}_i, \bar{s}_i^2) \) utility of investor \( i \) with
  - \( v_{1i} \equiv \partial v_i / \partial \bar{w}_i > 0, v_{12} \equiv \partial v_i / \partial s_i^2 < 0 \).
The investor's decision problem may be written as

$$\max_{\bar{W}_i} V_i (\bar{W}_i, z^2)$$

(3)

subject to

$$\bar{W}_i = \sum_j z_{ij} \bar{p}_j - R \sum_j (z_{ij} - \bar{z}_{ij}) r_j$$

(4)

$$z^2 = \sum_j \sum_k z_{jk} \omega_{jk}$$

(5)

The first order conditions for an optimum are

$$V_{i1} (\bar{p}_1 - R \bar{p}_0) + 2 V_{i2} \sum_k z_{ik} \omega_{jk} = 0, \ (j = 1, ..., n)$$

(6)

and the second conditions are satisfied by virtue of the assumption of risk aversion. Defining $\Omega^*$ as the variance covariance matrix $[\omega_{jk}]$ and using boldface type to denote vectors, the vector of fractional asset demands may be written

$$z_i = \theta_i^{-1} \Omega_{-1}^{*1} (\bar{p}_1 - R \bar{p}_0)$$

(7)

where $\theta_i^{-1} = -V_{i1} / 2V_{i2}$ is a measure of the investor's risk tolerance. Equation (7) is a statement of the Tobin separation theorem, that investor demands for risky assets differ only by a scalar multiple.
Market clearing requires that \( \sum \mathbf{z}_i = \mathbf{1} \) where \( \mathbf{1} \) is a vector of units. Then the equilibrium initial price vector is obtained by summing (7) over \( i \) and imposing the market clearing condition:

\[
\mathbf{p}_0 = \frac{1}{R} \left\{ \mathbf{p}_1 - \theta_m \mathbf{\Omega}^{-1} \right\}
\]

(8)

where \( \theta_m = (\sum \mathbf{z}_i^{-1})^{-1} \). In this form the CAPM expresses equilibrium asset prices in terms of the exogenous variables, the distribution of end of period prices, investor risk aversion parameters and the interest rate, although it should be noted that in general the market risk aversion parameter \( \theta_m \) will depend upon the endogenously determined distribution of wealth. This formulation corresponds to that of Lintner (1965) and emphasizes the one-period nature of the model and the exogeneity of the end of period prices. However, the CAPM is most often written as a necessary condition for the equilibrium rates of return, although this obscures the distinction between endogenous and exogenous variables.

In what follows we shall work with the rate of return formulation; thus define \( x_{ij} = z_i^{p,j} j_0 \), the amount invested in security \( j \); \( \mu_j = \frac{p_j 1}{P_j 0} - 1 \), the expected rate of return and \( \sigma_{jk} = \omega_{jk} / P_j 0 P_k 0 \) the covariance of the rates of return between securities \( j \) and \( k \). Making these substitutions in (4) and (5), the first order conditions (6) become

\[
\nu_j (\mu_j - r) + 2 \nu_{j2} \sum_k x_{jk} \sigma_{jk} = 0, \quad (j = 1, \ldots, n).
\]

(9)

Then, defining \( \mathbf{\Omega} \) as the variance-covariance matrix of rates of return, the vector of asset demands \( \mathbf{x}_i \) may be expressed as

\[
\mathbf{x}_i = \theta_i^{-1} \mathbf{\Omega}^{-1} (\mathbf{\mu} - \mathbf{1}).
\]

(10)

This is an alternative statement of the Tobin separation theorem and the portfolio \( \mathbf{\Omega}^{-1} (\mathbf{\mu} - \mathbf{1}) \) corresponds to the point of tangency in Figure 1. This portfolio itself may be decomposed into the two portfolios \( \mathbf{\Omega}^{-1} \mathbf{\mu} \) and \( \mathbf{\Omega}^{-1} \mathbf{1} \). The former is the solution to the problem of finding the minimum variance portfolio of risky assets with a given expected payoff, and the latter is the solution to the problem of finding the global minimum variance portfolio of risky assets; these two portfolios plot at points \( O \) and \( V \) in the figure. As Merton (1972) has shown, the whole locus may be constructed from just these two portfolios.

Let \( V_m \) denote the aggregate market value of all assets in the market portfolio and let \( \mathbf{v}_m \) denote the vector of market proportions. Combining the market clearing condition \( \sum \mathbf{x}_j = \mathbf{V}_m \mathbf{v}_m \) with (10) yields

\[
\mathbf{\mu} - \mathbf{1} = \theta_m V_m \mathbf{v}_m.
\]

(11)
This form of the CAPM expresses asset risk premia as proportional to the covariances of their returns with the returns on the market portfolio; this of course is no more than the condition for the market portfolio to correspond to the tangency point in Figure 1. Equation (11) contains the market risk aversion parameter $\theta_m$. This can be eliminated by pre-multiplying (11) by $v_m$ and solving for $\theta_m = (\mu_m - r) / \sigma_m^2$, where $\mu_m$ and $\sigma_m^2$ are the expected return and variance of return on the market portfolio respectively. Then, substituting for $\theta_m$ in (11) we have the equation of the ‘security market line’:

$$\mu_j - r = \beta_j (\mu_m - r)$$

(12)

where $\beta_j$$ = \sigma_j \sigma_m / \sigma_m^2$. In this form the CAPM is a relative pricing model which relates the risk premium on individual securities to the risk premium on the market portfolio. The proportionality factor, $\beta_j$, often referred to as the ‘beta coefficient’, is the coefficient from the regression of $\tilde{R}_j$, the return on security $j$, on $\tilde{\kappa}_m$, the return on the market portfolio:

$$\tilde{R}_j = \alpha_j + \beta_j \tilde{\kappa}_m + \tilde{\varepsilon}_j$$

(13)

where $\tilde{\varepsilon}_j$ is an orthogonal error term. Taking expectations in the market model equation (13), the asset pricing equation (12) is seen to imply the restriction $\alpha_j = (1 - \beta_j)r$. This restriction, and the existence of a positive risk premium on the market portfolio, are the major empirical predictions of the Sharpe–Lintner model. They have been the subject of extensive empirical tests.

**Taxes and restrictions on riskless transactions**

The absence of short sales restrictions is not critical to the Sharpe–Lintner model, since in equilibrium all investors hold the market portfolio, which does not involve short sales. The assumption is critical, however, for all the remaining models we shall consider which involve more than a single basis fund of risky securities.

Thus, following Black (1972) and Brennan (1970), assume that there are no opportunities for riskless borrowing or lending, and that each security pays predetermined dividends which are taxed in the hands of the investor at the rate $t_i (i = 1, \ldots, m)$. Denoting the dividend yield by $\delta_j$, and assuming that investor preferences are defined over the moments of after tax wealth, the first order conditions corresponding to (9) are

$$V_{ij} (\mu_j - t_j \delta_j - \lambda_i) + 2 \sum_k \sigma_{jk} \Omega^{-1} x_i = 0, \ (j = 1, \ldots, n).$$

(14)

where $\lambda_i$ is the Lagrange multiplier associated with the constraint that all wealth be invested in risky securities. The vector of asset demands may be written as

$$x_i = \delta_j^{-1} \Omega^{-1} \mu - (\beta_j^{-1} \lambda_i) \Omega^{-1} 1 - (\beta_j^{-1} t_i) \Omega^{-1} \delta.$$
Note first that if $\ell_j = 0$ the optimal portfolio for any preferences can be constructed from the two mutual funds $\Omega^{-1}\mu_i$ and $\Omega^{-1}1$. Heterogeneous taxation of dividends introduces the third mutual fund, which can be interpreted as the solution to the problem of finding the minimum variance portfolio with a given total dividend. Aggregating the demand vectors, and imposing the market clearing conditions, yields an asset pricing equation which contains three utility dependent parameters, $\lambda_m$, $\theta_m$ and $t_m$, corresponding to the three funds in (15):

$$\mu - \lambda_m1 = \theta_m\Omega\nu_m + t_m\delta$$

(16)

$t_m$, the market tax rate, is a weighted average of the personal tax rates, and $\lambda_m$, the market shadow interest rate, is referred to for historical reasons as the zero beta return. When $t_m = 0$, (16) is just the condition for the market portfolio to be the tangency portfolio when the interest rate is $\lambda_m$. Thus the Black model, which does not include taxes, differs from the Sharpe–Lintner model only in leaving unspecified the relevant (shadow) riskless interest rate.

Non-marketable assets

Mayers (1972) has considered the effect of introducing an extreme form of market imperfection, namely, an absolute prohibition on trading certain assets. This is important, for a substantial part of total wealth is not held as part of well-diversified portfolios, on account either of prohibitions on trade (human capital), or of market imperfections such as transaction costs and information asymmetries. Thus let $\tilde{h}_i$ denote the expected payoff on the non-marketable wealth (human capital) of investor $i$, and let $\sigma^j_{ik}$ denote the covariance between the return on marketable security $j$ and the human capital of investor $i$. Then the expression for $W_i$ must be increased by $\tilde{h}_i$ and the variance of end of period wealth becomes $S_i^2 = \Sigma_j \Sigma_k \tilde{h}_i\nu_j\nu_k + \Sigma_j \Sigma_k \tilde{h}_i\nu_j\nu_k + \sigma^2$. The asset demand vector can then be written as

$$x_i = \theta_i^{-1}\Omega^{-1}(\mu - \nu) - b_i$$

(17)

where $b_i = \Omega^{-1}\sigma^i_j$ is the vector of coefficients from the regression of the return on human wealth on the marketable security returns. Defining $x^e_i = x_i + b_i$ as the vector of effective asset demands, we see from (17) that effective asset demands exhibit the standard separation property. This reflects the fact that, while the returns on human capital are not directly marketable, the component of the return which is linearly related to the returns on the marketable securities is indirectly marketable by appropriate offsetting positions in the marketable securities. The asset holdings of the individual may be represented as the sum of effective asset holdings $x^e_i$ and an investment in the component of human wealth whose return is orthogonal to the returns on marketable assets. We refer to this as approximate portfolio separation since the first component exhibits portfolio separation, and the second component has no effect on the relative demands for marketable assets.

The Mayers model leads to an asset pricing equation which is identical to that of the Sharpe–Lintner model if the market portfolio is defined as the sum of the effective investment vectors $x^e_i$. 

Inflation and international asset pricing
Stochastic inflation has no effect on the foregoing results, provided that a common inflation rate can be defined for all investors and returns are restated in real terms. However, the international asset pricing models of Solnik (1974) and Stulz (1981) distinguish between nationalities precisely on the basis of their price indices, which may differ on account of either a violation of commodity price parity or differences in tastes and consumption baskets (see Adler and Dumas, 1983).

Define \( \pi_i \) as the inflation rate in the numeraire currency for investor \( i \). Then, to a high order of approximation, which becomes exact as the time interval approaches zero, the mean and variance of real wealth can be written as

\[
\bar{W}_i = \sum_j x_i j (\mu_j - r) + W_{0i}(1 + r - \pi_i + \sigma^j_{\pi\pi}) - \sum_j x_i j \sigma^j_{\pi\pi}
\]

\[ (18) \]

\[
\sigma^2_i = \sum_j \sum_k x_i j x_k j \sigma^j_{\pi\pi} - 2W_{0i} \sum_j x_i j \sigma^j_{\pi\pi} + W_{0i}^2 \sigma^j_{\pi\pi}
\]

\[ (19) \]

where \( W_{0i} \) is the investor's initial wealth.

The asset demand vector is then

\[
x_i = \theta_i^{-1} \Omega^{-1}(\mu - rI) + b_i
\]

\[ (20) \]

where \( b_i = W_{0i} \Omega^{-1} \sigma^j_{jj} \) is the vector of coefficients from the regression at the individual's aggregate inflation risk, \( W_{0i} \pi_i \), on security returns. If we compare (20) with (17), it is apparent that this international asset pricing model is isomorphic to the Mayers' non-marketable wealth model with individual inflation risks playing the same role as human capital.

Black (1974) has modelled segmentation in international capital markets by introducing a tax on foreign security holdings for residents of one country. This model is isomorphic to Brennan's (1970) tax model, if the foreign securities are thought of as paying dividends on which only domestic residents are taxable. Stulz (1981) extends Black's model by prohibiting negative taxes on short sales: as one might expect, this causes some indeterminacy in the pricing relations since the marginal conditions of portfolio optimality are no longer always satisfied.

Intertemporal models

Merton (1973) showed that the classical one-period CAPM can be extended to an intertemporal setting in which investors maximize the expected utility of lifetime consumption. With continuous trading and suitable restrictions on the stochastic process of asset prices, the essential mean-variance analysis is retained, the major innovation being that at each instant the individual may be represented as maximizing the expected utility of a derived utility function, defined over wealth and a set of \( S \) state variables describing the future investment and consumption opportunity sets. The state dependent derived utility function induces \( (S + 1) \) fund separation in the risky asset portfolio, and the vector of risky asset demands may be written
where $\xi_s$ is the vector of covariances of asset returns with the change in state variable $S$ and $\gamma_\mu$ depends on the utility function. Aggregation of asset demands and the imposition of the market clearing condition lead to an asset pricing equation in which asset risk premia are a linear function of covariances with aggregate wealth and covariances with changes in the state variables or factors that described the investment opportunity set. In the absence of prior information about the relevant state variables this model is empirically indistinguishable from the arbitrage pricing theory. Breeden (1979) showed that if consumption preferences are time separable this ‘multi-beta’ pricing model can be collapsed to a single beta measured with respect to changes in aggregate consumption, the ‘consumption’ CAPM (CCAPM), and much effort has been expended on testing this form of the model despite the difficulties of measuring consumption flows.

Campbell (1993) developed a model with recursive utility which, unlike the standard time-additive utility function defined over consumption, does not satisfy the von Neumann–Morgenstern axioms but does allow the intertemporal marginal rate of substitution to vary independently of risk aversion. This model contains elements of both the CAPM and the CCAPM in that expected returns depend on the covariances of asset returns with both consumption and the market return.

Recent empirical developments

During the 1990s renewed interest in Merton’s (1973) ‘intertemporal’ CAPM (ICAPM) was generated by the empirical failures of both the CAPM and the CCAPM, the increasing evidence of time variation in investment opportunities, and the empirical success of an atheoretical three-factor model of security returns developed by Fama and French (FF) (1992; 1993) to account for high returns on small firms and the low returns on growth stocks relative to value stocks. The FF model could be interpreted as a version of either the APT or the ICAPM if no restrictions were placed on the types of factors that could enter these models. However, the factors that are important for pricing in the APT are those that explain the covariance of (one-period) returns, while the factors in the ICAPM are those that forecast future returns. Merton (1973) had suggested the interest rate as an example of an ICAPM state variable, and Nielsen and Vassalou (2006) showed formally that the only state variables that are relevant for the ICAPM are those with information about the current and future interest rate and the slope of the capital market line which is shown as $rM$ in Figure 1. Brennan, Wang and Xia (2004) constructed a version of the ICAPM in which the interest rate and slope of the capital market line follow a joint Markov process, and showed that its empirical performance was at least as good as that of the FF model. Brennan and Xia (2006) used this framework to derive expressions for the prices of cash flow claims which depend explicitly on current capital market conditions as measured by the interest rate and the slope of the capital market line, as well as on the characteristics of the underlying cash flow. This implies that stock prices vary with discount rates as well as cash flow expectations, and Campbell and Vuolteenaho (2004) showed that, if market betas are decomposed into components due to changes in cash flow expectations and to changes in discount rates, then risk premia are associated primarily with the cash flow component of beta. These models attribute the low returns on growth stocks to the greater proportion of their risk arising from discount rate changes.

The classic CAPM may hold even with time variation in investment opportunities. Constantinides (1980; 1982) has identified two sets of sufficient conditions for the simple CAPM to hold with a time varying interest rate. In his models the social investment opportunity set is stationary and consists only of risky investments: stochastic variation in the interest rate then does not affect the CAPM relation if there is either demand aggregation or full Pareto efficiency of asset markets. Either condition is sufficient for prices to be determined as though there existed a single representative individual; for such an individual stochastic variation in the interest rate is irrelevant since the interest rate represents only a shadow price and not a real investment opportunity. Finally, the single period nature of the CAPM is retained if individuals behave myopically, ignoring stochastic variation in the investment opportunity set; this occurs if and only if the utility function is logarithmic.

Time variation in the distribution of asset returns can affect tests of asset pricing models even if the CAPM is true. For example, if betas and risk premia are time varying, then average returns need not be related to average betas as predicted by the CAPM even if period by period returns and betas are. Lettau and Ludvigson (2001) argued that the predictive power of the CCAPM is considerably enhanced by allowing the covariances of asset returns to depend on a measure of the aggregate consumption–wealth ratio. However, Lewellen and Nagel (2006) argued that time variation in risk premia is unlikely to be sufficient to account for the observed value anomaly.

capital controls

Kristin J. Forbes
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Capital controls can take many different forms and are broadly defined as any restrictions on the movement of capital across a country's borders. This article focuses on the debate on the merits of capital controls for emerging markets and developing economies. It describes the potential costs and benefits of capital controls, focusing on the recent empirical literature evaluating the impact of capital controls.

Keywords

Bretton Woods system; bubbles; capital account liberalization; capital controls; distortions; Dutch disease; encaje (Chile); fixed exchange rates; foreign direct investment; International Monetary Fund; Keynes, J. M.; Kindleberger, C.; monetary policy; Nurkse, R.; portfolio investment; risk diversification

Article

Capital controls are any restrictions on the movement of capital into or out of a country. Capital controls can take a wide variety of forms. For example, capital controls can be quantity-based or price-based, or apply to only capital inflows, only capital outflows, or all types of capital flows. Capital controls can also be directed at different types of capital flows (such as at bank loans, foreign direct investment or portfolio investment) or at different types of actors (such as at companies, banks, governments or individuals).

Most developed countries believe that the benefits from the free movement of capital across borders outweigh the costs, and therefore have very limited (if any) capital controls in place today. For emerging markets and developing economies, however, there has been a long-standing debate on the desirability of capital controls. Assessing the impact of capital controls is complicated due to a number of factors, including the various forms in which they can be structured. This article discusses the recent debate on capital controls, focusing on the theoretical arguments for and against controls and the existing empirical
capital controls: The New Palgrave Dictionary of Economics
evidence on their impact.

History of the debate

Throughout the 20th century, economists have regularly expressed concerns about international capital flows. For example, in the 1940s Ragnar Nurkse worried about ‘destabilizing capital flows’ and in the 1970s Charles Kindleberger described the role of capital in driving ‘manias, panics and crashes’ (see Nurkse, 1944; Kindleberger, 1978). When the world’s leading economies met at Bretton Woods in 1944 to formulate rules governing the international financial system, John Maynard Keynes and other delegates debated the role of capital controls. The resulting compromise required that members of the International Monetary Fund (IMF), one of the newly created international monetary institutions, allow capital to be freely exchanged and convertible across countries for the purpose of all current account transactions, but permitted members to implement capital controls for financial account transactions. Most countries had capital controls in place at this time.

Over the following years, however, many developed countries gradually removed their capital controls, so that by the 1980s most had few controls in place. In the early and mid-1990s, many emerging markets and developing countries also began to lift their capital controls. The impact initially appeared to be positive – capital flowed into countries with liberalized capital accounts, investment and growth increased, and asset prices rose. In fact, support for lifting capital controls was so widespread that in 1996–7 leading policymakers discussed amending the rules agreed to at Bretton Woods to extend the IMF’s jurisdiction to include capital movements and make capital account liberalization a goal of the IMF. In mid-1997, however, a series of financial crises started in Asia and spread across the world, appearing to disproportionately affect emerging markets that had recently liberalized their capital accounts. This series of crises sparked a reassessment of the desirability of capital controls for emerging markets and developing economies.

In a sharp sea change, many leading policymakers and economists began to support the use of capital controls for emerging markets in some circumstances, especially taxes on capital inflows. Much of this support was based on the belief that controls on capital inflows could reduce a country’s vulnerability to financial crises. From 2002 to 2005, several emerging markets (such as Colombia, Russia and Venezuela) also implemented new controls on capital inflows, largely to reduce the appreciations of their currencies. Over the same period, however, several large emerging markets (such as India and China) moved in the opposite direction and lifted many of their existing controls.

Benefits and costs of capital controls

The free movement of capital across borders can have widespread benefits. Capital inflows can provide financing for high-return investment, thereby raising growth rates. Capital inflows – especially in the form of direct investment – often bring improved technology, management techniques, and access to international networks, all of which further raise productivity and growth. Capital outflows can allow domestic citizens and companies to earn higher returns and better diversify risk, thereby reducing volatility in consumption and income. Capital inflows and outflows can increase market discipline, thereby leading to a more efficient allocation of resources and higher productivity growth. Implementing
capital controls can reduce a country's ability to realise these multifaceted benefits. On the other hand, the free movement of capital across borders can also have costs. Countries reliant on foreign financing will be more vulnerable to ‘sudden stops’ in capital inflows, which can cause financial crises and/or major currency depreciations. Large volumes of capital inflows can cause currencies to appreciate and undermine export competitiveness, causing what is often called the ‘Dutch disease’. The free movement of capital can also complicate a country's ability to pursue an independent monetary policy, especially when combined with a fixed exchange rate. Finally, capital inflows may be invested inefficiently due to a number of market distortions, thereby leading to overinvestment and bubbles that create additional challenges. Capital controls could potentially reduce these costs from the free movement of capital.

**Empirical evidence on capital controls**

Since capital controls can have costs and benefits, evaluating the desirability and aggregate impact of capital controls is largely an empirical question. (See Eichengreen, 2003, on the potential costs and benefits of capital controls.) Not surprisingly, an extensive literature has attempted to measure and assess the effects of capital controls.

The most studied experience with capital controls is the Chilean *encaje* – a market-based tax on capital inflows from 1991 to 1998 so structured that the magnitude of the tax decreased with the maturity of the capital flow. Chile's experience with capital controls is generally viewed positively, largely due to Chile's strong economic performance during the period the controls were in place. Empirical studies of the impact of Chile's capital controls, however, have reached several general conclusions. First, there is no evidence that the capital controls moderated the appreciation of Chile's currency (which was the primary purpose of the capital controls). Second, there is little evidence that the controls protected Chile from external shocks. Third, there is some evidence that the controls raised domestic interest rates (at least in the short term). Fourth, there is some evidence that the controls did not affect the volume of capital inflows, but did lengthen the maturity of capital inflows. Finally, the capital controls significantly raised the cost of financing for small and medium-sized firms and distorted the mechanisms by which Chilean companies procured financing. The general conclusion from this work is that Chile's strong economic performance during the 1990s resulted from sound macroeconomic and financial policies, not the capital controls, and that the capital controls had both costs and benefits. (See Forbes, 2007, for more information on this literature and the Chilean capital controls.)

A second major branch of literature examining the impact of capital controls focuses on the effects of lifting capital controls (that is, capital account liberalization). The majority of this work uses macroeconomic data, typically focusing on how capital account liberalization raises economic growth using cross-country growth regressions. Prasad et al. (2003) is a detailed survey of this literature and shows that, although several papers find a robust, positive effect of capital account liberalization on growth, other papers find no significant effect, and most papers find mixed evidence. This literature is generally read as showing weak evidence that lifting capital controls may have some positive effect on growth.

There are several explanations for the inconclusive results in this macroeconomic literature assessing the impact of capital controls. First, it is extremely difficult to measure capital account openness and to
capital controls: The New Palgrave Dictionary of Economics

capture the various types of capital controls in a simple measure that can be used for empirical analysis. Second, different types of capital flows and controls may have different effects on growth and other macroeconomic variables. For example, controls on portfolio investment may be more beneficial than other types of capital controls. Third, the impact of removing capital controls could depend on a range of other factors that are difficult to capture in cross-country regressions, such as a country’s institutions, financial system, corporate governance or even the sequence in which different controls are removed. Fourth, capital controls can be very difficult to enforce (especially for countries with undeveloped financial markets) so the same capital control may have different degrees of effectiveness in different countries. Finally, most countries that remove their capital controls undertake simultaneously a range of reforms and undergo structural changes, so that it can be difficult to isolate the impact of removing the controls. (For additional details on the challenges in measuring the impact of capital controls, see Eichengreen, 2003; Forbes, 2006; Magud and Reinhart, 2006; and Prasad et al., 2003.)

Given these challenges in measuring the impact of capital controls, it is not surprising that the empirical literature has had difficulty documenting their effects on growth at the macroeconomic level. To put these results in perspective, however, the current status of this literature is similar to the literature in the 1980s and 1990s on how trade liberalization affects economic growth. Economists generally believe that trade openness raises growth, but most of the initial work on this topic also focused on cross-country, macroeconomic studies and reached inconclusive results. At a much earlier date, however, several papers using microeconomic data and case studies found compelling evidence that trade liberalization raises productivity and growth.

Similarly, recent work based on microeconomic data has been much more successful than the macroeconomic literature in documenting the effects of capital controls. Forbes (2006) surveys this new literature, which covers a variety of countries and periods, uses a range of approaches and methodologies, and builds on several different fields. This literature has, to date, reached five general results. First, capital controls reduce the supply of capital, raise the cost of financing, and increase financial constraints – especially for smaller firms and firms without access to international capital markets. Second, capital controls reduce market discipline in financial markets and the government, leading to a more inefficient allocation of capital and resources. Third, capital controls distort decision-making by firms and individuals as they attempt to minimize the costs of the controls, or even evade them outright. Fourth, the effects of capital controls vary across different types of firms and countries, reflecting different pre-existing economic distortions. Finally, capital controls can be difficult and costly to enforce, even in countries with sound institutions and low levels of corruption. Therefore, this series of microeconomic studies suggests that capital controls have widespread and pervasive costs, but has not yet provided significant evidence of the benefits of capital controls.

Conclusions

The debate on the effects and desirability of capital controls is likely to continue and to motivate new academic research. Most economists agree that countries should gradually lift their capital controls as they grow and develop, and that developed countries should have few (if any) capital controls in place. Most economists also believe that the free movement of capital can have widespread benefits, but that in countries with weak financial systems, poorly developed institutions, and vulnerable macroeconomies the free movement of capital can also generate distortions and increase a country’s vulnerability. As a
result, emerging markets and developing countries that currently have capital controls should work to address the shortcomings in their economies as they liberalize their capital accounts. There continues to be widespread disagreement, however, on the exact sequencing of these reforms and the optimal pace of capital account liberalization for emerging markets and developing economies.

How capital gains and losses are distinct from income raises subtle and unresolved issues. Whereas national accountants measure income as the sum of the value of production and net current transfers, thus excluding stock revaluations that change the level of wealth, Hicks's definition implies that expected stock revaluations count as income. Such revaluations due to inflation benefit net debtors but mean losses for households. Irreversible environmental damage and depletion of non-renewable resources are often treated as capital loss, but great uncertainty affects the estimation of consequences, rendering the emergence of an objective methodology for economic decisions is particularly difficult.

Keywords
capital gains and losses; capital gains taxation; comprehensive definition of income; depreciation; exhaustible resources; expected and unexpected capital gains or losses; Fisher, I.; Haig–Simons definition of income; Hicks, J. R.; income, definition of; inflation; intergenerational equity; national accounting; residential real estate; uncertainty

Article
National accounting has made the definition of capital gains and losses rather precise in practice, but fundamentally their distinction from income raises quite subtle issues, about which great economists have long been wavering. Whenever it becomes important, inflation gives to some of these issues a fresh relevance. Much remains to be learned, moreover, on how capital gains affect economic behaviour and how the allocation of resources ought to deal with the capital losses resulting from current activity.

Definition
Although the reference books such as United Nations (1969) are not explicit enough about this basic
capital gains and losses: The New Palgrave Dictionary of Economics

notion, national accounting systematically applies the following

\[ \Delta W = Y + CT + CG - C \]  
(1)

where \( \Delta W \) is the variation of wealth between the beginning and end of the period under consideration, \( Y \) is income, \( CT \) the net capital transfer received (gifts, bequests, capital taxes and subsidies), \( CG \) the net capital gain and \( C \) consumption. The identity applies to any agent or group of agents. This identity may be taken as the \textit{de facto} definition of net capital gains (that is, gains \textit{minus} losses), to the extent that well-defined rules are used for the flows \( Y, C \) and \( CT \), which appear in the current accounts, and to the extent that wealth is assumed to be unambiguously determined.

Looking carefully at the existing rules, one, however, realizes that the distinction between income and net capital gain is conventional to a large extent. It is precisely on the choice of this convention that some important questions about the definition of incomes lie.

Chapter 7 of Fisher (1906) shows that defining the concept of income was not an easy task for economists. Fisher's own preferred definition, ‘the services of capital’, may not seem quite clear, but it can be identified with consumption. This would make the whole of investment belong to capital gains, a solution that was seriously discussed by Samuelson (1961) but has hardly any advocate today. At the other extreme, the ‘comprehensive definition of income’, also called the Haig–Simons definition, was proposed by economists studying income taxes (Haig, 1921; Simons, 1938); income would be equal to the sum of consumption and wealth increase, thus leaving neither capital gains, nor capital transfers in eq. (1). One now most commonly refers to the definition introduced by Hicks (1939, p. 172), ‘A man's income is the maximum value which he can consume during a week, and still expect to be as well off at the end of the week as he was at the beginning’.

National accountants, however, measure income as the sum of the value of production and net current transfers. Production is essentially computed from physical outputs and inputs, valued at current prices and aggregated. This means that stock revaluations that explain part of the change of wealth are not incomes but capital gains or losses. Hicks’s definition, on the contrary, implies that expected stock revaluations belong to income. In eq. (1) only windfalls would be true capital gains. But whether the change of value of an asset should be classified as expected or not is most often not clear. (How long in advance should it have been expected? Should an outside observer be able to make sure that the asset holder had expected the change?) The distinction between expected and unexpected capital gains or losses, however, remains essential in economic analysis.

**Inflation**

The most sizeable asset revaluations result from changes of the price level. When inflation is important, a good proportion of these revaluations are, moreover, expected by all agents. Their occurrence then plays a role in the determination of the equilibrium of all exchanges and economic operations, inducing
in particular high interest rates. On the other hand, the change of nominal wealth becomes of little interest in comparison with the change of real wealth; ‘real capital gains’ should then be distinguished from nominal ones. Hence, inflation perturbs the significance of normal accounting rules; new measurements are required for correct assessments of income flows (Jump, 1980).

This applies first to business accounting, in which reference to historical costs underestimates physical assets and depreciation of fixed capital, while it overestimates net returns from financial assets. This explains the search for new or alternative accounting rules that would be better suited in cases of fast inflation and would more correctly draw the line between income and capital gains or losses. This search went as far as the stage of implementation in the United Kingdom (see Walton, 1978).

At the level of the whole economy, when the rules of national accounting are applied, real capital gains and losses resulting from variations of the general level of prices are important. Typically they benefit enterprises and government, which are net debtors, whereas they mean large losses for households. When all these capital gains and losses are imputed to incomes, on the ground that they must have been expected, the current accounts of firms and government appear substantially more favourable, whereas sizeable redistribution is also found as between groups of households (see Bach and Stephenson, 1974; Babeau, 1978; Wolff, 1979).

The question has been considered whether national account practices should not be revised so as to better record true incomes in times of inflation (see Hibbert, 1982). A prerequisite is the regular production of national balance sheets. When this is done, important capital gains and losses, due for instance to booms in real estate or share prices, also appear beyond those due to changes of the general price level.

**Capital gains in economic behaviour**

Most econometric studies tend to neglect capital gains as flows, although wealth and indebtedness are often taken into account. The role of capital gains on the consumption behaviour of households has, however, been studied. Up to now the results have been rather inconclusive (Bhatia, 1972; Peek, 1983; Pesaran and Evans, 1984).

In all likelihood the difficulty comes from the fact that some capital gains are purely transitory, whereas most of them have some degree of permanence, but this degree varies widely from one to the other. A pure windfall is comparable to an exceptional gift; accidental losses or war damages occur once for all, whereas capital losses due to an inflation that is expected to last may appear to be as permanent as interest incomes, even sometimes as wage incomes. But to classify capital gains according to their supposed permanence is far from being an obvious operation.

Gains on the value of corporate shares have a permanent component following from the firms' policy of retaining part of their profits. This is why increases of retained earnings have been considered as likely to increase household consumption, but not as much as an increase of permanent income would, since the size of undistributed profits varies a good deal with business conditions (Feldstein and Fane, 1973; Malinvaud, 1986).

The problem becomes still more complex when capital gains are correlated with cost changes for items of household wealth. An extreme case occurs when prices of residential real estate increase: owners of houses make a capital gain, but simultaneously the cost of housing increases by the corresponding
amount; whether houses are let or used by their owners, a stimulating effect on real consumption is
doubtful.

**Capital gains and losses**

The existence of capital gains and losses raises a number of issues for the theory of allocation of
resources, for instance what should be the taxation of capital gains (David, 1968; Green and Sheshinski,
1978), or how best to organize insurance against capital losses. But particular attention nowadays
concerns the damages that economic activity causes to the environment and to reserves of exhaustible
resources (Fisher, 1981).

Not all environmental effects mean capital losses; many of them are just externalities in the normal
course of economic activity. But irreversible damages to the forests, the soil or even the climate must
also be recognized and are usually not recorded as consumption or as inputs to production. Depletion of
non-renewable reserves is similarly often treated as capital loss.

The detrimental effects of many of these losses will appear mainly in a rather distant future. Whether or
not losses should be accepted – what for instance should be the optimal speed of depletion of natural
resources – raises difficult questions of intergenerational equity, on which economists have
uncomfortably to enter the field of social philosophy.

The problem cannot be discarded here on the ground that proper discounting makes the distant future
negligible. Indeed, in the purest case, the shadow discounted price of an exhaustible resource is as high
in the future as it is now, for as long as the resource will remain used (Hotelling, 1931). The remote
future must then be taken into account for present decisions.

It is moreover notorious that enormous uncertainties affect the purely physical estimation of the
consequences involved. Neither the effects of carbon dioxide emission on the climate, nor the existing
reserves of fossil fuels, nor the future emergence of appropriate technologies for the wider use of
renewable energy can be securely assessed. Under such circumstances, the emergence of an objective
methodology for economic decisions is particularly difficult.

Abstract

Capital gains taxation is the taxation of gains or losses from owning assets, usually as part of an income tax. Typically, tax systems measure capital gains or losses upon realization so that capital gains are taxed only when assets are sold. These realization-based tax rules create a number of behavioural incentives. Investors have an incentive to maximize the value of tax deferral by delaying the sale of assets. Capital gains taxes can also affect incentives for investing in risky assets. The realization-based tax rules also complicate the estimation of the revenue consequences of changing the tax rate on capital gains.

Keywords

capital gains and losses; capital gains taxation; inflation; tax base; tax incentives for saving; tax planning; taxation of corporate profits

Article

Capital gains taxation involves the taxation of changes in asset values, usually in the context of an income tax rather than as a separate tax. Under a pure income tax, these gains or losses would be measured on a periodic basis (for example, annually) and would be adjusted for inflation. However, actual tax systems tend to deviate in several important ways from this hypothetical treatment. The most important of these deviations is that capital gains are typically measured upon the realization of the gain or loss rather than under accrual accounting. The taxation of capital gains creates a wide variety of incentive issues, especially given the deviations between their tax treatment under a pure income tax and their treatment under actual tax rules.

Administrative issues

While the concept of a capital gain or loss from the ownership of an asset is straightforward, administering a tax on capital gains is a complicated part in the income tax codes of most countries. The primary difficulty arises from the challenge of measuring the size of a capital gain or loss over a specified period of time. This difficulty has led to most capital gains being taxed upon realization rather than as they accrue. The exceptions to this general rule tend to be for relatively sophisticated investors (for example, brokers) on assets that are relatively liquid and easily valued (for example, publicly traded equities). Realization-based taxation means that taxpayers keep records of the purchase price of assets, known as the basis in the asset, and calculate the gain or loss as the difference between the sales price and this basis when the asset is sold. The basis in an asset can be adjusted over time, with the most common type of adjustment being for the depreciation allowances accorded to depreciable assets. An important issue in measuring capital gains is whether the gain is adjusted for changes in purchasing power created by inflation. Countries vary in their treatment of capital gains created by inflation. Most countries include the portion of the gain that is due to inflation in the tax base, but a few countries allow the asset's tax basis to be adjusted for inflation so that the tax base includes only the real portion of the capital gain. A pure income tax would allow for an adjustment for inflation, but such an adjustment would be part of a system that adjusted all forms of capital taxation for inflation.

In many countries, capital gains face lower marginal tax rates than other sources of income. Two rationales motivate these lower tax rates. First, policymakers may want to encourage investment in activities that generate capital gains. Second, the preferential tax rates provide an ad hoc method of adjusting tax burdens for inflation in tax systems that do not index the measurement of capital gains for inflation. These preferential rates, which can include the exemption of capital gains from income taxation, often depend on meeting a minimum holding period (for example, preferential rates apply to ‘long-term’ capital gains that are earned on assets held for longer than one year) and may apply only to specific types of assets (for example, gains on corporate stock qualify for preferential tax rates but gains on collectibles do not).

Another cumbersome feature of capital gains taxation is the specific rules dealing with how gains and losses offset each other. Typically, these loss-offset provisions limit a taxpayer's ability to use capital losses to offset other sources of income. The motivation for these limitations is that realization-based taxation provides taxpayers with the option of deferring the tax on gains but accelerating the deductions for losses through a strategy of holding on to appreciated assets but selling assets with losses.

In terms of administration, Auerbach (1991) and Auerbach and Bradford (2004) propose tax systems that allow for realization-based tax rules that would mimic the incentive and revenue effects of accrual taxation of capital gains. Such tax reforms would eliminate many of the complicated incentive effects created by current administrative rules for capital gains taxation.

Incentive effects

Taxing capital gains creates a variety of incentive, or disincentive, effects. Since taxing capital gains is typically part of a broader regime to tax capital income, the tax on capital gains can affect incentives to save. As a tax on capital income, the capital gains tax reduces the return to saving, which can have a theoretically ambiguous effect on the level of savings in the economy. Of course, since many countries provide preferential tax treatment for capital gains compared with other forms of capital income, tax policy towards capital gains often increases the return to saving by reducing the effective tax rate on
savings compared with a regime without preferential tax rates for capital gains. Capital gains taxation can also affect incentives for taking risk. A tax on capital gains from risky investments reduces the expected return to these investments, which one might expect would discourage investment in risky assets. However, the tax on capital gains also reduces the variance in the payoffs to investing in risky assets and this reduction in variance may encourage investors to increase their investments in risky assets. The net effect of the reduction in both the expected return and the variance in returns may actually imply that the theoretical effect of a higher tax rate on capital gains is an increase in the amount of risk taking (see Domar and Musgrave, 1944). This result, however, rests on the symmetric tax treatment of gains and losses. When loss offset rules are imperfect, such that gains face a higher marginal tax rate than losses, then the theoretical predictions are much more complicated and it becomes more likely that the capital gains tax reduces the amount of risk taking in the economy because gains face a higher tax rate than losses. The relative tax treatment of capital gains and other forms of capital income can also affect investors' portfolio choices (see Poterba, 2002; Poterba and Samwick, 2002). If capital gains face lower effective tax rates, due to either preferential tax rates or the ability to defer taxes by deferring realization of income, investors may prefer to invest in assets that are likely to generate capital gains rather than assets that generate interest or dividend income. In addition to affecting portfolio decisions, the relative tax treatment of different forms of capital income may also affect relative asset prices and expected returns (see Klein, 1999). The realization-based feature of capital gains taxation creates several tax planning incentives (see Stiglitz, 1983). By not selling an appreciated asset, an investor can postpone paying the tax liability on the associated capital gain. This deferral of taxation reduces the discounted value of the tax (assuming that the statutory tax rate will remain constant in the future). This incentive to delay the realization of capital gains is known as the 'lock-in' effect since the tax liability that would be triggered by selling an asset reduces the incentive for investors to sell appreciated assets and locks them into holding assets. In the United States, the incentive to defer the realization of capital gains is compounded by tax rules that allow heirs to step-up the basis of appreciated assets that they inherit, which eliminates the income tax on capital gains on bequeathed assets. In addition to incentives to delay the realization of capital gains, realization-based taxation also creates an incentive to accelerate the realization of capital losses since these losses can reduce taxation on other types of income (though this offset is possibly limited by loss offset rules) or capital gains on other assets (see Constantinides, 1983; Poterba, 1987; Auerbach, Burman and Siegel, 2000). This pattern of selective realization leads to the tax planning advice that taxpayers should sell their losers and hold their winners. In essence, realization-based taxation provides taxpayers with an option of whether to pay taxes, and it is typically more advantageous to exercise this option for assets that have lost value. While most of the incentives discussed above deal with decisions made by investors, the tax treatment of capital gains can also affect the supply of different assets. For example, corporations may alter their payout policies in response to the relative tax treatment of dividends and capital gains. To the extent that capital gains face a lower effective tax rate than dividends at the investor level, corporations have an incentive to retain earnings so that investors can recognize income as capital gains rather than distribute earnings as dividends. Retaining earnings due to this tax rate differential does not necessarily imply that it leads to an increase in corporate investment. Instead of increasing investment, corporations that eschew dividends can repurchase shares as an alternative mechanism to distribute cash to shareholders.
capital gains taxation: The New Palgrave Dictionary of Economics

(see Green and Hollifield, 2003). These share repurchases allow investors to time their tax liabilities since the decision to sell shares back to the firm is discretionary and, for the shareholders who sell, the income associated with the transaction faces capital gains tax rates rather than dividend tax rates.

Revenue consequences

One of the more contentious issues surrounding capital gains taxation is the effects of capital gains taxes on government revenues. From the government's perspective, the incentive effects discussed above create opportunities for lost revenue. While the overall revenue effect of capital gains taxation depends on the whole myriad of incentives discussed above, much of the empirical literature on this issue has focused on the capital gains realization decisions of individuals. An important empirical issue has been separating how capital gains realizations respond to short-run fluctuations in the tax rate (or anticipated changes in tax rates) from how long-term realizations behaviour responds to the tax rate (or the 'permanent' response to tax changes). Auerbach (1988) examines the time series evidence in the United States and documents a large timing response of capital gains to anticipate tax rate changes but finds limited evidence of a permanent response of capital gains realizations to tax rates. Burman and Randolph (1994) examine a panel of US household taxpayers; their results also point towards a much larger transitory response than permanent response to changes in capital gains tax rates. Taken together, these studies cast doubt on the claim that reductions in capital gains tax rates can be self-financing.

capital measurement

W. Erwin Diewert and Paul Schreyer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Capital measures provide an indicator of wealth and of capital services, the contribution of assets to production. The wealth stock is the market value of assets, whereas capital services are measured in proportion to the quantity of past investment, adjusted for the relative efficiency of different vintages and capital goods in production. Although the two measures of capital are different, they are derived from a single theoretical framework whose centrepiece is a fundamental equilibrium relationship between stocks and flows of capital. Index number theory is used to guide the empirical implementation of stock and flow measures.

Keywords

aggregation; asset inflation; asset pricing; asset values; Böhm-Bawerk, E.; capital measurement; capital services; capital utilization; depreciation; fixed base (chain) indexes; geometric (declining balance) depreciation model; index numbers; interest, market rates; linear efficiency decline model; one-hoss shay efficiency model; price and quantity indexes; producer equilibrium; production function; rates of return; rental price; stocks and flows; straight line depreciation model; user cost; value ratios; Walras, L.

Article

Capital measures are constructed for two main purposes: (1) to measure wealth (the market value of assets) and (2) to analyse the role of capital in production. Because capital is durable, the value of using it in any given year is not the same as the value of owning it. There are thus different measures of capital depending on the purpose of accounting. However, these different measures should be consistently derived from a single framework.

The scope of the discussion below is restricted to fixed assets and land; we do not deal with financial or intangible assets, inventories or environmental assets.

Fundamental relations between stocks and flows of capital

In equilibrium, the stock value of an asset is equal to the discounted stream of future rental payments for capital services that the asset is expected to yield, an insight that goes at least back to Walras (1874) and Böhm-Bawerk (1888).

Let the price of an n-period old asset purchased at the beginning of period \( t \) be \( p^t_n \). When prices change over time, it is necessary to distinguish between the observable rental prices for the asset at different ages in period \( t \) and future expected rental prices. Let \( f^t_n \) be the rental price of an n-period old asset at the beginning of period \( t \). Then the fundamental equation relating the stock value of an asset, \( p^t_n \), to the sequence of rental prices by age, \( \{ f^t_n : n = 0, 1, 2, \ldots \} \) is:
\[
p_n^t = \left[ (1 + i^t) / (1 + r^t) \right] f_{n+1}^t + \left[ (1 + i^t) / (1 + r^t) \right]^2 f_{n+2}^t + \left[ (1 + i^t) / (1 + r^t) \right]^3 f_{n+3}^t + \ldots n = 0, 1, 2, \ldots
\]

where the \( i^t \) are expected rates of change of rental prices that are formed at the beginning of period \( t \). For simplicity, it has been assumed that \( i^t \) does not depend on the asset’s age. The term \( 1 + r^t \) is the discount factor that makes a dollar received at the beginning of period \( t \) equivalent to a dollar received at the beginning of period \( t + 1 \). Thus, the \( r_n^t \) are one-period nominal interest rates where the assumption has been made that the term structure of interest rates is constant. However, as the period \( t \) changes, \( r^t \) and \( i^t \) can change. The sequence of stock prices \( \{p_n^t\} \) is not affected by general inflation provided that it affects the expected asset inflation rates \( i^*_n \) and the nominal interest rates \( r_n^t \) in a proportional manner.

The rental prices \( \{f_n^t\} \) are potentially observable. In producer equilibrium, the ratio of any pair of rental prices equals the relative marginal productivity of the corresponding capital goods; see Hulten (1990).

By successive insertion for different \( P_n^t \), (1) can be transformed into:

\[
P_n^t = f_n^t + \left[ (1 + i^t) / (1 + r^t) \right] p_{n+1}^t
\]

or

\[
f_n^t = (1 + r^t)^{-1}[p_n^t(1 + r^t) - (1 + i^t)P_{n+1}^t] = [p_n^t - (1 + i^t)P_{n+1}^t / (1 + r^t)]; \quad n = 0, 1, 2, \ldots
\]

Christensen and Jorgenson (1969) derived a version of (3) for the geometric depreciation model and end-of-period rental payments. Other variants are due to Christensen and Jorgenson (1973), Diewert (1980; 2005), Jorgenson (1989), Hulten (1990) and Diewert and Lawrence (2000).

(3) represents the rental price or user cost of an \( n \)-year old asset: the cost of using it during a period is given by the difference between the purchase price at the beginning of the period \( P_n^t \) and the value of the depreciated asset \((1 + i^t)P_{n+1}^t = P_{n+1}^{t+1}\) at the end of period \( t \). Since this offset to the initial expense will be received only by the end of the period, it must be divided by the discount factor \((1 + r^t)\).

**Depreciation, asset prices and user costs**

Depreciation is typically defined as the decline in asset value as one goes from an asset of a particular age to the next oldest at the same point in time; see Hicks (1939), Hulten and Wykoff (1981a; 1981b), Hulten (1990), Jorgenson (1996) and Triplett (1996). Define the depreciation rates \( \delta_n^t \) for an asset that is \( n \) periods old at the start of period \( t \) as:

\[
\delta_n^t = 1 - \left[ P_{n+1}^t / P_n^t \right]; \quad n = 0, 1, 2, \ldots
\]
Thus, given \( \{ p_n^t \} \), the period \( t \) sequence of \( \{ \delta_n^t \} \) is determined. Conversely, given \( \{ \delta_n^t \} \) and the price of a new asset in period \( t \), \( \{ p_n^t \} \) is determined.

\[
p_n^t = (1 - \delta_0^t)(1 - \delta_1^t)(1 - \delta_{n-1}^t)p_0^t; \quad n = 0, 1, 2, ...
\]

With expressions (5) and (3), the sequence of user costs \( \{ f_n^t \} \) can be expressed in terms of the price of a new asset at the beginning of period \( t \), \( p_0^t \), and \( \{ \delta_n^t \} \):

\[
f_n^t = (1 + r^t)^{-1}(1 - \delta_0^t)(1 - \delta_1^t)(1 - \delta_{n-1}^t)[(1 + r^t) - (1 + i^t)(1 - \delta_n^t)]p_0^t = (1 + r^t)^{-1}[r^t + \delta_n^t(1 + i^t) - i^t]p_n^t; \quad n = 0, 1, 2, ...
\]

Thus, given any one of these sequences, all of the other sequences are completely determined. This means that assumptions about depreciation rates, the pattern of user costs by age or the pattern of asset prices by age cannot be made independently of each other. This point was first explicitly made by Jorgenson and Griliches (1967; 1972).

**Aggregation**

Asset prices are relevant for the construction of *wealth measures* of capital, and the user costs are relevant for the construction of *capital services measures*. Let there be \( N \) different types of assets and let the quantity of period \( t \) investment in asset \( i \) be \( l_i^t \) with a sequence of asset prices \( \{ p_n^i, i \} \). Then the value of the period \( t \) wealth stock is:

\[
W_i^t = p_{0,i}^t l_i^{t-1} + p_{1,i}^t l_i^{t-2} + p_{2,i}^t l_i^{t-3} + \ldots + i = 1, 2, ..., N.
\]

To turn to capital services (we set aside issues of capital utilization), the flow of services that an asset of a particular age delivers is proportional to the corresponding quantity of past investment. The value of capital services for all ages of a given asset class \( i \) during period \( t \) using the sequence of user costs \( \{ f_n^i, i \} \) is:

\[
S_i^t = f_{0,i}^t l_i^{t-1} + f_{1,i}^t l_i^{t-2} + f_{2,i}^t l_i^{t-3} + \ldots + i = 1, 2, ..., N.
\]
The value aggregates $W^t_i$ and $S^t_i$ can be decomposed into separate price and quantity components by standard index number methods, if each new unit of capital lasts only a finite number of periods, $L$. Define the period $t$ price, user cost and quantity vectors, $p^t_i$, $f^t_i$ and $k^t_i$ respectively, as follows:

$$p^t_i = [p^t_{i^0}, p^t_{i^1}, ..., p^t_{i^{L-1}}]; f^t_i = [f^t_{i^0}, f^t_{i^1}, ..., f^t_{i^{L-1}}]; k^t_i = [k^t_{i^0-1}, k^t_{i^1-2}, ..., k^t_{i^{L-1}-1}]; i = 1, 2, ..., N. \hspace{1cm} (9)$$

Fixed base or chain indexes may be used to decompose value ratios into price-change and quantity-change components. The values of $W^t_i$ and $S^t_i$ relative to their values in the preceding period, $W^{t-1}_i, S^{t-1}_i$ have the following index number decomposition:

$$W^t_i / W^{t-1}_i = p^W_i (f^{t-1}_i, f^t_i, k^{t-1}_i, k^t_i) Q^W_i (f^{t-1}_i, f^t_i, k^{t-1}_i, k^t_i); i = 1, 2, ..., N; \hspace{1cm} (10)$$

$$S^t_i / S^{t-1}_i = p^S_i (f^{t-1}_i, f^t_i, k^{t-1}_i, k^t_i) Q^S_i (f^{t-1}_i, f^t_i, k^{t-1}_i, k^t_i); i = 1, 2, ..., N; \hspace{1cm} (11)$$

where $p^W_i$, $p^S_i$ and $Q^W_i$, $Q^S_i$ are bilateral price and quantity indexes respectively. In particular, $Q^S_i$ measures the service flow of type $i$ assets into production. It is thus an appropriate measure of capital input.

A functional form has to be chosen. For empirical work, Diewert (1976; 1992) has shown that the Fisher (1922) ideal price and quantity indexes appear to be ‘best’ from the axiomatic viewpoint, and can also be given strong economic justifications.

The above index number approach to aggregating over vintages of capital was first suggested by Diewert and Lawrence (2000) and it is more general than the usual aggregation procedures for homogenous assets, which essentially assume that the different ages of the same capital good are perfectly substitutable so that linear aggregation techniques can be used. However, most researchers use an index number approach to form price and quantity aggregates across different types of assets. The overall values of the period $t$ wealth stock and capital services are respectively:

$$W^t = p^W_1 Q^W_1 W^t_1 + p^W_2 Q^W_2 W^t_2 + p^W_3 Q^W_3 W^t_3 + ... \hspace{1cm} (12)$$
Akin to (10)–(11), the value aggregates $W_t$ and $S_t$ can be decomposed into separate price and quantity components. Define the period $t$ price and quantity vectors, $P^W_t, P^S_t$ and $K^W_t, K^S_t$ respectively, as follows:

$$s^t \equiv \sum_{n=1}^{N} \left( p^S_{1,n} q^S_{1,n} + p^S_{2,n} q^S_{2,n} + p^S_{3,n} q^S_{3,n} + \cdots \right)$$

(13)

$$p^W_t = \left( p^W_{1,t}, p^W_{2,t}, \ldots, p^W_{N,t} \right); p^S_t = \left( p^S_{1,t}, p^S_{2,t}, \ldots, p^S_{N,t} \right); K^W_t = \left( K^W_{1,t}, K^W_{2,t}, \ldots, K^W_{N,t} \right); K^S_t = \left( K^S_{1,t}, K^S_{2,t}, \ldots, K^S_{N,t} \right).$$

(14)

The values of $W_t$ and $S_t$ relative to their values in the preceding period, $W_{t-1}$ and $S_{t-1}$, have the following index number decomposition:

$$\frac{W_t}{W_{t-1}} = p^W(p^W_{t-1}, p^W_t, K^W_{t-1}, K^W_t) q^W(p^W_{t-1}, p^W_t, K^W_{t-1}, K^W_t);$$

(15)

$$\frac{S_t}{S_{t-1}} = p^S(p^S_{t-1}, p^S_t, K^S_{t-1}, K^S_t) q^S(p^S_{t-1}, p^S_t, K^S_{t-1}, K^S_t)$$

(16)

where $P^W, P^S$ and $Q^W, Q^S$ are bilateral price and quantity indexes respectively. In particular, $Q^S$ measures the overall service flow of capital into production.

Empirical determination of rates of return and asset price changes

Rates of return $r_t$ can be based either on a balancing procedure or on market interest rates. The balancing procedure postulates that the value of capital services is equal to the value of gross operating surplus as shown by the national accounts plus the capital income of the self-employed. A rate of return is then chosen so that this equality holds. If market interest rates are used, there is still a choice between ex ante and ex post rates. Most empirical work on capital services has relied on an ex post balancing procedure based on Jorgenson and Griliches (1967; 1972) and Christensen and Jorgenson (1969). However, empirical problems arise when these methods yield highly volatile and sometimes negative user costs of capital. The debate has therefore continued – see Harper, Berndt and Wood (1989), Diewert (1980; 2005) and Schreyer (2006).

Possibilities for the choice of the asset inflation rates $i_t$ include using the ex post asset price changes (consistent with the ex post, balancing procedure for rates of return), forecasting ex ante rates on the basis of ex post rates and assuming that expected asset price changes are equal to general inflation. The latter implies that the term $r_t - i_t$ in the user cost expression (6) becomes a real rate of return that is simple to measure and typically not too volatile. At the same time, the procedure may induce a bias in user costs and capital measures if the prices of different assets move with different trends and/or if asset prices move very differently from general inflation.
Empirical determination of rates of depreciation

Possibilities for determining depreciation rates include a number of approaches. First, information on market prices of assets of different age at the same point in time can be used to derive measures of depreciation. Empirical studies include Hall (1971), Beidelman (1973), Hulten and Wykoff (1981a; 1981b) and Oliner (1996). The literature has been reviewed by Hulten and Wykoff (1996) and Jorgenson (1996). The second approach uses rental prices for assets where they exist, along with information on the rate of return and on asset prices to solve the user cost eq. (6) for the rate of depreciation; for a review see Jorgenson (1996). The third approach is based on production function estimation where output is regressed on non-durable inputs and past investment. The estimated coefficients of the investment variable can be used to identify a constant rate of depreciation. Empirical studies using this approach include Epstein and Denny (1980), Pakes and Griliches (1984), Nadiri and Prucha (1996) and Doms (1996). The fourth method relies on insurance and other expert appraisals.

The fifth method makes assumptions about the relative efficiency sequence \( \left\{ \frac{f_i^n}{f_0^i} \right\} \) and the service life of assets, and then derives, via (1) and (5), a consistent measure of the rate of depreciation. For example, the one-hoss Shay model of efficiency states that an asset yields a constant level of services throughout its useful life of \( L \) years: \( \frac{f_i^n}{f_0^i} = 1 \) for \( n = 0, 1, 2, \ldots, L - 1 \) and zero for \( n = L, L + 1, L + 2, \ldots \). Another example is a model of linear efficiency decline, where the sequence \( \left\{ \frac{f_i^n}{f_0^i} \right\} \) is given by \( \frac{f_i^n}{f_0^i} = \frac{[L - n]}{L} \) for \( n = 0, 1, 2, \ldots, L - 1 \) and zero for \( n = L, L + 1, L + 2, \ldots \).

The sixth method makes direct assumptions about the depreciation sequence \( \left\{ \frac{P_i^n}{P_0^n} \right\} \). The most frequent approaches are the straight line depreciation model and the geometric or declining balance model. Under the former, there is a constant amount of depreciation between every vintage: \( \frac{P_i^n}{P_0^n} = \frac{[L - n]}{L} \) for \( n = 0, 1, 2, \ldots, L \) and zero for \( n > L \). Under the latter, which dates back to Matheson (1910), there is a constant rate of depreciation \( \delta_i^n = \delta \) for \( n = 0, 1, 2, \ldots \). The geometric model greatly simplifies the algebra of capital measurement and has been supported empirically through studies on used asset markets; see Hulten and Wykoff (1981a; 1981b). When there is only information on the average asset life \( L \), the double declining balance method determines the rate of depreciation as \( \delta = 2 / (L + 1) \).

capital theory (paradoxes)

Luigi L. Pasinetti and Roberto Scazzieri
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Capital theory has led economists to discover relationships that look ‘paradoxical’ or counter-intuitive, as they run counter widely accepted ‘parables’. The transformation of microeconomic diminishing returns relations into a macro-social law induced the mistaken belief of an inverse, monotonic relation between the interest rate (and profit rate, taken as the ‘price of capital’) and the quantity of capital per head. Subsequent work alerted economists to the difficulty of finding aggregate measures of heterogeneous capital goods, and to the possibility that a falling rate of interest (and of profit) may be associated with a decrease (not an increase) of the quantity of capital per head.

The idea that capital theory might lead economists to discover forms of ‘paradoxical’ behaviour emerged in the economic literature of the 1960s largely as an outcome of developments in the field of production theory (linear production models leading to enquiries into discrete and discontinuous relations). What happened in capital theory is in fact a special instance of a more general phenomenon. Economists sometimes tend to examine a large domain of economic phenomena by adapting theoretical concepts that had originally been devised for a much narrower range of special issues. The discoveries of ‘paradoxical’ relations derive from the fact that their process of generalization often turns out to be ill-conceived and misleading, if not entirely unwarranted.

For a long time, in capital theory it had been taken for granted that there is a unique, unambiguous profitability ranking of production techniques in terms of capital intensity, along the scale of variation of the rate of interest. The discovery that this is not necessarily true has induced many economists to speak of ‘paradoxes’ in the theory of capital. But the roots of apparently paradoxical behaviour are to be found, not in the economic phenomena themselves, but in the economists' tendency to rely on too simple 'parables' of economic behaviour.

Traditional beliefs about capital are deeply rooted in the history of economic analysis, and may be traced back to pre-classical literature. As will be shown in the next section, a long post-classical tradition was then developed on that basis. The length of ancestry might explain the survival of conventional beliefs.

The emergence of the conventional view

The notion of ‘capital’ was associated for a long time with investible wealth and its income generating power, and was largely independent of detailed consideration of the function of invested wealth in the production process. The earliest development of capital theory took place within the accounting framework of a pre-industrial economy (William Petty, John Locke, Richard Cantillon). Within this perspective, capital was often associated with purely financial transactions (lending and borrowing) and the relationship between capital and rate of interest came quite naturally to be conceived as the relationship between loanable funds and their price (see Cannan, 1929, pp. 122–53). The origin of the belief in an inverse monotonic relation between the demand for capital and the rate of interest may be traced back to this phase of the literature. The distinction between capital as a fund of purchasing power and capital as a 'sum of values' embodied in physical assets remained in the background (see Hicks, 1977, p. 152), but was bound, in time, to generate tension ‘between the physical and financial conceptions of capital’ (Cohen and Harcourt, 2005, p. xli).

The association of capital with the process of production did not come to the fore until quite late, in spite
of certain isolated anticipations. (John Hicks, 1973, p. 12, even quotes Boccaccio's *Decameron* on the issue.) The description of capital as a stock of means of production became common with the Physiocrats and the classical economists. In this period, Cesare Beccaria (1804, ms 1771–72) presented what Jean-Baptiste Say considered to be the first analysis of ‘the true functions of productive capitals’ (Say, 1817, p. xliii). Soon after him, Adam Smith (1776) built upon the distinction between ‘productive’ capital and ‘unproductive’ consumption his theory of structural dynamics and economic growth. Finally, David Ricardo gave a definite shape to classical capital theory by examining the relationship between capital accumulation and diminishing returns and by considering in which way different proportions of capital in different industries might influence the relative exchange values of the corresponding commodities (Ricardo, 1817, ch. 1, sections 4 and 5).

Classical capital theory is characterized by lack of interest in the purely financial dimension of investment. As a result, the relation between capital accumulation and the rate of interest recedes into the background and is substituted by the relation between real capital accumulation and the rate of profit. In this way, the foundations of capital theory shifted from the exchange to the production sphere, and the demand-and-supply mechanism was confined to the process by which the rate of interest is maintained equal to the rate of profit in the long run. However, a number of economists (starting with Johann Heinrich von Thünen, Mountifort Longfield and Nassau William Senior) continued to be interested in the income-generating function of capital at the level of the individual investor, and tried to combine this approach with the emphasis on the productive function of capital that had emerged in the classical literature. The marginal productivity theory of capital and interest was developed as an answer to this conceptual problem. The essential features of that theory may be clearly seen in Thünen, who suggested a relationship between the rate of interest \((i)\) and the rate of profit \((r)\) quite different from the one found in Ricardo. The reason for this is that Ricardo had taken \(r\) to be fixed for the individual entrepreneur, so that equality between \(i\) and \(r\) was brought about by adjustment between the supply and demand for loans in the financial markets. Thünen suggested a different adjustment mechanism by taking \(r\) to be variable for the individual entrepreneur, so that the attainment of the long-run equality between the rate of profit and the rate of interest came to depend on the change in the physical productivity of capital as much as on adjustment in the financial markets (see Thünen, 1857).

This view is founded upon a thorough transformation of the Ricardian theory of diminishing returns and provided the logical starting point for the later marginalist theory of diminishing returns from aggregate capital. The analytical and historical process leading to this outcome is a rather complex one, and it is best understood by distinguishing two separate stages. In the first stage, the law of diminishing returns, which Ricardo considered to hold for the economy as a whole in the long run, was applied to the short-run behaviour of the individual entrepreneur. As result, the change in input proportions within any given productive unit is associated with the change in the physical productivity of capital. Here the variation of the capital stock is unlikely to influence the system of prices, so that the decrease (or increase) in the return from the last ‘increment of capital’ could be unambiguously associated with an increase (or decrease) in the physical capital stock. The second stage consisted in extending the above result to the variations in the aggregate quantity of capital available in the economic system as a whole.

The process which we have described made it possible to transform the classical conception of diminishing returns from a macro-social law into a microeconomic relation derived from the law of variable proportions. This new type of diminishing returns was then extended to the ‘macro-social’ sphere once again. As a result, it became possible to think that the rate of interest and the rate of profit...
capital theory (paradoxes) : The New Palgrave Dictionary of Economics

... are associated with the physical marginal productivity of aggregate capital: an increase in the relative quantity of capital with respect to the other inputs would be associated with lower marginal productivity of capital and thus with a lower equilibrium rate of interest and rate of profit. This inverse monotonic relation between the rate of interest (and the rate of profit) and the quantity of capital per head eventually became an established proposition of capital theory. The relevance of this relation can be seen from the attempts by William Stanley Jevons (1871), Eugen von Böhm-Bawerk (1889) and John Bates Clark (1899) to found on the theory of the marginal productivity of factors the explanation of the distribution of the social product among factors of production under competitive conditions.

Further light on the conceptual roots of the marginalist view of capital is shed by the contributions of Jevons and Böhm-Bawerk. In their theories, profit is considered as the remuneration due to the capitalist as a result of the higher productiveness of ‘indirect’ or ‘roundabout’ processes of production than of processes carried out by ‘direct’ labour only. The generalization of the marginal principles which they carried out is thus associated with the description of the production process as an essentially ‘financial’ phenomenon in which final output, like interest in financial transactions, could be considered as ‘some continuous function of the time elapsing between the expenditure of the labour and the enjoyment of the result’ (Jevons 1879, p. 266). The subsequent discovery of ‘anomalies’ in the field of capital accumulation was possible when economists started to question this extension of capital theory from the financial to the productive sphere, and when the technical structure of production was examined on its own grounds independently of the ‘financial’ aspect which might be considered to be characteristic of ‘the typical business man’s viewpoint’ (Hicks, 1973, p. 12).

Anticipations of debate

It has just been shown that microeconomic diminishing returns provided the foundations for a theory of the diminishing marginal productivity of social capital, which was extended from the microeconomic sphere by way of logical analogy. The pitfalls of this approach did not take long to emerge, as economic analysis came to grips with the full complexity of the production process. Knut Wicksell, discovered that, in the case of an economic system using heterogeneous capital goods, it might be impossible to describe diminishing returns from aggregate capital. The reason for this is that a variation in the capital stock might be associated with a change in the price system that would make it impossible to compare the quantities of capital before and after the change (see Wicksell, 1901–6, pp. 147 ff. and 180). Wicksell also recognized that this difficulty is characteristic of capital because ‘labour and land are measured each in terms of its own technical unit … capital, on the other hand, … is reckoned, in common parlance, as a sum of exchange value’ (1901–6, p. 149).

The special difficulty associated with heterogeneous capital goods is in fact an outcome of a particular procedure by which the fundamental theorems concerning capital and interest had been formulated with reference to the idealized setting of an isolated producer, and then extended by analogy to the case of the ‘social economy’. The drawbacks of this methodology were perspicaciously noted by Nicholas Kaldor in the late 1930s, when he complained that capital theory had been developed starting with ‘a … specialised set-up, with the picture of Robinson Crusoe engaged in net-making’ rather than with the
‘general case’ of ‘a society where all resources are produced and the services of all resources co-operate in producing further resources’ (Kaldor, 1937, p. 228.) Kaldor also noted that, had the analysis started with the ‘general case’, ‘a great deal of the controversies concerning the theory of capital might not have arisen’ (Kaldor, 1937, p. 228).

It is remarkable that so many ‘paradoxical’ results of modern capital theory were subsequently discovered precisely as an outcome of the procedure here described by Kaldor.

The stage of modern controversy was set by the consideration of two distinct problems: (a) the measurement of ‘aggregate capital’ in models with heterogeneous capital goods; and (b) the discovery that production techniques that had been excluded at lower levels of the rate of profit might ‘come back’ as the rate of profit is increased (this phenomenon is known as reswitching of technique).

Joan Robinson started the discussion by calling attention to the difficulties inherent in any physical measure of aggregate capital (Robinson, 1953–4). She also pointed out the ‘curiosum’ that the degree of mechanization associated with a higher wage rate and a lower rate of profit might be lower than the degree of mechanization associated with a lower wage rate and a higher rate of profit. (She attributed this ‘curiosum’ to Miss Ruth Cohen, but later on she attributed it to her reading of Sraffa's Introduction to Ricardo's Principles.)

Immediately afterwards, David Champernowne discovered that, in general, we must admit ‘the possibility of two stationary states each using the same items of equipment and labour force yet being shown as using different quantities of capital, merely on account of having different rates of interest and of food-wages’ (Champernowne, 1953–4, p. 119). Champernowne also admitted that the inverse monotonic relation between the rate of profit and the quantity of capital per head (as well as the inverse monotonic relation between the rate of profit and capital per unit of output) might not be generally true: ‘it is logically possible that over certain ranges of the rate of interest, a fall in interest rates and rise in food-wages will be accompanied by a fall in output per head and a fall in the quantity of capital per head’ (Champernowne, 1953–4, p. 118). Champernowne's explanation of what appeared to be perverse behaviour from the point of view of traditional theory was that changes in the interest rate can be associated with changes in the cost of capital equipment even if the physical capital stock is unchanged. As a result, perverse behaviour was attributed to pure ‘financial’ variations and a physical measure of capital was still thought to be possible. This Champernowne tried to obtain by introducing a chain index method for measuring capital (Champernowne, 1953–4, p. 125). A few years later, Joan Robinson again took up the same issue in her Accumulation of Capital (1956, pp. 109–10). The reason she gave for the ‘Ruth Cohen curiosum’ is quite different from the one proposed by Champernowne. She explicitly recognized that ‘financial’ factors such as a higher wage rate and a lower rate of interest would have ‘real’ consequences by influencing the actual choice of technique. (In the ‘perverse’ case a lower rate of interest would be associated with the choice of the less mechanized technique.)

When a few years later Michio Morishima attempted a multi-sectoral generalization of Joan Robinson's simple model he confirmed the possibility of a positive relationship between the rate of interest and the degree of mechanization of a technique (Morishima, 1964, p. 126). Finally John Hicks came up with the same problem when examining ‘the response of technique to price changes’ in the framework of a simple economy consisting of a consumption good ‘industry’ and a net investment good ‘industry’, and in which the same capital good is used in both industries (see Hicks, 1965, pp. 148–56).

But, in spite of all these anticipations, it must be admitted that the issue of technical reswitching was not
given an important place in economic theory before the publication of Piero Sraffa's *Production of Commodities by Means of Commodities* (1960). It is with Sraffa's work that the phenomenon took a prominent place. Sraffa was able to show that heterogeneity of capital goods and of 'capital structures' (different proportions between labour and intermediate inputs in the various processes of production) would normally give rise, with the variation of the rate of profit and of the unit wage, ‘to complicated patterns of price-movement with several ups and down’ (Sraffa, 1960, p. 37). This phenomenon would in turn bring about changes in the ‘quantity of capital’ that are not generally related to the rate of profit in a monotonic way. Reswitching of technique and reverse capital deepening are thus derived from a general property of production models with heterogeneous capital goods. (See reswitching of technique and reverse capital deepening.)

**Neoclassical parables and the capital controversy**

Following the publication of Sraffa's book, a lively debate on capital theory suddenly flared up in the 1960s, and the way it did is itself an interesting event.

It has already been pointed out that, when propositions derived from individual behaviour are applied to the more complex case of the ‘social economy’, the extension is admittedly possible on condition that the social economy has a number of special features making it identical, from the analytical point of view, to the case of the isolated individual. To test these features, the social economy is often described in terms of a ‘parable’ in which those particular conditions are satisfied. This ‘parable’, though unrealistic, is taken to be useful, from an heuristic or a persuasive point of view.

In this vein Paul Samuelson attempted to construct a ‘surrogate production function’ by analogy with microeconomic behaviour (Samuelson, 1962). His work can be considered as the first explicit attempt to get rid of the complexities of an economic system with heterogeneous capital goods by constructing a model in which that system is described in terms of an ‘aggregate parable’ with physically homogeneous capital. After introducing the assumption that ‘the same proportion of inputs is used in the consumption-goods and [capital-] goods industries’ (Samuelson, 1962, pp. 196–7), Samuelson was able to prove that ‘the Surrogate (Homogeneous) Capital … gives exactly the same result as does the shifting collection of diverse capital goods in our more realistic model’ (1962, p. 201). In particular, ‘the relations among w, r, and Q/L that prevail for [the] quasi-realistic complete system of heterogeneous capital goods’ could ‘be shown to have the same formal properties as does the parable system’ (1962, p. 203). This result was taken to be a justification for using the surrogate production function ‘as a useful summarizing device’ (1962, p. 203). In fact, Pierangelo Garegnani, who was present at a discussion of a draft of Samuelson's paper, did point out that Samuelson's result is crucially dependent on the assumption of equal proportions of inputs (see Garegnani, 1970). Samuelson acknowledged Garegnani's criticism in a footnote to his paper and admitted that it would be a ‘false conjecture’ to think that the ‘extreme assumption of equi-proportional inputs in the consumption and machine trades could be lightened and still leave one with many of the surrogate propositions’ (Samuelson, 1962, p. 202n). But Samuelson and various other economists continued to look for conditions that would ensure a monotonic relation between the rate of profit and the choice of technique even in presence of a nonlinear relation between w and r.

The outcome appeared a few years later. David Levhari, a Ph.D. student of Samuelson's, in his
dissertation and then in a paper for the Quarterly Journal of Economics, claimed he had proved that reswitching of the whole production matrix would be impossible if this matrix is of the ‘irreducible’ or ‘indecomposable’ type (Levhari, 1965). This property – Levhari claimed – would exclude reswitching and thus make it possible to extend the use of a ‘surrogate production function’ to the nonlinear case with production technologies for basic commodities.

However, Levhari's theorem was disproved by Luigi Pasinetti in a paper at the Rome First World Congress of the Econometric Society in 1965. Pasinetti's final draft of his paper was published in the November 1966 issue of the Quarterly Journal of Economics (Pasinetti, 1966) together with papers written in the meantime by David Levhari and Paul Samuelson (1966), Paul Samuelson (1966), Michio Morishima (1966), Michael Bruno, Edwin Burmeister and Eytan Sheshinski (1966) and Pierangelo Garegnani (1966). This set of papers was called by the journal editor ‘Paradoxes in Capital Theory: A Symposium’, thereby originating the term. Paul Samuelson concluded the discussion with a ‘Summing up’ in which he admitted that ‘the simple tale told by Jevons, Böhm-Bawerk, Wicksell, and other neoclassical writers’, according to which a falling rate of interest is unambiguously associated with the choice of more capital-intensive techniques, ‘cannot be universally valid’ (Samuelson, 1966, p. 568).

The various contributions to this discussion showed that reswitching might occur both with ‘decomposable’ and ‘indecomposable’ technology matrices. This result was proved in different ways by Pasinetti (1965; 1966), Morishima (1966), Bruno, Burmeister and Sheshinski (1966) and Garegnani (1966). Samuelson stated in his summing up that ‘reswitching is a logical possibility in any technology, indecomposable or decomposable’ (1966, p. 582). He then called attention to the associated phenomenon of reverse capital deepening and concluded that ‘there often turns out to be no unambiguous way of characterizing different processes as more “capital-intensive”, more “mechanized”, more “roundabout”’ (1966, p. 582).

Although the logical possibility of reswitching was admitted by all participants in the discussion, Bruno, Burmeister and Sheshinski raised doubts as to its empirical relevance: ‘there is an open empirical question as to whether or not reswitching is likely to be observed in an actual economy for reasonable changes in the interest rate’ (Bruno, Burmeister and Sheshinski, 1966, p. 545n). The same doubt was expressed in Samuelson's summing up (Samuelson, 1966, p. 582). Bruno, Burmeister and Sheshinski also mentioned a theorem, which they attributed to Martin Weitzman and Robert Solow, according to which reswitching of technique may be excluded, in a model with heterogeneous capital goods, provided at least one capital good is produced by ‘a smooth neoclassical production function’, if ‘labour and each good are inputs in one or more of the goods produced neoclassically’ (Bruno, Burmeister and Sheshinski, 1966, p. 546). This theorem is based on the idea that ‘setting the various marginal productivity conditions and supposing that at two different rates of interest the same set of input–output coefficients holds, the proof follows by contradiction’ (Bruno, Burmeister and Sheshinski, 1966, p. 546).

It is worth noting that Weitzman–Solow's theorem is simply a consequence of the idea that, in the case of a commodity produced by a neoclassical production function, each set of input–output coefficients ought to be associated in equilibrium with a one-to-one correspondence between marginal productivity ratios and input price ratios. No ratio between marginal productivities would be associated with more than one set of input prices, and this is taken to exclude the possibility that the same technique be chosen at alternative rates of interest, and thus at different price systems. The Weitzman–Solow theorem is at the origin of a line of arguments that has been followed up by a number of other authors, such as David
Starrett (1969) and Joseph Stiglitz (1973). These authors have pursued the idea that ‘enough’ substitutability, by ensuring the smoothness of the production function, is sufficient to exclude reswitching of technique. However, non-reswitching theorems of this type involve that, for each technique of production, the capital stock may be measured either in physical terms or at given prices. For in a model with heterogeneous capital goods, if we allow prices to vary when the rate of interest or the unit wage are changed, there is no reason why the same physical set of input–output coefficients might not be associated with different price systems: even in the case of a continuously differentiable production function, the marginal product of ‘social’ capital cannot be a purely real magnitude independent of prices. Once it is admitted that ‘in general marginal products are in terms of net value at constant prices, and hence may well depend upon what those prices happen to be’ (Bliss, 1975, p. 195), it is natural to allow for different marginal productivities of the same capital stock at different price systems. It would thus appear that reswitching of technique does not carry with it any logical contradiction even in the case of a smoothly differentiable production function.

But Pasinetti also pointed out that the concept of neoclassical substitutability is itself a very restrictive concept indeed, as it requires the possibility of infinitesimal variations of each input at a time. In fact, Pasinetti noted that it is possible to have a continuous variation of techniques (that is, continuous substitutability) along the w–r relation and yet wide discontinuities in the variation of many inputs between one technique and another, thus making reswitching a quite normal phenomenon (see Pasinetti, 1969). Moreover, and even more significantly, a non-monotonic relation between the rate of profit and capital per man may well be obtained even in the absence of reswitching (Pasinetti, 1966; Bruno, Burmeister and Sheshinski, 1966). This last possibility calls attention to the phenomenon that lies at the root of the various ‘paradoxes’ in the theory of capital: the fact that, unless special assumptions are made, a change in the rate of profit and in the unit wage at given technical coefficients is associated with a change of relative prices.

This debate continued for a few years in the late 1960s and early 1970s, with a series of journal articles (see for example Robinson and Naqvi, 1967) and books (see for example Harcourt, 1972). In particular, John Hicks presented a ‘Neo-Austrian’ model in *Capital and Time* (1973), concluding that reswitching of technique can be excluded only in the special case in which all the techniques have the same ‘duration parameters’, which means the same ‘construction period’ and ‘utilization period’ (1973, pp. 41–4). In the end, numerous details were added. Yet the basic essential results remained those that had come out of Sraffa’s book and of the symposium on ‘Paradoxes in Capital Theory’. It is instructive to see that, in a recent exchange of views that has appeared in the *Journal of Economic Perspectives* (2003, Spring and Winter issues), Franklin Fisher (2003), Geoff Harcourt in Cohen and Harcourt (2003) and Luigi Pasinetti (2003), when asked to succinctly summarize the issues at stake, have essentially restated their original positions.

### Aftermath and ways ahead

The discovery of paradoxes in capital theory has had a number of important repercussions, mostly beyond its original context. For it stimulated a large amount of analytical and empirical research on some of the issues that had been discussed in the controversy, without pressing the attention towards the fundamentals, as had been the case with the original debates. In many instances, the recent
developments have been motivated by the need to face the problem of measuring the stock of capital goods in economic systems subject to advances of technical knowledge and structural change, or some of the associated issues in the theory of economic dynamics. In this section we shall refer to some of these developments without pretending to give a complete picture, but with the purpose of identifying the main lines of inquiry.

A first area of research has been the analysis of the necessary conditions for the empirical measurement of aggregate capital. Franklin Fisher elaborated a research line he had himself started in an earlier contribution (Fisher, 1969) and called attention to the fact that the aggregation of outputs, as well as that of productive factors, ‘requires separability in each firm’s production function’ (Fisher, 1987, p. 55). He also noted that, under constant returns, the two highly restrictive assumptions of no specialization and generalized capital augmentation are necessary, whereas, in most cases of non-constant returns, aggregation would not be allowed even when assuming the same production function for all firms (Fisher, 1987, p. 55). Robert Gordon proposed to measure collections of heterogeneous capital goods, under condition of embodied technical change, by considering the associated ‘net revenue at a given set of prices \( w \) of variable inputs’ (Gordon, 1993, p. 106; see also Gordon, 1990). Edward Denison did find Gordon's proposal objectionable and proposed instead to ‘equate’ new capital goods with the old ones by ‘what their relative costs would be if both were produced at a common date’ (Denison, 1993, pp. 89–90). An interesting link between this literature and the capital controversy debate has been suggested by Charles Hulten, who has called attention to the advantages of a ‘recursive description of the production possibility set’, in which the assumption of capital as an original input is dropped, and ‘capital and labour are assumed to produce gross output and capital which is one period older’ (Hulten, 1992, p. S15). Hulten's formulation highlights the central role of knowledge advances embodied in new capital goods and suggests the relevance, for distinct purposes, of gross outputs and net outputs ‘as indicators of capacity and economic welfare’ (Hulten, 1992, p. S11). Alexandra Cas and Thomas Rymes have specifically addressed the issue of whether ‘knowledge of the constant-price aggregate stock of capital would, for the comparison of economies, permit one to “predict” certain variables’ (Cas and Rymes, 1991, p. 7; emphasis added). In particular, they investigated capital measurement issues brought about by embodied technical change, and proposed a set of ‘new measures’ aimed at taking the fact into account that ‘the net capital stocks of each industry and at the aggregate are themselves being produced with increased efficiency when the capital goods industries are experiencing advances in technical knowledge’ (Cas and Rymes, 1991, p. 67). The same authors relate their measures of changing capital stocks under conditions of structural change to ‘Pasinetti's concepts of vertically integrated sectors and productivity aggregated by end use’ (Cas and Rymes, 1991, pp. 90–1). This point of view highlights the common ground behind recent attempts to measure stocks of heterogeneous capital goods in terms of an aggregate concept of productive capacity, be it Pasinetti's ‘unit of vertically integrated productive capacity’ (Pasinetti, 1973; 1981), Cas and Rymes' ‘new measures of multifactor productivity’ (Cas and Rymes, 1991), or Hulten's ‘accounting for capacity’ (Hulten, 1992). In all these cases, the producibility of capital goods is emphasized, as is the close connection between advances of technical knowledge and the reshuffling of inter-industry relationships (particularly those affecting intermediate goods). Philippe Aghion and Peter Howitt have commented on recent discussions about capital measurement for an economy subject to advances of knowledge by recalling Joan Robinson's view that the real issue is not
so much about the measurement of capital as rather about the meaning one wishes to assign to any given collection of capital goods (Aghion and Howitt, 1998, p. 435).

Another line of investigation has concerned the attempt to assess the empirical (or computational) relevance of capital paradoxes, as distinct from their theoretical possibility. In this connection, Stefano Zambelli has used computer simulations in order to investigate the ‘realism’ of capital paradoxes in artificial economies (Zambelli, 2004). This author has found a significantly higher likelihood that the capital–labour ratio be positively related to the rate of profit, contrary to the conventional belief of a negative relationship between these two variables. This result is consistent with the empirical investigation carried out by Zonghie Han and Bertram Schefold (2006). These authors have compared pairs of techniques from the OECD input–output database, and have found that ‘observed cases of reswitching and reverse capital deepening are more than flukes’ (Han and Schefold, 2006, p. 22), even if we are far from observing what has been called an ‘avalanche of switchpoints’ (Schefold, 1997, pp. 278–80).

A third line of research has carried the discussion of capital paradoxes into the field of dynamic economic theory. The literature relevant in this connection is itself quite differentiated. For example, Frank Hahn (1966) called attention to his earlier discovery of zones of instability in economies with heterogeneous capital goods, and pointed out that reswitching should be considered as one amongst the multiple causes of instability in capital markets (Hahn, 1982). It is interesting that this line of argument, while maintaining that reswitching is a special case of a larger class of phenomena, at the same time and rather surprisingly also makes reswitching to be more general than was the case with earlier treatments of the same phenomenon. For capital paradoxes are no longer mainly associated with an economy with heterogeneous capital goods and a uniform rate of profit, but are ‘extended’ to the case of multi-sectoral economies with many different capital goods and a multiplicity of rates of interest (and rates of profit). Luigi Pasinetti followed a different approach, and examined the analytical features of a dynamic economy in which market interactions are not explicitly examined (Pasinetti, 1981). In this case, too, there are reasons to think that reswitching and reverse capital deepening would not represent exceptional cases, and would not be limited to the institutional framework of a perfectly competitive economy. Other authors have examined the relationship between capital paradoxes and dynamic stability, and have argued that reswitching of technique and reverse capital deepening are neither necessary nor sufficient conditions for the economic system to show lack of stability and irregular behaviour (Mandler, 2005). It has also been emphasized that ‘reswitching’ adds an important element of instability, the importance of which depends on the process of adaptation, but also on the utility function’ (Schefold, 2005, p. 467).

More generally, the discovery of capital paradoxes has stimulated a deeper understanding of the features of continuity and discontinuity in the dynamics of economic systems. This line of research has its point of departure in a phenomenon detected by Luigi Pasinetti shortly after the climax of the controversy (Pasinetti, 1969). In Pasinetti’s more recent words, ‘the vicinity, even the infinitesimal vicinity, of any two techniques on the scale of variation of the rate of profits does not entail at all vicinity of such techniques … discontinuities in input use.’ (Pasinetti, 2000, p. 409). John Barkley Rosser Jr. has picked up such suggestions and has investigated the discontinuities in order to identify the implications of capital paradoxes for the analysis of the optimal dynamic path followed by an economy characterized by ‘an infinite, differentiable technology’ (Rosser, 1983, p. 182). This author acknowledges that it may
sometimes be impossible to directly observe reswitching along optimal adjustment path (as maintained, for example in Burmeister and Hammond, 1977), but he notes that this would only happen ‘at the price of dynamic discontinuities’, that is, on the condition that the economic system be able to ‘jump over’ the zone associated with intermediate techniques. The above result has been interpreted as showing that ‘in a world of infinite and smooth technologies, reswitching is to be “observed” by observing discontinuities in optimal dynamic paths’ (Rosser, 1983, p. 183; see also Rosser, 2000, pp. 213–20). This point of view emphasizes the analytical importance of capital paradoxes as characteristic instances of the discontinuities that may be generated by the nonlinearity of certain structural relationships. In this way, the propositions discovered during the capital controversies of the mid-20th century are found to be consilient with much later developments in the economic analysis of nonlinear dynamic systems.

**Synthesis**

The source of most of the difficulties that have emerged in capital theory may be traced back to the fact that ‘capital’ may be conceived in two fundamentally different ways: (a) as a ‘free’ fund of resources, which can be switched from one use to another, without any significant difficulty: this is what may be called the ‘financial’ conception of capital; (b) as a set of productive factors that are embodied in the production process as it is carried out in a particular productive establishment: this is what may be called the ‘technical’ conception of capital.

The idea that there exists an inverse monotonic relation between the rate of interest and the demand for capital was born in the financial sphere. The parallel idea of an inverse monotonic relation between the rate of profit and the ‘quantity of capital’ employed in the production process is the outcome of a long intellectual process of extensions and generalizations reviewed earlier in this essay. But the recent debate on capital theory has conclusively proved that such extensions and generalizations are devoid of any foundation. It is logically impossible to make the ‘financial’ and the ‘technical’ conceptions of capital coincide, except under very restrictive conditions indeed. More precisely, there is no unambiguous way in which a decreasing rate of profit may be related to the choice of alternative techniques, in terms of monotonically increasing capital intensity, be this considered in terms of capital per unit of output or of capital per unit of labour.

These analytical results are hardly in dispute by now. But their ultimate significance and relevance for economic theory have been, and remain, controversial.

A group of economists have been so impressed by the new discoveries in capital theory, concerning the relations between rate of profit, capital per head, capital per output, and technical progress, as to become convinced that these discoveries are calling for a reconstruction of economic theory from its very foundations. It is stressed that the traditional beliefs are due to mistaken generalizations from the theory of short-run microeconomic behaviour, and it is argued that the economic theory (‘marginal economic theory’) that led to mistakes and inconsistencies should be abandoned. It is also pointed out that the obvious alternative is a resumption and development of the more comprehensive approach to value, distribution and growth of the classical economists (see Garegnani, 1970; 2005, and, in a different context, Pasinetti, 1981).

A second line of interpretation maintains that economic theorists should be prepared to give up the analytical tools of equilibrium analysis and concentrate much more on the actual historical dynamics of
economic systems. In this vein, reswitching of technique is acknowledged as a logical possibility but doubts are expressed on its importance in actual economic history (see Robinson, 1975, pp. 38–9; Hicks, 1979, p. 57).

A third line of interpretation is taken by more traditionally minded theoretical economists. It is argued that the discovery of ‘anomalies’ in the field of capital theory does point to an important deficiency in ‘marginal’ economic theory, which leads to the inevitable abandonment of the concept of ‘aggregate capital’. However, it is also argued that there is a way of overcoming this deficiency without giving up the basic premises of traditional theory, and in particular without rejecting the application of the demand-and-supply framework to the study of production. This way induces to concentrating the analysis either on the study of ‘short-run’ (‘temporary’) equilibria, in which the physical stocks of capital are given, or on the equilibrium of an intertemporal economy, in which goods are described by taking their dates of delivery into account. In either case, the logical possibility (or ‘existence’) of an equilibrium price vector is studied without explicitly considering the movement of ‘free’ capital from one use to another. In this approach, the importance of ‘capital paradoxes’ is explicitly recognized, but the associated difficulties are transferred either to the field of stability analysis or to the theory of the long-period supply of saving as financial capital (see, respectively, Hahn, 1982; Bliss, 2005).

A fourth line of interpretation has been pursued by many empirically oriented economists. It is acknowledged that the notion of ‘aggregate’ technical capital is untenable in terms of theory, but it is also argued that the utilization of aggregate production functions may be justified on pragmatic terms, due to supposedly satisfactory econometric fit (see, for example, Fisher, 1971; Fisher, Solow and Kearl, 1977). This view however, is by no means widely accepted. It has in fact been vigorously challenged by Paolo Sylos Labini (1995), who has reviewed the estimates that have emerged from using the Cobb–Douglas production function and has shown that such a ‘production function, when estimated econometrically, tends to yield, in general, poor results’ (Felipe and Fisher, 2003, p. 251; see also McCombie, 1998; and Felipe and Adams, 2005). In a recent evaluative essay on aggregation in production functions, Jesus Felipe and Franklin Fisher have sharply criticized the continued use of aggregate parables. In particular, they maintain that ‘the revival of growth theory during the last two decades no doubt has produced important discussions, and seemingly interesting empirical results’ but ‘authors do not realize that they are using a tool whose lack of legitimacy was demonstrated decades ago’ (Felipe and Fisher, 2003, pp. 250–1). The same economists emphasize that ‘the impossibility of testing empirically the aggregate production function’ is ‘substantially more serious than a mere anomaly’, and that ‘macroeconomists should pause before continuing to do applied work with no sound foundation and dedicate some time to studying other approaches to value, distribution, employment, growth, technical progress etc., in order to understand which questions can legitimately be posed to the empirical aggregate data’ (Felipe and Fisher, 2003, pp. 256–7). It is interesting that the theoretical and empirical researches that have taken up this challenge have devoted attention to the construction of a ‘capacity measure’ of the stock of technical capital that would allow comparisons across different states of technology without having recourse to the traditional ‘parables’ (see, for example, Pasinetti, 1973; 1981; Cas and Rymes, 1991; Hulten, 1992).

Finally, let us note how the discovery of ‘paradoxes’ in capital theory has contributed to stimulating research into the dynamic properties of economic systems outside the world of steady state comparisons. In particular, some economists have attempted the theoretical investigation of regularities in the long-run
dynamics of economic systems by suggesting a reformulation of the classical theory of structural change in a disaggregated framework (see Pasinetti, 1981; 1993; Hagemann, Landesmann and Scizzieri, 2003). Others have investigated the complex interaction of behavioural patterns along a dynamic trajectory, and have called attention to increasing returns and other nonlinear phenomena in structurally adaptive economic systems (see Anderson, Arrow and Pines, 1988; Arthur, Durlauf and Lane, 1997). Whatever the view that is taken, the major victim of the debate has been the Böhm-Bawerk–Clark–Wicksell theory of capital that was so patiently constructed towards the end of the 19th century. This theory relied on a conception of ‘aggregate capital’ that was taken as measurable independently of the rate of profit and of income distribution. Such a conception of ‘capital’ has had to be jettisoned, which has stimulated reformulations of the pure theory of capital. There has been on the one hand a return to the Walrasian general equilibrium theory in its intertemporal formulation, and on the other hand a remarkable revival of classical political economy. The controversy had also a number of less striking but perhaps longer-term consequences. The consideration of paradoxes has alerted economists to the richness and complexity of economic relationships, and to the need to avoid a process of generalization from the consideration of special cases. In any case the debate seems to have compelled theoretical economists to be more rigorous about the nature and limits of their assumptions. In many important cases, it has also brought about a change in the main focus of their analysis. All this leads one reasonably to expect as unlikely that the next generation of economists will leave the issue of capital theory at rest.

capital theory

Robert A. Becker
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Capital theory examines the special role played by time in resource allocation studies. The determination of the interest rate and functional distribution of income as well as how rational agents invest are analysed within single- and multi-sector general equilibrium frameworks. Here, agents exercise perfect foresight over alternative consumption and capital accumulation programs. Efficient programs are characterized. Representative and multi-agent infinitely lived households are studied. Equivalence principles link the equilibrium programs and optimal paths. Heterogeneous agent models with borrowing constraints are reviewed. A behavioural model of intertemporal choice is also compared to its constant discounting counterpart.

Article

1 Introduction

Capital theory examines the special role played by time in resource allocation studies. The determination of the rate of interest and the functional distribution of income are considered along with the development of criteria for evaluating investment decisions. Contemporary capital theory focuses on the intertemporal choices undertaken by rational actors within a general equilibrium setting where all prices and allocations are determined by market clearing. The central role played by time is that producing goods and services to supply future consumption requires withdrawing some output from current consumption in order to create the produced means of production, or capital goods, which enable future production to be undertaken in conjunction with other factors such as labour and land. That agents seek to make their investment decisions rationally is taken as a fundamental premise of capital theoretic models. The rationality hypothesis is implemented by assuming that agents maximize a utility function over paths of future consumption and that producers maximize the present discounted value of their profits. A specification of the degree of foresight must be postulated together with an assumption on which spot and futures markets are open for trade. Consumption and investment decisions are realized in a market equilibrium.

2 Dated commodities and prices

The classical general equilibrium model developed over the last half of the 20th century by Arrow, Debreu, McKenzie and their followers was sufficiently abstract that it could model any number of different economic activities by the device of named goods: a commodity was specified by its physical characteristics, date of availability, contingent events upon which its availability depended, as well as its location. For example, a consumption good available now was differentiated from the same physical commodity available at a different date even if the location or contingent events were the same at both dates. Capital theoretic models focused on the pure role of time assume certainty (no contingent events) and the same location. The simplest models assume that there is just one consumption good and that its characteristics are the same at each point of time. Only the date of its availability differentiates goods. These are the deterministic models. Agents are supposed to exercise perfect foresight over the paths of all relevant variables in this case. Other models treat both time and uncertainty by way of dated goods and contingent events. Rational expectations about the future probability distributions of variables are assumed to describe agents' behaviour. The basic principles and issues in capital theory are most easily reviewed in the deterministic setting with risk and uncertainty treated as a non-trivial extension of the basic theory.

The classical general equilibrium model assumes a finite number of commodities. In the deterministic intertemporal setting this means there are a finite number of dated commodities. Consumers have a finite planning horizon; time unfolds in discrete periods, \( t = 1, 2, \ldots, T \). A finite number of goods are available at each date, indexed by \( j = 1, 2, \ldots, N \). This makes for \( NT \) commodities. Consumers' preferences are defined over a commodity space contained in an \( NT \)-dimensional Euclidean space. Similarly, producers' technology sets were defined in the same commodity space. Competitive prices are established through a market mechanism on the presupposition that markets operate for all \( NT \) commodities. The classic existence of
equilibrium and welfare theorems apply under appropriate assumptions on the consumption and production sectors as well as the relations between them. This formal connection between intertemporal and atemporal static general equilibrium theory offers little that is new or special to capital theory. It is the recognition that time places restrictions on preferences and technologies that specialize the abstract Walrasian model to the type more suited to answering capital theoretic questions about interest rate determination and the corresponding division of the model's output among its participating consumers and resource owners. The distinguishing feature of capital theoretic models is their focus on infinite horizon decision problems. The motivation for this lies in the open-ended nature of the economic problem. Economies do not have foreseeable ends and the problem of saving and investing for future consumption seemingly goes on forever, even though all the decision makers know that our planet's time is limited. But that terminal date is so far in the future that we might as well act today as if an infinite horizon is a good approximation to a very long but finite horizon. The theoretical advantage of the infinite horizon is that it allows us to draw a sharp formal distinction between the short and the long runs. The short run represents the transitional time that model solutions follow, whereas the long run constitutes the solutions' properties as time runs towards infinity. The classical focus on the stationary state, or 'long period', presumes there is a long run and that the economy evolves towards it.

Frank Ramsey (1928) modelled infinite horizons in a seminal article on optimal growth. He argued that discounting by the planner was ethically indefensible. Ramsey's modern followers from Paul Samuelson to the present day have studied both undiscounted and discounted models. Von Neumann's (1937) celebrated model of capital accumulation at a maximum balanced growth rate implicitly assumed an infinite horizon. A balanced program occurs when each type of capital good grows from one period to the next at the same constant rate. By focusing attention on balanced growth paths, it would seem reasonable that von Neumann understood those programs might correspond to that model economy's long-run position. The infinite horizon assumption has a long tradition in capital theory and finance (for example, the consol bonds issued by the United Kingdom; see Goetzmann and Rouwenhorst, 2005, for other examples).

This article concentrates entirely on the discounted case and its connection to general competitive analysis. The primary focus is taken to be the one-sector discounted Ramsey model. Capital theory is viewed as a branch of general equilibrium theory. The masterful surveys by McKenzie (1986; 1987) lay out the undiscounted as well as discounted models for many capital goods and multiple sectors in great generality. His surveys also provide details on how those models can evolve over time (the so-called turnpike theorems) as well as general comparative dynamics results.

Ramsey (1928) formulated his seminal model in continuous time. The models presented here are cast in discrete time with periods $t = 1, 2, \ldots$. This turns out to have some technical advantages over continuous time modelling as well as expository advantages as economic concepts are more readily grasped by readers unschooled in the calculus of variations and its modern development, optimal control theory.

3 Neoclassical capital theory: the one-sector model

3.1 The discounted Ramsey optimal growth model

Neoclassical capital theory is illustrated by the properties exhibited in the discrete time one-sector discounted Ramsey optimal growth model (Ramsey, 1928). This model encapsulates the fundamental consumption–investment trade-offs that a decision maker considers when choosing a consumption plan.
over time to achieve a maximum lifetime utility. The model is simplified in many ways. There is a single decision maker, or planner, acting over an infinite horizon. There is no uncertainty or shocks that would make output available in the future look like a random variable when viewed from the present. The model examines an aggregated economy. There is a single all-purpose consumption good produced using capital goods (carried over from the previous period) and fixed labour. The capital and consumption goods available at each time are physically identical and can be costlessly converted from consumption to capital (and vice versa) at a one-to-one rate. The planner decides how much to consume in the current period and how much to save for next period's production. Capital depreciates entirely within the period. It is circulating as it is used up within the production period. Extensions to include durable capital that depreciates at a fixed rate are straightforward. The planner's exogenously given initial stock of capital produces goods available in the first period. The planner obtains utility from consumption at each time and maximizes the discounted sum of future utilities. The discount factor on future utility is a given constant. The planner's intertemporal optimization problem is:

\[
\sup_{\{c_t, k_{t-1}\}} \sum_{t=1}^{\infty} \delta^{t-1} u(c_t) \text{ by choice of } \{c_t, k_{t-1}\}_{t=1}^{\infty},
\]

subject to:

\[
c_t + k_t \leq f(k_{t-1}) \text{ for } t = 1, 2, \ldots; c_t \geq 0, k_{t-1} \geq 0 \text{ all } t; \ k_0 \leq k, \text{ where } k > 0 \text{ is given.}
\]

Feasible programs are sequences \(\{c_t, k_{t-1}\}_{t=1}^{\infty}\) which satisfy (2). Assume \(u: [0, \infty) \to [0, \infty)\) is strictly concave, increasing, twice continuously differentiable, \(u(0) = 0\), and satisfies the Inada condition:

\[\lim_{c \to 0^+} u'(c) = \infty.\]

The production function \(f: [0, \infty) \to [0, \infty)\) is strictly concave, increasing, twice continuously differentiable, \(f(0) = 0\), satisfies \(\lim_{k \to 0^+} f(k) = \infty\), and \(\lim_{k \to \infty} f'(k) < 1\) (also called Inada conditions). There is a maximum sustainable stock, \(b > 0\), with \(f(b) = b\) and \(0 < b < b\). The discount factor, \(\delta\), satisfies \(0 < \delta < 1\); \(\delta = 1 / (1 + \bar{\gamma})\), where \(\bar{\gamma} > 0\) is the pure rate of time preference (or rate of impatience). There is a unique optimal program, \(\{\bar{c}_t, \bar{k}_{t-1}\}_{t=1}^{\infty}\). Its discounted utility sums,

\[\sum_{t=1}^{\infty} \delta^{t-1} u(\bar{c}_t) < \infty.\]

The optimal growth problem has a time consistency property: The optimal sequence \(\{\bar{c}_t, \bar{k}_{t-1}\}_{t=1}^{\infty}\) has the property that \(\{\bar{c}_{t+\tau}, \bar{k}_{t-1+\tau}\}_{t=1}^{\infty}\) solves the optimization problem with objective starting at time \(\tau\), subject to \(c_{t+\tau} + k_{t+\tau} \leq f(k_{t-1+\tau})\) for \(t = 1, 2, \ldots\) and \(k_0 = k\). Calender time is irrelevant: if the planner's objective is moved forward \(\tau\) periods and the initial capital stock is maintained at the new starting time, then the optimal capital and consumption sequence are
identical to the ones initiated at time $\tau = 0$. The reason for this is 
\[ \sum_{t=1}^{\infty} \delta^{t-1} u(c_{t+\tau}) = \delta^\tau \sum_{t=1}^{\infty} \delta^{t-1} u(c_{t+\tau}), \]
which is multiple of (1) and the set of feasible programs is unchanged. Hence, the optimal solution is unchanged from the same initial condition even though time has simply been reset to start at $\tau$.

The optimal program satisfies $(\bar{e}_{t}, \bar{k}_{t-1}) > 0$ for each $t$. The Kuhn–Tucker necessary conditions for an optimum, known as the Euler, or no-arbitrage conditions, are:

\[ \delta t' \left( \bar{k}_t \right) u' \left( \bar{e}_{t+1} \right) = u' \left( \bar{e}_t \right), \text{ for each } t. \]  
(3)

If the planner's horizon is a finite period, $T$, then (3) and the complementary slackness condition
\[ \delta^{T-1} u' \left( \bar{e}_T \right) k_T = 0 \]
obtain. The latter condition states capital's terminal value is zero. For the infinite horizon case of interest, it is natural to conjecture the transversality condition holds as a necessary condition for optimality:

\[ \lim_{T \to \infty} \delta^{T-1} u' \left( \bar{e}_T \right) k_T = 0. \]  
(4)

This condition's necessity can be formally demonstrated in many problems. The conditions (3) and (4) are also sufficient conditions for optimality under the maintained hypotheses governing the concavity of the single period return function, $u$, and the production function, $f$.

Equation (3) expresses the unprofitability of the one-period reversed arbitrages developed below. An arbitrage represents a feasible change in the optimal path. Reversed arbitrages perturb the optimum for finitely many consecutive periods. Unreversed arbitrages change the optimal path permanently from some given time on to infinity. A necessary condition for an optimal path is that no arbitrage increase the discounted sum of future utilities above the optimal discounted utility. The necessity of the transversality condition can be interpreted as a type of no-arbitrage condition for unreversed arbitrages which never return to the optimal path.

Suppose that the consumption and capital sequences $(\bar{e}_t, \bar{k}_{t-1}) > 0$ (for each $t$) are optimal for the given initial capital stock. Then, the planner cannot increase utility by undertaking the following activity: at time $t$ marginally increase the capital stock to be carried to time $t+1$. This costs the planner $u' \left( \bar{e}_t \right)$ utils on the margin. Now invest this extra capital to obtain $f' \left( \bar{k}_t \right)$ additional units of goods in period $t+1$ from the production sector. Convert this additional income into consumption at $t+1$ worth $u' \left( \bar{e}_{t+1} \right)$ utils on the margin. This implies the marginal benefit of this incremental investment measured at $t+1$ is
Capital Theory: The New Palgrave Dictionary of Economics

Now discount this by the utility discount factor $\delta$ to place the marginal benefit at time $t+1$ and marginal cost at time $t$ in comparable utility units. The marginal benefit cannot exceed the marginal cost along an optimal solution to the household's problem. This is formally expressed by the inequality $\delta f'(k_t)u_t' > u_{t+1}'(k_{t+1})$, for each $t$. Since the capital stock at time $t$ is positive, then this arbitrage calculation can be repeated for an increase in consumption at time $t$ paid for by lower consumption at time $t+1$. In this case, the inequality is reversed and (3) holds.

This model has one special solution: it is the stationary optimal program $(c^*, k^*)$, with $c^* = f(k^*) - k^*$ and $\delta f'(k^*) = 1$. By concavity of $f$, this program has the property that $k^*$ solves the problem $\max_{k \geq 0} \{ \delta f(k) - k \}$. This is a form of the dynamic non-substitution theorem: the stationary optimal capital stock is independent of the planner's felicity function and depends only on technology and the planner's discount factor. The equation $\delta f'(k^*) = 1$ is also the Euler equation for the program $c_t^* \equiv c^*$ and $k_{t-1}^* = k^*$ for each $t \geq 1$. That is, if the initial capital stock is $k^*$, then it is optimal to maintain that capital stock for ever. The program $\{c_t^*, k_{t-1}^*\}_{t=1}^\infty$ is constant, or stationary, over time. Hence the name: the stationary optimal program (also called the steady state). In the case $\delta = 1$ the steady state maximizes stationary consumption over all feasible stationary consumption levels (it is the optimal stationary consumption path) and is called the golden-rule consumption level while the corresponding stationary capital stock is the golden-rule capital stock. For the discounted case, $0<\delta<1$, the steady states are also known as the modified golden-rule consumption and capital stock.

The optimal path of the infinite horizon problem with initial stocks $k \neq k^*$ converges monotonically to the stationary optimal program $(c^*, k^*)$, with $c^* = f(k^*) - k^*$ and $\delta f'(k^*) = 1$. For example, if $0<k<k^*$, then the optimal capital sequence, $\{k_{t-1}^*\}_{t=1}^\infty \neq k^*$. Moreover, paths do not cross: if $0<k<k'$, then $\bar{k}_t < \bar{k}'_t$, where $\{\bar{k}'_{t-1}\}_{t=1}^\infty$ is optimal from initial stocks, $k'$. The convergence of the optimal path implies it is bounded, and the transversality condition holds as a necessary condition for optimality in this model. Conversely, a feasible program satisfying the Euler equations and transversality condition is an optimal program. The convergence property of the optimal capital sequences is also known as the turnpike theorem: the optimal capital sequence from any initial starting stock converges to the modified golden-rule capital stock. The corresponding consumption sequences likewise converge (monotonically) to the golden-rule consumption level. The turnpike theorem's conclusion suggests that there is a distinction between the economy's long-run steady state and the short-run transitional dynamics that describe how the economy approaches that stationary optimal program. One consequence of the turnpike theorem is that optimal programs spend infinitely many periods in any neighborhood of the steady state. In that sense, the steady state is a good approximation for the transitional dynamics over long periods of time. The choice of the analyst lies in determining how small that neighbourhood is, and hence how many periods the economy is not 'sufficiently close' to the model's long-run solution.

The canonical example

The logarithmic utility, Cobb–Douglas production economy is an important example of Ramsey's optimal
growth problem. Many writers refer to it as the canonical example of the one-sector model since its solution is explicitly found. The planner's single period utility function is \( u(c_t) = \ln c_t \) and the production function has the Cobb–Douglas form \( f(x) = x^\rho \) where \( 0 < \rho < 1 \) is a technology parameter (it is capital's constant share of total income in a competitive equilibrium setting). The Ramsey optimal growth problem for this specification (and no depreciation) can be solved explicitly by a variety of techniques (see Becker and Boyd, 1997, for one such approach based on symmetry techniques). The solution is described by the consumption policy function \( g(k) = (1 - \delta \rho)k^\rho \) and the capital policy function \( h(k) = \delta k^\rho \). At each date, the policy functions tell the decision maker how much to consume and how much to save given the current level of the capital stock, \( k \). The optimal capital and consumption sequences are given by iterating the policy functions. Carrying out that iteration for example leads to the explicit solution for the capital sequence:

\[
x_t(k) = (\delta \rho)^{\rho t-1} + \ldots + 1 \cdot k^\rho t
\]

The capital and consumption policy functions in this example have constant marginal propensities to save and consume, respectively. Solow's (1956) growth model postulated savings and consumption functions of this type within a one-sector framework with a Cobb–Douglas production function in order to model the process of economic growth. Solow also assumed exogenous technological progress in the form of labour augmenting technical change, whereby each worker becomes more productive at an exponentially growing rate. Solow aimed his model at describing stylized facts of economic growth. The model was not formally set up to reflect microeconomic based optimizing behaviour at the level of individual consumption–saving decisions. The canonical version of Ramsey's discounted model provides such a microfoundation for Solow's descriptive theory in case there is no exogenous technical progress.

Let \( k_t = x_t(k) \). The policy functions satisfy the no arbitrage condition. Let \( c_t = (1 - \delta \rho)k_t^{\rho} \) and \( c_{t+1} = (1 - \delta \rho)k_t^{\rho} \), where \( k_t \) is the capital stock at time \( t \). The no arbitrage condition is:

\[
\frac{c_t}{\delta c_{t-1}} = \frac{(1 - \delta \rho)k_t^{\rho}}{\delta (1 - \delta \rho)k_{t-1}^{\rho}} = \rho k_t^{\rho-1} = f'(k_t).
\]

This solution can also be shown to satisfy the transversality condition, which takes the form here:

\[
\lim_{t \to \infty} \frac{\rho k_t^{\rho-1} \delta t - 1}{c_t} = 0.
\]
Therefore, the policy functions tell us how to find the optimal solution to this optimal growth problem. The optimal policy functions have the time consistency property as well. The qualitative features of the optimal solution also follow from the policy functions. The most important observation is that the optimal capital sequence is monotonic as can be shown by iterating the capital policy function. Notice that each optimal path converges to the unique positive fixed point of the capital policy function, \( k^* \), where \( h(k^*) = k^* \), which implies that:

\[
k^* = (\delta \rho) \frac{1}{1 - \rho}.
\]

This is the model's modified golden-rule capital stock. If the positive initial capital is below the modified golden rule, then the economy accumulates capital and the sequence of optimal capital stocks increases and converges to the modified golden-rule capital stock. Similarly, the optimal capital stocks decrease and converge to the modified golden rule when the starting stock is larger than the positive fixed point. If the initial capital happens to equal the modified golden-rule stocks, then it will be optimal to maintain those stocks in every period. Thus, the modified golden rule is a steady state of the dynamical system:

\[
k_{t+1} = h(k_t) = \delta \rho k_t^\rho.
\]

The corresponding consumption sequence is also monotonic since the consumption policy function is increasing in capital. The resulting consumption sequence converges to the modified golden-rule consumption level defined by:

\[
\zeta^* = (1 - \delta \rho)(k^*)^\rho.
\]

The convergence of the optimal capital and consumption sequences illustrates the turnpike theorem. The monotonicity property for optimal capital sequences can also be viewed as a non-crossing property: if \( k < k' \) are two different starting stocks, then \( h(k) = k_1 < k'_1 = h(k') \). Continuing in this way we see that, when two starting stocks are compared, the lower one always provides less capital than the higher one at any time along the optimal program.

The steady state's sensitivity to the discount factor is readily shown for \( 0 < \delta < 1 \) for the general discounted one-sector model. Let \( k^* = k^*(\delta) \) denote the steady state capital stock as a function of the discount factor.

The condition \( \delta f'(k^*(\delta)) = 1 \) implies upon differentiation that \( dk^*/d\delta > 0 \). This comparative steady state result means that a more patient planner (there is a marginal increase in discount factor) produces a larger stationary optimal capital stock. Some writers on capital theory call this the capital deepening response to a change in the discount factor. The corresponding result for the consumption path \( \ell^*(\delta) = f(k^*(\delta)) - k^*(\delta) \) states \( d\ell^*/d\delta > 0 \) as well. This is called non-paradoxical consumption behaviour. Note that this comparative steady state exercise does not compare the optimal program starting from \( k^* \) given the new discount factor to the optimal stationary plan \( k^* \) for the old discount factor.

Comparative steady state exercises merely compare the steady states before and after a parameter change without evaluating the economy's transition path from one steady state to another. Comparative dynamics results are available for the one-sector model which include studying the transition from one steady state to another in response to a parameter change. The planner considers all feasible plans in response to a change in one of the economy's deep taste or technology parameters. In particular, it is possible to compare the optimal programs before and after the parameter changes. For example, if the planner's discount factor increases (or, equivalently, the pure rate of time preference declines), then the planner becomes more patient. If the planner's discount factor increases from \( \delta \) to \( \delta' \), with \( 0 < \delta < \delta' < 1 \), then the optimal capital paths starting from the same initial capital stock satisfy the conditions \( k_{t+1}^* > k_t^* \) for each time – there is a generalized capital deepening response because the economy's capital stock is increased at each time. Indeed, the discount factor's initial impact is to increase the first period's capital stocks at the expense of first period consumption since the initial capital stocks and first period output are unchanged after the discount factor increases. As the new consumption program converges monotonically to a larger modified golden-rule consumption level, \( c^*(\delta') \), it follows that eventually (that is, in finite time) \( \bar{c}_t(\delta') > \bar{c}_t(\delta) \) must obtain. These comparative dynamics results are easily verified for the canonical example with log utility and Cobb–Douglas production.

It is interesting to note that the monotonicity and non-crossing properties of the one-sector model are robust. For example, the concavity of the production function can be relaxed while preserving these qualitative properties. The production function is non-classical provided there is an inflection point, \( 0 < k_I < b \) such that \( f''(k) > 0 \) for \( k < k_I \) and \( f''(k) < 0 \) for \( k > k_I \). Non-classical production functions can arise in fishery models when representing the production of a new generation of fish from the existing population. See Becker and Boyd (1997, ch. 5) for details on the non-classical production extensions.

Generalizations of the one-sector model's turnpike property (the convergence of optimal capital sequences to the modified golden-rule stock) are also available for some multi-capital goods models, as found in McKenzie's surveys. The original turnpike theorem for many capital goods models was conjectured by Dorfman, Samuelson and Solow (1958) in the von Neumann model framework without an explicit consumption criterion. Radner (1961) provides the first rigorous proof of a turnpike theorem for a von Neumann style model with a unique maximum balanced growth path and a finite planning horizon. Radner's theory evaluated alternative programs from a given initial vector of capital stocks according to a criterion based on the value of those stocks in the program's final time period. As with Dorfman, Samuelson and Solow's model, Radner's theorem did not apply to a Ramsey-style planner with an objective based on discounted utility. Radner's value loss technique for demonstrating the turnpike theorem did turn out to apply to undiscounted Ramsey models as well as some forms of the discounted model, as summarized in McKenzie's survey articles.

Another generalization focuses on the representation of the intertemporal utility function. Some recursive
Utility functions, which generalize the time consistency property of the time additive utility function, can be specified for concave production models while retaining the qualitative properties of optimal paths, such as capital monotonicity. The basic notion of a recursive utility function is illustrated below. The general theory of recursive utility functions is exposited by Becker and Boyd (1997).

Flexible time preference underlies many classic writings on capital theory – the agents discount factor depends on the underlying consumption stream. Recursive utility functions are one family of utilities that allow the steady state consumption stream to influence the corresponding discount factor. The brief development of recursive utility theory given here is grounded in a re-examination of the time consistency property of the planner's optimal choice in the one-sector discounted Ramsey model.

The discounted additive utility function, $U$, over infinite consumption streams $c = \{c_1, c_2, \ldots\}$ is defined by the formula:

$$U(c) = \sum_{t=1}^{\infty} \delta^{t-1} u(c_t)$$

where $u$ is a bounded, strictly increasing, and strictly concave function on $[0, \infty)$ with $0<\delta<1$ as before. The time consistency property discussed above reflects the property that $U$ is recursive: the behaviour embodied in this additive representation of utility has a self-referential property, that is, the behaviour of the planner over the infinite time horizon $t = 1, 2, \ldots$ is guided by the behaviour of that agent over the tail horizon $t = T, T + 1, T + 2, \ldots$ (for each $T$) hidden inside the original horizon. For this additive utility function, recursivity means the objective from time $T + 1$ to $+\infty$ has the same form as the objective starting at time $T = 0$ (except for some time shifts in consumption dates). Formally, $U$ may be rewritten as:

$$\sum_{t=1}^{\infty} \delta^{t-1} u(c_t) = \sum_{t=1}^{T} \delta^{t-1} u(c_t) + \delta^{T} \sum_{t=T+1}^{\infty} \delta^{t-1} u(c_{t+T}),$$

where the last sum gives the utility of the stream $\{c_{T+1}, c_{T+2}, \ldots\}$. The utility of the consumption stream $c$ can be written as the function:

$$U(c) = u(c_1) + \delta U(Sc),$$

where $S$ is the shift operator: $Sc = \{c_2, c_3, \ldots\}$. Let the projection operator, $\pi$, be defined by the formula $\pi c = c_1$. The general notion of a recursive utility function is that the utility function $U$ can be written in the form:
for an appropriate real-valued function $W$ defined on $[0, \infty) \times \mathcal{U}$, where $\mathcal{U}$ is the range of $U$. $W$ is called the *aggregator function*. For the additive function, $W(c, y) = u(c) + \delta y$ for $y \in \mathcal{U}$. There are other examples of recursive utility functions. The Epstein–Hynes utility function developed below is generated by the *EH aggregator* $W(c, y) = (-1 + y) \exp(-v(c))$, where $v$ is a strictly concave, increasing function of $c$ with $v(0) > 0$.

The general theory of recursive utility functions provides a way to recover the utility function $U$ from specification of the aggregator. Intuitively, $U$ can be found by recursively substituting it into the equation $U(c) = W(u(nc), U(Sc))$. This substitution is performed by the recursive operator $T_W$ defined by:

$$(T_W U^0)(c) = W(u(nc), U^0(Sc)),$$

where $U^0$ is considered the initial seed in this recursive substitution. For example, if $U^0 = 0$, the zero function that annihilates all consumption streams, then the $N^\text{th}$–iterate of $T_W$ is:

$$(T_W^N 0) = W(c_1, W(c_2, \ldots, W(c_N, 0) \ldots)).$$

The recursive utility function is the unique fixed point of the operator $T_W$. The general theory provides conditions under which $T_W$ has a unique fixed point and the successive iterates $T_W^N$ converge to that fixed point independently of the choice of the initial seed function, $U^0$. Lucas and Stokey (1984) first proposed the specification of utility functions via aggregators and provided the basic theory of the recursion operator for bounded aggregators when consumption streams were elements of the set of all real-valued non-negative bounded sequences.

The basic ideas in recursive utility theory are readily illustrated for the case of the EH aggregator. This yields an example where the planner's utility function has flexible time preference and a recursive structure. A planner whose preferences over consumption streams is defined by the EH aggregator can be shown by recursive substitution to have the utility function $U$, which takes the form:

$$U(c) = -\sum_{t=1}^{\infty} \exp\left(-\sum_{s=1}^{t} v(c_s)\right)$$

(6)
where \( \forall: \mathbb{R}^+ ightarrow \mathbb{R}^+ \) is strictly concave, increasing, and satisfies \( \forall(0) > 0 \). Equation (6) is known as the *Epstein–Hynes (EH) utility function* after the continuous time analogue from Epstein and Hynes (1983); (6) was also studied in Epstein (1983). The EH utility from the consumption sequence's tail, \( (c_{T+1}, c_{T+2}, \ldots) \), appears in the last term of the following expression breaking down the utility over the entire consumption path into segments for the first \( T \) periods and the subsequent periods:

\[
- \sum_{t=1}^{\infty} \exp \left( - \sum_{s=1}^{t} \forall(c_s) \right) = - \sum_{t=1}^{T} \exp \left( - \sum_{s=1}^{t} \forall(c_s) \right) + \exp \left( - \sum_{T}^{\infty} \forall(c_s) \right) \times \left[ - \sum_{T=1}^{\infty} \exp \left( - \sum_{s=T+1}^{\infty} \forall(c_s) \right) \right]
\]

Hence, the utility of the tail of the program is just a time-shifted form of the utility of the original program – this is the identifying characteristic of a recursive utility function based on stationary preferences.

The steady state conditions for this economy are found by working out the no arbitrage conditions for the optimal growth problem which maximizes (6) subject to (2) and letting the consumption and capital sequences be constant sequences. Then the steady state conditions become:

\[
f'(k^*) = 1 / \exp(\forall(c^*)), \tag{7}
\]

where \( k^* \) is the aggregate steady state capital stock. Since \( \exp(\forall(0)) > 1 \) and \( c^* + k^* = f(k^*) \), one can solve (7) for a unique long-run capital and consumption level. The capital monotonicity property holds for the optimal solution to the problem of maximizing (6) subject to (2) when the neoclassical production function satisfies the concavity and Inada conditions for the discounted Ramsey model (see Becker and Boyd, 1997, ch. 5, for a detailed proof and Beals and Koopmans, 1969, for the seminal article on recursive utility in optimal growth theory). In particular, if the initial capital stock is smaller than the steady state stock, then the economy's capital stock increases at each time and converges to the steady state; likewise, an initial capital stock above the steady state leads to a declining capital stock over time which converges to the steady state stock. The non-crossing property also obtains.

### 3.2 Equilibrium equivalence principles

The optimal growth model connects to the central questions of the determination of prices, including the rate of interest, and the functional distribution of income, by way of reinterpreting the optimal program as a competitive equilibrium for a fully specified dynamic general equilibrium model. This relationship is
capital theory: The New Palgrave Dictionary of Economics

obtained by proving a version of the fundamental welfare theorems for this economy. The traditional welfare theorems based on finitely many goods must be adapted to the case of infinitely many dated commodities. There is more than one way to interpret the equilibrium model. The first interpretation is one with perfect foresight and a sequence of budget constraints, one for each time. Prices are reckoned in units of current consumption. The second interpretation links the neoclassical model with Irving Fisher's theory of interest rate determination and emphasizes his famous *separation principle*. The Fisherian equilibrium model is also one where agents act with perfect foresight.

At the core of either equilibrium model's interpretation is what Christopher Bliss (1975) called the *orthodox vision of capital theory*: an economy accumulating capital will generate rising wages and a falling rate of interest. Since capital increases over time, labour–capital complementarity implies workers are more productive and their wage rises. Diminishing returns set in and the rental rate falls as so many early writers on capital theory hypothesized in their verbal models. One of Ramsey's great contributions was to provide a consistent mathematical model of this story.

3.2.1 The PFCE equivalence principle

The competitive economy consists of an infinitely lived representative *household*, or *consumer sector*, and a *production sector*. The representative household's preferences coincide with the Ramsey style planner introduced above. The representative household is derived for an economy with a continuum of identical infinitely lived households whose preferences coincide with the Ramsey style planner. These households' preferences and endowments are identical. The total labour supply of all households has unit mass. In a *symmetric equilibrium* each household will take the same action given the same endowment, so it is sufficient to examine the decisions undertaken by a representative household who is also taken as supplying the economy's labour services to the production sector. The production sector's production function is the same as the one in the corresponding optimal growth model.

The representative consumer forecasts sequences of rental and wage rates to maximize lifetime utility subject to a sequence of budget constraints, one for each period. Formally, the household sector solves for given \(\{r_t, w_t\}_{t=1}^{\infty}\) the problem:

\[
\sup_{\{g_t\}_{t=1}^{\infty}} \sum_{t=1}^{\infty} \delta^{t-1} u(c_t)
\]

by choice of the non-negative sequences \(\{k_t, c_t\}_{t=1}^{\infty}\) subject to:

\[
c_t + k_t = w_t + (1 + r_t)k_{t-1} \text{ for } t = 1, 2, \ldots
\]

(8)

http://www.dictionaryofeconomics.com.proxy.library.csu.edu/article?id=pde2008_C000575&goto=B&result_number=203
and $k_0 \leq k$. Here $k$ is the initial capital stock (the same one as in the Ramsey optimal growth problem), $r_t$ is the one-period rental rate on capital, and $w_t$ is the wage rate earned by inelastically supplying one unit of labour in each time period. The prices $r_t$ and $w_t$ are reckoned in units of consumption available at time $t$. The consumer's problem has a no arbitrage condition analogous to the one obtained in the optimal growth problem:

$$\delta(1 + r_t)u'(c_{t+1}) = u'(c_t) \text{ for each } t.$$  

The transversality condition is necessary for equilibrium programs as defined below. The combination of the transversality condition and the no arbitrage equation is also sufficient for a consumption–capital sequence to solve the consumer's problem for a given profile of wages and rental factors.

Producers take the rental rate as given and solve the following myopic maximization problem for the production sector's capital demand at each time period:

$$\sup_{x \geq 0} f(x) - (1 + r_t)x.$$  

Here, $x$ denotes a level of aggregate capital; the profit maximizing solution is denoted $k_{t-1}$, the planned capital demand at time $t$. It only depends on the current rental rate, $r_t$. The problem's point input–point output structure reflects the absence of adjustment costs or other structural production lags and the fact that all forward-looking consumption–investment decisions reside in the household sector. The necessary and sufficient condition for a positive capital stock to solve the production sector's optimization problem at time $t$ is:

$$f'(k_{t-1}) = 1 + r_t,$$

which uniquely determines $k_{t-1}$ in terms of $1 + r_t$. The total capital income is

$$(1 + r_t)k_{t-1} = f'(k_{t-1})k_{t-1}.$$  

The wage bill is the residual 'profit' given by:

$$w_t = f(k_{t-1}) - (1 + r_t)k_{t-1}.$$
Notice that \( w_t = f(k_{t-1}) - f'(k_{t-1})k_{t-1} \). In the Cobb–Douglas case with \( f(k) = k^\rho \), then this economy labour's share of the total output or national product, \( k_{t-1}^\rho \), is \( 1-\rho \) and capital's share is \( \rho \). The total supply of goods in period \( t \) is \( f(k_{t-1}) \) as a result of one-period profit maximization. Sequences \( \{ 1 + r_t, w_t, c_t, k_{t-1} \}_{t=1}^{\infty} \) constitute a perfect foresight competitive equilibrium (PFCE) provided that:

- (PFCE-1) \( \{ c_t, k_{t-1} \}_{t=1}^{\infty} \) solve the consumer's problem given \( \{ 1 + r_t, w_t \}_{t=1}^{\infty} \);
- (PFCE-2) \( f'(k_{t-1}) = 1 + r_t \), and
- (PFCE-3) \( w_t = f(k_{t-1}) - (1 + r_t)k_{t-1} \) for each time \( t \).

These three conditions yield via Walras's Law the materials balance condition, \( c_t + k_t = f(k_{t-1}) \) for each \( t \) and \( k_0 = k \).

The equivalence principle tells us that for this dynamic economy the PFCE allocation is the same as the Ramsey planner's solution. Hence, a PFCE allocation is an optimum and vice versa. The argument is the no arbitrage conditions for the equilibrium and optimal growth problems coincide, and the respective transversality conditions hold as necessary conditions in their respective problems. The sufficiency of these conditions is used to finish the proof.

A PFCE determines the functional distribution of income as the payments to each productive factor at each point in time. Labour receives its wage and capital is paid its capital income. The share of income received by each factor is a constant and time independent when production is Cobb–Douglas. The functional distribution of income at each time also yields the representative agent's personal income by adding the two source's income at each time. Multi-agent models differentiate the personal income an agent enjoys at each time from the corresponding functional distribution of income.

### 3.2.2 The Fisher competitive equilibrium equivalence principle

The capital theoretic foundation for the present value investment criterion is the Fisher separation principle derived from Fisher’s ‘second approximation’, which portrays the intertemporal consumption–investment decision of agents as a two-stage process. In the first stage, investment opportunities are exploited to realize a maximum value of initial wealth. The solution to the first-stage problem is found by maximizing the net present value over all feasible projects. Given competitive prices (and implicit discount rates), all agents whose intertemporal utility functions satisfy a mild non-satiation requirement will be led to choose the same wealth maximizing investment projects. In the second stage, those agents take their maximized wealth and access perfect capital markets to borrow and lend in order to obtain the most preferred lifetime consumption pattern.

The Fisher competitive equilibrium is the infinite horizon analogue of the Fisher separation principle. There is a single lifetime budget constraint; the savings–investment decision is separated from the consumption decision. Consumers maximize utility given their maximized wealth obtained as residual claimants to the production sector's discounted profit streams. Discounted profits are maximized within that sector. Letting \( \{ r_t \} \) be the sequence of interest rates and \( q_t = \prod_{\tau=1}^{t} (1 + r_{\tau})^{-1} \) the discounted price of time \( t \) consumption, define the profit function by \( \pi(k, \{ r_t \}) = \max \{ \sum_{t=1}^{\infty} q_t [ f(k_{t-1}) - (1 + r_t)k_{t-1} ] : k_0 = k \} \).
A sequence \( \{ r_t, c_t, k_t \} \) forms a Fisher competitive equilibrium (FCE) if:

- (FCE-1) \( \pi(k, \{ r_t \}) = \max \{ \sum_{t=1}^{\infty} q_t [ f(k_{t-1}) - (1 + r_t)k_{t-1} ] : k_0 = k \} \);
- (FCE-2) Consumers maximize \( \sum_{t=1}^{\infty} \delta^{t-1} u(c_t) \) subject to the budget constraint \( \sum_{t=1}^{\infty} q_t c_t = \pi(k, \{ r_t \}) + k \);
- (FCE-3) The market clearing condition \( c_t = f(k_{t-1}) - k_{t-1} \) holds.

Once again, by matching first-order conditions and transversality conditions the sufficiency conditions for the agents' optimization problems imply that the allocation \( \{ c_t, k_t \} \) in a FCE \( \{ r_t, c_t, k_t \} \) is an optimum, and vice versa: given the optimal allocation \( \{ c_t, k_t \} \), there is a sequence of interest rates such that the triple \( \{ r_t, c_t, k_t \} \) forms a FCE. The result is the Fisher equivalence theorem.

The twin equivalence theorems for the PFCE and FCE models connect Ramsey's theory of optimal growth in an aggregate economy to Fisher's theory of consumption and investment in an intertemporal choice market model as well as to Solow's descriptive growth theory (the logarithmic utility, Cobb–Douglas production function example has a constant marginal propensity to save, as assumed in Solow's growth model). The qualitative properties of the optimal growth model carry over to the two formulations of dynamic competitive economies. In the case where the initial capital stocks are smaller than the modified golden-rule stocks, the capital monotonicity property of the optimal program implies that the consumption sequence increases, the sequence of wage rates is increasing, and the sequence of interest rates/rental rates is decreasing. The orthodox vision of capital theory holds for the one-sector optimal growth model once the dynamic equilibrium is interpreted by way of the PFCE and FCE equivalence principles.

### 3.3 Many agents

The equivalence principles for the discounted Ramsey model postulate a representative agent. The orthodox vision of capital theory carries over to some forms of neoclassical capital theory when many distinct agents replace the assumption of a representative infinitely lived household. The introduction of many distinct consumers raises interesting questions concerning the determination of equilibrium prices and the distribution of personal (and factor) income both in short and long runs.

Frank Ramsey's seminal contribution to optimal growth also addressed the long-run, or steady state, distribution in a competitive economy. He conjectured that, with households having different rates of impatience, the steady state equilibrium would have very unequal income and wealth distributions. The most patient household would enjoy the maximum sustainable consumption (‘bliss’ in his conception) and all other households would consume at a minimal level necessary to sustain their lives. This was not a particularly new idea at the time his paper was published. The notion that time preference differences operating in a market economy might promote long-run differences in income and wealth can be found in the writings of such eminent economists as John Rae in 1834 and in several books by Irving Fisher beginning with his great work on the rate of interest first published in 1907. The Ramsey conjecture can be examined in two distinct neoclassical settings. The first deals with a natural extension of the optimal growth model to one of Pareto optimal growth. Agents are allowed to borrow and lend. The equilibrium version is analogous to the FCE set-up. Households have a single budget constraint expressed in present value terms. Here, long-run income distribution can be extreme if individuals have different discount factors – the
relatively impatient ones receive NO income. The second formulation is one of temporary equilibrium where markets are incomplete – households are forbidden to borrow against their future labour income (each person's capital stock is constrained to be non-negative at each time) and face a sequence of budget constraints, as in the PFCE model. In this setting, the relatively impatient households consume their wage income and the most patient household consumes wage and capital income – a modern formulation of Ramsey's two-class society.

3.3.1 Pareto optimal growth with many agents

Suppose there are \( H \) households \((h = 1, 2, \ldots, H)\) with one-period return functions \( u_h \) of the type met in the optimal growth setting. Let \( c^h_t \) denote agent \( h \)'s consumption at time \( t \) and suppose that each agent's discount factor is the same \( \delta = \delta_h \) with \( 0 < \delta < 1 \). Introduce welfare weights \( \lambda = (\lambda_1, \lambda_2, \ldots, \lambda_H) \geq 0 \) and \( \sum_{h=1}^{H} \lambda_h = 1 \). Given a weight vector \( \lambda \), the Pareto optimal growth problem is to solve:

\[
\sup_{t=1}^{\infty} \sum_{h=1}^{H} \lambda_h [\delta^{t-1} u_h(c^h_t)]
\]

subject to \( \left( \sum_{h=1}^{H} c^h_t \right) + k_t \leq f(k_{t-1}), \ t = 1, 2, \ldots, c^h_t, k_{t-1} \geq 0, k_0 \leq k, \ h = 1, 2, \ldots \)

The planner seeks a path of consumption for each person and an aggregate capital path satisfying the constraints with the maximum weighted discounted future utility. This problem can be rewritten in an interesting manner.

Given a weight vector \( \lambda \), define on \( \mathbb{R}^+ \) the real-valued function \( u^*_\lambda \) as the following program's optimal value function:

\[
u^*_\lambda(c) = \sup \left\{ \sum_{h=1}^{H} \lambda_h u^*_h(c^h): \sum_{h=1}^{H} c^h = c, \ c^h \geq 0 \right\}.
\]
If $u_h$ is a concave, continuous, increasing function on $[0, \infty)$, and twice continuously differentiable function on $(0, \infty)$, then $u_h^*$ is concave, increasing in $c$, and continuously differentiable. Note that the Inada condition

$$u'_h(0) = +\infty \quad \text{and} \quad \lambda \ h > 0$$

imply $c_h > 0$ in the solution to (10) whenever $c > 0$. This also implies

$$u_{\lambda}^{\ast'}(0) = +\infty$$

holds. Of course, if $\lambda \ h = 0$, then $c_h = 0$ in the solution to (10).

The Pareto optimal growth model is then given by the classic discounted Ramsey model:

$$\sup_{t=1}^{\infty} \sum_{t=1}^{\infty} \delta^{t-1} u_{\lambda}(c_t)$$

subject to $c_t + k_t \leq f(k_{t-1})$, $t = 1, 2, ..., c_t, k_{t-1} \geq 0$, $k_0 \leq k$.

This problem has a unique solution under our basic assumptions. The neoclassical optimal growth model's properties obtain for this Pareto optimal growth model: the optimal aggregate consumption and capital sequences are monotonic and converge to the modified golden-rule consumption, $c^*$, and capital, $k^*$. Notice that the steady state capital stock and aggregate consumption levels are independent of the welfare weights. However, given $c^*$, the steady state allocations to the various households do depend on those weights by way of the solution to (10) with $c = c^*$. Different weights will distribute the steady state aggregate consumption differently. Consumption is equally distributed in the steady state if and only if the welfare weights are equal with $\lambda = 1/H$. Along dynamic equilibrium paths aggregate consumption growth also implies each household's consumption grows provided that agent's welfare weight is positive.

The preservation of the capital monotonicity property in this Pareto optimal growth problem suggests that the orthodox vision applies to its equilibrium counterpart. It turns out that with many agents the form of the equivalence principle is more subtle than with a single, representative, agent. The essential issue is the same problem that arises with the classical welfare theorems in finite dimensional commodity spaces — a Pareto optimum may only be a competitive equilibrium with transfer payments. Once this problem is handled, the basic equivalence principles carry over to the many agent case provided all households discount future utility at the same rate. The orthodox vision prevails.

The orthodox vision's realization in the Pareto optimal growth problem with equal discount factors does not extend to a model with heterogeneous agents and distinct discount factors. In this case, the household with the largest discount factor is the most patient one. The modified golden-rule capital stock, $k^*$, is still well-defined. However, Le Van and Vailakis (2003) prove the Pareto optimal capital sequence initiated at $k^*$ converges to it in the long-run — but it is not a constant sequence: if the economy starts with the stocks $k^*$, then it is optimal for the planner to deviate from those stocks and only return to them asymptotically. The
The resulting optimal capital sequence cannot be monotonic, although the authors show it can be eventually monotonic. In part, this reflects the fact that the households enjoy time-varying consumption along their optimal path. The aggregate consumption levels change over time, but the first household emerges as the dominant consumer in the limit. The heterogeneous agent extension of the neoclassical representative agent theory does not exhibit the orthodox vision.

3.3.2 The Ramsey equilibrium model

The Ramsey equilibrium developed in Becker (1980) and reviewed in Becker (2006) interprets Ramsey's original long-run steady state conjecture with heterogeneous agents in a modern fashion. The basic model is developed for the case of agents with time additively separable utility functions with fixed discount factors. Each agent has a different discount factor, so one household is more patient than all the others. The technology is specified by a one-sector model with a single all-purpose consumption–capital good as before. The general complete market competitive one-sector model treats budget constraints as restricting the present value of an agent's consumption to be smaller than or equal to the agent's initial wealth defined as the capitalized wage income plus the present value of that person's initial capital. This allows us to interpret the choice of a consumption stream as if the agent were allowed to borrow and lend at market-determined present value prices subject to repaying all loans. Markets are complete – any intertemporal trade satisfying the present value budget constraint is admissible at the individual level. The Ramsey equilibrium model changes the budget constraint from a single one reckoned as a present value to a sequence, one for each period. Agents are forbidden to borrow against their future labour income, so they cannot capitalize the future wage stream into a present value. Markets are incomplete. It becomes crucial to track the evolution of each person's capital stock. This is unnecessary in the complete market models when all values entering the budget constraint are present values.

The incomplete market structure shows itself in an individual's budget constraint. At each time, a household's available income is derived from rental returns on its capital stocks, and its wage rate (all labour is alike and inelastically supplied). Expenditure at each time is for consumption goods and for capital goods to be carried over to the next period in order to earn rental income. The borrowing constraint takes the form of a non-negativity constraint on the capital stock holdings in each time period. The formal constraint is analogous to (8) with superscripts attached to individual consumption and capital holdings.

The heterogeneous discount factor, incomplete market economy, differs in another important respect: the operation of a borrowing constraint in the individual household problems also breaks the possibility of an equilibrium allocation arising as the economy's optimal allocation. The welfare maximization approach favoured in the complete market theory is inapplicable.

The Ramsey model has a unique stationary equilibrium in which only the most patient household has capital. That agent also enjoys a labour income. All other households consume their wages and own no capital. The model's dynamics have some distinctive features when compared with the capital and consumption monotonicity characteristic of the representative agent neoclassical model. The main results for the Ramsey equilibrium model appear in a series of papers beginning with Becker and Foias (1987).

The survey article by Becker (2006) reviews those results as well as others in detail. Here, it is enough to note that the Ramsey equilibrium aggregate capital starting from an arbitrary distribution of initial capital stocks eventually has the capital monotonicity property in the case where the production function's elasticity of substitution is greater than or equal to 1, a condition satisfied by the Cobb–Douglas production function. In this case, the orthodox vision of capital eventually holds. If that elasticity of substitution condition fails,
then Becker and Foias showed it was possible for a two-period equilibrium cycle to exist; the orthodox vision necessarily fails.

3.4 Behavioural economics and quasi-geometric discounting

The discounted Ramsey model where the planner discounts future utilities at a constant rate is the fundamental dynamic model in macrodynamics and economic growth theory. The time consistency of the optimal plan, based on the stationarity of the planner's utility function (even in the general recursive case) has been questioned by behavioural economics researchers on the basis of experiments and empirical evidence. For example, Ainslie (1991, p. 334) states that a majority of adults report they would rather have $50 immediately rather than $100 in two years, but almost no one chooses $50 in four years instead of receiving $100 in six years. If these individuals have stationary preferences, the mere passage of four years calendar time should not change the ranking of $50 in year four to $100 in year six if $50 was preferred in the present to $100 in two years. Thus, Ainslie concludes these individuals are time-inconsistent in their intertemporal preference ranking. Ainslie, as well as many others (notably Laibson, 1997; also see the survey by Frederick, Loewenstein and O'Donoghue, 2002, for detailed summaries of the evidence and related references based on works by psychologists and economists) argue a different discounting function that describes real human behaviour better than the constant discounting model. The quasi-geometric discounting model developed below illustrates the simplest form of an alternative discounting function that these researchers argue better describes real human intertemporal choices. The quasi-geometric discounting function is an important example of the _hyperbolic discounting functions_ appearing in behavioural discussions of time preference. The time preference reversals reported by Ainslie can be thought of as a criticism of standard discounted utility models in much the same way as the Allais paradox in risky choice experiments provides evidence against the expected utility model.

The standard constant discounting model's discounting function is \( D(t) = \delta^{t-1} \), where \( 0 < \delta < 1 \) is the discount factor and \( t \geq 1 \). The function \( D \) is also called the _exponential discount function_. The quasi-geometric discounting model posits a discounting function of the form \( d(t) = \beta \delta^{t-1} \), where \( \beta > 0 \) is a parameter. The case \( \beta = 1 \) corresponds to the exponential discount function. If \( \beta < 1 \), there is short-run impatience – the decision maker is willing to save in the future, just not in the present. If \( \beta > 1 \), then there is short-run patience – the decision maker is more willing to consume in the future rather than the present. It is known from the fundamental paper by Strotz (1955) that, if a dynamic optimizing planner's discount factor does not have an exponential form, then the resulting optimal solution found from maximizing utility discounted to the present date will be time inconsistent. Thus, a planner solving the problem of maximizing the quasi-geometric utility function:

\[
U(c) = u(c_1) + \beta [\delta u(c_2) + \delta^2 u(c_3) + \ldots]
\]

subject to (2) will exhibit time inconsistency. The solution \( \{t, k_{t-1}\}_{t=1}^{\infty} \) so found will change if the
planner is able to re-optimize at time 2. That new solution \( \left\{ k^2_t, k^2_{t-1} \right\}_{t=2}^{\infty} \) will have the property that \( k_2^2 \neq k_2^1 \) when \( k_1^1 = k_1^2 \) expresses the initial condition for the second period's optimization problem. Put differently, unless the planner can credibly commit to implementing the solution found in the first period, the planner will make another choice of optimal plans once period 2 is attained than the one originally found at time 1. The time inconsistent solution found in period 1 is really not an optimum as the planner would not implement it when called on to do so in the absence of a credible commitment to that plan.

Phelps and Pollak (1968) proposed a different way to arrive at a solution to the problem of maximizing (12) subject to (2). Their approach recognizes the planner must correctly anticipate future actions. The choice of \( c_t \) at some future date \( t \) alters the planner's capital stock and impacts the choices of consumption levels for all times past \( t \). These impacts must be somehow considered by the planner in the present when the optimal plan is determined.

Phelps and Pollak imagined the planner as really infinitely many planners, each a generation that lives, saves and consumes over just one period. The discount factor, \( \delta \), measures impatience; the parameter \( \beta \) reflects the degree to which the current generation values future generations' utility relative to their own utility. Perfect altruism corresponds to the case \( \beta = 1 \) whereas imperfect altruism arises whenever \( \beta < 1 \).

Later writers, following Laibson (1997), interpreted the generations as different selves, one for each time period. In either interpretation, the planner acts as if there are really infinitely many selves in the infinite-horizon Ramsey-styled optimization problem. Phelps and Pollak go on to argue the Ramsey optimal growth problem should be considered as a game with the many selves as the players. A Nash equilibrium of this game constitutes a solution to the planner's problem in the sense that no self (or generation) can improve its payoff given the actions taken by future selves (generations). Modern game theory research published after Phelps and Pollak's article suggests that such a game might have many equilibrium points. One possibility is the Markov perfect equilibrium concept. A Markov perfect equilibrium is time consistent. At time \( t \), no histories of past choices or measurement of the capital stock are assumed to matter for outcomes beyond the current value of the aggregate capital stock that is presented to the self active at that moment. Other equilibrium notions can be formulated to reflect the game's history as play unfolds over time. Trigger strategies provide one way to do this. Of course, a fundamental equilibrium existence question arises for Markov perfect equilibrium as well as those equilibrium concepts derived from the selves adopting trigger strategies.

A Markov perfect equilibrium is represented by a time independent capital policy function, \( g(k) \), that the current self expects to govern all future selves' saving and capital accumulation decisions. In this way, the aggregate capital stock is expected to evolve according to the dynamical system \( k_t = g(k_{t-1}) \) with \( k_0 = k_0 \), the capital stock endowment available at time 0. Note that this function depends only on the currently available capital stock. To solve the planner's quasi-geometric utility optimization problem is to find such a policy function. Recall that a policy function of this type characterized the solution to the canonical version of the discounted Ramsey model and reflected the underlying time consistency property of the planner's stationary utility function. It is also a Markov perfect equilibrium in the quasi-geometric case where \( \beta = 1 \) and \( u(c) = \ln c \) with \( f(k) = k^\alpha \). Of course, a major technical problem is to show a Markov perfect equilibrium exists in models where \( \beta \neq 1 \). For the log utility, Cobb–Douglas production model, a Markov perfect equilibrium has been constructed in the quasi-geometric case with \( \beta < 1 \) by Krusell, Kurucu and Smith (2002). They showed that there is a Markov perfect equilibrium with policy function:
\[ k' = g(k) = \frac{\beta \delta \alpha}{1 - \alpha \delta (1 - \beta)} k^\alpha, \]

a functional form that agrees with the canonical example's capital policy function when \( \beta = 1 \). Iteration of this capital policy function (13) from the given initial capital stock produces a monotonic aggregate capital sequence. The qualitative properties of this particular Markov perfect equilibrium in this parameterized quasi-geometric model is the same as the qualitative properties of the canonical discounted Ramsey model, even though the two models' quantitative properties differ. For example, the two models have different steady states. The similarity was noted in Barro's (1999) continuous time model; he dubbed this similarity an observational equivalence result as the two models could not be distinguished empirically on the basis of their qualitative features alone.

3.5 Efficient programs

Programs which are optimal for the discounted Ramsey model as well as its more general recursive utility formulations have an important efficiency property: there is no other feasible consumption sequence that provides more consumption in at least one period and as much in any other when compared with the optimal consumption path. This efficiency property can be studied in capital accumulation models in its own right as a minimal requirement for any reasonable objective function. Considered on its own, the efficiency criterion does not do much to single out a specific course of action for the planner. However, it can be used to eliminate some candidate optima without further reference to a specific welfare function. Moreover, examining efficient programs of consumption and capital accumulation can be undertaken in models with infinitely lived agents as well as models with finitely lived, overlapping generations where the economy evolves over an infinite horizon.

The interest in intertemporal efficiency stems from Malinvaud's (1953) seminal paper. He presented the first extension of Koopmans' activity analysis of efficient allocations in a static production world to an open-ended economy with a recursive technological structure, such as the aggregative one-sector model. He was also the first to recognize that the analog of Koopmans' profit conditions for characterizing an efficient program had to be supplemented in an infinite framework. This new terminal condition, the transversality condition (seen in the above discussion of the optimal growth model) was shown to be sufficient for an efficient program satisfying the profit conditions for an appropriate set of shadow prices.

Efficient programs are discussed below for the aggregative one-sector model. A sequence \( \{c_t\} \) satisfying (2) for some capital stock sequence is inefficient if there is an alternative consumption program \( \{c'_t\} \) satisfying (2) for some capital stock sequence that offers at least as much consumption in every period and more consumption in at least one period. A sequence \( \{c_t\} \) satisfying (2) for some capital stock sequence is efficient if it is not inefficient. The efficiency criterion ranks programs as either efficient or inefficient. The planner's objective is to select an efficient program. The efficiency criterion presumes that consumption may never be satiated in any period. An infinite number of efficient programs exists in the discounted Ramsey model – for a fixed, finite, time period \( T \), define a feasible program by consuming nothing for
periods $t = 0, 1, \ldots, T - 1$, and letting the capital stock accumulate according to the difference equation $k_t = f(k_{t-1})$, with $k_0 = 0$. At time $T$, consume the resulting $f(k_{T-1})$ and set $k_T = 0$. For each time after $T$, consume zero and accumulate no capital. Such a path is efficient. Since $T$ is arbitrary, there are infinitely many efficient paths.

Efficient programs providing consumption in every period also exist. One important example is the path found by first solving for the combination of consumption and capital stock which maximizes stationary (or, sustainable) consumption. This problem solves the problem $\max \{ f(x) - x : x \in [0, b] \}$. The solution, denoted $k_s$, satisfies $f'(k_s) = 1$ and called the golden-rule capital stock; the corresponding golden-rule consumption, $c_g$, is defined by the relation $c^g = f(k^g) - k^g$. The interpretation is that if the economy's initial capital stock happens to equal the golden-rule stock, then it is efficient for the planner to choose this stock for all time and maintain the largest possible stationary consumption.

The golden-rule pair $(c^g, k^g)$ has an important relationship to the problem of characterizing efficient programs. The specific result is called the Phelps theorem (see Phelps, 1966, p. 59). It is a sufficient condition for an attainable path to be inefficient. A path $\{c_t, k_t\}$ satisfying (2) also satisfies the Phelps condition if there is an $\varepsilon > 0$ and a natural number $T(\varepsilon)$ such that for all $t \geq T(\varepsilon)$, $k_t \geq k_s + \varepsilon$. The Phelps condition is equivalent to $\liminf_{t \to \infty} k_t > k^g$. Phelps' theorem states that a feasible program satisfying the Phelps condition is inefficient. In particular, the path of pure accumulation found by iterating $k_t = f(k_{t-1})$ for all $t$ with $k_0 = 0$ is inefficient as this program converges to the maximum sustainable capital stock. Any feasible program for which the capital stocks converge to a stock larger than the golden-rule stock is also inefficient.

Note that such a program would have the own rate of return, $f'(k_{t-1}) - 1 < 0$ for all $t$ sufficiently large. In particular, this would imply $\prod_{t=1}^{T} f'(k_{t-1}) \to 0$ as $T \to \infty$. It turns out that this is a general property of inefficient programs, as shown by Cass (1972). Intuitively, these inefficient programs have shadow interest rates, $r_t = f'(k_{t-1}) - 1$ that are negative (no market mechanism is identified in this discussion, so the interpretation of $f'(k_{t-1}) - 1$ is provisionally made as a shadow price). It is reasonable then to presume that programs with positive shadow interest rates for all time are efficient. The precise criterion that is necessary and sufficient to characterize inefficient programs was identified by Cass (1972). He proved his result with additional curvature assumptions on the production function (which restrict the rate of change of capital's marginal product as capital accumulates, or decumulates) as well as assumed $f'(0) < \infty$. His theorem states that a feasible path is inefficient if and only if:

$$\sum_{t=1}^{\infty} \left( \prod_{s=1}^{t} f'(k_{s-1}) \right) < \infty.$$  

Notice that if a path satisfies this Cass condition, then $\prod_{s=1}^{t} f'(k_{s-1}) \to 0$ as $t \to \infty$, which is the Phelps sufficient criterion for inefficiency. Cass interpreted his condition as saying that the term $\prod_{s=1}^{t} f'(k_{s-1})$ goes to zero 'sufficiently fast'. The term $\prod_{s=1}^{t} f'(k_{s-1})$ represents the shadow future value of a marginal
unit of capital in period 0. The Cass criterion's necessity then asserts that for an inefficient program, the future value of a marginal unit of capital at time 0 is bounded from above. This implies that the terms of trade from present to future never become very favorable (Cass, 1972, p. 207). General forms of the Cass criterion for one-sector models are discussed in the survey by Becker and Majumdar (1989) as well as additional applications to overlapping generations models and interpretations of these conditions for decentralized planning mechanisms. The survey by Tirole (1990) focuses on the connection between the Cass criterion for inefficient programs and the potential for the shadow prices associated with efficient programs to exhibit a type of bubble whereby the shadow market price of a unit of capital differs from its present discounted value of future shadow rental returns.

4 Controversies and critiques

Neoclassical capital theory has long been controversial. The famous Cambridge Controversies about whether or not the one-sector neoclassical model's properties were either sensible, or could be generalized, produced a substantial literature. See Birner (2002) for a thorough review of both sides' positions. Earlier references include Harcourt (1972), Bliss (1975), and Burmeister (1980). A few key points are noted here. The debates centred on whether or not there really is something called aggregate capital, whether or not it could be measured independently of the establishment of an equilibrium interest rate, and whether or not an increase in the steady state interest rate necessarily reduced steady state capital.

Bliss (1975) argued that aggregating capital was not more difficult than aggregating any other collection of commodities. It was enough to place a partial order on a vector of capital goods defining one vector of capital goods to be at least as much as another vector. Standard utility function existence theorems would imply the existence of a continuous, real-valued, order preserving functional representation that could be interpreted as an aggregate capital good. Burmeister (1980) gave conditions under which a generalized steady state regularity condition applied to a many capital goods model permitted theorists to construct an aggregate capital stock and aggregate production function with the desired neoclassical properties (at least across steady states). It should also be noted that there are models where there is a natural measure of an aggregate capital stock in physical terms. For example, the capital stock in renewable resource theories such as ones arising in fishery models measures the fish population as a biomass: the mass of living organisms present in a population at a particular point of time. Biomass can be measured as either a weight or as so many calories. Its measurement does not depend on any prices or other quantities that might be established only in an equilibrium. Of course, this is a special situation.

One practical way of arriving at a measure of aggregate capital is to compute its capital value. This can be done by multiplying the prices of the various underlying capital goods times their respective quantities. Presumably, these prices represent these capital goods' discounted future returns (for example, monetary or cash flows). Capitalization of future payments requires an interest rate (or a term structure of interest rates in case the rate of interest varies over time). It follows that capital value cannot be computed independently of the determination of prices. Critics of neoclassical theory stressed this issue. Modern equilibrium models establish the determination of capital goods prices and interest rates in an equilibrium configuration, for both the short and the long runs (this is one task solved by equivalence principles in many capital goods models, when those results are available).

The comparative steady state result for the one-sector neoclassical model is that the steady state capital stock, $k(\delta)$, viewed as a function of the discount (long-run interest) factor $\delta^{-1}$, has the property $dk/d\delta > 0$. 

The famous reswitching controversy attacks the generality of this result. In multi-sectoral models (even with aggregate capital) the choice of steady state production techniques can give rise to a particular capital–labour ratio arising from two different long-run interest rates.

The Cambridge controversies highlight the special features of the one-sector neoclassical theory. Those arguments concentrated on comparing steady states and either ignored or downplayed the role for transitions from one steady state to another in response to an exogenous change in an economy's deep taste or technology parameters. The debate also largely ignored the accumulation programs that flowed from the planner's decision when starting with initial capital other than the steady state level. The more dynamic view of modern capital theorists emphasizes the full dynamic possibilities open to the planner.

The orthodox vision applied to an aggregative economy portrays saving and consumption activities undertaken within the private sector as promoting a path of accumulation tending towards a steady state. When the economy's capital stock is initially smaller than its stationary level there is growth, and the rate of return on capital falls over time. This portrait of capital accumulation is consistent with the dynamics of the one-sector Ramsey optimal growth – perfect foresight equilibrium model provided there is a representative household whose preferences are taken as the planner's objective.

Bliss (1975) criticized the orthodox vision for models with many distinct capital goods as a single rate of interest could not be defined, and therefore the idea that growth accompanied a declining rate of interest made no sense. Subsequent research has shown that, even in aggregate capital Ramsey optimal growth models with a well-defined interest rate, the economy might not follow the orthodox vision provided there were at least two sectors producing a consumption good distinct from the capital good. The problem was that optimal cycles or even chaotic trajectories could emerge with a sufficiently impatient planner (see Boldrin and Woodford, 1990). Heterogeneous discount factor models also turn out to differ fundamentally from the representative agent theory, even in the classical one-sector case. The orthodox vision will only apply to some economies when there are heterogeneous discount factors.

The Cambridge controversy focuses on the difficulties of aggregating different types of capital and consumption goods. There are also difficulties inherent in interpreting results obtained for representative agent economies. The failure of the orthodox vision noted above is one such example. There is another, perhaps more fundamental, criticism of representative agent-based capital theories. The conditions under which the many different individuals populating a model economy's preferences might be aggregated so that the economic theorist can study the model as if there is a single, stand-in, representative agent are so restrictive as to make conclusions drawn from single agent models flawed on logical grounds alone. See Hartley (1997) for a detailed discussion of the representative agent controversy.

The idea of a representative agent economy such as the Ramsey model is that the aggregate activity in the economy generated by many different consuming and producing actors can be understood as the activity of a single entity, the representative agent, which acts exactly like each of the consuming and producing actors. By studying the microeconomic behaviour of those individuals we can also find the behaviour of the representative agent, and vice versa. However, the argument is made that, even if the microfoundations of each agent are well understood, it does not follow that their aggregate behaviour is explained by the representative agent that behaves exactly like them. Micro-behaviour need not translate into macro-behaviour of the same type. For example, the representative agent Ramsey model's capital monotonicity property holds up in the welfare optimum version of the many agent theory when agents have the same discount factors, but different one-period utility functions and possibly different initial capital stocks. The planner whose preferences are represented by the welfare function (11) does not give rise to the exact same behaviour as that of each of the individual agents' preferences underlying it – individual consumption
sequences differ from the aggregate, although they behave qualitatively the same (for example, they are monotonic). This distinction is even more pronounced in case agents also have different discount factors – the impatient agents' consumption tends to zero while the most patient one's consumption remains positive for all time. The aggregate consumption evolves over time in a very different manner from that of individual consumption streams.

5 Capital theory with many sectors and capital goods

Controversies surrounding the neoclassical capital theory of the one-sector model are partly attenuated by studying models with many sectors and types of capital goods. This general form of the theory emphasizes a disaggregated viewpoint, although it also applies to aggregative models. It should also be noted that specifying a multisector model need not be the same as formulating a many capital good model. There are two-sector models with aggregative capital and single-sector models with joint production of many distinct capital and consumption goods.

5.1 Pricing and the portfolio equilibrium condition

The major conceptual difference between the one-sector and multisector perfect foresight equilibrium models lies in the form taken by the no-arbitrage condition. This is readily seen in the two-sector model. Suppose there are two sectors consisting of a consumption goods sector and a capital goods sector. The capital and consumption goods are aggregate commodities, as in the one-sector model, but are conceived as distinct goods in the two-sector framework. Suppose that $i_{t+1}$ is the one-period interest rate measured in units of a numeraire commodity, $r_{t+1}$ is the rental rate on a unit of capital measured in the numeraire's units, and $q_{t+1}$ is the unit purchase price for a unit of capital as measured in the numeraire's units. Suppose that the purchase of a unit of capital at time $t$ entitles its owner to receive the rental flows from the next period on as long as the unit remains in service. Assume further that capital does not depreciate. One requirement for a perfect foresight equilibrium is that there are no one-period reversed arbitrage opportunities. Let an equilibrium path obtain with the prices $\{i_{t+1}, r_{t+1}, q_{t+1}\}$. Suppose the household decision maker acquires another unit of capital at time $t$. This costs the household $q_t$ units of the numeraire. The opportunity cost of this action in the numeraire's units is $i_{t+1}q_t$, the interest charge that could have been earned otherwise. To reverse this capital acquisition at time $t+1$ the household will sell that unit of capital for $q_{t+1}$ units of the numeraire. This gives the capital gain (loss) equal to $q_{t+1} - q_t$. The household also gets to keep the one-period rental, $r_{t+1}$. This one-period reversed arbitrage is unprofitable if the marginal revenue equals the marginal cost reckoned in units of the numeraire. That is,

$$i_{t+1}q_t = r_{t+1} + q_{t+1} - q_t.$$  

(14)

This equation reflects the absence of arbitrage opportunities in a perfect foresight competitive equilibrium.
This perfect foresight equation is also called the portfolio equilibrium condition because it expresses the absence of arbitrage opportunities in the manner in which the agent's wealth is held. Rearranging this equation yields

\[
i_{t+1} = \frac{r_{t+1}}{q_t} + \frac{q_{t+1} - q_t}{q_t},
\]

which says that the one-period interest rate, \(i_{t+1}\), equals the capital good's own rate of return, \(r_{t+1}/q_t\), plus the capital gain yield, \((q_{t+1}-q_t)/q_t\).

Note that \(q_t=1\) holds in the one-sector model. This is the price of the consumption good in units of the numeraire commodity (chosen to be current consumption) since the capital and consumption goods are identical. Hence, there is no capital gain yield in that case and

\[
i_{t+1} = r_{t+1}.
\]

The interest rate equals the rental rate for capital goods. Thus, even if there is a single capital good, the portfolio equilibrium condition differs when the one-sector and two-sector models are compared.

Next, consider an aggregate model with an exhaustible resource. Suppose there are neither extraction nor storage costs. The aggregate capital stock at the end of time period \(t\) that is available for consumption at time \(t+1\) is denoted by \(k_t\) and is interpreted as the amount of the resource remaining at the end of time \(t\). Consumption at time \(t\), \(c_t\), represents a withdrawal from the stock \(k_{t-1}\). Then the materials balance condition is \(c_t+k_t=k_{t-1}\). The initial size of the resource stock is \(k\). There is no rental return in this model; the resource owner's returns are entirely capital gain yields. The perfect foresight equation takes the form

\[
i_{t+1} = \frac{q_{t+1} - q_t}{q_t}.
\]

If the rate of interest is a constant: \(i_{t+1}=r>0\), then (17) is a linear difference equation with solution \(q_{t+1}=(1+r)q_0\), where \(q_0\) is the resource's initial price. This implies Hotelling's \(r\)-per cent rule (Hotelling, 1931) holds in a perfect foresight equilibrium – the equilibrium (current) price of the resource, \(q_t\), increases over time at rate of interest, \(r\).
In models with several distinct capital goods the portfolio equilibrium condition applies to each capital
good separately. If there are $m$ capital goods, then the portfolio equilibrium condition takes the form:

$$i_{t+1}^j = \frac{r_{t+1}^j}{q_t^j} + \frac{q_{t+1}^j - q_t^j}{q_t^j}, \text{ for } j = 1, 2, \ldots, m.$$  

(18)

Here, the superscript $j$ labels capital good $j$. With many capital goods households have a variety of options
for holding their wealth. The rates of return on any portfolio of capital stocks must be equalized or there
will be a one-period reversed arbitrage opportunity. Hence, eq. (18) is the equilibrium condition expressing
the absence of such arbitrage opportunities.

The major pricing differences between the one-sector and multisector models concern the form of the
portfolio equilibrium condition. It is possible to develop equivalence principles for multisector models
along the lines of the one-sector theory by making appropriate adjustments in the pricing of capital goods to
reflect their multiplicity in the budget constraints and production sector while also recognizing the portfolio
equilibrium form of the no-arbitrage conditions in the PFCE and FCE settings.

Establishing the formal equivalence between optimal accumulation models and their equilibrium
counterparts in many capital good models requires the equilibrium economy to impose a transversality
condition on itself, just as in the one-sector case. The general question is how is the initial price determined
so that the equilibrium price profile satisfies the conditions for achievement of a Ramsey-styled central
planning solution. This is the crux of the *Hahn problem*. The modern perfect foresight interpretation is that
this problem is solved whenever a transversality condition obtains as necessary for an equilibrium. This
requires the household sector to be forward looking over the infinite horizon, and markets to operate on all
dates and for all commodities. Some writers on capital theory take a critical view of these conditions and
argue that markets cannot be relied on to set the correct initial prices, and so the resulting equilibrium path
is inefficient. On the other hand, a comparison of idealized markets with idealized planning, as embodied in
the equivalence principles, suggests that at the most theoretical level the Hahn problem is resolved when
rational, forward-looking agents conduct their economic activities in a complete market setting over an
infinite horizon.

### Final comments

The constraints of the neoclassical one-sector model can be used to substitute for consumption in the
felicity function by noting $u(c_t) = u(f(k_{t-1}) - k_t)$, where $c_t \geq 0$ if and only if $f(k_{t-1}) - k_t \geq 0$. The
current period's payoff depends only on the stocks of capital at the beginning and end of the period. This
observation results in a reformulation of the one-sector model focused on the capital stock sequences. Let $u(0)=0$ to simplify the exposition. Let $D = \{(x, y) \in \mathbb{R}_+ \times \mathbb{R}_+ : f(x) - y \geq 0\}$. Note that $(0,0) \in D$. The
felicity function $v(x, y) = u(f(k_{t-1}) - k_t)$ has domain $D$ and $v(0,0)=0$. The properties of $u$ and $f$ imply
that $v$ is increasing in its first argument and decreasing in its second argument. The concavity of $u$ and $f$ also
imply that \( v \) is a concave function defined on the convex set \( D \). The planner continues to discount future utility by the factor \( \delta \), \( 0 < \delta < 1 \). This alternative representation of the neoclassical model, called the *reduced form model*, gives rise to an optimal growth problem with the planner choosing the sequence \( \{k_t\}_{t=0}^{\infty} \) to achieve

\[
\sup_{\{k_t\}_{t=0}^{\infty}} \sum_{t=1}^{\infty} \delta^{t-1} v(k_{t-1}, k_t); \quad (k_{t-1}, k_t) \in D \text{ for each } t, \text{ and } 0 \leq k_0 \leq k.
\]

(19)

This form of the one-sector model is just one realization of the general reduced form model. A complete exposition of this general structure's properties is found in McKenzie's surveys. The reduced form model can accommodate many varieties of capital theoretic problems including multisector and multi-capital good models, von Neumann's model of economic growth, exhaustible and renewable resource models, as well as individual firm investment theory when there are costs of adjusting the firm's capital stocks. The capital stocks of the one-sector model are replaced by a vector of capital stocks where each component represents a particular capital good; the set \( D \) is then contained in a multi-dimensional Euclidean space. Schefold (1997) is a recent treatment of multisector models derived from Sraffa's (1960) perspective on capital accumulation models that also revisits the reswitching controversy in a dynamic equilibrium setting. Also see Burmeister (1980) for a critical exposition of Sraffa's contribution. Burgstaller (1995) reviews models from the Sraffa tradition as well as neoclassical models in continuous time in order to find their common ground and connections to earlier capital theories.

Article
Capital utilization is given different interpretations in the economic literature. If a machine is available for use during, say, a day, then various levels of utilization can be obtained by varying the duration of operations within the day. For any fixed duration within the day, however, it is also possible to vary the machine's rate of utilization by varying its speed. In each case there is variation in capital utilization, but both physical and economic characteristics differ widely in the two cases. Moreover, even with duration and speed constant within the day, some writers define variations in capacity utilization via variations in
the variable inputs employed with a given machine per day relative to some maximum or optimum daily output. Unfortunately, these as well as other writers frequently use the terms ‘capital utilization’ and ‘capacity utilization’ interchangeably.

The discussion here will focus on the analysis of variations in the duration of operations. A brief historical perspective sets the stage for a presentation of modern theory and applications, including links to the issues of speed and capacity. A succinct conclusion provides implications for closely related economic issues.

**Historical perspective**

Concern with the duration of operations dates to the late 18th century and the spread of the factory system in England. Early writing emphasized the appropriate length of the working day relative to its social consequence for workers and its economic consequence for capitalists. Positions on these issues were developed in the context of debates over the various Factory Acts in England. These discussions usually assumed the length of the working day to be the same for capital and labour.

Marx provides a most interesting example of the development of economic thinking on duration up to his time. The length of the working day is given substantial attention in his work (1867, ch. 10); indeed, it provides the cornerstone for his theory of exploitation (see, for example, Morishima, 1973, ch. 5); yet Marx pays only minor attention to the separation of capital's work day from labour's work day which is at the centre of modern analysis.

Marshall, like his predecessors, was interested in duration because of its implications for the well-being of workers and the viability of the economic system. But he saw the separation of the work day of labour from the work day of capital inherent in shift-work systems as an opportunity for resolving the conflicting interests of workers and capitalists with respect to the length of the work day. Thus he becomes an advocate of the adoption of multiple shifts early in his professional career (1873) and maintained his interest in the topic throughout his career (see, for example, 1923, p. 650).

Marshall's emphasis became the basis for the work of Robin Marris (1964), who treats capital utilization as a synonym for shift-work. Interestingly enough, the other modern pioneer, Georgescu-Roegen (for example, 1972), stresses the choice of the daily duration of operations, acknowledges Marx's emphasis on the topic, but overlooks Marshall as well as Marris. Both view the choice of duration at the plant level, either directly or through the selection of a shift-work system, as a long-run or ex ante decision, that is, before the plant is built. Moreover, both assume the ex post elasticity of substitution to be zero, that is, within the day no variations in choice of technique are allowed once the factory is built.

However, while Marris uses discrete techniques of production and discrete systems of utilization to describe the structure of the firm's optimization problem, Georgescu-Roegen uses a continuous production function and a continuous index of the daily duration of operations; these differences of method do not generate substantial differences in results.

Both economists use their analyses to argue against anachronistic social legislation and draw implications from their work for an important contemporary economic problem, namely, the improvement of economic conditions in developing countries.

Before presenting the modern theory and its applications it is useful to note a few salient facts. Thanks to Foss's efforts (1981) there are reliable estimates of the average workweek of capital (plant hours) in US
manufacturing for 1929 and 1976 – 67 and 82 hours, respectively. These estimates can be compared to an average workweek for labour of 50 hours in 1929 and 40 hours in 1976. Furthermore, Foss views the rise in capital's workweek between 1929 and 1976 as an underestimate of the increase in shift-work, because of the decrease in the number of days worked per week during this same period. The most thorough update of this data work is Beaulieu and Mattey (1998). It generates an average workweek of capital for manufacturing during the period 1974–92 of 97 hours per week. These ‘facts’ underlie interest in the topic and the frequent identification of capital utilization with shift-work.

Modern theory and applications

A number of contributions have incorporated the choice of duration into the neoclassical theory of the firm. This work is most concisely exposited using a model which relies on duality theory to generate the main results available in this literature (see Betancourt, 1986).

The firm's optimization problem is viewed as a two-stage procedure. In the first stage the decision-maker generates a cost function for each given level of duration; in the second stage the decision-maker selects from these cost functions that one which leads to least total cost. The end result in the two-input case is:

\[
C^* = dC(w^*, r^*, x^*).
\]

For a given reference unit of duration, \(w^*\) represents the average wage rate, \(r^*\) the price of capital services, \(x^*\) the level of output, while \(d\) represents an index of duration of operations, \(C\) is a classical cost function, and \(C^*\) represents the total cost of operations at the optimal level of duration.

For example, if an eight-hour shift starting during normal hours is the reference unit of duration, as duration increases beyond this reference period: the average wage rate (\(w^*\)) increases because of shift differentials due to workers' preferences for normal hours or social legislation; and the price of capital services per eight-hour shift decreases, although there will be two opposite tendencies in this case. The daily price of a unit of capital increases due to the additional wear and tear created by the longer duration, but this price is now spread over a greater number of hours, and the price of capital services per eight-hour shift (\(r^*\)) decreases. Betancourt and Clague (1981, ch. 2, sect. 2) provide a detailed discussion of why the second effect predominates. Finally, as duration increases, the same daily output is spread over a greater number of hours, and the level of output per eight-hour shift (\(x^*\)) decreases.

The formulation in (1) yields the main insights about capital utilization or shift-work at the plant level offered by the early literature that followed Georgescu- Roegen and Marris. A brief listing of these results is as follows: (i) high shift differentials or overtime rates discourage capital utilization by increasing \(w^*\); (ii) technologies with high degrees of returns to scale discourage utilization by raising the costs of operating at low levels of output (\(x^*\)); (iii) technologies with high degrees of capital intensity encourage capital utilization because the consequent fall in the relevant cost of capital (\(r^*\)) affects a
higher percentage of costs; and (iv) technologies with abundant *ex ante* substitution possibilities encourage utilization because they lower the costs of taking advantage of the consequent fall in the cost of capital ($r^*$) through the building of a more capital intensive factory. These four factors are the main long-run determinants of optimal duration on the cost side.

In addition, two other characteristics of the utilization decision are worth stating. First, factories built to operate at high levels of utilization will be designed to use capital-intensive techniques. Second, how exogenous changes in input costs affect duration depends critically on the *ex ante* elasticity of substitution. For instance, if this elasticity is greater than unity, under constant returns to scale an exogenous fall in the price of capital lowers the costs of building the plant to operate longer hours.

One application of the model is as the theoretical basis for empirical studies of the choice of duration at the plant level. The model's implications were consistent with several different bodies of plant level data (see Betancourt and Clague, 1981, chs 4–8) across non-continuous process industries. Recent work using more detailed plant level data for specific industries, for example automobiles, confirms the role of the number of shifts as a long-run margin of adjustment and it stresses the importance of changes in duration through overtime and daily closings as short-run margins of adjustment in the United States (Bresnahan and Ramey, 1994). Detailed studies of the auto industry for Europe and Japan (Anxo et al., 1995, chs 12 and 13, respectively) are also consistent with this long-run role for the number of shifts.

Mayshar and Halevy (1997) develop a model that allows for *ex post* substitution possibilities as a short-run margin of adjustment. The above studies imply that there is a choice of duration, even in the short run, but in some industries continuous processes dominate and the choice is really to operate or not operate the process. A major extension of the model that captures this feature is provided by Das (1992), who develops and estimates a discrete dynamic programming model for the cement industry at the kiln level. In this context a plant is basically an additive collection of kilns and Das allows for three decisions, namely, operate, retire or keep idle a kiln in any plant.

Alternative approaches to the non-convexities that arise at the plant level have been developed by looking at the industry as the unit of analysis. Prucha and Nadiri (1996) provide an insightful and sophisticated example of this option applied to the US electrical machinery industry by making endogenous the capital utilization decision in the context of dynamic factor demand models. In a similar industry setting, Cardelllichio (1990) uses the assumption of Leontief production functions at the mill level to analyse utilization for the lumber industry as a whole.

From a theoretical perspective an application of the model in (1) has been as the basis for the choice of duration in standard two-sector general equilibrium models. In the context of the international trade literature, Betancourt, Clague and Panagariya (1985), for example, use the specific-factors model with variable utilization to reconcile the dual scarcity explanation of Anglo-American trade in the 19th century with the empirical evidence on observed utilization levels. In the context of the public finance literature Coates (1991) generalizes the standard analysis of the incidence of the corporate profits tax by allowing for variable utilization. He concludes that overestimates of the burden of the tax in the order of 10–60 per cent are most probable as a result of ignoring this long-run margin of adjustment in a general equilibrium context. A more abstract general equilibrium approach allowing for firm's decisions over duration and starting times as well as for worker's preferences over these work schedules has been developed recently by Garcia Sanchez and Vazquez Mendez (2005). Its main substantive result replicates one partial equilibrium result noted above, namely, that high capital intensity in the form of a
high capital–labour ratio leads to an increase in utilization.
A short-run perspective has played an important role in dramatizing the policy implications of high levels of utilization for employment and output, since in this perspective a doubling of utilization implies a doubling of employment and output. Nevertheless a long-run perspective (see Betancourt and Clague, 1981, chs 9–11) provides a far less optimistic view about the likelihood of these outcomes. Ironically the evaluation of a shorter workweek for labour in Europe, which is analytically similar, has been carried out primarily from a short-run perspective (for example, Anxo et al, 1995, ch. 14). Garcia Sanchez and Vazquez Mendez (2005), however, suggest this topic as one for potential application of their long-run model.

Related issues: speed and capacity

The relations between duration, speed and capacity are difficult to analyse and provide an opportunity for confusion. To start, consider a dual representation of the cost function in (1). Namely,

\[ x = dF(K, L) \]  
\[ (2) \]

where \( x \) is the level of daily output, that is, \( x=dx^*=dF \); \( F \) is a neoclassical production function defined over the reference period of duration; \( K \) represents both the level of the capital stock employed and the rate of capital services, which implies that the speed of operations \( (v) \) is constant and set at unity; and \( L \) represents labour services per reference period of duration. Alternatively, those who analyse variations in utilization through choice of speed represent the productive process as follows:

\[ x = F(vK, L) \]  
\[ (3) \]

where all variables have been previously defined. In (3) duration is set at unity.
Writers who employ (3) assume that the price of the capital stock is an increasing function of speed or utilization (for example, Smith, 1970). Since costs are defined as
\[ C=r(v)K+wL, \]  
where \( r' (v)>0 \), the cost of a unit of capital services obtained by increasing speed is an increasing function of \( v \). While in the duration model the price of the capital stock \( r(d) \) is an increasing function of duration \( (r' (d)>0) \), the cost of a unit of capital services obtained by increasing duration is a decreasing function of duration, that is, \( r^*=r (d)/d \) and \( r'' (d)<0 \). This difference implies that models with one utilization variable to describe the productive process can generate nonsensical economic results if this variable is interpreted as representing either duration or speed, because the behaviour of
costs can represent only one of the two interpretations. To illustrate, a recent body of literature relates capital utilization, economic growth and the speed of convergence (for example, Chatterjee, 2005), by assuming depreciation to increase with utilization at an increasing rate. This makes sense if one justifies increases in utilization as a result of increases in speed. Yet this literature justifies increases in utilization as a result of increases in duration through increases in the average workweek of capital.

Another interesting feature of the ‘speed’ model stems from the first-order conditions for cost minimization, which can be used to show that, if \( v, K \) and \( L \) are treated as choice variables, at the optimum, \( r(v) = r'(v)v \). When duration and speed are endogenous this characteristic generalizes to \( r(v, d) = r_v(v, d) v \) and optimal speed is determined by optimal duration (Madan, 1987). This is consistent with the finding by Bresnahan and Ramey (1994) for the auto industry that line speed and the number of shifts are long-run margins of adjustment.

Consider now the representation of the productive process underlying the typical definitions of capacity utilization. Namely,

\[
\dot{x} = F(K, L)
\]

where all variables are defined as before and speed and duration set at unity. Using (4), Panzar’s (1976) definition of capacity becomes:

\[
h(K) = \max \frac{F(K, L)}{L}
\]

where \( h(K) \) is an increasing function of \( K \). This definition leads to an output-based definition of short-run capacity utilization; that is:

\[
CU = \frac{x}{x_{\text{max}}}
\]

where \( x_{\text{max}} \) is given by (5).

When capital equipment is capacity-rated in terms of output units, as in electricity generation, one can measure directly the denominator of (6) and short-run capital and capacity utilization coincide (cf. Winston, 1982, ch. 5). In general, however, the denominator in (6) is not well defined. An alternative
procedure is to define the denominator in (6) as the optimal level of output, $x^0$. For instance, in the literature on dynamic factor demand models $x^0$ is defined as the optimal level of output when the capital stock is endogenous (for example, Morrison, 1985; also see Prucha and Nadiri, 1996, for a generalization). Since ‘optimal’ output varies with the specification of the optimization problem, one can generate a variety of reasonable definitions of capacity utilization which measure different concepts. Not surprisingly, the corresponding empirical definitions fail to move together (de Leeuw, 1979) or with the average workweek of capital (Beaulieu and Mattey, 1998).

**Implications**

Perhaps the most important economic implication of the analysis of capital utilization above is for our understanding of technical change at the aggregate level. Ignoring increases in duration understates the contribution of capital services to output growth and, thus, overstates the estimates of technical change or the Solow residual in standard sources of growth analysis. Beaulieu and Mattey's estimate of the annual rate of growth in the average workweek of capital for manufacturing over the 1974–91 period is 0.17. They use employment per shift as weights, which are the appropriate ones, and find that only 25 per cent of the variation in growth can be accounted for by overtime.

Macroeconomists have pursued this issue but emphasized its business cycle implications. That is, when the Solow residual is adjusted for the workweek of capital it ceases to be pro-cyclical. For instance, Shapiro (1993) made this point in a widely cited paper. His results continued to hold in Beaulieu and Mattey’s more recent data and they have given rise to a substantial literature that we will not explore here. One implication of this finding noted by Shapiro is that it casts doubts on alternative explanations of the behaviour of the residual stressing market power when there are substantial costs to adjusting the workweek of capital, for example through the shift differential.

There is an early literature on the human costs of shift-work which may be captured through the shift differential. Betancourt and Clague (1981, ch. 12) conclude from their review of this literature that observed shift differentials of four to five per cent in the United States substantially underestimate the human costs of shift-work. This conclusion is consistent with estimates in an unpublished paper by Shapiro (1995) that the marginal shift premium is 25 per cent. A strand of literature in labour economics on compensating differentials has considered shift-work. Kostiuk (1990) obtains estimates of the shift differential of well above ten per cent in the unionized sector for both 1979 and 1985. He relies on Census of Population Survey data for his analysis.

An issue neglected in the recent literature is the role of obsolescence in capital utilization. Marris (1964) argued that an increase in the rate of obsolescence should strengthen the economic incentive for shift-work, since it ameliorated disincentive effects of wear and tear depreciation. In the last few decades we have observed systematic shifts from mechanical technologies to electronic technologies, which diminish wear and tear costs and increase the rate of obsolescence. This shift should, thus, have provided an incentive for increased capital utilization. Yet, to my knowledge, the economic literature has not addressed this issue explicitly.

Finally, an important reason for interest in capital utilization as an economic variable is the existence of transaction costs and market imperfections. These frictions make ownership of capital equipment and structures attractive relative to rentals for instantaneous capital services. Of course these rental markets
do not exist in most cases. A substantial recent literature in industrial organization investigates the effect of transaction costs, including incompleteness of contracts and agency costs, on incentives and the evolution of institutions. With one exception, it has not addressed the impact of changes in transaction costs and market imperfections on capital utilization. The exception is the work of Hubbard (2003) on the trucking industry. He shows that improvements in monitoring technology in the form of on board computers increase capacity utilization, which in this industry coincides with short-run capital utilization just as in the electricity generation industry. Issues of long-run capital utilization and relevance for other industries, however, remain unexplored in this context.

Capitalism is a unique historical formation with core institutions and distinct movements. It involves the rise of a mercantile class, the separation of production from the state, and a mentality of rational calculation. Its characteristic logic revolving around the accumulation of capital reflects the omnipresence of competition. It displays broad tendencies to unprecedented wealth creation, skewed size distributions of enterprise, large public sectors, and cycles of activity. Whereas students of capitalism traditionally envisaged an end to the capitalist period of history, modern economists show little interest in historical projection.

Article

Capitalism is often called market society by economists, and the free enterprise system by business and government spokesmen. But these terms, which emphasize certain economic or political characteristics, do not suffice to describe either the complexity or the crucial identificatory elements of the system. Capitalism is better viewed as a historical ‘formation’, distinguishable from formations that have preceded it, or that today parallel it, both by a core of central institutions and by the motion these institutions impart to the whole. Although capitalism assumes a wide variety of appearances from period
to period and place to place – one need only compare Dickensian England and 20th-century Sweden or Japan – these core institutions and distinctive movements are discoverable in all of them, and allow us to speak of capitalism as a historical entity, comparable to ancient imperial kingdoms or to the feudal system.

The most widely acknowledged achievement of capitalist societies is their capacity to amass wealth on an unprecedented scale, a capacity to which Marx and Engels paid unstinting tribute in *The Communist Manifesto*. It is important to understand, however, that the wealth amassed by capitalism differs in quality as well as quantity from that accumulated in precapitalist societies. Many ancient kingdoms, such as Egypt, displayed remarkable capacities to gather a surplus of production above that needed for the maintenance of the existing level of material life, applying the surplus to the creation of massive religious or public monuments, military works or luxury consumption. What is characteristic of these forms of wealth is that their desirable attributes lay in the specific use-values – war, worship, adornment – to which their physical embodiments directly gave rise. By way of decisive contrast, the wealth amassed under capitalism is valued not for its specific use-values but for its generalized exchange-value. Wealth under capitalism is therefore typically accumulated as commodities – objects produced for sale rather than for direct use or enjoyment by their owners; and the extraordinary success of capitalism in amassing wealth means that the production of commodities makes possible a far greater expansion of wealth than its accumulation as use-values for the rulers of earlier historical formations.

Both Smith and Marx stressed the importance of the expansion of the commodity form of wealth. For example, Smith considered labour to be ‘productive’ only if it created goods whose sale could replenish and enlarge the national fund of capital, not when its product was intrinsically useful or meritorious. In the same fashion, Marx described the accumulation of wealth under capitalism as a circuit in which money capital (M) was exchanged for commodities (C), to be sold for a larger money sum (M′), in a never-ending metamorphosis of M–C–M′.

Although the dynamics of the M–C–M′ process vary greatly depending on whether the commodities are trading goods or labour power and fixed capital equipment, the presence of this imperious internal circuit of capital constitutes a prime identificatory element for capitalism as a historical genus. As such, it focuses attention on two important aspects of capitalism. One of these concerns the motives that impel capitalists on their insatiable pursuit. For modern economists the answer to this question lies in ‘utility maximization’, an answer that generally refers to the same presumed attribute of human nature as that which Smith called the ‘desire of bettering our condition’. The unappeasable character of the expansive drive for capital suggests, however, that its roots lie not so much in these conscious motivations as in the gratification of unconscious drives, specifically the universal infantile need for affect and experience of frustrated aggression. Such needs and drives surface in all societies as the desires for prestige and for personal domination. From this point of view, capitalism appears not merely as an ‘economic system’ knit by the appeals of mutually advantageous exchange, but as a larger cultural setting in which the pursuit of wealth fulfils the same unconscious purposes as did the pursuit of military glory or the celebration of personal majesty in earlier epochs. Such a description conveys the force of the ‘animal spirits’ (as Keynes referred to them) that both set into motion, and are appeased by, the M–C–M′ circuit. (Heilbroner, 1985, ch. 2; Sagan, 1985, chs 5, 6).

A second general question raised by the centrality of the M–C–M′ circuit concerns the manner in which the process of capital accumulation organizes and disciplines the social activity that surrounds it. Here analysis focuses on the institutions necessary for the circuit to be maintained. The crucial capitalist
institution is generally agreed to be private property in the means of production (not in personal chattels, which is found in all societies). The ability of private property to organize and discipline social activity does not however lie, as is often supposed, in the right of its owners to do with their property whatever they want. Such a dangerous social licence has never existed. It inheres, rather, in the right accorded its owners to withhold their property from the use of society if they so wish.

This negative form of power contrasts sharply with that of the privileged elites in precapitalist social formations. In these imperial kingdoms or feudal holdings, disciplinary power is exercised by the direct use or display of coercive force, so that the bailiff or the seneschal are the agencies through which economic order is directly obtained. The social power of capital is of a different kind – a power of refusal, not of assertion. The capitalist may deny others access to his resources, but he may not force them to work with them. Clearly, such power requires circumstances that make the withholding of access an act of critical consequence. These circumstances can only arise if the general populace is unable to secure a living unless it can gain access to privately owned resources or wealth. Capital thus becomes an instrument of power because its owners can establish claims on output as their *quid pro quo* for permitting access to their property.

Access to property is normally attained by the relationship of ‘employment’ under which a labourer enters into a contract with an owner of capital, usually selling a fixed number of working hours in exchange for a fixed wage payment. At the conclusion of this ‘wage-labour’ contract both parties are quit of further obligation to one another, *and the product of the contractual labour becomes* the property of the employer. From this product the employer will pay out his wage obligations and compensate his other suppliers, retaining as a profit any residual that remains.

In detail, forms of profit vary widely, and not all forms are specific to capitalism – trading gains, for example, long predate its rise. Explanations of profit vary as a consequence, but as a general case it can be said that all profits depend ultimately on inequality of economic position. When the inequality arises from wide disparities of knowledge or access to alternative supplies, profits typically emerge as the mercantile gains that were so important in the eyes of medieval commentators, or as the depredations of monopolistic companies against which Adam Smith inveighed. When the inequality stems from differentials in the productivity of resources or productive capability we have the quasi-rents to which such otherwise different observers as Marshall and Schumpeter attribute the source of capitalist gain.

And when the inequality is located in the market relationship between employer and worker it appears as the surplus value central to Marxian and, under a different vocabulary, to classical political economy. As Smith put it, ‘Many a workman could not subsist a week, few could subsist a month, and scarce any a year without employment. In the long-run the workman may be as necessary to his master as his master is to him; but the need is not so immediate’ (Smith [1776] 1976, p. 84).

This is not the place to enter into a discussion of these forms of profit, all which can be discerned in modern capitalist society. What is of the essence under capitalism is that gains from whatever origin are assigned to the owners of capital, not to workers, managers or government officials. This is a clear indication both of the difference of capitalism from, and its resemblance to earlier social formations. The difference is that product itself now flows to owners of property who have already remunerated its producers, not to its producers – usually peasants in precapitalist societies – who must then ‘remunerate’ their lords. The resemblance is that both arrangements channel a social surplus into the hands of a superior class, a fact that again reveals the nature of capitalism as a system of social domination, not merely of rational exchange.
Thus we can see that the successful completion of the circuit of accumulation represents a political as well as an economic challenge. The attainment of profit is necessary for the continuance of capitalism not alone because it replenishes the wherewithal of each individual capitalist (or firm) but because it also demonstrates the continuing validity and vitality of the principle of $M - C - M'$ as the basis on which the formation can be structured. Profit is for capitalism what victory is for a regime organized on military principles, or an increase in the number of adherents for one built on a proselytizing religion.

The evolution of capitalism

Capitalism as a ‘regime’ whose organizing principle is the ceaseless accumulation of capital cannot be understood without some appreciation of the historic changes that bring about its appearance. In this complicated narrative it is useful to distinguish three major themes. The first concerns the transfer of the organization and control of production from the imperial and aristocratic strata of precapitalist states into the hands of mercantile elements. This momentous change originates in the political rubble that followed the fall of the Roman empire. There merchant traders established trading niches that gradually became loci of strategic influence, so that a merchantdom very much at the mercy of feudal lords in the 9th and 10th centuries became by the 12th and 13th centuries an estate with a considerable measure of political influence and social status. The feudal lord continued to oversee the production of the peasantry on his manorial estate, but the merchant, and his descendant the guild master, were organizers of production in the towns, of trade between the towns and of finance for the feudal aristocracy itself.

The transformation of a merchant estate into a capitalist class capable of imagining itself as a political and not just an economic force required centuries to complete and was not, in fact legitimated until the English revolution of the 17th and the French revolution of the 18th centuries. The elements making for this revolutionary transformation can only be alluded to here in passing. A central factor was the gradual remonetization of medieval European life that accompanied its political reconstitution. The replacement of feudal social relationships, mediated through custom and tradition, by market relationships knit by exchange worked steadily to improve the wealth and social importance of the merchant against the aristocrat. This enhancement was accelerated by many related developments – the inflationary consequence of the importation of Spanish gold in the 16th century, which further undermined the rentier position of feudal lords; the steady stream of runaway serfs who left the land for the precarious freedom of the towns and cities, placing further economic pressure on their former masters; the growth of national power that encouraged alliances between monarchs and merchants for their mutual advantage; and yet other social changes (see Pirenne, 1936; Hilton, 1978).

The overall transfer of power from aristocratic to bourgeois auspices is often subsumed under the theme of the rise of market society; that is, as the increasingly economic organization of production and distribution through purchase and sale rather than by command or tradition. This economic revolution, from which emerge the ‘factors of production’ that characterize market society, must however be understood as the end product of a political convulsion in which one social order is destroyed to make way for a new one. Thus the creation of a propertyless waged labour force – the prerequisite for the appearance of labour-power as a commodity that would become enmeshed in the $M - C - M'$ circuit – is a disruptive social change that begins in England in the late 16th century with the dispossession of peasant occupants from communal land and does not run its course until well into the 19th century. In similar fashion, the transformation of feudal manors from centres of social and juridical life into real
capitalism: The New Palgrave Dictionary of Economics

estate, or the destruction of the protected guilds before the unconstrained expansion of nascent capitalist enterprises, embody wrenching socio-political dislocations, not merely the smooth diffusion of pre-existing economic relations throughout society. It is such painful rearrangements of power and status that underlay the ‘great transformation’ out of which capitalist market relationships finally arise (Polanyi, 1957, Part II).

A second theme in the historical evolution of capital emphasizes a related but distinct aspect of political change. Here the main emphasis lies not so much in the functional organization of production as in the separation of a traditionally seamless web of rulership, extending over all activities within the historical formation, into two realms, each concerned with a differentiated part of the whole. One of these realms involved the exercise of the traditional political tasks of rulership – mainly the formation and enforcement of law and the declaration and conduct of war. These undertakings continued to be entrusted to the existing state apparatus which retained (or regained) the monopoly of legal violence and remained the centre of authority and ceremony. The other realm was limited to the production and distribution of goods and services; that is, to the direction of the material affairs of society, from the marshalling of the workforce to the amassing and use of the social surplus. In the fulfilment of this task, the second realm also extended its reach beyond the boundaries of the territorial state, insofar as commodities were sold to and procured from outlying regions and countries that became enmeshed in the circuit of capital.

The formation of these two realms was of epoch-making importance for the constitution of capitalism. The creation of a broad sphere of social activity from which the exercise of traditional command was excluded bestowed on capitalism another unmistakable badge of historic specificity; namely, the creation of an ‘economy’, a semi-independent state within a state and also extending beyond its borders. This in turn brought two remarkable consequences. One of these was the establishment of a political agenda unique to capitalism, in which the relationship of the two realms became a central question around which political discussion revolved, and indeed continues to revolve. In this discussion the overarching unity and mutual dependency of the two realms tends to be overlooked. The organization of production is generally regarded as a wholly ‘economic’ activity, ignoring the political function performed by the wage–labour relationship in disciplining the workforce in lieu of bailiffs and seneschals. In like fashion, the discharge of political authority is regarded as essentially separable from the operation of the economic realm, ignoring the provision of the legal, military and material contributions without which the private sphere could not function properly or even exist. In this way, the presence of two realms, each responsible for part of the activities necessary for the maintenance of the social formation, not only gives to capitalism a structure entirely different from that of any precapitalist society but also establishes the basis for a problem that uniquely preoccupies capitalism; namely, the appropriate role of the state vis-à-vis the sphere of production and distribution.

More widely recognized is the second major effect of the division of realms in encouraging economic and political freedom. Here the capitalist institution of private property again takes centre stage, this time not as a means of arranging production or allocating surplus, but as the shield behind which designated personal rights can be protected. Originally conceived as a means for securing the accumulations of merchants from the seizures of kings, the rights of property were generalized through the market into a general protection accorded to all property, including not least the right of the worker to the ownership of his or her own labour-power.

Now the wage–labour relationship appears not as means for the subordination of labour but for its
emancipation, for the crucial advance of wage-labour over enslaved or enserfed labour lies in the right of the working person to deny the capitalist access to labour-power on exactly the same legal basis as that which enables the capitalist to deny the worker access to property. There is, therefore, an institutional basis for the claim that the two realms of capitalism are conducive to certain important kinds of freedom, and that a sphere of market ties may be necessary for the prevention of excessive state power. This is surely an important part of Smith's celebration of the society of ‘natural liberty’, and has been the basis of the general conservative endorsement of capitalism. Unquestionably, the greatest achievements of human liberty thus far attained in organized society have been achieved in certain advanced capitalist societies. One cannot, however, make the wider claim that capitalism is a sufficient condition for freedom, as the most cursory survey of modern history will confirm.

A third theme in the evolution of capitalism calls attention to the cultural changes that have accompanied and shaped its institutional framework. Much emphasis has been given to this theme in the work of Weber and Schumpeter, both of whom stress the historic distinctions between the essentially rational – that is, means-ends calculating – culture of capitalist civilization compared with the ‘irrational’ cultures of previous social formations. Here it is important to recognize that rationality does not refer to the principle of capitalism, for we have seen that the impetus to amass wealth is only a sublimation of deeper-lying non-rational drives and needs, but to the behavioural paths followed in the pursuit of that principle. The drive to amass capital can be analysed in terms of a calculus that is less readily apparent, if indeed present at all, in the search for other forms of prestige and power. This pervasive calculating mind-set is itself the outcome both of the abstract nature of exchange-value, which makes possible commensurations that cannot be carried out in terms of glory or sheer display, and of the pressures exerted by the marketplace, which penalize economic actors who fail to follow the arrow of economic advantage. Capitalism is therefore distinguishable in history by the predominance of a prudent, accountant-like comparison of costs and benefits, a perspective discoverable in the mercantile pockets of earlier formations but highly uncharacteristic of the tempers of their ruling elites (see Weber, 1930; Schumpeter, 1942, ch. XI).

The cultural change associated with capitalism goes further, however, than the rationalization of its general outlook. Indeed, when we examine the general culture of capitalist life we are most forcibly struck by an aspect that precedes and underlies that highlighted above. This is the presence of an ideological framework that contrasts sharply with that of pre-capitalist formations. I do not use the word ideology in a pejorative sense, as denoting a set of ideas foisted on the populace by a ruling order in order to manipulate it, but rather as a set of belief systems to which the ruling elements of the society themselves turn for self-clarification and explanation. In this sense, ideology expresses what the dominant class in a society sincerely believes to be the true explanations of the questions it faces. That which is characteristic of the ideologies of earlier formations is their unified and monolithic character. In the ancient civilizations of which we know, an all-embracing world view, usually religious in nature, explicates every aspect of life, from the workings of the physical universe, through the justification of rulership, down to the smallest details of social routines and attitudes. By way of contrast, the ideology that emerges within capitalism is made up of diverse strands, more of them secular than religious and many of them in some degree of conflict with other strands. By the end of the 18th century, and to some degree before, the explanation system to which capitalist societies turn with respect to the workings of the universe is science, not religious cosmology. In the same manner, rulership is no longer regarded as the natural prerogative of a divinely chosen elite but perceived as ‘government’; that
is, as the manner in which ‘individuals’ create an organization for their mutual protection and advancement. Not least, the panorama of work and the patterns of material life are perceived not as the natural order of things but as a complex web of interactions that can be made comprehensible through the teachings of political economy, later economics. The individual threads of these separate scientific, political-individualist and economic belief systems originate in many cases before the unmistakable emergence of capitalism in the 18th century, but their incorporation into a skein of culture provides yet another identifying theme of the history of capitalist development.

Within this skein, the ideology of economics is obviously of central interest for economists. A crucial element of this belief system involves changes in the attitude towards acquisitiveness itself, above all the disappearance of the ancient concern with good and evil as the most immediate and inescapable consequence of wealth-gathering. As Hirschman has shown, this change was accomplished in part by the gradual reinterpretation of the dangerous ‘passion’ of avarice as a benign ‘interest’, capable of steadying and domesticating social intercourse rather than disrupting and demoralizing it (Hirschman, 1977). Other crucial elements of understanding were provided by Locke's brilliant demonstration in *The Second Treatise on Government* (1690) that unlimited acquisition did not contravene the dictates of reason or Scripture, and by the full pardon granted to wealth-seeking by Bentham, who demonstrated that the happiness of all was the natural outcome of the self-regarding pursuit of the happiness of each. The problem of good and evil was thus removed from the concerns of political economy and relegated to those of morality; and economics as an inquiry into the workings of daily life was thereby differentiated from earlier inquiries, such as the reflections of Aristotle or Aquinas, by its explicit disregard of their central search for moral understanding. Perhaps more accurately, the constitution of a ‘science’ of economics as the most important form of social self-scrutiny of capitalist societies could not be attempted until moral issues, which defied the calculus of the market, were effectively excluded from the field of its investigations.

The logic of the system

This conception of capitalism as a historical formation with distinctive political and cultural as well as economic properties derives from the work of those relatively few economists interested in capitalism as a ‘stage’ of social evolution. In addition to the seminal work of Marx and the literature that his work has inspired, the conception draws on the writings of Smith, Mill, Veblen, Schumpeter and a number of sociologists and historians, notable among them Weber and Braudel. The majority of present-day economists do not use so broad a canvas, concentrating on capitalism as a market system, with the consequence of emphasizing its functional rather than its institutional or constitutive aspects.

In addition to the characteristic features of its institutional ‘nature’, capitalism can also be identified by its changing configurations and profiles as it moves through time. Insofar as these movements are rooted in the behaviour-shaping properties of its nature, we can speak of them as expressing the logic of the system, much as conquest or dynastic alliance express the logic of systems built on the principle of imperial rule, or the relatively changeless self-reproduction of primitive societies expresses the logic of societies ordered on the basis on kinship, reciprocity and adaptation to the givens of the physical environment.

The logic of capitalism ultimately derives from the pressure exerted by the expansive M–C–M′ process, but it is useful to divide this overall force into two categories. The first of these concerns the
‘internal’ changes impressed upon the formation by virtue of its necessity to accumulate capital – its metabolic processes, so to speak. The second deals with its larger ‘external’ motions – changes in its institutional structure or in important indicia of performance as the system evolves through history. The internal dynamics of capitalism spring from the continuous exposure of individual capitals to capture by other capitalists. This is the consequence of the disbursement of capital-as-money into the hands of the public in the form of wages and other costs. Each capitalist must then seek to win back his expended capital by selling commodities to the public, against the efforts of other capitalists to do the same. This process of the enforced dissolution and uncertain recapture of money capital in the circuit of accumulation is, of course, the pressure of competition that is the social outcome of generalized profit-seeking. We can see, however, that competition cannot be adequately described merely as the vying of suppliers in the marketplace. As both Marx and Schumpeter recognized, competition is at bottom a consequence of the mutual encroachments bred by the capitalist drive for expansion, not of the numbers of firms contending in a given market.

The process of the inescapable dissolution and problematical recapture of individual capitals now gives rise to the activities designed to protect these capitals from seizure. The most readily available means of self-defence is the search for new processes or products that will yield a competitive advantage – the same search that also serves to facilitate the expansion of capital through the development of new markets. Competition thus reinforces the introduction of technological and organizational change into the heart of the accumulation process, usually in two forms: attempts to cheapen the cost of production by displacements of labour by machinery (or of one form of fixed capital by another); or attempts to gain the public's purchasing power by the design of wholly new forms of commodities. As a consequence, one of the most recognizable attributes of capitalist ‘internal’ dynamics has been its constant revolutionizing of the techniques of production and its continuous commodification of material life, the sources of its vaunted capacity to change and elevate living standards.

A further internal change also arises from the expansive pressures of the core process of capital accumulation. This is a threat to the capacity as a whole to extract a profit from the production of commodities. This tendency arises from the long-run effect of rising living standards in strengthening the bargaining power of labour versus capital. There is no way in which individual enterprises can ward off this threat by cutting wages, for in a competitive market system they would thereupon lose their ability to marshall a workforce. Their only protection against a rising tendency of the wage level is to substitute capital for labour where that is possible. For the system as a whole, the need to hold down the bargaining power of labour must therefore hinge on a generalization of individual cost-reducing efforts, through the system-wide displacement of labour by machinery, or by the direct use of government policies to maintain a profit-yielding balance between labour and capital, or by systemic failures – ‘crises’ – that create generalized unemployment. Whether attempted by deliberate policy or brought about by the outcome of spontaneous market forces, the pressure to secure a profit-compatible level of wages thus becomes a key aspect in the internal dynamics of the system.

A final attribute of the internal logic of capitalism must also be traced to its core process of accumulation. This is the achievement of a highly adaptive method of matching supplies against demands without the necessity of political intervention. This cybernetic capacity is surely one of the historical hallmarks of capitalism, and is regularly emphasized in the ‘comparative systems approach’ in which the responsive capacities of the market mechanism are compared with the inertias and rigidities of systems in which tradition or command (planning) must fulfil the allocational task. A critique of the
successes and failures of the market system cannot be attempted here. Let us only emphasize that the workings of the system itself derive from institutional attributes whose genesis we have already observed – namely, the establishment of free contractual relations as the means for social coordination; the establishment of a social realm of production and distribution from which government intervention is largely excluded; the legitimation of acquisitive behaviour as the social norm; and activating the whole, the imperious search for the enlargement of exchange-value as the active principle of the historical formation itself.

Large-scale tendencies

From the metabolism of capitalism also emerges its larger ‘external’ motions – the overall trajectory often described as its macroeconomic movement, and the configurational changes that are the main concern of institutional economics. It may be possible to convey some sense of these general movements if we note three general aspects characteristic of them.

We have already paid heed to the first of these, the tendency of the capitalist system to accumulate wealth on an unparalleled scale. Some indication of the magnitude of this process emerges in the contrast between the increase in per capital GNP of developed (capitalist) and less-developed (noncapitalist) countries:

Table 1 GNP per capita (1960 dollars and prices)

</table>

After our lengthy discussion of the central role of accumulation within capitalism it does not seem necessary to relate this historic trend to its institutional base. Two somewhat neglected aspects of the overall increase in wealth seem worth mentioning, however. The first is that the increase in per capita GNP includes both augmentations in the volume of output and an extension of the M–C–M′ process itself within the social world. This is manifested in a continuous implosion of the accumulation process within capitalist societies – the process of the commodification of material life to which we earlier referred – and its explosion into neighbouring noncapitalist societies.

This explosive thrust calls attention to the second attribute of the overall expansion of wealth. It is that capital, as such, knows no national limits. From its earliest historic appearance, capital has been driven to link its ‘domestic’ base with foreign regions or countries, using the latter as suppliers of cheap labour-power or cheap raw materials or as markets for the output of the domestic economy. The consequence has been the emergence of self-reinforcing and cumulative tendencies towards strength at the centre, to which surplus is siphoned, and weakness in the periphery, from which it is extracted. The economic dimensions of this global drift are immediately visible in the previous table. This is the basis for what has been called the ‘development of underdevelopment’ as the manner in which ancient patterns of international hegemony are expressed in the context of capitalist relationships (Myrdal, 1957, Part I: Baran, 1957, chs V–VII).
We turn next to a different overall manifestation of the larger logic of capitalist development – its changes in institutional texture. There have been, of course, many such changes in the long span of Western capitalist experience – indeed, it is the very diversity of the faces of capitalism that prompted our search for its deep-lying identifying elements. Nonetheless, two changes deserve to be singled out, not only because of their sweeping magnitude and transnational occurrence, but because they have deeply altered the evolutionary logic of the system itself. These have been the emergence within all modern capitalisms of highly skewed size distributions of enterprise, and of very large and powerful public sectors.

The general extent of these transformations is sufficiently well known not to require detailed exposition here. Suffice it to illustrate the trend by contrasting the largely atomistic composition of manufacturing enterprise in the United States at the middle of the 19th century with the situation in the 1980s, when seven-eighths of all industrial sales were produced by 0.1 per cent of the population of industrial firms. The enlargement of the public sector is not so dramatic but is equally unmistakable. During the present century in the United States, its size (measured by all government purchases of output plus transfer payments) has increased from perhaps 7.5 per cent of GNP to over 35 per cent, a trend that is considerably outpaced by a number of European capitalisms.

The first of these two large-scale shifts in the configuration can be directly traced to the pressures generated by the M–C–M′ circuit. The change from a relatively homogeneous texture of enterprise to one of extreme disparities of size is the consequence not only of differential rates of growth of different units of capital, but of defensive business strategies of trustification and merger, and the winnowing effect of economic disruptions on smaller and weaker units of capital. There is little disagreement as to the endemic source of this transformation in the dynamics of the marketplace and the imperative of business expansion.

The growth of large public sectors is not so immediately attributable to the accumulation process proper but rather results from changes in the logic of capitalist movements after the concentration of industry has taken place. Here the crucial change lies in the increasing instability of the market mechanism, as its constituent parts cease to resemble a honeycomb of small units, individually weak but collectively resilient, and take on the character of a structure of beams and girders, each very strong but collectively rigid and interlocked. It seems plausible that this rigidification was the underlying cause of the increasingly disruptive nature of the crises that appeared first in the late 19th century and climaxed in the great depression of the 1930s; and it is widely accepted that the growth of the public sector mainly owes its origins to efforts to mitigate the effects of that instability or to prevent its recurrence.

This brings us to the last general aspect of capitalist development; namely, the tendency for interruptions and failures to break the general momentum of capital accumulation. Perhaps no aspect of the logic of capitalism has been more intensively studied than these recurrent failures in the accumulation process. In the name of stagnation, gluts, panics, cycles, crises and long waves a vast literature has emerged to explain the causes and effects of intermittent systematic difficulties in successfully negotiating the passage from M to M′. The variables chosen to play strategic roles in the explanation of the phenomenon are also widely diverse: the saturation of markets; the undertow of insufficient consumption; the technological displacement of labour; the pressure of wages against profit margins; various monetary disorders; the general ‘anarchy’ of production; the effect of ill-considered government policy, and still others.

Despite the variety of elements to which various theorists have turned, a common thread unites most of
their investigations. This is the premise that the instabilities of capitalist growth originate in the process of accumulation itself. Even theorists who have the greatest confidence in the inherent tendency of the system to seek a steady growth path, or who look to government intervention (in modern capitalism) as the main instability-generating force, recognize that economic expansion tends to generate fluctuations in the rate of growth, whether from the ‘lumpy’ character of investment, volatile expectations, or other causes. In similar fashion, economists who stress instability rather than stability as the intrinsic tendency of the system do not deny the possibility of renewed accumulation once the decline has performed its surgical work; indeed, Marx, the most powerful proponent of the inherently unstable character of the $M\rightarrow C\rightarrow M'$ process, was the first to assert that the function of crisis was to prepare the way for a renewal of accumulation.

In a sense, then, the point at issue is not whether economic growth is inherently unstable, but the speed and efficacy of the unaided market mechanism in correcting its instability. This ongoing debate mainly takes the form of sharp disagreements with respect to the effects of government policy in supplementing or undermining the corrective powers of the market. The failure to reach accord on this issue reflects more than differences of informed opinion with regard to the consequences of sticky wages or prices, or ill-timed government interventions, and the like. It should not be forgotten that, from the viewpoint of capitalism as a regime, interruptions pose the same threats as did hiatuses in dynastic succession or breakdowns of imperial hegemony in earlier formations. It is not surprising, then, that the philosophic predilections of theorists play a significant role in their diagnoses of the problem, inclining economists to one side or the other of the debate on the basis of their general political sympathies with the regime, rather than on the basis of purely analytic considerations.

**Periodization and prospects**

All the foregoing aspects of the system can be traced to its inner metabolism, the money–commodity–money circuit. This is much less the case when we now consider the overarching pattern of change described by the configuration of the social formation as a whole as it moves from one historic ‘period’ to another.

Traditionally these periods have been identified as early and late mercantilism; pre-industrial, and early and late industrial capitalism; and modern (or late, or state) capitalism. These designations can be made more specific by adumbrating the kinds of institutional change that separate one period from another. These include the size and character of firms (trading companies, putting-out establishments, manufactories, industrial enterprises of increasing complexity); methods of engaging and supervising labour (cottage industry through mass production); the appearance and consolidation of labour unions within various sectors of the economy; technological progress (tools, machines, concatenations of equipment, scientific apparatus); organizational evolution (proprietorships, family corporations, managerial bureaucracies, state participation). David Gordon has coined the term ‘social structure of accumulation’ to call attention to the changing framework of technical, organizational and ideological conditions within which the accumulation process must take place. Gordon's concept, applied to the general problem of periodization, emphasizes the manner in which the accumulation process first exploits the possibilities of a ‘stage’ of capitalism, only to confront in time the limitations of that stage which must be transcended by more or less radical institutional alterations (Gordon, 1980).

The idea of an accumulation process alternately stimulated and blocked by its institutional constraints
provides an illuminating heuristic on the intraperiod dynamics of the system, but not a theory of its long-run evolutionary path. This is because not all national capitalisms make the transitions with equal ease or speed from one social structure to another, and because it is not apparent that the pressures of the M–C–M’ process push the overall structure in any clearly defined direction. Thus Holland at the end of the 17th century failed to make the leap beyond mercantilism, and England in turn in the second half of the 19th century failed to create a successful late industrial capitalism. In this regard it is interesting that the explanatory narratives of the great economists apply with far greater cogency to the evolutionary trends within periods than across them – Smith's scenario of growth in *The Wealth of Nations*, for instance, containing no suggestion that the system would move into an industrial phase with quite different dynamics, or Marx's depiction of the laws of motion of the industrialized system containing no hint of its worldwide evolution towards a state-underwritten structure. Although the inner characteristics of the M–C–M’ process enable us to apply the same generic designation of capitalism to its successive species-forms, it does not seem to be possible to demonstrate, even after the fact, that the transition from one stage to another had to be made, or to predict before the fact what the direction of institutional adjustment will be.

These cautions apply to the prospectus confronting capitalism in our day. Its long post World War II boom seems to have been based on three attributes of the social structure of accumulation of that time. One of these was the increasing interconnection between the political and the economic realms, not merely to provide a public base for mass consumption but to utilize the state's power of finance and international leadership to promote foreign private trade and production. Japanese capitalism has been the much cited case in point for the latter development. A second characteristic of the boom was the extraordinary development of technology, based on the close integration of scientific research and technical application. A third was the pronounced bourgeoisification of working-class life, especially in Europe and Japan, greatly reducing the spectre of class conflict in capitalist politics.

On the basis of these developments capitalism enjoyed the longest uninterrupted period of accumulation in its history, from the early 1950s to the mid-1970s. Not only was the boom uninterrupted save for minor and shortlived recessions, but on the wings of its new technological breakthroughs, and under the auspices of its active state cooperation, capitalism made extraordinary advances in introducing its core institutions into many areas of the underdeveloped world.

This halcyon period came to a sharp end in 1980 when growth rates in the United States and Europe fell precipitously. Some, although not all of the causes of this depression can be ascribed to an exhaustion of the expansionary possibilities within the postwar social structure of accumulation. The effect of enlarged and sustained public expenditure gradually shifted from the encouragement of production to the inducement of inflation, thus setting the stage for the adoption of the tight money policies that finally broke the back of the boom. As markets became saturated, the advances in technology lost their capacity to stimulate capital expansion and attention was increasingly directed to their system-threatening aspects – ecologically dangerous products, employment-eroding processes and sovereignty-defying enhancements of the international mobility of money capital and commodities. The international character of capital acquired extraordinary importance, as multinational corporations transplanted fixed capital into underdeveloped regions, from which it launched artillery barrages of commodities back on its domestic territory. And not least, the bourgeoisification of labour may have removed a traditional source of adaptational pressure from capitalism.

It is not possible to foretell how these challenges will be met, or what institutional changes will be
forced upon the capitalist world as their consequence, or which capitalist nations will find the institutional and organizational means best suited to continue the accumulation process in this newly emerging milieu. Thus there is no basis for predicting the longevity of the social formation, either in its national instantiations or as a formational whole.

But while history forces on us a salutary agnosticism with regard to the long-term prospects for capitalism, it is interesting to note that all the great economists have envisaged an eventual end to the capitalist period of history. Smith describes the accumulation process as ultimately reaching a plateau when the attainment of riches will be ‘complete’, followed by a lengthy and deep decline. Ricardo and Mill anticipate the arrival of a ‘stationary state’, which Mill foresees as the staging ground for a kind of associationist socialism. Marx anticipates a series of worsening crisis, each crises serving a temporary rejuvenating function but bringing closer the day when the system will no longer be able to manage its internal contradictions. Keynes foresees ‘a somewhat comprehensive socialization of investment’; Schumpeter, an evolution into a kind of bureaucratic socialism. By way of contrast, contemporary mainstream economists are largely uninterested in questions of historic projection, regarding capitalism as a system whose formal properties can be modelled, whether along general equilibrium or more dynamic lines, without any need to attribute to these models the properties that would enable them to be perceived as historic regimes and without pronouncements as to the likely structural or political destinations towards which they incline. At a time when the need for institutional adaptation seems pressing, such an historical indifference to the fate of capitalism, on the part of those who are professionally charged with its self-clarification, does not augur well for the future.

American social scientist. Born in Philadelphia, the son of Mathew Carey, he was a prolific author, and his influence, though short-lived, spread from Pennsylvania throughout the nation and to Europe. Carey's economic views were sharply at variance with those of Ricardo and Malthus, and reflect the optimism characteristic of American conditions favourable to economic expansion, conditions from which Carey himself benefited as a successful entrepreneur and promoter. The two leading themes of his writings were protectionism and harmony of interests. In his first book, *Essay on the Rate of Wages* (1835), he opposed trade restrictions as running counter to the providential order. But in *The Past, the Present, and the Future* (1848) and in later writings, he vigorously appealed for tariff protection as fulfilling his law of association, a law that called for diversified and balanced regional development. Narrow specialization and foreign trade would violate this law. In *The Slave Trade* (1853) Carey suggested protectionism for the South, where it would foster industrial development.

The scope of Carey's optimistic belief in a harmonious order gradually widened. In his first book he postulated harmony between capitalists and workers, the former benefiting from rising profits and the latter from wages that rose as a result of the accumulation of capital. In his *Principles of Political Economy* (1837–40) the landowner becomes part of the harmonious order, with his earnings depicted as a return on his capital rather than a gift of nature. Population growth does not disturb the harmony as it is restrained by social conditioning. There are further attacks against the Ricardian rent theory in *The Past, the Present, and the Future*, where cultivation is said to move from inferior to superior land, not vice versa as Ricardo had taught, and with returns increasing rather than decreasing. In the *Principles of Social Science* (1858–9) Carey expands his vision of a harmonious order to apply to the universe, and in *The Unity of Law* (1872) he maintains that cosmic and social laws are identical. Carey has been characterized as ‘easily the most perverse and the most original American political economist before Veblen’ (Conkin, 1980, p. 261).

The eldest of nine children of Margaret Aitkin and James Carlyle, Thomas Carlyle was born at Ecclefechan in Scotland on 4 December 1795. While Carlyle's contributions ranged over many fields (including history, literary and social criticism, biography, translation and political commentary), in economics he is remembered chiefly as the originator of the epithet 'the dismal science' (‘The Nigger Question’, 1849; in Miscellaneous Essays, vol. 7, p. 84). Among ‘the professors of the dismal science’, one M'Croudy (J.R. McCulloch) is a principal target of Carlyle's criticism. Yet Carlyle's writings on economics are more extensive than this small measure of recognition might suggest, and his key criticisms of the economic and political tendencies of the 'present times' (as he called them) are contained essentially in three works: Chartism, (1840), Past and Present (1843) and Latter-Day Pamphlets (1850). Almost inevitably, Carlyle's characteristically romantic reaction to the decline of authority and the rise of utilitarian individualism led him into head-on collision with the prevailing economic doctrines of the day. Since, for Carlyle, the challenge of democracy to the ancien régime had been carried forward under the mistaken banner ‘Abolish it, let there henceforth be no relation at all’ (1850, p. 21), it was natural for him to hold that laissez-faire, free competition, the law of supply and demand, and the ‘cash nexus’ were no more than ‘superficial speculations … to persuade ourselves … to dispense with governing’ (1850, p. 20). Although Carlyle's account of the 'cash-nexus' was adopted verbatim by Marx and Engels in the opening pages of The Communist Manifesto, in the latter sections of that document his overall position is roundly attacked (see there the reference to the ‘Young England’, of which Carlyle was a prominent member).

There is also a thinly veiled attack on Carlyle's ‘dissatisfaction with the Present … and affection and regret towards the Past’ in John Stuart Mill's Political Economy (1848, pp. 753–4). However, at Carlyle's hands the utilitarian calculus of pleasure and pain fared little better. It was charged with
ignoring all those sentiments, aspirations and interests which distinguished the human from other animals and was dubbed by Carlyle ‘the Pig Philosophy’ (1850, p. 268). Though Carlyle had few if any followers among economists, he exerted a profound impact upon the thinking of John Ruskin, and he may correctly be regarded as a principal exemplar in England of that reactionary or feudal brand of ‘socialism’ criticized by Marx and Engels in the Communist Manifesto. Carlyle died in Chelsea on 5 February 1881 and was buried in Ecclefechan.

cartels

Margaret C. Levenstein and Valerie Y. Suslow
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Cartels are associations of firms that restrict output or set prices. They may divide markets geographically, allocate customers, rig bids at auctions, or restrict non-price terms. They have often been formed with the active participation or support of state actors. In contrast to the pre-Second World War period, today most cartels are illegal in most jurisdictions. The average duration of cartels is between five and seven years, but the distribution of duration is skewed: a large number of cartels break down within a year but a sizable proportion last for over a decade.

Keywords

antitrust enforcement; barriers to entry; cartels; cheating; collusion; communication; concentration; coordination; entry; innovation; price fixing; price wars; productivity growth; trust

Article

Producers form cartels with the goal of limiting competition to increase profits. Cartels are associations of independent firms that restrict output or set prices. They may divide markets geographically, allocate customers to specific producers, rig bids at auctions, or restrict non-price terms offered to customers. They have often been formed with the active participation or support of state actors. In contrast to the pre-Second World War period, today most cartels are illegal in most jurisdictions.

Upon its creation a cartel immediately faces three key problems: coordination, cheating and entry. In a dynamic economy, the solution to these problems will change over time, so successful cartels must develop an organizational structure that allows them to re-solve these problems continuously. Stigler's (1964) classic article highlights the incentive to cheat as the most important source of instability undermining cartels. In a repeated setting, a firm weighs the expected gain from cheating today (the benefit from cheating) with the expected reduction in future discounted profits that follows cheating (the cost of cheating). In order for firms to be willing to refrain from cheating, the following must hold:
where $\Pi^m$ is the one-period cartel profit, $n$ is the number of firms in the industry, and $\delta^t$ is the discount rate. Thus, collusion is easier to achieve the larger the difference between cartel and non-cartel profits, the smaller the number of firms, and the more patient these firms are (Tirole, 1988).

Friedman (1971) demonstrates that firms may use ‘off the equilibrium path’ threats of price wars in retaliation for cheating to provide firms with the incentive not to cheat. However, because in his model any cheating would be observed immediately and therefore subject to swift retaliation, firms do not cheat and price wars are not observed. In the Green and Porter class of models (Green and Porter, 1984; Abreu, Pearce and Stacchetti, 1986), firms cannot observe one another's output (or pricing) actions nor infer them with certainty from public information. Economic fluctuations require that firms revert to equilibrium ‘punishment’ or ‘price war’ behaviour at times in order to maintain the incentives necessary to achieve collusion. Thus, the appearance of on-and-off collusion does not represent inherent cartel instability, but rather a mechanism that cartels use to stabilize themselves.

This theoretical perspective also implies a second mechanism for increasing cartel stability: a cartel may invest in information collection in order to better monitor individual firm activities. Improved monitoring both deters cheating and allows cartels to avoid costly price wars that arise from the inability to distinguish cheating from external shocks.

The most successful cartels actively work to create barriers to entry. Sometimes this is done through collective predation, as in Scott Morton (1997) in which incumbent cartel members successfully deterred entry by financially weaker and smaller firms. In other cases, cartels have turned to the state to create regulations, tariffs, or provide anti-dumping protection with the goal of excluding outsiders. Cartels sometimes use vertical exclusion (for example, a joint sales agency) or restrict access to technology (for example, via a patent pool) to limit entry.

Cartels use direct and repeated communication to overcome obstacles to coordination. Cartel negotiations often begin with discussions of prices and market shares, but expand over time to restrict cheating in non-price dimensions, such as terms of sale, advertising, transport costs, and production capacities. Firm asymmetries and changes in firms' costs can make these negotiations challenging. Slade (1989) suggests that price wars arise from changes in firm or industry characteristics. These price wars then facilitate the learning necessary for firms to re-establish collusion. Cartels also learn how to structure incentives so that collusion is more profitable in the long run than cheating. For example, successful cartels often fashion self-imposed penalties or other compensation schemes for firms that exceed cartel quotas. Cartels sometimes develop elaborate internal hierarchies allowing for communication at various levels of management. A hierarchical cartel structure allows for high-level information exchange and bargaining activities to be separated from regional or local information exchange and monitoring efforts. When trust is particularly difficult to establish and firms doubt the accuracy of communication or data exchanges, cartels often turn to a third party – such as a trade
association – to facilitate information sharing. The average duration of cartels measured over a range of countries and time periods is between five and seven years (Levenstein and Suslow, 2006). There is considerable dispersion in cartel duration: the standard deviation of duration is almost as high as the average. Observed cartel duration is very skewed, with a large number of cartels lasting less than a year or two and a long tail of cartels that endure for a decade or more.

Predictable fluctuations in product or industry demand do not generally undermine effective cartels, but rapid industry growth and unexpected shocks do. Macroeconomic fluctuations, which are close to common knowledge, have little impact on cartel stability. Many successful cartels develop an organizational structure that allows them to weather cyclical fluctuations. Cartels that are disrupted by observable cyclical fluctuations may be inherently fragile.

Large customers can undermine cartel stability by increasing the incentive to cheat, as posited by Stigler (1964) and tested by Dick (1996). On the other hand, large customers sometimes benefit from the existence of a cartel if they receive preferential pricing compared with that received by their smaller competitors, and can even contribute to its stability.

Although posited by theory, there is no simple empirical relationship between industry concentration and the likelihood of collusion. This may reflect sampling bias in studies that focus on prosecuted cartels, since cartels with many firms or with the involvement of an industry association may be easier to detect. Or it may be that industries with a small number of firms are able to collude tacitly without resorting to explicit cartels. Finally, it may reflect the endogeneity of concentration: collusion may allow more firms to survive and remain in the market (Sutton, 1991; Symeonidis, 2002).

Analyses of the impact of cartels on prices and profits generally use one of three approaches: changes in price following cartel formation, comparison between ‘good times’ and ‘price war’ periods, and, comparison between the cartel price and a counterfactual or ‘but-for’ price that would have prevailed in the absence of collusion. Connor and Lande (2005) provide an exhaustive survey of studies of cartel price effects. They conclude that the median overcharge resulting from cartels is approximately 25 per cent.

Cartels can also affect investment and productivity. Cartel participants have often argued that cartels increase investment and productivity growth by allowing firms to smooth production over time. Others have argued that, by removing the pressure of competition, cartels reduce innovation and productivity growth. Theoretical models have suggested that cartels lead to increased investment in capacity either because excess capacity can deter entry and provide enforcement (Dixit, 1980) or because, when price competition is suppressed, firms compete in other dimensions (Feuerstein and Gersbach, 2003). In some cases, cartels explicitly restrict investment in new capacity. Where there are not such explicit restrictions, empirical studies have found cartels are associated with increases in investment. On the other hand, no consistent relationship between cartels and productivity growth or innovation has been established empirically (Symeonidis, 2002).

As firms have become increasingly global, international antitrust law and policy has faced new challenges. Competition authorities have increased enforcement, attempted to harmonize practices and procedures, and increased cooperation across jurisdictions. The United States is the country with the longest history of prosecuting explicit collusion, with state laws antedating the national ban on price fixing enacted with the passage of the Sherman Act of 1890. Many Western European countries adopted
laws against price fixing following the Second World War, but also allowed a large number of exemptions. Since the mid-1990s these exemptions have been sharply reduced, and dozens of other countries have banned price fixing for the first time. Enforcement activities against cartels, and international cartels in particular, rose sharply in the United States in the late 1990s. European countries, including the newest members of the European Union, have also increased their enforcement activities against cartels, as have countries in Asia, Africa and Latin America. Price fixing – long a criminal offence in the United States – has now been criminalized in several other countries, including the United Kingdom and Ireland. This increased enforcement has demonstrated that cartels continue to be active in a wide range of industries in the 21st century.

Article

Along with Knut Wicksell and David Davidson, Gustaf Cassel was the founder of modern economics in Sweden. He started as a mathematician and began his career as an economist by treating problems of railway rates and progressive taxation from a mathematical point of view. In order to deepen his understanding of economics he went to Germany, where he attended the seminars of Schönberg, Cohn and other traditional representatives of the economic profession. After visits to England, where he made the acquaintance of Marshall and of Sidney and Beatrice Webb, and a short period of lecturing at the university of Copenhagen, in 1902 Cassel took up a position as associate professor in economics at the university of Stockholm. In 1904 he was appointed a professor in economics and public finance. As holder of the chair he acquired a series of gifted pupils, Gunnar Myrdal and Bertil Ohlin among others, who, although they developed the theoretical heritage of Wicksell rather than that of Cassel, became the founders of the Stockholm School of economics. Before the First World War Cassel frequently served as a government expert on problems of railway rates, taxation, state budgets and banking and his involvement in problems of economic policy increased with the post-war economic problems. During the 1920s he became an adviser to the League of Nations on monetary problems and was commonly regarded as a leading international authority in this field, lecturing and publishing widely. All his life he worked also as a columnist for the Swedish daily paper Svenska Dagbladet. Although Cassel was originally liberal, he progressively turned more and more conservative denouncing the labour movement, the welfare state and Keynesianism in the name of ‘Modern Scientific Principles’. It is no easy task to evaluate the contributions of Gustav Cassel to economics. He never cared much
about paying homage to his predecessors, from whom he sometimes took over fruitful ideas, while at the same time being unjustifiably critical towards other theorists. His expositions are not seldom marred by contradictions and a vagueness in expression, only scantily veiled by his mastery in round and polished sentences. At the same time Cassel took a keen interest in very many fields of economic theory and practice, he had a firm grip on empirical economics and his gifts in tracking down the relevant and essential aspects of economic problems were unusual. These qualities, in combination with a forceful and pedagogical exposition and, on the top of this, an imperturbable conviction of being the chosen spokesman for progress and the principles of science, made him influential not only among men of practical matters but also among fellow economists.

Cassel's main work is his *Theoretische Sozialökonomie* (1918) but his most important theoretical ideas were in fact conceived already around the turn of the century. In his essay ‘Grundsätze für die Bildung der Personentarife auf den Eisenbahnen’ (1900b), he criticized the idea of calculating railway rates on the basis of average costs and instead advocated marginal cost pricing. For a railway enterprise as a monopolistic business unit, rates which equalized marginal costs and marginal revenues were the optimal ones, though this might imply that some rates were lower than average costs. Even if the principle had been advocated already in 1885 by the American railway economist A.T. Hadley, it was succinctly formulated by Cassel.

Venturing into general economic theory, Cassel in these years also criticized Ricardo's labour theory of value in the essay ‘Die Produktionskostentheorie Ricardos und die ersten Aufgaben der theoretischen Volkswirtschaftslehre’ (1901), presented an outline of his own theory of price, ‘Grundriss einer elementaren Preislehre’ (1899) and developed a theory of interest in *The Nature and Necessity of Interest* (1903). The Ricardian labour theory of value was, according to Cassel, untenable because it assumed that the labour–capital ratio was equal in different enterprises and industries, that labour was homogeneous and that the marginal land did not pay any rent. He did not care to take issue with the Marxian development of the labour theory of value. The labour theory of value belonged to the so-called one-sided value theories. But so did the marginal utility theory of value, which was deficient primarily because it lacked a clearly conceptualized unit of measurement for utility but also because goods, according to Cassel, are not generally divisible and the valuations of goods are not continuous functions of the supply. Therefore, Cassel suggested that one should do away with all conceptions of value and rest content with money prices and not bother with what might lie behind money prices. Thus Cassel did not consider the fact that money itself may vary in value, nor that the marginal utility of money certainly varies between individuals. Following Marshall, Cassel explained prices by reference to supply and demand and, following Walras, he devised a general equilibrium model for market prices in the form of a system of simultaneous equations. In fact, Cassel's price theory is a simplified version of the theory of Walras, who was characterized as ‘in a sense one of my precursors’. However, by popularizing Walras, Cassel contributed much towards the understanding of the mutual interdependencies in a market economy. It was quite logical that the theory of interest that Cassel devised also should be based upon supply and demand, viz. supply of waiting and demand for the use of capital, as a special case of the general theory of price, and he boldly asserted that waiting and use denoted the same thing. Although his theory of interest, showing a close resemblance to that of Senior, was not original, it still merits our attention because of its vivid illustrations and some striking applications. This is particularly the case for Cassel's argument against the idea of a continually falling rate of interest. Given that most saving is made in order to safeguard a permanent future level of income, the shortness of life puts a ceiling under
the rate of interest. This was the necessary and sufficient condition for the necessity of interest. The year after the publication of *The Nature and Necessity of Interest*, Cassel also published his theory of the business cycle and his theory of the secular development of the general level of prices in two articles in the Swedish journal *Ekonomisk tidskrift*, ‘Om kriser och dåliga tider’ (1904a) and ‘Om förändringar i den allmänna prisnivån’ (1904b). Both these theories were later incorporated and somewhat elaborated in his *Theoretische Sozialökonomie* (1918). In his theory of the business cycle Cassel was evidently influenced by Spiethoff and Tugan-Baranowsky, who recently had made public their theories explaining the business cycle with reference to the variations in investment of fixed capital and of loanable funds. What is really new in Cassel's treatment is his precise formulation of the accelerator principle, which he expounds with reference to the relationship between the demand for freight and the output of ships. The treatment of growth theory had to await the publication of his *Theoretische Sozialökonomie* and also on this point Cassel was wholly original, in fact foreshadowing the Harrod growth formula by his own formula for ‘the uniformly progressing economy’, the only difference being that Cassel worked with an average instead of a marginal capital coefficient.

Cassel's theory of the secular development of the general level of prices also demands our attention as a piece of brilliant imagination and was as late as 1930, after Kitchin's refinements, accepted as the theoretical basis for the first interim report of the gold delegation of the League of Nations. Cassel's theory was a straightforward quantity theory of money. By calculating the relative variations of gold output in relationship to a calculated normal need of gold for preserving a constant general level of prices, Cassel showed that there was a very good correlation between the relative variations of gold output and the corresponding variations in the general level of prices. Cassel's theory met with all the objections the quantity theory of money usually meets and in addition a series of more specific criticism: that it presupposes a constant ratio between velocity (V) and transactions (T), which is difficult to believe; that it overlooks the important role of silver in the 19th century as well as the varying proportions of the more relevant variable monetary gold; and that a case as good as Cassel's could be made, and in fact was made by Warren and Pearson, by making the gold price rather than gold output the effective cause of price changes. But since Kitchin's (and Woytinski's) calculations, taking only monetary gold in regard, showed a still better fit between the variations of gold output and prices, Cassel's theory is still a serious candidate.

After this first period of theoretical activity around the turn of the century, Cassel mainly devoted his energy to synthesizing and propagating his ideas on the national and the international scene. The only really new element in his theoretical set-up was the famous purchasing power parity theory of the exchange rates, according to which the international rates of exchanges are determined by the purchasing power of the national currencies. It is easy to show that this is a rather poor general theory for the explanation of the exchange rates. But it contained a pragmatic truth during and after the First World War, when trade balances and, hence, the supply and demand of currencies, to a great extent, were determined by the course of rapid inflation in different countries. It is precisely this instinct for pragmatic truths that explains Cassel's success and influence in the international community of bankers and politicians during the 1920s. In his memoranda to the international conferences of the League of Nations Cassel first and foremost advocated stability of monetary affairs by means of control of the quantity of money, increased interest rates and cut-downs of state expenditures. But he was also critical towards the subsequent ruthless policy of deflation creating widespread unemployment and new disequilibria in world trade as well as intolerable debt burdens. Together with Keynes he criticized the
unwillingness of the claimants to the German war debt to receive German goods as payment. When confronted by the permanent unemployment of the 1920s, Cassel concentrated his attacks on trade unions and the level of wages and untiringly explained the gospel contained in Say's Law. During the course of the 1930s it became all too clear that Gustav Cassel had been left behind by the march of events and of economic theory. It was his tragedy that he himself, who once waved his magic wand over international economic affairs, could not bear the truth. After some years of protracted rearguard skirmishes he devoted himself to more philosophical problems and wrote up a voluminous autobiography characteristically entitled ‘In the Service of Reason’ (I förnuftets tjänst, 1940–41). His last words on his death-bed were ‘A world currency!’

Selected works

**Bibliography**

A good biography of Cassel has yet to appear. The biography by his secretary, Ingrid Giobel-Lilja (1948), may be consulted for biographical details, especially as regards his family life. Böhm-Bawerk (1914) made a critical examination of Cassel's theory of interest, and Wicksell (1919) published a very critical review of *Theoretische Sozialökonomie*. A more descriptive account of Cassel's main work is to be found in Mitchell (1969); Gunnar Myrdal (1945) wrote an obituary; and Gustafsson (1964) offers another overall evaluation with emphasis on Cassel's theory of long-run prices.

Caste system

Susan Wolcott
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

India’s caste system performed two fundamental functions: insurance through transfers between caste members and, in villages, insurance through protected job assignments across castes. In most of India the landlord had a social responsibility to maintain his lower caste workers in lean periods. This division of labour has been viewed as coercive and exploitative. Yet many groups changed their caste occupation, both upward and downward in ritual ranking. During industrialization, traditional occupational categories did not restrict occupational choices in new industries, but caste continued to play a role in recruitment and support during work stoppages.

Akerlof, G.; caste system; division of labour; India; industrialization; insurance

Article

The caste system in India is a division of society into ranked, hereditary, endogamous occupational groups. It is loosely based on the four varnas of Brahmanas (priests), Kshatriyas (warriors and aristocracy), Vaishyas (merchants) and Shudras (the servants of the others). Castes either belonged to one of these four, or were below them in the hierarchy; these latter are the so-called untouchables. In practice, the varnas are less important than were the relationships among and between the numerous sub-castes, or jatis. The sub-castes were specific to each region and were the true functional unit of the caste system. They were, for example, the endogamous unit. And obligations of jati members to each other were much stronger than were obligations of caste members more generally. Below the terms ‘jati’ and ‘caste’ are used interchangeably.

Caste was not a monolithic institution. Reviewing the historical literature on caste, Rudner (1994, p. 25) notes that it is impossible for any one description to capture the ‘on-the-ground diversity of India’s caste systems’. He suggests as a definition: ‘complex, multilayered, multifunctional corporate kin groups with enduring identities, a variety of rights over property, and crucial economic roles, often within large
regions’. Because of this diversity, caste’s role in the Indian economy varied across regions and across groups. But two functions were fundamental: insurance through transfers between caste members and, in village India, insurance through protected job assignments across castes. On the first of these, Srinivas (1962, p. 70) writes, ‘joint family and caste provide for an individual in our society some of the benefits which a welfare state provides for him in the industrially advanced countries of the West’. Economists have completely ignored this aspect of caste. But in the modern period it seems to be economically significant: financial transfers among rural villagers are common in developing countries. However, this practice is much more common in India than in any other country yet studied (Cox and Jimenez, 1990, Table 1). As caste ties are weakening over time and as income rises, it is likely that such transfers were even more prevalent historically.

And across castes, because each _jati_ was, at least in theory, occupationally segregated in the villages of colonial India, it played a protected role in the economic order and had a claim on the wealth produced by the village. This relationship is called the _jajmani_ system in much of India, and the _baluta_ system in Maharashtra (Kolenda, 1978).

A particular division of responsibilities is that between landlords and agricultural labourers. Especially in north, south and east India, the landlord had a social responsibility to maintain his workers in lean periods. Platteau (1995) reviews the literature on this topic and presents a mathematical formalization of this relationship. Greenough (1982) gives an account of the strains on this system and its ultimate collapse in an extreme crisis.

This division of labour has also been viewed as coercive and exploitative. Akerlof (1976) models a situation in which groups can be confined to inferior occupations by social opprobrium. Maddison (1971, p. 28) argues that these occupational divisions were not only coercive but also foolish: ‘One might think that some of the lowest productivity occupations were invented simply to provide everyone with a job in a surplus labor situation, but there was no shortage of land and the productivity of the economy would have been higher if there had been greater job mobility.’

But these authors exaggerate the rigidity of the caste system in regard to occupational segregation. Mukerjee (1937) provides a long list of groups which had changed their caste occupation, both upward and downward in ritual ranking, as well as lists of splitting and merging sub-castes. He argues that, although there was rigid social control within the caste, the system revealed ‘plasticity’ in regard to economic incentives. As an example of this, Commander (1983) notes that historical sources imply that the Chamars of the United Provinces – hereditarily leather workers – were for much of the 19th century largely agricultural labourers. He argues cogently that, although ritual and custom were important in determining economic rewards and relative position in the _jajmani_ system, so were land availability and labour scarcity.

Did caste have a role in modern industrialization? The best survey on this subject remains that of Morris (1960). One point is obvious. Traditional occupational categories did not restrict occupational choices in new industries. Whether or not caste affected the economic lives of the workforce in other ways is less clear. Morris (1960, p. 128) writes that he ‘is inclined to the view that _jati_ relationships ultimately are irrelevant in the factory’. Most analysts argue, however, that, because of the economically supportive links between _jati_ members, caste did have a role in recruitment and support during work stoppages.
Caste system: The New Palgrave Dictionary of Economics
(Chandavarker, 1994; Klass, 1978). The differentiated and fluid nature of caste makes a general statement impossible.

The term, meaning ‘the science of exchanges’, was proposed as a replacement for the name ‘political economy’ by the Rev. Richard Whately in his 1831 Drummond Lectures at Oxford on political economy (Whately, 1831). As the leader of the group of embattled religious and economic liberals at Oriel College, Oxford, during the 1820s, Whately, a distinguished logician, had become tutor and lifelong friend of the economist Nassau W. Senior. In his Drummond Lectures, Whately was concerned to refute the dominant Oxford view that political economy, being concerned with wealth, was materialistic and opposed to Christianity. In focusing on exchanges, Whately denounced Adam Smith's definition of the scope of political economy as the science of wealth.

Whately defined man as ‘an animal that makes exchanges’, pointing out that even the animals nearest to rationality have not ‘to all appearance, the least notion of bartering, or in any way exchanging one thing for another’ (Whately, 1831, p. 7). Focusing on human acts of exchange rather than on the things being exchanged, Whately was led almost immediately to a subjective theory of value, since he saw that ‘the same thing is different to different persons’ (p. 8) and that differences in subjective value are the foundation of all exchanges.

In 1831 Whately was named Archbishop of Dublin, where he promptly used his influence to create and financially support a permanent five-year Whately Chair of Political Economy at Trinity College. For the rest of his life Whately personally selected the holders of the chair; as a result, the Whately professors carried on their mentor's tradition of catallactics and subjective utility theory. In contrast to John Stuart Mill's development of economics as a science of the abstraction ‘economic man’, man engaged only in avaricious pursuit of wealth, the third holder of the Whately Chair, James Anthony Lawson (1817–87), developed the idea of economics as catallactics, as studying exchanging man.
Lawson, holder of the chair in his twenties (1841–6), and later to become an MP and Attorney-General for Ireland, stated in his first lecture that economics views man ‘in connection with his fellow-man, having reference solely to those relations which are the consequences of a particular act, to which his nature leads him, namely, the act of making exchange’ (Lawson, 1844, pp. 12–13). Yet, Lawson himself fell back on discussions of wealth in his second lecture, demonstrating that, in their specific exposition, the catallacticians had not yet fully emancipated themselves from the older definitions of the scope and nature of political economy (Kirzner, 1960).

One pseudonymous English writer who adopted catallactics in this period was Patrick Plough, who included and explained the term in the title of his tract, *Letters on the Rudiments of a Science, called, formerly, improperly, Political Economy, recently more pertinently, Catallactics* (London, 1842).

Catallactics reached the status of a self-conscious school of thought in the writings of the zealous and indefatigable Scottish lawyer and economist Henry Dunning Macleod. Stressing value as the result of a subjective desire of the mind, Macleod furthered the emancipation of economics from material wealth by showing that immaterial goods or services are also subjects of exchange. Macleod insisted that catallactics was the only correct school of economic thought and traced back the origins of the school beyond Whately to the late 18th-century French philosopher Etienne Bonnot de Condillac. While Condillac, in his *Le commerce et le gouvernement* (1776), did not actually use the term catallactics, he defined economics as the philosophy of commerce, or the science of exchanges. Condillac also noted that value stems only from mental desires, and hence demand, for exchangeable goods, and proclaimed that men engage in exchange precisely because each man values what he gains in exchange more than what he gives up. Hence both parties to an exchange gain in value (Macleod, 1863, pp. 530–5).

The catallactic school found its culmination in the United States, in Arthur Latham Perry (1830–1905), for half a century a highly influential professor of political economy at Williams College. Perry endorsed the Macleod view of the history of economic thought, the sound catallactic school descending from Condillac through Whately and Macleod. He went beyond the inconsistencies of his forerunners, however, by purging the word ‘wealth’ from economics altogether, and proposing the ‘property’ – that which can be bought and sold – be used as a term denoting valuable things not yet sold and therefore in need of an estimate of their value (Perry, 1865).

While interest in the catallactic approach faded after the work of Perry, a variant appeared in the early work of Schumpeter (1908). In this manifesto for the reconstruction of economic theory, Schumpeter wished to purge economics of all concern about purposeful human motives or actions and replace it with exclusive concentration on mechanistic alterations of economic quantities. Exchanges then become ‘purely formal’ variations in economic quantities of goods (Schumpeter, 1908, pp. 49–55, 86, 582; Machlup, 1951; Kirzner, 1960).

Schumpeter did, however, manage to contribute positively to the catallactic approach. Whately and his followers had strongly rejected any element of Crusoe economics, since for them economic analysis had to be confined to interpersonal exchange. In Schumpeter’s formalistic approach, actions of Crusoe could alter the placement of quantities of economic goods and therefore could be considered ‘exchanges’. It remained for Ludwig von Mises (1949) to bring back the term catallactics in his treatise on economics, and to broaden it by embedding its analysis of the market, or the science of exchanges, in the wider discipline of ‘praxeology’, the science of human action. Crusoe economics then becomes
vindicated in the broader sense of analysing Crusoe's actions and his use of resources to achieve his values and goals, as well as in the sense of exchanging his present state for a more satisfying one.

Abstract

Catastrophic risks are defined here as events of low or unknown probability that if they occur inflicts enormous losses often having a large non-monetary component. The Indian Ocean tsunami of 2004 is at the lower level of the catastrophic-risk scale of destruction; examples from higher levels including large asteroid strikes, pandemics and global warming. The challenge is to modify the principles of cost–benefit analysis to deal with serious problems caused by uncertainty (as distinct from risk), nonlinearity in value-of-life estimates, the need to project social discount rates into the distant future, and the difficulty of devising suitable policy instruments.

Article

The Indian Ocean tsunami of December 2004 and, less than a year later, the flooding of New Orleans as a result of Hurricane Katrina focused attention on a type of disaster to which policymakers pay too little attention – a disaster that has a low or unknown probability of occurring but that, if it does occur, creates enormous losses. Great as were the death toll, the physical and emotional suffering of survivors, and property damage caused by the tsunami, and the even greater property damage caused by the flooding of New Orleans, even greater losses could be inflicted by other disasters of low (but not negligible) or unknown probability. The asteroid that exploded above Siberia in 1908 with the force of a hydrogen bomb might have killed millions of people had it exploded above a major city. Yet that asteroid was only about 200 feet in diameter, and a much larger one (among the thousands of dangerously large asteroids in orbits that intersect the earth’s orbit) could strike the earth and, wherever it struck, cause the
total extinction of the human race through a combination of shock waves, fire, tsunamis, and blockage of sunlight. Other catastrophic risks include, besides earthquakes such as the one that caused the 2004 tsunami, natural epidemics (the 1918–19 Spanish influenza epidemic killed between 20 million and 40 million people), nuclear or biological attacks by terrorists, certain types of lab accident (one discussed later in this article), and abrupt global warming. The probability of catastrophes resulting, whether or not intentionally, from human activity appears to be increasing because of the rapidity and direction of technological advances.

The economic approach to catastrophe

It is generally believed that the prediction, assessment, prevention, and mitigation of catastrophes is the province of science. However, economic analysis has an important role to play, as well. Able scientists can commit analytical errors when discussing policy that economists would easily avoid. Thus, Barry Bloom, dean of the Harvard School of Public Health, has criticized the editors of leading scientific journals for having taken the position that ‘an editor may conclude that the potential harm of publication outweighs the potential societal benefits’ (Bloom, 2003, pp. 48, 51). (The specific reference is to publications from which terrorists could learn how to create lethal bioweapons.) Bloom calls this ‘a chilling example of the impact of terrorism on the freedom of inquiry and dissemination of knowledge that today challenges every research university’ (Bloom, 2003, p. 51). The implication – that freedom of scientific research should enjoy absolute priority over every other social value – neglects the need to weigh costs and benefits in order to determine the best balance between public safety and scientific progress.

To illustrate the economic approach to catastrophe, suppose that a tsunami as destructive as the Indian Ocean tsunami occurs on average once a century and kills 250,000 people. That is an average of 2,500 deaths per year. Even without attempting a sophisticated estimate of the value of life to the people exposed to the risk, one can say with some confidence that, if an annual death toll of 2,500 could be substantially reduced at moderate cost, the investment would be worthwhile. A combination of educating the residents of low-lying coastal areas about the warning signs of a tsunami (tremors and a sudden recession in the ocean), establishing a warning system involving emergency broadcasts, telephoned warnings, and air-raid-type sirens, and improving emergency response systems would have saved many of the people killed by the Indian Ocean tsunami, probably at a total cost below any reasonable estimate of the average losses that can be expected from tsunamis. Relocating people away from coasts would be even more efficacious, but, except in the most vulnerable areas or in areas in which residential or commercial uses have only marginal value, the costs would probably exceed the benefits. For annual costs of protection must be matched with annual, not total, expected costs of tsunamis.

As another example, consider the question of optimal precautions against the type of flood that inundated New Orleans. In 1998 it was estimated that it would cost $14 billion to prevent such a flood; the estimated ‘economic’ cost (which ignores the loss of life and physical and emotional suffering) of the recent flood is $100 billion to $200 billion; and the Corps of Engineers estimated the annual probability of such a flood at 1 in 300. If we take the lower cost and assume that the $14 billion investment would eliminate the probability of a flood within 30 years, a period in which the probability of a flood if the measures were not taken would be a shade under ten per cent, yielding an expected
benefit from the flood-control measures of $10 billion, the measures would flunk a cost–benefit test. Note that the calculation does not include discounting future benefits to present value; the reason is that the benefits are likely to grow – a flood that occurred 30 years hence would be likely to do more damage because property values would increase.

**Value of life estimates**

What might tip the balance in favour of the flood-control measures would be monetizing the expected loss of life and other human suffering. There is now a substantial economic literature inferring the value of life from the costs people are willing to incur to avoid small risks of death; if from behaviour toward risk one infers that a person would pay $70 to avoid a 1 in 100,000 risk of death, his value of life would be estimated at $7 million ($70/.00001), which is in fact the median estimate of the value of life of an American (Viscusi and Aldy, 2003, pp. 5, 18, 63). The value of this transformation is simply that, once a risk is calculated, its expected cost is instantly derived simply by multiplying the risk by the value of life. But there is significant nonlinearity to be considered at both ends of the risk spectrum. At the high end, if one is asked what he would demand to play one round of Russian roulette, the typical answer will be a good deal more than 1/6 of $7 million. At the low-probability end of the risk spectrum, there is a tendency to write the cost of the risk down to or near zero (see, for example, Kunreuther and Pauly, 2004; Viscusi, 1997). In other words, the studies from which the $7 million figure is derived may not be robust with respect to risks of death either much larger or much smaller than the 1 in 10,000 to 1 in 100,000 range of most of the studies – and we do not know what the risk of death from a tsunami was to the people killed, though it was probably towards the low end of the range.

Even if we disregard this issue, because value of life is positively correlated with income, the $7 million figure cannot be used to estimate the value of life of the people killed by the Indian Ocean tsunami, or at least most of them (and perhaps likewise the people killed in the New Orleans flood, most of whom were poor). Additional complications arise from the fact that the deaths were only a part of the cost inflicted by the disaster – the injuries, the suffering, and the property damage that also resulted from the tsunami have to be estimated along with the efficacy and expense of precautionary measures that would have been feasible. The risks of smaller but still destructive tsunamis that such measures might protect against must also be factored in; nor is the ‘once a century’ risk estimate much better than a guess. Nevertheless, it seems apparent that the total cost of the tsunami was high enough to indicate that precautionary measures would have been cost-justified.

The tsunami, unlike the New Orleans flood, could not have been prevented. The only possible precautionary measures would have been either a warning system to enable prompt evacuation or permanently relocating population away from the coastline. Similar measures would have been possible alternatives to preventive measures for New Orleans as well, especially a system for prompt evacuation; but such a system would not have prevented either property damage or massive if temporary population relocation, both of which were huge costs of the flood.

**The political economy of catastrophe prevention and response**

Since precautionary measures of some kind taken in anticipation of a tsunami on the scale that occurred
would clearly have been cost-justified, why were they not taken? Tsunamis are a common consequence of earthquakes, which themselves are common; and tsunamis can have other causes besides earthquakes – a major asteroid strike in an ocean would create a tsunami that would dwarf the Indian Ocean one. The answer, or answers, may be economic in character.

First, although a once-in-a-century event is as likely to occur at the beginning of the century as at any other time, it is much less likely to occur some time in the first decade of the century than some time in the last nine decades of the century. (The point is simply that the probability is greater the longer the interval being considered: one is more likely to catch a cold in the next year than in the next 48 hours.) Politicians with limited terms of office and thus foreshortened political horizons are likely to discount low-risk disaster possibilities steeply because the risk of damage to their careers from failing to take precautionary measures is truncated.

Second, to the extent that effective precautions require governmental action, the fact that government is a centralized system of control makes it difficult for officials to respond to the full spectrum of possible risks against which cost-justified measures might be taken. Given the variety of matters to which they must attend, officials are likely to have a high threshold of attention below which risks are simply ignored. The US government, preoccupied with terrorist threats, paid insufficient attention to the risk of a disastrous flood of New Orleans, though the risk was understood to be significant.

Third, where risks are regional or global rather than local, many national governments, especially in the poorer and smaller countries, may drag their heels in the hope of taking a free ride on the larger and richer countries. Knowing this, the latter countries may be reluctant to take precautionary measures and by doing so reward and thus encourage free riding. Again, there is a US parallel: state and local government may stint on devoting resources to emergency response, expecting aid from other state and local governments and the federal government.

Fourth, countries are poor often because of weak, inefficient, or corrupt government, characteristics that may disable poor nations from taking cost-justified precautions. Again there is a US parallel: Louisiana is a poor state and New Orleans, which has a very large poor population, has a reputation for having an inefficient and even corrupt government.

And fifth, the positive correlation of per capita income with value of life suggests that it is quite rational for even a well-governed poor country to devote proportionately fewer resources to averting calamities than rich countries do. This would also be true of a poor state or city of the United States.

The failure to act in accordance with cost–benefit principles is dominant characteristic of public policy towards catastrophic risk. An example is the asteroid menace, which is analytically similar to the menace of tsunamis. The National Aeronautics and Space Administration, with an annual budget of more than $10 billion, spends only $4 million a year on mapping dangerously close large asteroids, and at that rate may not complete the task for another decade, even though such mapping is the key to an asteroid defence because it may provide many years of advance warning. Deflecting an asteroid from its orbit when it is still hundreds of millions of miles away from hitting the earth appears to be a feasible undertaking. Although asteroid strikes are less frequent than tsunamis, there have been enough of them to enable the annual probabilities of various magnitudes of such strikes to be estimated, and from these estimates an expected cost of asteroid damage can be calculated. As in the case of tsunamis, if there are measures, beyond those being taken already, that can reduce the expected cost of asteroid damage at a lower cost, thus yielding a net benefit, the measures should be taken, or at least seriously considered.
**Cost–benefit analysis under uncertainty**

Often it is not possible to estimate the probability or magnitude of a possible catastrophe; the situation is one of uncertainty rather than of risk; how then can cost–benefit analysis, or other techniques of economic analysis, help us in devising responses to such a possibility? The probability of bioterrorism or nuclear terrorism, for example, cannot be quantified; nevertheless, there is rough sense of the range of possible losses that such terrorism would inflict – a range that has no upper limit short of the extinction of the human race – and from this it can be inferred that, even if the probability of such a terrorist attack is small, the expected cost – the product of the probability of the attack and of the consequences if the attack occurs – probably is quite high.

An example of how economic analysis can produce insights even when catastrophic risks are non-quantifiable involves the Relativistic Heavy Ion Collider (RHIC) that went into operation at Brookhaven National Laboratory in Long Island in 2000. As explained by the distinguished English physicist Sir Martin Rees, the collisions in RHIC might conceivably produce a shower of quarks that would ‘reassemble themselves into a very compressed object called a strangelet…. A strangelet could, by contagion, convert anything else it encountered into a strange new form of matter…. A hypothetical strangelet disaster could transform the entire planet Earth into an inert hyperdense sphere about one hundred metres across’ (Rees, 2003, pp. 120–1). Rees considers this ‘hypothetical scenario’ exceedingly unlikely, yet points out that even an annual probability of 1 in 500 million is not wholly negligible when the result, should the improbable materialize, would be so total a disaster.

Concern with such a possibility led John Marburger, the director of the Brookhaven National Laboratory, to commission a risk assessment by a committee of distinguished physicists before authorizing RHIC to begin operating. The committee concluded that the risk of a strangelet disaster was negligible. No cost–benefit analysis of RHIC was conducted, with or without including the risk of a strangelet disaster on the cost side. RHIC cost $600 million to build, and its annual operating costs were expected to be $130 million. No attempt was made to monetize the benefits that the experiments conducted in it were expected to yield; because the experiments are designed to satisfy scientific curiosity rather than to create knowledge that is likely to lead to the invention of useful products, estimation of the benefits is impossible. They may be slight.

The probability of a strangelet disaster in the course of RHIC's planned ten-year life cannot actually be quantified, though there have been attempts. One team of physicists estimated the probability of a strangelet disaster as no more than 1 in 50 million. The official risk-assessment team offered a series of upper-bound estimates, including a 1 in 500,000 probability of a strangelet disaster over the ten-year period, which is 100 times greater than the other's team's estimate. These really are wild, as well as wildly divergent, guesses. Still another uncertainty is what dollar figure to place on the destruction of the earth and all its human and other inhabitants, given the nonlinearity of value of life estimates. Yet, given these uncertainties, the fact that the benefits of RHIC may be quite small suggests that the possibility, remote as it may seem, of a strangelet disaster would weigh heavily, in an economic analysis, against the project. There are more than six billion people on Earth – not to mention unborn future generations – and if their average value of life is estimated at a modest $1 million, the cost of extinction would be $6 quadrillion, and a 1 in 100 million annual risk of a strangelet disaster would yield an annual expected extinction cost of $60 million for ten years to add to the $130 million in annual operating costs and the initial investment of $600 million – roughly a one-third increase in total cost. This could well be
Global warming: risk and response

Another, more familiar, example of the difficulty of quantifying catastrophic risk is the problem of global warming. The Kyoto Protocol, which came into effect by its terms when Russia signed it although the United States has not done so, requires the signatory nations to reduce their carbon dioxide emissions to a level seven to ten per cent below what they were in the late 1990s, but exempts developing countries, such as China, a large and growing emitter, and Brazil, which is destroying large reaches of the Amazon rainforest, much of it by burning. The effect of carbon dioxide emissions on the atmospheric concentration of the gas is cumulative, because carbon dioxide leaves the atmosphere (by being absorbed into the oceans) at a much lower rate than it enters it, and therefore the concentration will continue to grow even if the annual rate of emission is cut down substantially. Between this phenomenon and the exemptions, there is a widespread belief that the Kyoto Protocol will have only a slight effect in arresting global warming; yet the tax or other regulatory measures required to reduce emissions below their level of six years ago will be very costly.

The Protocol's supporters generally are content to slow the rate of global warming by encouraging – by means of heavy taxes (for example, on gasoline or coal) or other measures (such as quotas) that will make fossil fuels more expensive to consumers – conservation measures such as driving less or driving more fuel-efficient cars that will reduce the consumption of these fuels. But from an economic standpoint that is probably either too much or too little. It is too much if, as most scientists believe, global warming will continue to be a gradual process, producing really serious effects – the destruction of tropical agriculture, the spread of tropical diseases such as malaria to currently temperate zones, dramatic increases in violent storm activity (increased atmospheric temperatures, by increasing the amount of water vapour in the atmosphere, increase precipitation), and a rise in sea levels (eventually to the point of inundating most coastal cities) – only toward the end of the 21st century. By that time science, without prodding by governments, is likely to have developed economical ‘clean’ substitutes for fossil fuels (there already is a clean substitute – nuclear power) and even economical technologies for either preventing carbon dioxide from being emitted into the atmosphere by the burning of fossil fuels, or removing it from the atmosphere.

But the Protocol is too little and too late, as a response to the costs of global warming, if the focus is changed from gradual to abrupt global warming. At various times in the Earth's history, drastic temperature changes have occurred in the course of just a few years. During the Younger Dryas epoch of about 11,000 years ago, shortly after the end of the last ice age, global temperatures soared by about 14 degrees Fahrenheit in the course of a decade. Because the earth was still cool from the ice age, the effect of the increased warmth on the human population was positive. But a similar increase in a modern decade would have devastating effects on agriculture and on coastal cities, and might even cause a shift in the Gulf Stream that would result in giving all of Europe a Siberian climate.

Because of the enormous complexity of the forces that determine climate, and the historically unprecedented magnitude of human effects on the concentration of greenhouse gases, the possibility that continued growth in that concentration could precipitate – and within the near rather than the distant future – a sudden warming similar to that of the Younger Dryas cannot be excluded. Indeed, no probability, high or low, can be assigned to such a catastrophe. But it may be significant that, while
catastrophic risk: The New Palgrave Dictionary of Economics

Dissent continues, many climate scientists are now predicting dramatic effects from global warming within the next 20 to 40 years, rather than just by the end of the century (Lempinen, 2005). It may be prudent, therefore, to try to stimulate an increase in the rate at which economical substitutes for fossil fuels, and technology both for limiting the emission of carbon dioxide by those fuels when they are burned in internal-combustion engines or electrical generating plants, and for removing carbon dioxide from the atmosphere, are developed. This can be done by stiff taxes on carbon dioxide emissions. Such taxes give the energy industries, along with customers of theirs such as airlines and manufacturers of motor vehicles, a strong incentive to finance R&D designed to create economical clean substitutes for such fuels and devices to ‘trap’ emissions at the source before they enter the atmosphere. Given the technological predominance of the United States, it is important that these taxes be imposed on US firms, which they would be if the United States ratified the Kyoto Protocol.

One advantage of the technology-forcing tax approach over public subsidies for R&D is that the government would not be in the business of picking winners – the affected industries would decide what R&D to support – and another is that the brunt of the taxes could be partly offset by reducing other taxes, since emission taxes would raise revenue as well as inducing greater R&D expenditures. It might seem that subsidies would be necessary for technologies that would have no market, such as technologies for removing carbon dioxide from the atmosphere. There would be no private demand for such technologies because, in contrast to ones that reduce emissions, technologies that remove already emitted carbon dioxide from the atmosphere would not reduce any emitter's tax burden. But this problem is easily solved by making the tax a tax on net emissions. Then an electrical generating plant or other emitter could reduce its tax burden by removing carbon dioxide from the atmosphere as well as by reducing its own emissions of carbon dioxide into the atmosphere.

It might seem that, because the demand for conventional fuel sources is inelastic in the short run, the imposition of stiff taxes or quotas required by the Kyoto Protocol would have little effect on the level of emissions. But the significance of the taxes, which actually depends on the inelasticity of demand, is that it would create both pressures and resources for finding a technological fix that would counter the cumulative effect of emissions on the atmospheric concentration of carbon dioxide by driving annual emissions to zero or even below.

Global warming: the discounting problem

A further advantage of focusing on the risk of abrupt rather than gradual global warming is that it allows the vexing problem of discount rate to be elided. The problem is acute when concern focuses on gradual global warming. Suppose that a $10 billion expenditure on capping emissions today would have no effect on human welfare during this century but, by slowing global warming, would produce a savings in social costs of $100 billion in 2100. At a discount rate of three per cent, the present value of $100 billion a century from now is only $5 billion. That would make the expenditure of $10 billion today seem a very poor investment. (For the sake of simplicity, benefits that are expected to accrue after 2100 are ignored in this analysis.) The same amount of money invested in financial instruments could be expected to grow to $192 billion by 2100, on the assumption of a three per cent real interest rate for the next 100 years (though in fact interest rates cannot be forecast over such a long period). If the fund were then disbursed to the victims of global warming, they would be better off than if the $100 billion cost of global warming assumed to be incurred in that year had been averted. Less conservative investments,
moreover, would yield larger expected returns – ten per cent or more rather than three per cent. But it is not a real alternative to spending $10 billion now to invest it in a fund for future victims of global warming. No such fund will be created, and so they will not be compensated. In circumstances such as this, discounting future to present values is not a method of helping people to decide how to manage their affairs in the way most conducive to maximizing their welfare. Rather, it is a method of maximizing global wealth without regard to its distribution among persons. In the case of gradual global warming, the victims are likely to be concentrated in poor countries, so that basing policy on the discounted costs of global warming would further immiserate the future inhabitants of those countries by increasing the authorized level of emissions harmful to them.

A discount rate based on market interest rates tends to obliterate the interests of remote future generations. The implications are drastic. ‘At a discount rate of five per cent, one death next year counts for more than a billion deaths in 500 years. On this view, catastrophes in the further future can now be regarded as morally trivial’ (Parfit, 1984, p. 357). (What right would the Romans have had to regard our lives as worthless in deciding whether to conduct dangerous experiments?) The trade-off is only slightly less extreme if one substitutes 100 years for 500. At a five per cent discount rate, the present value of one dollar to be received in 100 years is only three-quarters of a cent – and if for money we substitute lives, then to save one life this year we should be willing to sacrifice almost 150 lives a century hence. And yet not to discount future costs at all would be absurd, certainly as a practical political matter. For then the present value of benefits conferred on our remote descendants would approach infinity.

Measures taken today to arrest global warming would confer benefits not only in 2100 but in every subsequent year, perhaps for millions of years. The present value of $100 billion received every year for a million years at a discount rate of zero per cent is $100 quadrillion.

But the vexing problem of how much weight to give to the welfare of remote future generations can be finessed, at least to some extent, if not solved. A discounted present value can be equated to an undiscounted present value simply by shortening the time horizon for the consideration of costs and benefits. For example, the present value of an infinite stream of costs discounted at four per cent a year is equal to the undiscounted sum of those costs for 25 years, while the present value of an infinite stream of costs discounted at one per cent a year is equal to the undiscounted sum of those costs for 100 years. The formula for the present value of one dollar per year forever is $1/r$, where $r$ is the discount rate. So if $r$ is four per cent, the present value is $25$, and this is equal to an undiscounted stream of one dollar per year for 25 years. If $r$ is one per cent, the undiscounted equivalent is 100 years.

One way to argue for the four per cent rate (that is, for truncating our concern for future welfare at 25 years) is to say that we're willing to weight the welfare of the next generation as heavily as our own welfare but that's the extent of our regard for the future. One way to argue for the one per cent rate is to say that we are willing to give equal weight to the welfare of everyone living in this century, which will include us, our children, and our grandchildren, but beyond that we don't care. Looking at future welfare in this way, we may be inclined towards the lower rate, which would have dramatic implications for willingness to invest today in limiting global warming. The lower rate could even be regarded as a ceiling. Most people have some regard for human welfare, or at least the survival of some human civilization, in future centuries. We are grateful that the Romans didn't exterminate the human race in chagrin at the impending collapse of their empire.

Another way to bring future consequences into focus without conventional discounting is by aggregating risks over time rather than expressing them in annualized terms. If we are concerned about what may
happen over the next century, then instead of asking what the annual probability of a collision with a ten-kilometre-wide asteroid is, we might ask what the probability is that such a collision will occur within the next 100 years. An annual probability of 1 in 75 million translates into a century probability of roughly 1 in 750,000. That may be high enough – in view of the consequences if the risk materializes – to justify spending several hundred million, perhaps even several billion, dollars to avert it.

Inverse cost–benefit analysis

A helpful approach to cost–benefit analysis under conditions of extreme uncertainty is what can be called ‘inverse cost–benefit analysis’ (Posner, 2004, pp. 176–84). Analogous to extracting probability estimates from insurance premiums, it involves dividing what the government is spending to prevent a particular catastrophic risk from materializing by what the social cost of the catastrophe would be if it did materialize. The result is an approximation to the implied probability of the catastrophe. Expected cost is the product of probability and consequence (loss): $C = PL$. If $P$ and $L$ are known, $C$ can be calculated. If instead $C$ and $L$ are known, $P$ can be calculated: if $1$ billion ($C$) is being spent to avert a disaster that if it occurs will impose a loss ($L$) of $100$ billion, then $P = C / L = .01$. If $P$ so calculated diverges sharply from independent estimates of it, this is a clue that society may be spending too much or too little on avoiding $L$. It is just a clue, because of the distinction between marginal and total costs and benefits. The optimal expenditure on a measure is the expenditure that equates marginal cost to marginal benefit. Suppose we happen to know that $P$ is not .01 but .1, so that the expected cost of the catastrophe is not $1$ billion but $10$ billion. It doesn't follow that we should be spending $10$ billion, or indeed anything more than $1$ billion, to avert the catastrophe. Perhaps spending just $1$ billion would reduce the expected cost of catastrophe from $10$ billion all the way down to $500$ million and no further expenditure would bring about a further reduction, or at least a cost-justified reduction. For example, if spending another $1$ billion would reduce the expected cost from $500$ million to zero, that would be a bad investment, at least if risk aversion is ignored.

The federal government is spending about $2$ billion a year to prevent a bioterrorist attack (increased to $2.5$ billion for 2005 under the rubric of ‘Project BioShield’) (Office of Management and Budget, 2003, pp. 37–8; US Department of Homeland Security, 2004). The goal is to protect Americans, so in assessing the benefits of this expenditure casualties in other countries can be ignored. Suppose the most destructive biological attack that seems reasonably possible on the basis of what little we now know about terrorist intentions and capabilities would kill 100 million Americans. We know that value-of-life estimates may have to be radically discounted when the probability of death is exceedingly slight. But there is no convincing reason for supposing the probability of such an attack less than, say, 1 in 100,000; and the value of life that is derived by dividing the cost that Americans will incur to avoid a risk of death of that magnitude by the risk is about $7$ million. Then, if the attack occurred, the total costs would be $700$ trillion – and that is actually too low an estimate because the death of a third of the population would have all sorts of collateral consequences, mainly negative. Let us, still conservatively however, refigure the total costs as $1$ quadrillion. The result of dividing the money being spent to prevent such an attack, $2$ billion, by $1$ quadrillion is $1/500,000$. Is there only a 1 in 500,000 probability of a bioterrorist attack of that magnitude in the next year? One doesn't know, but the figure seems too low. It doesn't follow that $2$ billion a year is too little to be spending to prevent a bioterrorist attack; one
must not forget the distinction between total and marginal costs. Suppose that the $2 billion expenditure reduces the probability of such an attack from .01 to .0001. The expected cost of the attack would still be very high – $1 quadrillion multiplied by .0001 is $100 billion – but spending more than $2 billion might not reduce the residual probability of .0001 at all. For there might be no feasible further measures to take to combat bioterrorism, especially when we remember that increasing the number of people involved in defending against bioterrorism, including not only scientific and technical personnel but also security guards in laboratories where lethal pathogens are stored, also increases the number of people capable, alone or in conjunction with others, of mounting biological attacks. But there are other response measures that should be considered seriously. And one must also bear in mind that expenditures on combating bioterrorism do more than prevent mega-attacks; the lesser attacks, which would still be very costly both singly and cumulatively, would also be prevented. Costs, moreover, tend to be inverse to time. It would cost a great deal more to build an asteroid defence in one year than in ten years because of the extra costs that would be required for a hasty reallocation of the required labour and capital from the current projects in which they are employed. And so would other crash efforts to prevent catastrophes. Placing a lid on current expenditures would have the incidental benefit of enabling additional expenditures to be deferred to a time when, because more will be known about both the catastrophic risks and the optimal responses to them, considerable cost savings may be possible. The case for such a ceiling derives from comparing marginal benefits to marginal costs; the latter may be sharply increasing in the short run.

Catchings, Waddill (1879–1967)

Robert W. Dimand

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

business cycle; Catchings, W.; Federal Reserve System; Foster, W.; Harrod–Domar growth theory; Keynesianism; short run and long run; monetarism; Pollak Foundation for Economic Research

Article

An investment banker and heterodox monetary economist, Waddill Catchings was born in Sewanee, Tennessee, on 6 September 1879, and died in Pompano Beach, Florida, on 31 December 1967. He graduated from Harvard College in 1901 and Harvard Law School in 1904. Joining the New York City law firm Sullivan & Cromwell on a salary of ten dollars a week, Catchings proved skilful in managing the affairs of companies that went into receivership during the financial panic of 1907, and became president of three ironworks. During the First World War, Catchings worked in the export department of J. P. Morgan & Company, then the US purchasing agent for the British and French governments. A Harvard classmate of Arthur Sachs, Catchings joined Goldman, Sachs & Company in 1918 as partner in charge of underwriting, helping to organize General Foods and National Dairy Products (later Kraft). Catchings complained that his Harvard professors ‘casually explained that their theories would hold true in the long run. But what people are interested in is the short, not the long, run. So I made up my mind that as soon as I had enough money I would set about reconciling these two phases of business – theory and practice’ (quoted in his obituary in the New York Times, 1 January 1968). In 1920, Catchings and his Harvard classmate William Trufant Foster (a rhetoric professor and college administrator) established the Pollak Foundation for Economic Research, directed by Foster, funded by Catchings, and dedicated to promoting their belief that, in Catchings's words, ‘If business is to continue zooming, production must be kept at high speed, whatever the circumstances’ (New York Times obituary). High and growing levels of production could be maintained by high and growing levels of consumer spending, and the business cycle could be eliminated by appropriate Federal Reserve policy and by keeping public works projects in reserve for economic downturns. In addition to a syndicated newspaper column, Foster and Catchings wrote Money (1923), Profits (1925), Business without a Buyer (1927), The Road to Plenty (1928), and Progress and Plenty (1930), all Pollak Foundation Studies. Gleason (1959) and Carlson (1962) consider
Foster and Catchings as possible precursors of Keynesian macroeconomics and Harrod–Domar growth theory. The four per cent annual increase in currency and credit endorsed by Foster and Catchings is a possible forerunner of monetarism, but they opposed any mandating of a price level rule, preferring a goal of maintaining prosperity (Tavlas, 1976).

In December 1928, Catchings launched the Goldman Sachs Trading Corporation (GSTC), a closed-end investment trust (ten per cent owned by Goldman, Sachs & Company) which in July 1929 launched the Shenandoah Corporation, another closed-end investment trust, 40 per cent owned by GSTC, followed in August by the Blue Ridge Corporation, with Shenandoah owning a majority of Blue Ridge's common shares. At their peak, this highly leveraged pyramid controlled $500 million of investments, but it was swept away in the stock market crash. GSTC shares, which were initially sold to the public at $104, reached $326 (thanks in part to $57 million that GSTC spent buying its own shares by March 1929, and more purchases later) before falling to $1.75. Catchings had launched Shenandoah and Blue Ridge without consulting the Sachs brothers (who were in Europe in the summer of 1929), and in May 1930 his partners forced his resignation, paying him $250,000 despite his capital account's deficit.

Catchings withdrew from the Pollak Foundation (whose endowment disappeared in the crash) to concentrate on his own finances, and moved to California. In the 1950s Catchings was a director of Chrysler, Standard Packaging, and Warner Brothers. After Foster died in 1950, Catchings collaborated with Charles F. Roos (a co-founder of the Econometric Society) on *Money, Men and Machines* (1953). Denouncing Keynesian economics, Catchings and Roos accused the Federal Reserve System of interfering with economic freedom and destabilizing the economy through roller-coaster monetary policies in futile attempts to keep higher wages from causing higher prices. Their book won the Freedoms Foundation's George Washington Honor Medal. Catchings's last books were *Do Economists Understand Business?* (1955), *Bias Against Business* (1956), and *Are We Mismanaging Money?* (1960).

Categorical outcome (or discrete outcome or qualitative response) regression models are models for a discrete dependent variable recording in which of two or more categories an outcome of interest lies. For binary data (two categories) probit and logit models or semiparametric methods are used. For multinomial data (more than two categories) that are unordered, common models are multinomial and conditional logit, nested logit, multinomial probit, and random parameters logit. The last two models are estimated using simulation or Bayesian methods. For ordered data, standard multinomial models are ordered logit and probit, or count models are used if ordered discrete data are actually a count.

Article

Categorical outcome models are regression models for a dependent variable that is a discrete variable recording in which of two or more categories, usually mutually exclusive, an outcome of interest lies. Categorical outcome models are also called discrete outcome models or qualitative response models, and are examples of a limited dependent variable model. Different models specify different functional forms for the probabilities of each category. These models are binomial or multinomial models, usually estimated by maximum likelihood.

Key early econometrics references include McFadden (1974), Amemiya (1981), Manski and McFadden

Binary outcomes: logit and probit models

Binary outcomes provide the simplest case of categorical data, with just two possible outcomes. An example is whether or not an individual is employed and whether or not a consumer makes a purchase. For binary outcomes the dependent variable $y$ takes one of two values, for simplicity coded as 0 or 1. If $y_i = 1$ with probability $p_i$, then necessarily $y_i = 0$ with probability $1 - p_i$, where $i$ denotes the $i^{th}$ of $N$ observations. Regressors $x_i$ are introduced by parameterizing the probability $p_i$, with

$$p_i = \Pr[y_i = 1|x_i] = F(x_i' \beta),$$

where $F(\cdot)$ is a specified function and a single-index form is assumed. The obvious choice of $F(\cdot)$ is a cumulative distribution function (CDF) since this ensures that $0 < p_i < 1$. The two standard models are the logit model with $p_i = \Lambda(x_i' \beta) = \frac{e^{x_i' \beta}}{1 + e^{x_i' \beta}}$, where $\Lambda(z) = \frac{e^{z}}{1 + e^{z}}$ is the logistic CDF, and the probit model with $p_i = \Phi(x_i' \beta)$, where $\Phi(\cdot)$ is the standard normal CDF.

Interest usually lies in the marginal effect of a change in regressor on the probability that $y = 1$. For the $r^{th}$ regressor, $\frac{\partial p_i}{\partial x_{ir}} = F'(x_i' \beta) \beta_r$ where $F'$ denotes the derivative of $F$. The sign of $\beta_r$ gives the sign of the marginal effect, if $F$ is a continuous CDF since then $F' > 0$, though the magnitude depends on the point of evaluation $x_i$. Common methods are to report the average marginal effect over all observations or to report the marginal effect evaluated at $\bar{x}$.

Parameter estimates are usually obtained by maximum likelihood (ML) estimation. Given $p_i$, the density can be conveniently expressed as $f(y_i) = p_i^{y_i}(1 - p_i)^{1-y_i}$. On the assumption of independence over $i$, the resulting log-likelihood function is

$$\ln L(\beta) = \sum_{i=1}^{N} \left\{ y_i \ln F(x_i' \beta) + (1 - y_i) \ln (1 - F(x_i' \beta)) \right\}.$$
It can be shown that consistency of the ML estimator requires only that \( p_i = F(x_i' \beta) \), that is, that the functional form for the conditional probability is correctly specified.

There is usually little difference between the predicted probabilities obtained by probit or logit, except for very low and high probability events. For the logit model \( \ln \left( \frac{p_i}{1 - p_i} \right) = x_i' \beta \), so that \( \beta \) gives the marginal effect of a change in \( x_{ir} \) on the log-odds ratio, a popular interpretation in the biostatistics literature.

A simpler method for binary data is OLS regression of \( y_i \) on \( x_i \), with White heteroskedastic robust standard errors used to control for the intrinsic heteroskedasticity in binary data. A serious defect is that OLS permits predicted probabilities to lie outside the (0,1) interval. But it can be useful for exploratory analysis, as OLS coefficients can be directly interpreted as marginal effects and standard methods then exist for complications such as endogenous regressors.

When one of the outcomes is uncommon, surveys may over-sample that outcome. For example, a survey of transit use may be taken at bus stops to over-sample bus riders. This is a leading example of choice-based sampling. Standard ML estimators are inconsistent and instead one must use alternative estimators such as appropriately weighted ML.

The preceding discussion presumes knowledge of \( F \). A considerable number of semiparametric estimators that provide consistent estimates of \( \beta \) given unknown \( F \) have been proposed. Manski’s (1975) smooth maximum score estimator was a very early example of semiparametric estimation.

**Index models**

Define a latent (or unobserved) variable \( y_i^* \) that measures the propensity for the event of interest to occur. If \( y_i^* \) crosses a threshold, normalized to be zero, then the event occurs and we observe \( y_i = 1 \) if \( y_i^* > 0 \) and \( y_i = 0 \) if \( y_i^* \leq 0 \). If \( y_i^* = x_i' \beta + u_i \), then

\[
 p_i = \Pr[y_i^* > 0] = \Pr[-u_i < x_i' \beta] = F(x_i' \beta),
\]

where \( F(\cdot) \) is the CDF of \(-u_i\).

The logit model arises if \( u_i \) has the logistic distribution. The probit model arises if \( u_i \) has the more obvious standard normal distribution, where imposing a unit error variance ensures model identification.

The probit model ties in nicely with the Tobit model, where more data are available and we actually observe \( y_i = y_i^* \) when \( y_i^* > 0 \). And it extends naturally to ordered multinomial data.

**Random utility models**

In many economics applications the binary outcome is determined by individual choice, such as whether
or not to work. Then the outcome should be the alternative with highest utility. The additive random utility model (ARUM) specifies the utility for individual \( i \) of alternative \( j \) to be 
\[
U_{ij} = x'_i \beta_j + \epsilon_{ij},
\]
where the error term captures factors known by the decision-maker but not the econometrician. Then

\[
\Pr[U_{i1} > U_{i0}] = \Pr[(\epsilon_{i0} - \epsilon_{i1}) \leq x'_i \beta_1 - x'_i \beta_0] = F(x'_i \beta_1 - x'_i \beta_0)
\]

where \( F \) is the CDF of \( (\epsilon_{i0} - \epsilon_{i1}) \). For components \( x_{ir} \) of \( x_i \) that vary across alternatives (so \( x_{i0r} \neq x_{i1r} \)) it is common to restrict \( \beta_{0r} = \beta_{1r} = \beta_r \). For components \( x_{ir} \) of \( x_i \) that are invariant across alternatives (so \( x_{i0r} = x_{i1r} \)) only the difference \( \beta_{1r} - \beta_{0r} \) is identified.

The probit model arises, after rescaling, if \( \epsilon_{i0} \) and \( \epsilon_{i1} \) are i.i.d. standard normal. The logit model arises if \( \epsilon_{i0} \) and \( \epsilon_{i1} \) are i.i.d. type 1 extreme value distributed with density \( f(\epsilon) = e^{-\epsilon} \exp(-e^{-\epsilon}) \). The latter less familiar distribution provides more tractable results when extended to multinomial models.

**Multinomial outcomes**

Multinomial outcomes occur when there are more than two categorical outcomes. With \( m \) outcomes the dependent variable \( y \) takes one of \( m \) mutually exclusive values, for simplicity coded as \( 1, \ldots, m \). Let \( p_j \) denote the probability that the \( j^{th} \) outcome occurs. The multinomial density for \( y \) can be written as

\[
f(y) = \prod_{j=1}^{m} p_j^{y_j} \text{ where } y_j, j = 1, \ldots, m, \text{ are } m \text{ indicator variables equal to 1 if } y = j \text{ and equal to 0 if } y \neq j.
\]

Introducing a further subscript for the \( i^{th} \) individual and assuming independence over \( i \) yields log-likelihood

\[
\ln L(\beta) = \sum_{i=1}^{N} \sum_{j=1}^{m} y_{ij} \ln p_{ij}
\]

where the probabilities \( p_{ij} \) are modelled to depend on regressors and unknown parameters \( \beta \).

There are many different multinomial models, corresponding to different parameterizations of \( p_{ij} \).

**Unordered multinomial models**

Usually the outcomes are unordered, such as in choice of transit mode to work. The benchmark model
for unordered outcomes is the multinomial logit model. When regressors vary across alternatives (such as prices), the conditional logit (CL) model specifies \( p_{ij} = \frac{e^{x_i'\beta}}{\sum_{k=1}^{m} e^{x_k'\beta}} \). If regressors are invariant across alternatives (such as gender), the multinomial logit (MNL) model specifies

\[ p_{ij} = \frac{e^{x_i'\beta}}{\sum_{k=1}^{m} e^{x_k'\beta}} \]

with a normalization such as \( \theta_1 = 0 \) to ensure identification. In practice some regressors may be a mix of invariant and varying across alternatives; such cases can be re-expressed as either a CL or MNL model.

The CL and MNL models reduce to a series of pairwise choices that do not depend on the other choices available. For example, the choice between use of car or red bus is not affected by whether another alternative is a blue bus (essentially the same as the red bus). This restriction, called the assumption of independence of irrelevant alternatives, has led to a number of alternative models.

These models are based on the ARUM. Suppose the \( j^{th} \) alternative has utility

\[ U_{ij} = x_i'\beta + \varepsilon_{ij}, \quad j = 1, ..., m. \]

Then

\[ p_{ij} = \Pr[U_{ij} \geq U_{ik} \text{ for all } k] = \Pr[(\varepsilon_{ik} - \varepsilon_{ij}) \leq (x_{ij}'\beta - x_{ik}'\beta) \forall k]. \]

The CL and MNL models arise if the errors \( \varepsilon_{ij} \) are i.i.d. type 1 extreme value distributed. More general models permit correlation across alternatives \( j \) in the errors \( \varepsilon_{ij} \).

The most tractable model with error correlation is a nested logit model. This arises if the errors are generalized extreme value distributed. This model is simple to estimate but suffers from the need to specify a particular nesting structure.

The richer multinomial probit model specifies the errors to be \( m \)-dimensional multivariate normal with \( (m+1) \) restrictions on the covariances to ensure identification. In practice it has proved difficult to jointly estimate both \( \beta \) and the covariance parameters in this model. A recent popular model is the random parameters logit model. This begins with a multinomial logit model but permits the parameters \( \beta \) to be normally distributed. For these two models there is no closed form expression for the probabilities and estimation is usually by simulation methods or Bayesian methods.

**Ordered multinomial models**

In some cases the outcomes can be ordered, such as health status being excellent, good, fair or poor.

The starting point is an index model, with single latent variable, \( y^\star_i = x_i'\beta + u_i \). As \( y^\star \) crosses a series of increasing unknown thresholds we move up the ordering of alternatives. For example, for \( y^\star > \alpha_1 \) health status improves from poor to fair, for \( y^\star > \alpha_2 \) it improves further to good, and so on. For the ordered logit (probit) model the error \( u \) is logistic (standard normal) distributed.

An alternative model is a sequential model. For example, one may first decide whether or not to go to
college \((v = 1)\) and if chose college then choose either two-year college \((v = 2)\) or four-year college \((v = 3)\). The two decisions may be modelled as separate logit or probit models.

A special case of ordered categorical data is a count, such as number of visits to a doctor taking values 0, 1, 2,\ldots. An ordered model can be applied to these data, but it is better to use count models. The simplest count model is Poisson regression with exponential conditional mean \(E[y|x_j] = \exp(x_j' \beta)\).

Common procedures are to use the Poisson but obtain standard errors that relax the Poisson restriction of variance-mean equality, to estimate the richer negative binomial model, or to estimate hurdle or two-part models or with-zeroes models that permit the process determining zero counts to differ from that for positive counts.

### Multivariate outcomes and panel data

Multivariate discrete data arise when more than one discrete outcome is modelled. The simplest example is bivariate binary outcome data. For example, we may seek to explain both employment status (work or not work) and family status (children or no children). The standard model is a bivariate probit model that specifies an index model for each dependent variable with normal errors that are correlated. Such models can be extended to permit simultaneity.

For panel binary data the standard model is an individual specific effects model with \(P_{it} = F(\alpha_i + x_{it}' \beta)\) where \(\alpha_i\) is an individual specific effect. The random effects model usually specifies \(\alpha_i \sim N(0, \sigma^2_\alpha)\) and is estimated by numerically integrating out \(\alpha_i\) using Gaussian quadrature. The fixed effects model treats \(\alpha_i\) as a fixed parameter. In short panels with few time periods consistent estimation of \(\beta\) is possible in the fixed effects logit but not the fixed effects probit model. If \(x_{it}\) includes \(Y_{i,t-1}\), a dynamic model, fixed effects logit is again possible but requires four periods of data.

Catholic economic thought

Pedro Teixeira and António Almodovar

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Although Catholic economics' roots date back to the beginnings of Christianity, its emergence as a structured discourse developed later and slowly. The establishment of a distinctive Catholic approach to modern social and economic problems had to await a more extensive development of the market system and the emergence of political economy. The most prolific period for Catholic economic thought began in 1891 and continued until the end of the Second World War. In the second half of the 20th century the church's interest focused on the analysis of such themes as development, international aid and cooperation.

Keywords
capitalism; Catholic economic thought; charitable contributions; class; concentration of wealth; economic freedom; exploitation; fair trade; foreign aid; just wage; natural law; poverty; redistribution of wealth; *Rerum Novarum*; Salamanca School; social justice; social responsibility; socialism; solidarity; subsidiarity; usury

Article

Catholic economic thought is the outcome of a series of efforts to evaluate the workings of economic life according to a definite set of religious principles. In its more evolved forms, these efforts have inevitably led to include the findings of political economy, and later of economics, in its assessment of economic life, but also to assess the findings of economic analysis itself. According to a strict ecclesiological perspective, only the hierarchy of the Church is authorized to identify the appropriate religious principles that are to be applied to the analysis of the livelihood of man. Therefore, some of the assessments made by Catholics may be considered by the Church's hierarchy as inappropriate.

Catholic economic thought is not to be confused with the social doctrine of the Catholic Church. Since 1891, the most relevant religious principles for the appraisal of social questions from a theological
perspective are gathered in the social doctrine of the Church, which is essentially based in the so-called social encyclicals, which are official documents written by several popes, often based on documents prepared by other high-ranking Church officials. These documents emerged as attempts to offer a better moral and philosophical framework for the workings of a modern society, not as in-depth and systematic discussions of man's economic life or as blueprints for a thorough discussion of economic concepts and theories. By being focused on the material aspects of life, Catholic economic thought is prone to give more emphasis to particular problems – such as usury and finance, social and labour questions or, later, the outline of an alternative economic and social system. However, Catholic economic literature has as a rule been less focused than political economy on technical aspects.

Catholic economic thought has an inescapable doctrinal and normative accent. Its 'ought' sentences are considered as quasi-positive ones, in the sense that they were allegedly meant by God to become factual statements in a society functioning in accordance with natural law (see Barrera, 2001, pp. 117–31). This normative stance acts as an explicit incentive for social action, in order both to amend the workings of existing institutions and to establish new ones – such as charitable institutions, cooperatives, institutions of mutual assistance, and particular ways of labour–capital association. In certain periods, when Catholics were more openly engaged in the revision of economic life, their thought went as far as to suggest the establishment of a specific economic system, which was a third way between the liberal and the socialist ones. But, even when they were more focused on the implementation of particular social and economic measures, people engaged in these initiatives also left some thoughts that are of more general interest.

Early attempts to formulate Catholic economic thought

Although the roots of Catholic economics date back to the beginnings of Christianity, the emergence of a structured discourse developed later and slowly. Thus, even if some of the basic Catholic principles for social and ethical teaching were already present in the gospels and in the patristic literature, the systematic theology of Aquinas was instrumental in the move towards a more organized approach to economic problems. The earliest scholarly attempt to produce an explicit and meaningful set of theological principles applied to economic problems was performed in the 16th century by authors belonging to the Salamanca School. Under the philosophical umbrella provided by Thomism, Dominicans like Vitoria, Soto, and Mercado, and Jesuits like Molina, Mariana and Lugo addressed the problems of usury, prices, and justice in wages. Although these ideas were not formally adopted by the Church, this literature was widely used by confessors in search of appropriate answers for the moral questions raised by the development of economic activity (on the economic thought of the school of Salamanca, see Grice-Hutchinson, 1978; 1993, and Camacho, 1998; these authors are also relevant as examples of a revival of Thomist moral theology, which they applied to international law: see Curran, 2002).

The 19th century

The establishment of a distinctive and clear-cut Catholic approach to modern social and economic problems had nevertheless to wait for a more extensive development of the market system and the
Catholic economic thought. By the late 1830s, the first Catholic political economists were already trying to infuse some basic Christian values into the teachings of classical political economy. Together with the socialists, they were concerned about the consequences of unbridled competition, the concentration of riches in the hands of the few, the exploitation of the poor and weak, and the existence of pervasive unemployment. However, contrary to socialists, Catholics thought that those evils, together with excessive materialism and burgeoning social and political unrest, were to be curbed by individuals renouncing material goods and by extended charity, not by abolishing private property or an expansion of the state. Their criticism voiced the fundamental Christian values of universal fraternity and respect for human dignity, as expressed in the Gospels and in the Apostolic letters.

It is important to note that in the mid-19th century there was a series of authors who wrote on economic subjects from a Catholic perspective before the *Rerum Novarum*, the encyclical of Pope Leo XIII on capital and labour, promulgated 15 May 1891. Among these we find the names of Charles de Coux, Alban de Villeneuve-Bargemont, Joseph Droz, Charles Périn, and Matteo Liberatore. The first four authors are representative of the Catholic perspectives that emerged gradually in the context of 19th-century France and Belgium. Three of them – Coux, Périn and Droz – were openly against any solution for economic problems that would require increased state intervention, and they asked the rich to voluntarily avoid all extreme forms of exploitation and competition; as a rule, they were reasonably sympathetic towards political economy, and may be considered as the forerunners of the conservative tendency that was later organized around the Angers school. Villeneuve-Bargemont had less confidence in voluntary individual action as a remedy for the emerging poor question. Contrary to the Catholic conservative approach, Villeneuve-Bargemont thought that the scale of the problem was so serious that the state should intervene in favour of the labouring masses before they fell irrevocably under the spell of socialism. Thus he may be considered as a precursor of the so-called progressive tendency, later developed by the Fribourg Union and the Liège school. Matteo Liberatore deserves mention, since he was one of the persons involved in the drafting of Leo XIII's *Rerum Novarum* (1891). His views were closer to Villeneuve-Bargemont than to Charles Périn, since he believed that modern poverty was a phenomenon that could not be solved by traditional means (charity), because its causes were embedded in modern social and economic organization. Modern exploitation and modern social unrest were seen not only as consequences of the acceptance of a social and economic model based on the erroneous philosophical notions underlying political economy, but also because the spread of the latter stimulated people to act in a way that damaged social cohesion. Contrary to materialist and utilitarian views, wealth should considered as a means, not an end, and should be distributed according to justice; and the human person should always be respected – meaning that in no circumstance should labour be considered as a mere commodity to be bought and sold in the market. Once individualism and competition were once again checked by an attention to mutual needs, modern phenomena such as the class struggle (between labour and capital) would vanish and a sense of mutually beneficial collaboration would take its place. Measures such as the re-establishment of updated medieval corporations – which had to be adapted to the new realities and not just re-established, were a possible institutional solution for bringing peace and harmony to the relations between producers, namely because they would help to resume natural social relations and reduce the moral, social, and professional void in which liberalism had placed the individuals. Efforts to promote the modern resurgence of these institutions were at the origins of what later became corporatism (see below).
The most prolific period for Catholic economic thought began in 1891 and continued up to the end of the Second World War. Stirred by Leo XIII's *Rerum Novarum*, the willingness to address social and economic questions gave rise to extensive debate and to intense publishing activity (see De Rosa 2004; Hobgood, 1991, p. 112).

The central issue of *Rerum Novarum* is the condition of workers, especially industrial workers, and the moral and material risks arising from what was seen as their degrading situation. Leo XIII made clear from the outset that he considered the major cause to be the political and economic transformations of the previous hundred years. This had destroyed or seriously damaged valuable traditional social structures such as medieval corporations. It had also launched a process of secularization of the legal and political framework, which had greatly diminished the moral influence of the Church. Liberalism had created a social vacuum in which unregulated competition, greed and usury had prospered, resulting in a substantial concentration of wealth and power. The latter eventually created an unbalanced distribution of privileges that made possible the exploitation of the workers by the all-mighty owners of capital. Leo XIII also asserted that the supposed remedies offered by socialists were inadequate to the task. In addition to the obvious problem of atheism, the crucial issue in the Church's critique of socialism was the former's concern with private property. Although the Church criticized the extreme capitalist/individualist/utilitarian uses of private property, these criticisms did not question its fundamental existence.

The Church proposed a new relationship between workers and capitalists. Workers should opt for non-violent ways of solving labour disputes, and should perform faithfully and completely the tasks that were allocated to them. In return, paramount among the duties of capitalists was the acknowledgment of and the respect for the human dignity of the workers. This meant respecting the workers' physical and intellectual health, and the payment of a fair family wage that would put a stop to the need for female and youth labour. Capitalists' social responsibility was central to the way Christians should relate to wealth. Leo XIII underlined the ephemeral and secondary nature of earthly wealth and success. If the Church accepted the inequality of property, it also cared for the poorest members of society, knowing that, unless these were actively supported, they would fall into a state of quasi-serfdom, which would lead to social disruption.

One of the outcomes of the *Rerum Novarum* was the development of an array of books, typically bearing the title of *Principles or Courses on Social Economics*. Often written by Jesuits for the use of both clergy and active Catholic laity, this peculiar type of book tried to re-embed the political economy into a social philosophy so as to secure a coherent and global society based on Christian values (Galindo, 1996, p. 143). The authors of such works had to perform complex scholarly work if they were to fulfil their aim. First, they had to explain classical political economy to their readers; then they had to introduce and explain the Pope's criticisms of the philosophical tenets underlying economic liberalism; next they had to deal with socialism, in order to make sure that this doctrine would not be seen as a possible alternative to the shortcomings of economic liberalism; and finally, they had to highlight the proper course of Catholic thought and action that was to be followed in order to put right contemporary evils. Authors that engaged in this type of work include Charles Antoine, S.J. (1896), Giuseppe Toniolo (1907–9) and Heinrich Pesch, S.J. (1905–26), the latter being considered by Schumpeter as the best.
example of neo-scholasticism (1954, p. 765). Another set of books focused on the outlines of a specifically Catholic system – a third, neo-corporative, way between liberalism and socialism. This system had its roots both in France (Mun, La Tour du Pin) and Germany (Vogelsang, Kettler), and was further developed under the auspices of the Liège School. It was eventually accepted, if not warmly supported, by the encyclical *Quadragesimo Anno*.

*Quadragesimo Anno* appeared in 1931, when Pius XI took the initiative in clarifying and updating the position of the Catholic Church on the economic and social condition of the contemporary world. His view was that, although capitalism per se was not an evil system, there was a problem with the way it had developed, for it had led to economic despotism, namely, a concentration of wealth which gave to a few members of society huge power, which was often used to influence and subjugate governments and countries. The subjugation of the state to the interests of a wealthy minority, whose power was nurtured by ambition, greed and speculative behaviour, fostered social disorder and could lead to the collapse of essential social bonds.

The Church supported the existence of private property, but it also underlined its dual nature (individual and social) and the difference between property ownership and property usage. Hence, the relations between capitalists and workers in the capitalistic system should be reorganized according to this view. According to Pius XI, labour and capital did have common interests, and this communality of efforts and purposes called for a sharing of both the responsibility for the productive process and of the wealth created, including the profits resulting from the productive activity. Commutative justice would be insufficient, and should be complemented by social justice.

Pius XI also emphasized the principle of subsidiarity. According to this principle, the state should not intervene when intermediate levels of society (associations, local community, and family) could act effectively. Social harmony ought therefore to be built upon the contribution of intermediate communities and groups, these taking multiple forms. However, the reconstruction of the social fabric, which had been ruined by unlimited competition and the concentration of wealth, required the state to regulate competition, subordinating it to the higher values of justice and charity. To accomplish the necessary rebalance of social power in order to promote the common good, Pius XI made explicit references to the advantages and risks of the emerging corporatist organization (in Italy and elsewhere). Overall, he thought that the advantages (pacifying society, curbing the insidious influence of socialist organizations, and bringing together workers and capitalists in the search for the common good) could outweigh the possible risks of bureaucratization and state dirigisme. Pius XI saw the establishment of the corporative system as a step in the right direction, towards a Christian social-economic order, through its contribution to a harmonious society and its emphasis on the pursuit of the common good.

**The post-war period**

At the beginning of the 1960s, the Catholic Church underwent profound institutional and theological changes. With the Second Vatican Council (1962–5), Thomism, the theological and philosophical basis of the earlier social and economic doctrine of the Church, lost its unique status (see Nichols, 2002, pp. 139–43). Vatican II also marked a change in the role of the laity, and opened the dialogue between different churches. Although until the early 1960s, socialism and communism stood at the forefront of Church's criticisms, some bridges were later to be established with Marxist sociology (see Curran, 2002,
Catholic economic thought: The New Palgrave Dictionary of Economics

pp. 201, 203).

The Catholic Church’s approach to economic problems also took a different direction in the second half of the 20th century, now focusing in the analysis of themes like development and North–South relationships, international aid and cooperation. This is particularly visible in John XXIII’s *Mater et Magistra* (1961) and Paul VI’s *Populorum Progressio* (1967). In the latter, Paul VI considered that the wealthiest nations had the duties of solidarity, justice and charity towards less developed ones, and that these duties should be addressed through international aid, fair trade and a framework conducive to mutual progress. He was particularly critical of free trade, since he regarded any exchange between unequals as potentially unjust. Hence, he called for fair and just competition between nations.

The social question was nevertheless not forgotten. In the *Mater et Magistra*, John XXIII stated that wages should not be left to market forces alone, for they should be determined by the laws of justice and equity. Private property was not to be considered solely as a right that should be protected, but also as an obligation to practise solidarity among human beings. John XXIII also gave explicit support to the political organization of workers in order to promote their legitimate rights. This text was also the first to address, and largely support, the so-called welfare state and its associated system of social insurance and social security, on the grounds of its contribution to the desirable redistribution of wealth. Although the Church kept its distance vis-à-vis socialism, Paul VI considered that there were some possibilities for cooperation between Catholics and socialist movements insofar as this contributed to a more just society (see his apostolic letter *Octogesima Adveniens* on the occasion of the 80th anniversary of *Rerum Novarum*, 1971).

The dialogue between economic analysis and theology was, if not on hold, at least withdrawn to the backstage. This is likely to have been for several different reasons, ranging from the changing priorities in theology and a new emergence of ecclesiological concerns with the inner life of the Church, to the growing professionalization of economics, which made it ever more difficult to acquire the desirable proficiency in both fields (see Wilson, 1997, pp. 88–9 and 113). In the late 1950s, Catholic writers like Achille Dauphin-Meunier and Jean-Yves Calvez had already begun to assert that the Church had no other wish than to present its own social doctrine. To these authors, the Church was not to offer or to support ‘an economic theory’ but only a ‘philosophical and religious clarification of the fundamental aspects of human existence within economic relationships’ (Calvez and Perrin, 1958, p. 11).

### The contemporary situation

Catholic social doctrine received a significant stimulus in the 1980s and 1990s with John Paul II. He used the 90th and 100th anniversaries of *Rerum Novarum* to express views on the economic realm. In *Laborem exercens* (1981) he focused on the role of work as a central feature of all human activity and therefore of all economic activity. He considered that contemporary developments in technological, economic and political conditions had reinforced the pastoral care that the Church should associate with all issues related to work, such as unemployment and lifelong learning. He criticized what he considered the error of considering human labour solely according to its economic purpose, and underlined the principle of priority of human labour over capital, which should not be attained through class or social warfare but by peaceful struggle for social justice. Likewise, in *Centesimus Annus* (1991) he focused on the harshness of the modern conditions of the working class and pointed out how erroneous the
collectivist and totalitarian solution was. Thus he insisted on the idea of redistribution of wealth in order to fulfil ‘the universal destination of material goods’. John Paul II also devoted special attention to economic and social development, with particular attention being paid to issues such as international division of labour, international debt and poverty. In the encyclical *Sollicitudo Rei Socialis* (1987) he criticized both ‘liberal capitalism’ and ‘Marxism collectivism’ and proposed a view of ‘authentic human development’ which was not only economic but also social and spiritual. Thus, underdevelopment had not only social and economic causes, but also moral ones, not the least being the lack of international solidarity that denied human interdependence beyond national or political borders. His position vis-à-vis social warfare and any possible analytical or political convergence with Marxism is vividly illustrated by the reaction of the Church's hierarchy to Liberation Theology, whose main proponents were either silenced or led to abandon the Catholic Church because of the restrictions imposed on them regarding teaching, preaching and writing.

Modern Catholic theology has focused on achieving a comprehensive and coherent presentation of social ethics (see Curran, 2002). Those who give a certain emphasis to economic aspects (see Barrera, 2001; Hobgood, 1991), always take care to reiterate ‘the caveat that [the Church's social teachings do] not offer an alternative school of thought between classical laissez-faire capitalism and socialist centralized planning’ (Barrera, 2001, p. viii). Notwithstanding this change of focus, the modern effort to systematize the teachings of the encyclicals has led in some cases to the identification of six basic principles: universal access, the primacy of labour, subsidiarity, socialization, solidarity, and stewardship (2001, p. 1, and table on p. 258). By means of these principles, the criticisms addressed to economics continue to stress its defective philosophical base and go on emphasizing the collective risks that are incurred by a society unwilling to restrain excessively individualist, materialist, and utilitarian behaviour. The claims of contemporary Catholic economic thought therefore continue to emphasize the need for justice and equity, something that can be achieved only through the establishment of corrective measures to the workings of the market in order to prevent its deleterious action on the social fabric. The basic appeal therefore remains, that economics should not refuse the normative approach provided by the Catholic view of mankind.

Economics was conceived as early as the classical period as a science of causes. The philosopher-economists David Hume and J. S. Mill developed the conceptions of causality that remain implicit in economics today. This article traces the history of causality in economics and econometrics, showing that different approaches can be classified on two dimensions: process versus structural approaches, and a priori versus inferential approaches. The variety of modern approaches to causal inference is explained and related to this classification. Causality is also examined in relationship to exogeneity and identification.

Article
1 Philosophers of economics and causality
The full title of Adam Smith's great foundational work, *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776), illustrates the centrality of causality to economics. The connection between causality and economics predates Smith. Starting with Aristotle, the great economists are frequently also the great philosophers of causality. Aristotle's contributions to economics are found principally in the *Topics*, the *Politics*, and the *Nicomachean Ethics*, while he lays out his famous four causes (material, formal, final and efficient) in the *Physics*. Material and formal causes are among the concerns of economic ontology, a subject addressed by philosophers of economics (see, for example, Mäki, 2001) albeit rarely by practicing economists. Sometimes, as for example in Karl Marx's grand theory of capitalist development, economists have appealed to final causes or teleological explanation (for a defence, see Cohen, 1978; for a general discussion, see Kincaid, 1996). But, for the most part, taking physical sciences as a model, economics deals with efficient causes. What is it that makes things happen? What explains change? (See Bunge, 1963, for a broad account of the history and philosophy of causal analysis.)

The greatest of the philosopher/economists, David Hume, set the tone for much of the later development of causality in economics. On the one hand, economists inherited from Hume the sense that practical economics was essentially a causal science. In ‘On Interest’, Hume (1742, p. 304) writes:

> it is of consequence to know the principle whence any phenomenon arises, and to distinguish between a cause and a concomitant effect. Besides that the speculation is curious, it may frequently be of use in the conduct of public affairs. At least, it must be owned, that nothing can be of more use than to improve, by practice, the method of reasoning on these subjects, which of all others are the most important; though they are commonly treated in the loosest and most careless manner.
On the other hand, Hume doubted whether we could ever know the essential nature of causation ‘in the objects’ (Hume, 1739, p. 165). Coupled with a formidable critique of inductive inference more generally, Hume’s scepticism has contributed to a wariness about causal analysis in many sciences, including economics (1739; 1777). The tension between the epistemological status of causal relations and their role in practical policy runs through the history of economic analysis since Hume.

2 History

2.1 Hume’s foundational analysis

Although Hume’s dominant concerns are moral, historical, political, and social (including economic), physical illustrations serve as his paradigm causal relationships. A (say, a billiard ball) strikes B (another ball) and causes it to move. Any analysis must address two key features of causality: first, causes are asymmetrical (in general, if A causes B, B does not cause A). Hume sees temporal succession (the movement of A precedes the movement of B) as accounting for asymmetry. Second, causes are effective. A cause must be distinguished from an accidental correlation and must bring about its effect. Hume sees spatial contiguity (the balls touch) and necessary connection (the movement of B follows of necessity from the movement of A) as distinguishing causes from accidents and establishing their effectiveness.

Hume was famously sceptical of any idea that could not be traced either to logical or mathematical deduction or to direct sense experience. He asks, whence comes the idea of the necessary connection of cause and effect? It cannot be deduced from first principles. So, he argues that our idea of necessary connection, which he concedes is the most characteristic element of causality, can arise only from our experience of the constant conjunction of particular temporal sequences. But this then implies that causality stands on a very weak foundation. For one corollary of Hume’s belief that all ideas are based either in logic or sense experience was that we do not have any secure warrant for inductive inference. Neither logic nor experience (unless we beg the question by implicitly assuming the truth of induction) gives us secure grounds from observing instances to inferring a general rule.

Therefore, what we regard as necessary connection in causal inference is really more of habit of mind without clear warrant. Causes may be necessarily connected to effects; but, for Hume, we shall never know in what that necessary connection consists.

While later philosophers have differed with Hume on the analysis of causality, his views were instrumental in setting the agenda, not only for philosophical discussions, but for practical causal analysis as well.

2.2 The 19th century: logic and statistics

Even more influential than Hume in shaping economics, John Stuart Mill, another philosopher/economist, was less sceptical about causal inference in general, but more sceptical about its application to economics. In his System of Logic (1851), Mill advanced his famous canons of induction: the methods of (a) agreement, (b) difference, (c) joint (or double) agreement and difference, (d) residues, and (e) concomitant variations. For example, according to the method of difference, if we have two sets of circumstances, one in which a phenomenon occurs and one in which it does not, and the circumstances agree in all but one respect, that respect is the cause of the phenomenon. Mill’s canons are essentially abstractions from the manner in which causes are inferred in controlled experiments. As such, Mill doubted that the canons could be easily applied to social or economic situations, in which a wide variety of uncontrolled factors are obviously relevant. Mill argued that economics was what Daniel M. Hausman (1992) has called an ‘inexact and separate science’, whose general principles were essentially known a priori and which held only subject to ceteris paribus clauses. Mill’s apriorism proved to be hugely influential in later economics. Lionel Robbins (1935) expressed considerable scepticism about the place of empirical studies within economic science. Some Austrian economists, such as Ludwig von Mises (1966), went so far as to deny that economics could be an empirical discipline at all. Mill’s apriorism also influenced those economists who see economic theory as similar to physical theory as a domain of universal laws.

Other 19th-century economists were less sceptical about the application of causal reasoning to economic data. For instance, W. Stanley Jevons (1863) pioneered the construction of index numbers as the core element of an attempt to prove the causal connection between inflation and the increase in worldwide gold stocks after 1849. Jevons’s investigation can be interpreted as an application of Mill’s method of residues (see Hoover and Dowell, 2001). He saw the various idiosyncratic relative price movements, owing to supply and demand for particular commodities, as cancelling out to leave the common factor that could only be the effect of changes in the money stock.

The 19th century witnessed extensive development in the theory and practice of statistics (Stigler, 1986). Inference based on statistical distributions and correlation measures was closely connected to causality. Adolphe Quetelet envisaged the inferential problem in statistics as one of distinguishing among constant, variable, and accidental causes (Stigler, 1999, p. 52). The economist Francis Ysidro Edgeworth pioneered tests of statistical significance (in fact Edgeworth may have been the first to use this phrase). He glossed the finding of a statistically significant result as one that ‘comes by cause’ (Edgeworth, 1885, pp. 187–8).
Further developments of statistical techniques, such as multiple correlation and regression, in the 20th century were frequently associated with causal inference. It was fairly quickly understood that, unlike correlation, regression has a natural direction: the regression of $Y$ on $X$ does not produce coefficient estimates that are the algebraic inverse of those from the regression of $X$ on $Y$. The direction of regression should respect the direction of causation.

By the early 20th century, however, the dominant vision of economics was one in which prices and quantities are determined simultaneously. This is as much true for Alfred Marshall (1930), who is often described (not perfectly accurately) as an advocate of partial equilibrium analysis, as it is for Léon Walras (1954), the principal font of modern general equilibrium analysis. Simultaneity does not necessarily rule out causal order, though it does complicate causal inference. Although regressions may have a natural causal direction, there is nothing in the data on their own that reveal which direction is the correct one – each is an equally eligible rescaling of a symmetrical and non-causal correlation. This is a problem of observational equivalence. And it is the obverse side of the now familiar problem of econometric identification: in this case, how can we distinguish a supply curve from a demand curve? The problem of identification was pursued throughout most of the first half of the 20th century until the fairly complete treatment by the Cowles Commission at mid-century (Koopmans, 1950; Hood and Koopmans, 1953; see Morgan, 1990, for a thorough treatment of the history of the identification problem).

The standard solution to the identification problem is to look for additional causal determinants that discriminate between otherwise simultaneous relationships. Both the supply of milk and demand for milk depend on the price of milk. If, however, the supply also depends on the price of alfalfa used to feed the cows and the demand also on the daily high temperature (which affects the demand for milk to make ice cream), then supply and demand curves can be identified separately. Identification can be viewed through the glasses of simultaneous equations, pushing causality into the background, or it can be viewed as a problem in causal articulation. In the first case, economists frequently use the language of exogenous variables (the price of alfalfa, the temperature) and endogenous variables (the price and quantity of milk). Exogenous variables can also be regarded as the causes of the endogenous variables. From the 1920s to the 1950s, different economists placed different emphasis on the causal aspects of identification (Morgan, 1990) and the various papers reprinted in Hendry and Morgan (1995).

Modern econometrics can be dated from the development of structural econometric models following the pioneering work in the 1930s of Jan Tinbergen, the conceptual foundations of probabilistic econometrics in Trgyve Haavelmo's (1944) 'Probability approach to econometrics', and the technical elaboration of the identification problem in the two Cowles Commission volumes. Structural models did not in themselves necessarily favor the language of identification over the language of causality. Indeed, in Tinbergen's (1951) textbook, dynamic, structural models are explicated with a diagram that uses arrows to indicate causal connections among time-dated variables. Nevertheless, after the econometric work of the Cowles Commission, two approaches can be clearly distinguished.

One approach, associated with Hermann Wold and known as process analysis, emphasized the asymmetry of causality, typically grounded it in Hume's criterion of temporal precedence (Morgan, 1991). Wold's process analysis belongs to the time-series tradition that ultimately produced Granger causality and the vector autoregression (see Section 3). The other approach, associated with the Cowles Commission, related causality to the invariance properties of the structural econometric model. This approach emphasized the distinction between endogenous and exogenous variables and the identification and estimation of structural parameters. Implicitly, structural modellers accepted Mill's a priori approach to economics. While they differed from Mill in their willingness to conduct empirical investigations, the selection of exogenous (or instrumental) variables was seen to be the province of a priori economic theory – a maintained assumption rather than something to be learned from data itself.

In his contribution to one of the Cowles Commission volumes, Herbert Simon (1953) showed that causality could be defined in a structural econometric model, not only between exogenous and endogenous variables, but also among the endogenous variables themselves. And he showed that the conditions for a well-defined causal order are equivalent to the well-known conditions for identification. Despite the equivalence, with the demise of process analysis and the ascendancy of structural econometrics – aided indirectly perhaps by a revival of Humean causal scepticism among the logical-positivist philosophers of science – causal language in economics virtually collapsed between 1950 and about 1990 (Hoover, 2004).

### 3 Alternative approaches to causality in economics

Different approaches to causality can be classified along two lines as shown in Figure 1. One the one hand, approaches may emphasize structure or process. On the other hand, approaches may rely on a priori identifying assumptions or they may seek to infer causes from data. The upper left cell, the a priori structural approach, represented by the Cowles Commission, dominated economics for most of the postwar period. But since we already discussed it at some length in Section 2, and since it was largely responsible for turning the economics profession away from explicit causal analysis, we add nothing more about it here and instead turn to the other cells in Figure 1.

**Figure 1**

Classification of approaches to causality in economics
3.1 The inferential structural approach

The most important of the inferential structural approaches is due to Simon (1953). Simon eschews temporal order as a basis for causal asymmetry and, instead, looks to recursive structure. As we observed in Section 2, Simon's account is closely related to the Cowles Commission's structural approach. Consider the bivariate system:

\[ Y_t = \theta X_t + \varepsilon_{1t}, \]

\[ X_t = \varepsilon_{2t}, \]
where the random error terms $\varepsilon_{it}$ are independent, identically distributed and $\Theta$ is a parameter. Simon says that $X_t$ causes $Y_t$, because $X_t$ is recursively ordered ahead of $Y_t$. One knows all about $X_t$ without knowing about $Y_t$ but one must know the value of $X_t$ to determine the value of $Y_t$. Equations (1) and (2) also appear to show that any intervention in (2), say a change in the variance of $\varepsilon_{2t}$, would transmit to (1); while any intervention in (1), say a change in $\Theta$ or the variance of $\varepsilon_{1t}$, would not transmit to (2). Apparently, $X_t$ could then be used to control $Y_t$.

Unfortunately, merely being able to write an accurate description of the two variables in the form of (1) and (2) does not guarantee either the apparent asymmetry of information or control. The same data can be repackaged into a statistically identical form with an apparently different causal order. For example, consider the following related system:

\begin{equation}
Y_t = \omega_{1t},
\end{equation}

(3)

\begin{equation}
X_t = \delta Y_t + \omega_{2t},
\end{equation}

(4)

where $\delta = \frac{\Theta \text{var}(\varepsilon_2)}{\Theta^2 \text{var}(\varepsilon_2) + \text{var}(\varepsilon_1)}$, $\omega_{1t} = \varepsilon_{1t} + \Theta \varepsilon_{2t}$ and $\omega_{2t} = (1 - \delta) \varepsilon_{2t} - \delta \varepsilon_{1t}$.

Equations (3) and (4) are derived from eqs. (1) and (2). The details of the algebra are not important. Essentially, (3) and (4) are linear combinations of (1) and (2) with multiplicative factors carefully chosen, so that the error terms $\omega_{1t}$ and $\omega_{2t}$ are uncorrelated. Such linear combinations preserve the values of $X_t$ and $Y_t$ and their statistical likelihood (that is, the two systems of equations have the same reduced form) and, so, describe the data equally well. Equations (3) and (4) have a form analogous to (1) and (2); but, on Simon's criterion, it appears that $Y_t$ causes $X_t$ on Simon's criterion. While it looks like the key parameters for (3) and (4) are derived from those of (1) and (2), we could have taken (3) and (4) as the starting point and derived (1) and (2) symmetrically. What we would like to do is to replace the equal signs with arrows that show that the causal direction runs from the right-hand to the left-hand sides in the regression equations in one of the systems, but not in the other. Unfortunately, there is no way to do this, no choosing between the systems, on the basis of a single set of data by itself. This is the problem of observational equivalence again.

The a priori approach of the Cowles Commission relies on economic theory to provide appropriate identifying assumptions to resolve the observational equivalence. Christopher Sims (1980) attacked the typical application of the Cowles Commission's approach to structural macroeconometric models as relying on 'incredible' identifying assumptions: economic theory was simply not informative enough to do the job. But Simon, who was otherwise supportive of the conception of causality in the Cowles Commission, took a different tack. Simon sees the problem as choosing between two alternative sets of parameters: which set contains the structural parameters, $\{\Theta$ and the variances of the $\varepsilon_{it}\}$ or $\{\delta$ and the variances of the $\omega_{it}\}$? Simon suggested that experiments – either controlled or natural – could help to decide. If, for example, an experiment could alter the conditional distribution of $X_t$ without altering the marginal distribution of $Y_t$, then it must be that $Y_t$ causes $X_t$, because this would be possible only if a structure like (3) and (4) characterized the data. If it did, a
change in the conditional distribution would involve either $\delta$ or the variance of $\omega_{2t}$, neither of which would affect the variance of $\omega_{1t}$. In contrast, if (1) and (2) truly characterized the causal structure of the data, a change to the conditional distribution of $X_t$ would, in fact, involve a change to the variance of $\varepsilon_{2t}$, which, according to the equivalences above, would alter either $\delta$ or the variance of $\omega_{2t}$. Similar relationships of stability and instability in the face of changes to the marginal distribution can also be demonstrated (Hoover, 2001, ch. 7). The appeal to experimental evidence is what marks Simon's approach out as inferential rather than a priori.

Hoover (1990; 2001) generalizes Simon's approach to the type of nonlinear systems of equations found in modern rational-expectations models. He shows that Simon's idea of natural experiments can be operationalized by coordinating historical, institutional, or other non-statistical information with information from structural break tests on what, in effect, amounts to the four regressions corresponding to (1)–(4) above generalized to include lagged dynamics. With allowances for complications introduced by rational expectations, the key idea is that, in the true causal order, interventions that alter the parameters governing the true marginal distribution do not transmit forward to the conditional distribution (characterized by (1) or (4)) nor do interventions in the true conditional distribution transmit backward to the marginal distribution (characterized by (2) or (3)). Since the true structural parameters are not known a priori, non-statistical information is important in identifying an intervention as belonging to the process governing one variable or another. Although avoiding the term ‘causality’, Favero and Hendry’s (1992) analysis of the Lucas critique in terms of ‘super-exogeneity’ is also a variant on Simon’s causal analysis (Ericsson and Irons, 1995; Hoover, 2001, ch. 7). Super-exogeneity is essentially an invariance concept (Engle, Hendry and Richard, 1983). Favero and Hendry find evidence against the Lucas critique (non-invariance in the face of changes in policy regime) in the super-exogeneity of conditional probability distributions in the face of structural breaks in marginal distributions – the same sort of evidence that Hoover cites as helping to identify causal direction.

The recent revival of causal analysis in microeconomics in the guise of ‘natural experiments’, although apparently developed independently of Simon, nonetheless proceeds in much the same spirit as Hoover's version of Simon's approach (Angrist and Krueger, 1999; 2001). This literature typically employs the language of instrumental variables. A natural experiment is a change in a policy or a relevant environmental factor that can be identified non-statistically. Packaged as an econometric instrument, the experiment can be used – in much the same way that variations in alfalfa prices and temperature were used in the example in Section 2 – to identify the underlying relationships and to measure the causally relevant parameters.

While the development of structural approaches in econometrics has largely been independent, there is some cross-fertilization between economists and philosophers (for example, Simon and Rescher, 1966); and recently philosophers of causality have looked to economics for inspiration and examples (for example, Cartwright, 1989; Woodward, 2003).

3.2 The inferential process approach

Perhaps the most influential explicit approach to causality in economics is due to Clive W. J. Granger (1969). Granger causality is an inferential approach, in that it is data-based without direct reference to background economic theory; and it is a process approach, in that it was developed to apply to dynamic time-series models (see Granger–Sims causality in this dictionary for technical details). Granger–Sims causality is an example of the modern probabilistic approach to causality, which is a natural successor to Hume (for example, Suppes, 1970). Where Hume required constant conjunction of cause and effect, probabilistic approaches are content to identify cause with a factor that raises the probability of the effect: $A$ causes $B$ if $P(A \mid \omega) > P(B)$, where the vertical ‘|’ indicates ‘conditional on’. The asymmetry of causality is secured by requiring the cause ($A$) to occur before the effect ($B$) (but the probability criterion is not enough on its own to produce asymmetry since $P(A \mid \omega) > P(B)$ implies $P(A \mid \omega) > P(A)$).

Granger’s (1980) definition is more explicit about temporal dynamics than is the generic probabilistic account, and it is cast in terms of the incremental predictability of one variable conditional on another:

$$X_t \text{ Granger-causes } Y_{t+1} \text{ if } P(Y_{t+1} \mid \text{ all information dated } t \text{ and earlier}) \neq P(Y_{t+1} \mid \text{ all information dated } t \text{ and earlier omitting information about } X).$$

This definition is conceptual, as it is impracticable to condition on all past information.

In practice, Granger causality tests are typically implemented through bivariate regressions. As an illustration, consider the regression equations:

$$Y_t = \Pi_{11}Y_{t-1} + \Pi_{12}X_{t-1} + \nu_{1t}$$
where the $\Pi_{ij}$ are parameters, and the $\nu_{it}$ are random error terms. In practice, lag lengths may be larger than one, but far less than the infinity implicit in the general definition. $X_t$ Granger-causes $Y_{t+1}$ if $\Pi_{12} \neq 0$, and $Y_t$ Granger-causes $X_{t+1}$ if $\Pi_{21} \neq 0$.

Sims (1972) famously used Granger causality to demonstrate the causal priority of money over nominal income. Later, as part of a generalized critique of structural econometric models, Sims (1980) advocated vector autoregressions (VARs) – atheoretical time-series regressions analogous to eqs (1) and (2), but generally including more variables with lagged values of each appearing in each equation. In the VAR context, Granger causality generalizes to the multivariate case.

While Granger causality has something useful to say about incremental predictability, there is no close mapping between Granger causality and structural notions of causality on either the Cowles Commission’s or Simon’s accounts (Jacobs, Leamer and Ward, 1979). Consider a structural model:

\begin{align*}
Y_t &= \theta X_t + \beta_{11} Y_{t-1} + \beta_{12} X_{t-1} + \epsilon_{1t} \tag{7} \\
X_t &= \gamma Y_t + \beta_{21} Y_{t-1} + \beta_{22} X_{t-1} + \epsilon_{2t} \tag{8}
\end{align*}

where $\epsilon_{1t}$ and $\epsilon_{2t}$ are identically distributed, independent random errors and $\theta$, $\gamma$, and the $\beta_{ij}$s are structural parameters. The independence of the parameters and the error terms implies that causality runs from the right-hand to the left-hand sides of each equation. Equations (5) and (6) can be seen as the reduced forms of (7) and (8).

We focus on $X$ causing $Y$. $X$ structurally causes $Y$ if either $\theta$ or $\beta_{12} \neq 0$. And $X$ Granger causes $Y$ if $\Pi_{12} = \frac{\beta_{12} + \theta \beta_{22}}{1 - \rho^2} \neq 0$. Thus, if $X$ Granger causes $Y$, then $X$ structurally causes $Y$. Note, however, that this result is particular to the case in which (7) and (8) represents the universe, so that (5) and (6) represent the complete conditioning on past histories of relevant variables. If the universe is more complex and the estimated VAR does not capture the true reduced forms of the structural system, which in practice they may not, then the strong connection suggested here does not follow.

More interestingly, even if (5)–(8) are complete, structural causality does not necessarily imply Granger causality. Suppose that $\beta_{12} = \beta_{22} = 0$, but $\theta \neq 0$, then $X$ structurally causes $Y$, but since $\Pi_{12} = 0$, $X$ does not Granger cause $Y$.

Now suppose that $X$ does not Granger cause $Y$. It does not necessarily follow that $X$ does not structurally cause $Y$, since if $\theta$, $\beta_{12}$, and $\beta_{22} \neq 0$, and $-\beta_{12} / \beta_{22} = \theta$, then it will still be true that $\Pi_{12} = 0$. This may appear to be an odd special case, but in fact conditions such as $-\beta_{12} / \beta_{22} = \theta$ arise commonly in optimal control problems in economics.

A simple physical example makes it clear what is happening. Suppose that $X$ measures the direction of the rudder on a ship and $Y$ the direction of the ship. The ship is pummeled by heavy seas. If the helmsman is able to steer on a straight course, effectively moving the rudder to exactly cancel the shocks from the waves, the direction of the rudder (in ignorance of the true values of the shocks) will not predict the course of the ship. The rudder would be structurally effective in causing the ship to turn, but it would not Granger-cause the ship’s course.
3.3 The a priori process approach

The upper right-hand cell of Figure 1 is represented by Arnold Zellner's (1979) account of causality (cf. Keuzenkamp, 2000, ch. 4, s. 4). Zellner's notion of causality is borrowed from the philosopher Herbert Feigl (1953, p. 408), who defines causation ‘... in terms of predictability according to law (or more adequately, according to a set of laws)’. On the one hand, Zellner opposes Simon and sides with Granger: predictability is a central feature of causal attribution, which is why his is a process account. On the other hand, he opposes Granger and sides with Simon: an underlying structure (a set of laws) is a crucial presupposition of causal analysis, which is why his is an a priori account.

Much obviously depends on what a law is. Zellner's own view is that a law is a (probabilistic) description of a succession of states of the world that holds for many possible boundary conditions and covers many possible circumstances. He couches his position in an explicitly Bayesian theory of inference. Feigl identifies causality with lawlikeness or predictability. It is the fact that formulae fit previously unexamined cases, as well as examined ones, which constitutes their lawlikeness. This is close to Simon's invariance criterion (the true causal order is the one that is invariant under the right sort of intervention).

The central problem, then, is how to distinguish laws from false generalizations or accidental regularities – that is, how to distinguish conditional relations invariant to interventions from regularities that are either not invariant or are altogether adventitious. Zellner believes that a theory serves as the basis for discriminating between laws and casual generalizations. Although Zellner's approach permits us to learn some things from the data, in keeping with the spirit of Bayesian inference, it does so within a narrowly defined framework (cf. Savage's, 1954, pp. 82–91, 'small world' assumption). Economic theory in Zellner's account restricts the scope of an investigation a priori.

Zellner objects to Granger causality for two reasons. First, it is not satisfactory to identify cause with temporal ordering, as temporal ordering is not the ordinary, scientific or philosophical foundation of the causal relationship. Second, Granger's approach is atheoretical. In order to implement it practically, an investigator must impose restrictions – limit the information set to a manageable number of variables, consider only a few moments of the probability distribution (in our exposition, just the mean), and so forth. For Zellner, if these restrictions cannot be explained theoretically, Granger's methods will discover only accidental regularities.

Zellner explicitly criticizes Granger for ignoring the need for theoretical basis for empirical investigation – implicitly focusing on only one side of a process in which theory informs empirics and empirics inform theory. He criticizes Simon for defining cause to be a formal property of a model (recursive order) without making essential reference to empirical reality. Zellner's criticism is, however, more aptly directed at the Cowles Commission's approach, since (as we saw in Section 3.1) Simon distinguishes himself through tying causal order to empirical inference.

3.4 Structural vector autoregressions

Not all approaches to causality fall quite neatly into the cells of Figure 1; or, more to the point, an approach that falls into one cell may morph into one that falls into another cell. The history of Sims's VAR program is an important case.

Sims (1980) advocated VARs as a reaction to the manner in which the Cowles Commission programme, which identified structural models through a priori theory, had been implemented (see Section 3.2). From a causal perspective, it was closely related to Granger's analysis. Starting with VAR such as eqs (5) and (6), Sims wished to work out how various 'shocks' would affect the variables of the system. This is complicated by the fact that the error terms in (5) and (6), which might be taken to represent the shocks, are not in general independent, so that a shock to one is a shock to both, depending on how correlated they are. Sims's initial solution was to impose an arbitrary orthogonalization of the shocks (a Choleski decomposition). In effect, this meant transforming (5) and (6) into a system like (6) and (7) and setting either \( \theta \) or \( \gamma \) to zero. This amounts to imposing a recursive order on \( X_t \) and \( Y_t \), such that the covariance matrix of the error terms is diagonal (that is, \( \epsilon_{1t} \) and \( \epsilon_{2t} \) are uncorrelated). A shock to \( X \) can then be represented by a realization of \( \epsilon_{1t} \) and a shock to \( Y \) by a realization of \( \epsilon_{2t} \).

Initially, Sims treated the choice of recursive order as a matter of indifference. Criticizing the VAR program from the point of view of structural models, Leamer (1985) and Cooley and LeRoy (1985) pointed out that the substantive results (for instance, impulse-response functions and innovation accounts) depend on which recursive order is chosen. Sims (1982; 1986) accepted the point and henceforth advocated Structural vector autoregressions (SVARs). SVARs can be identified through the contemporaneous causal order only. So, for example, to identify (5) and (6), it is enough to assume that either \( \theta \) or \( \gamma \) in (7) or (8) is zero; one need not make any assumptions about the \( \beta \). Ironically, since the initial impulse behind the VAR programme was to avoid theoretically tenuous identifying assumptions, the choice of restrictions on contemporaneous variables used to transform the VAR into the SVAR are typically only weakly supported by economic theory.

Nevertheless, the move from the VAR to the SVAR is a move from an inferential to an a priori approach. It is also a move from a fully non-structural, process approach to a partially structural approach, since the structure of the contemporaneous variables, though not of the lagged variables, is fully specified. The SVAR approach can, therefore, be seen as straddling the cells on the first line of Figure 1.

3.5 The graph-theoretic approach to causal inference
A final approach to causality in economics sometimes provides another example of an inferential structural approach, and sometimes straddles the cells on the second line of Table 1. Graph-theoretic approaches to causality were first developed outside of economics by computer scientists (for example, Pearl, 2000) and philosophers (for example, Spirtes, Glymour and Scheines, 2000), but have recently been applied within economics (Swanson and Granger, 1997; Akleman, Bessler and Burton, 1999; Bessler and Lee, 2002; Demiralp and Hoover, 2003).

The key ideas of the graph-theoretic approach are simple (see Demiralp and Hoover, 2003 or Hoover, 2005 for a detailed discussion). Any structural model can be represented by a graph in which arrows indicate the causal order. Equations (1) and (2) are represented by $X \rightarrow Y$ and eqs (3) and (4) by $Y \rightarrow X$. More complicated structures can be represented by more complicated graphs. Simultaneity, for instance, can be represented by double-headed arrows. The graphs allow us easily to see the dependence or independence among variables.

Pearl (2000) and Spirtes, Glymour and Scheines (2000) demonstrate the isomorphism between causal graphs and the independence relationships encoded in probability distributions. This isomorphism allows conclusions about probability distributions to be derived from theorems proven using the mathematical techniques of graph theory.

Many of the results of graph-theoretic analysis are straightforward. Suppose that $A \rightarrow B \rightarrow C$ (that is, $A$ causes $B$ causes $C$). $A$ and $C$ would be probabilistically dependent; but, conditional on $B$, they would be independent. Similarly for $A \leftarrow B \rightarrow C$. In each case, $B$ is said to screen $A$ from $C$. Suppose that $A \leftarrow B \rightarrow C$. Then, once again $A$ and $C$ would be dependent, but conditional on $B$, they would be independent. $B$ is said to be the common cause of $A$ and $C$. Now suppose that $A$ and $B$ are independent conditional on sets of variables that exclude $C$ or its descendants, and $A \rightarrow C \leftarrow E$ and none of the variables that cause $A$ or $B$ directly causes $C$. Then, conditional on $C$, $A$ and $B$ are dependent. $C$ is called an unshielded collider on the path $ACB$. (A shielded collider would have a direct link between $A$ and $B$.) These are the simplest relationships of probabilistic dependence and independence. More complex ones may also obtain in which $A$ is independent of $B$ only conditional on more than one other variable (say, $C$ and $D$).

A number of causal search algorithms have been developed (Spirtes, Glymour and Scheines, 2000). These start with information about correlations (or other tests of unconditional and conditional statistical independence) among variables. The most common of these, the PC algorithm, assumes that graphs are strictly recursive (known in the literature as acyclical) and starts with a graph in which all variables are causally connected with an unknown causal direction (represented by the headless arrow, ‘—‘). It then tests for independence among pairs of variables, conditioning on sets of zero variables, then one, then two, and so forth until the set of variables is exhausted. Whenever it finds independence, it removes the causal connection between the variables in the graph. Once the graph is pared down as far as it can be, it considers triples of variables in which two are conditionally independent but are connected through a third. If conditioning on that third variable renders the variables conditionally dependent, then that variable is an unshielded collider and it is connected to the other two variables with causal arrows running toward it. After all the unshielded colliders have been identified, further logical analysis can be used to orient additional causal arrows. For example, we might reason as follows: suppose we have a triple $A \rightarrow C \leftarrow E$, unless the causal arrow runs away from $C$ toward $B$, $C$ would be identified as an unshielded collider; but $C$ was not identified as an unshielded collider earlier in the search; therefore, the causal arrow must run away from $C$ toward $B$, so the graph becomes $A \rightarrow C \rightarrow E$.

Sometimes the data allow the complete orientation of a causal graph, but sometimes some causal connections are left undirected. In this case, the graph marks out an equivalence class, and the algorithm has identified 2! causal graphs consistent with the empirical probability distribution, where $n$ is the number of undirected causal connections.

While most applications of graph-theoretic methods assume that the true causal structures are recursive (that is, strictly acyclical), economics frequently treats variables that are cyclical or simultaneously determined. Although the recursiveness assumption is restrictive, it is an assumption that is also frequently made in the SVAR literature. Some progress has been made in developing graph-theoretic search algorithms for cyclical or simultaneous causal systems (Pearl, 2000, pp. 95–6, 142–3; Richardson, 1996; Richardson and Spirtes, 1999).

Swanson and Granger (1997) showed that estimates of the error terms of the VAR (the $u_t$ in eqs (5) and (6)) can be treated as the original time-series variables purged of their dynamics. A causal order identified on such variables corresponds to the causal order necessary to convert a VAR into an SVAR. Demiralp and Hoover (2003) present Monte Carlo evidence that the PC algorithm is effective at selecting the true causal connections among variables and, when signal strengths are high enough, moderately effective at directing them correctly. Search algorithms can, therefore, reduce or even eliminate the need to appeal to a priori theory when identifying the causal order of an SVAR.

Where Simon’s approach looked for relatively important interventions as a basis for causal inference to a structure, the graph-theoretic approach uses relatively routine random variations to identify patterns of conditional independence that map out causal structures. The two approaches are complementary: Simon’s approach may be used to resolve the observational equivalence reflected in causal connections that remain undirected after the application of a causal search algorithm.

4 From metaphysics to econometric practice

The analysis of causation was originally a branch of metaphysics. In moving from the scholastic to the practical, two deep divisions appeared among economists.

The first is the divide between those who believed that causality in economics could be characterized by relatively simple uniformities (the process approaches) and those who believed that it must be characterized by a rich understanding of the underlying mechanisms (the structural approaches). Economists debate the appropriate level at which to
characterize either the uniformities or the mechanisms – individual or aggregate. But this debate over the microfoundations of macroeconomics is another story. The second divide is between those who believe that economic logic itself gives privileged insight into economic behaviour (a priori approaches) and those who believe that we must learn about economic behaviour principally through observation and induction (the inferential approaches). These are old debates – unlikely to be resolved decisively to the satisfaction of all economists in the near future. How one aligns oneself in them largely determines which particular approaches to causality appear to be compelling in practical economic research.

central bank communication

Michael Ehrmann and Marcel Fratzscher
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Since the early 1990s, communication has become a primary tool for monetary authorities in managing expectations, both of financial markets and of the wider public, and an important ingredient in making the central bank accountable. The rapidly growing literature on central bank communication clearly confirms the importance of communication in managing expectations, thereby enhancing the effectiveness of monetary policy. Yet there is a large degree of heterogeneity in communication practices across monetary authorities in the world, and there continues to be a lively and controversial debate about what constitutes an optimal communication strategy.

Keywords

accountability; central bank; communication; expectations; financial markets; independence; inflation; monetary policy; objectives; policy decisions; predictability; transparency

Article

Central bank communication refers to the process by which monetary authorities convey information regarding their objectives, strategies and tools, as well as about their current assessment of the economic situation and the monetary stance. Such communication typically serves two purposes: making the central bank accountable, and enhancing the effectiveness of central bank policies.

Whereas only a few decades ago, transparency was usually seen as
counterproductive to an effective conduct of monetary policy, it is nowadays considered best practice in central banking. One trigger for this has been the move to grant independence to more and more central banks, which in turn entails an obligation of those central banks to be more accountable. Central banking laws often specify a number of obligations to ensure a central bank's accountability, which at the same time shape their communication policies. Testimonies to parliament and the requirement to deliver annual reports are examples. In several cases the relevant central banking acts also prescribe the targets for the monetary authority; their communication is therefore automatic, and not at the discretion of the central bank. At the same time, most central banks communicate substantially more often, and in much greater detail, than required by law.

As to the second purpose, it became increasingly clear throughout the 1990s that managing expectations is a central part of monetary policy, and that transparency is vital for that purpose. Given that communication is essential for accountability and transparency, central banks are now putting considerable effort into designing and conducting their communication policies.

Blinder et al. (2008), in their survey of the literature on central bank communication, derive the conditions under which central bank communication may matter for the conduct of monetary policy. A crucial issue in this regard is that a central bank usually has direct control only over a short-term interest rate, yet needs to influence interest rates at all maturities and to affect market expectations not just about current levels but about the future path of interest rates.

If the economic environment were constant, if the central bank was credibly committed to an unchanging policy rule, and if private agents had full information and rational expectations, the path of monetary policy could be inferred correctly from the central bank's observed actions (Woodford, 2005). In reality, of course, none of these conditions are likely to hold. In particular, in a changing environment economic agents are subject to a continuous learning process. The central banks' views are also of interest to the public in a world of uncertainty and asymmetric information, especially given the complexity and extent of the information that feeds into monetary policy decisions, which often require judgment and the use of heuristics (Svensson, 2003; King, 2005).

The revolution in thinking and practice that has taken place over the recent decades can be exemplified with the case of the US Federal Reserve, which
over the last 15 years has gone a long way towards greater transparency. For instance, it has started to issue statements instantaneously after each monetary policy decision, where the decision is not only announced, but also briefly explained, and to provide qualitative forward guidance about future monetary policy decisions. It has also expedited the release of the minutes of Federal Open Market Committee (FOMC) meetings, and it has increased the frequency and expanded the content of the publicly released forecasts for several economic variables made by FOMC members.

The announcement of a central bank's objective

If a central bank is granted independence from its government, it must be given a clearly defined mandate. This is generally done by defining central bank objectives, often in a quantified fashion. But even if a central bank is not given a quantitative objective, it often decides to provide its own quantification, or is required to do so. The potential effects of such a clarification and quantification are substantial. Not only do they make an independent central bank more (easily) accountable, since its actions can be assessed by cross-checking actual economic outcomes with those mandated; furthermore, the announcement of an objective, and in particular its quantification, provides a yardstick for the expectations of economic agents. The available empirical evidence demonstrates that increased transparency about central banks' strategies, and in particular the announcement of an explicit inflation objective, has fostered central bank credibility as well as the predictability of the path of monetary policy. Moreover, the recent trend towards more transparent central banking practices has certainly played a considerable part in improving the short-term predictability of policy decisions by many central banks over recent decades (BIS, 2004, pp. 73–80).

The announcement of central bank objectives may also have a direct bearing on economic outcomes. For instance, Benati (2008) finds that inflation persistence is considerably lower in countries with explicit inflation targets. Levin, Natalucci and Piger (2004) furthermore show that in inflation-targeting countries, private sector inflation expectations are not correlated with lagged inflation, indicating that inflation expectations are better anchored. This evidence has been corroborated by Gürkaynak, Levin and Swanson (2009), who show that in some advanced inflation-targeting countries, long-term inflation expectations are less responsive to macroeconomic data releases than in the United States, where no explicit inflation objective has been announced.
However, the fact that the announcement of a central bank's objective has an effect on inflation expectations need not automatically imply that there will be an effect on the ultimate objective. This question needs to be settled empirically. The available evidence is rather inconclusive at this stage, with for example Kuttner and Posen (1999) arguing that inflation is lower in inflation-targeting countries, whereas Ball and Sheridan (2005) cannot find any such evidence, given that also the countries in their control groups managed to achieve low inflation rates.

In sum, the empirical evidence suggests that the announcement of a central bank's objective is beneficial, since it eases the conduct of monetary policy through its effect on agents' expectations, and because it helps to achieve sound macroeconomic outcomes. At the same time, it does not seem to be the only means to achieve such outcomes.

The announcement of policy decisions

It is common practice nowadays among central banks to inform the public about monetary policy decisions as soon as the decision has been taken. There is substantial evidence that this practice improves the markets' understanding of monetary policy considerably. For example, Lange, Sack and Whitesell (2003) observe that the announcement of FOMC policy decisions since 1994 has enabled markets to improve their forecasts of monetary policy decisions. Furthermore, Demiralp and Jorda (2002) provide evidence that, by announcing changes to the intended federal funds rate in real time, it has been possible to move the federal funds rate with a smaller volume of open market operations, which indicates that the announcement of policy decisions can make policy implementation more efficient.

The communication of the current assessment of the economic situation and the monetary policy stance

By announcing an objective, and possibly releasing information about its monetary policy strategy, about the models used and about the variables considered in the economic analysis, a central bank aims to help the public better understand its broader framework and the way in which it reacts to different circumstances and contingencies. However, even if the broader framework is generally well understood, it will be impossible to communicate \textit{ex ante} all contingencies in such a way that the public can always deduce perfectly the central bank's assessment, just by interpreting the incoming...
macroeconomic data. Regular communication of the central bank's assessment of the current economic situation and the monetary policy stance does therefore remain important. Accordingly, central banks often release statements that provide explanations for a given policy decision, publish inflation and growth forecasts, and deliver speeches in the inter-meeting period.

As argued above, central banks have recently achieved a high degree of short-term predictability. Accordingly, markets react predominantly not to the announcement of a decision, but to the communication surrounding it, such as any explanation of the underlying reasons and any forward-looking component. Gürkaynak, Sack and Swanson (2005) find that longer-term maturities in the yield curve react in particular to the forward-looking component of the communication.

In line with this, Reeves and Sawicki (2007) show that the collective forms of Bank of England communication have a rather strong market impact, such as the minutes of the committee meetings and the Inflation Report. Communication by individual committee members, such as speeches or interviews, has nonetheless also been shown to be important. Kohn and Sack (2004) find that the testimonies by the FOMC chairman have substantial effects on financial markets, throughout the entire maturity spectrum. Financial market responsiveness to committee members' speeches have been identified, for example in Ehrmann and Fratzscher (2007) for the Federal Reserve, the Bank of England and the European Central Bank (ECB).

**Potential risks**

The evidence suggests that central bank communication is an important policy tool, with substantial effects on financial markets, and the potential to enhance the effectiveness of monetary policy making. However, as any effective tool, it needs to be properly utilized; otherwise, it can lead to undesired outcomes. Communicating too frequently, or providing too much information, can be damaging if there is a limit to how much information can be digested effectively (Kahneman, 2003). A widespread example where central banks limit their transparency relates to the blackout periods, whereby committee members would typically not make public statements about monetary policy-related issues just before policy meetings. As shown by Ehrmann and Fratzscher (2009), there are good reasons for adhering to such a rule, because communication during the blackout period leads to excessive market
volatility.
A debate has also centred around how central banks should communicate if
they receive noisy signals themselves. In coordination games in the vein of
Morris and Shin (2002), or in learning models like Dale, Orphanides and
Osterholm (2008), whether or not a central bank should communicate depends
crucially on the relative precision of the central bank’s and the private sector’s
information. However, it has been debated to what extent a case for limiting
central bank communication can arise in these models. With regard to the
coordination game literature, Svensson (2006) argues that central bank
communication would need a much (and implausibly) lower signal-to-noise
ratio than that of private information.
Clarity is essential for good communication. A possible risk to clarity can
arise because monetary policy is typically set by committees rather than by
single individuals. This can give rise to a ‘cacophony problem’ (Blinder,
2004, ch. 2) if too many disparate voices on a topic confuse rather than clarify
the message. Central banks take different approaches in that regard. Whereas
FOMC members communicate their individual views to the public (Bernanke,
2004), this is not so for the ECB, which now adheres to a one-voice policy
(Jansen and De Haan, 2006). Importantly, however, markets adapt to such
differences in communication style, for example by reacting more strongly to
statements by the chairperson of committees with dispersed communication,
and more equally to statements by all committee members if these
communicate in a collegial fashion (Ehrmann and Fratzscher, 2007).

Open issues

The recent research on central bank communication, surveyed in Blinder et al.
(2008), has provided a large number of relevant insights. Central bank
communication is an important policy tool, with substantial effects on
financial markets, and the potential to enhance the efficiency of monetary
policy making. However, what constitutes an optimal communication strategy
remains an unsettled issue. There is a large diversity in the communication
policies of central banks, because the design of communication policies must
take into account the cultural and institutional environment in which a central
bank operates. Accordingly, it is evident that ‘one size does not fit all’.
Other issues and debates remain unresolved at the time of writing. For
instance, there are different ways of providing forward guidance. It is difficult
to evaluate the recent approach of publishing projected paths for the central
bank's policy rate, given that we have gained only very limited experience to date. Another open issue relates to the transmission of central bank communication. The role of the media has barely been studied. Finally, while much of the empirical research has focused on the effects of communication on financial markets, a better understanding of the communication with the general public is required, since it is the general public whose inflation expectations eventually feed into the actual evolution of inflation – for example, through corresponding wage claims and savings, investment and consumption decisions.

central bank independence

Carl E. Walsh
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Many countries have implemented reforms designed to grant their monetary authorities greater independence from direct political influence. These reforms were justified by research showing central bank independence was negatively correlated with average inflation among developed economies. An important line of research developed measures of central bank independence and studied their relationship with inflation and real economic activity. Different theoretical approaches have been used to model central bank independence. Critics of the reform movements towards central bank independence have expressed concerns that independence can weaken the accountability of central banks.

Keywords

Bank of England; central bank independence; central banks; European Central Bank (ECB); Federal Reserve System; inflation; inflation targeting; monetary policy; price stability; rational expectations; Reserve Bank of New Zealand; Rogoff-conservative central bank

Article

Central bank independence refers to the freedom of monetary policymakers from direct political or governmental influence in the conduct of policy.

During the 1970s and early 1980s, major industrialized economies experienced sustained periods of high inflation. To explain these periods of inflation, one must account for why central banks allowed them to happen. One influential line of argument pointed to the inflation bias inherent in discretionary monetary policy if the central bank's objective for real output (unemployment) is above (below) the economy's natural equilibrium level or if policymakers simply prefer higher output levels (Barro and Gordon, 1983). Under rational expectations, the public anticipates that the central bank will attempt to expand the economy; as a consequence, real output is not systematically affected but average inflation is left inefficiently high.
This explanation for inflation raises the question why central banks might prefer economic expansions or have unrealistic output goals. Economists have frequently pointed to political pressures as the answer. Elected officials may be motivated by short-run electoral considerations, or may value short-run economic expansions highly while discounting the longer-run inflationary consequences of expansionary policies. If the ability of elected officials to distort monetary policy results in excessive inflation, then countries whose central banks are independent of such pressure should experience lower rates of inflation. Beginning with Bade and Parkin (1988), an important line of research focused on the relationship between the central bank and the elected government as a key determinant of inflation. This empirical research found that average inflation was negatively related to measures of central bank independence. Cukierman (1992) provides an excellent summary of the empirical work; references to the more recent literature can be found in Eijffinger and de Haan (1996) and Walsh (2003, ch. 8). The empirical findings led to a significant body of work addressing the following questions: what do we mean by central bank independence? How should central bank independence be measured? What causal interpretation should be placed on the empirical correlations between central bank independence and macroeconomic outcomes discovered in the data? What is the theoretical explanation for these correlations?

The meanining of independence

The historical, legal and de facto relationships between a country's government and its central bank are very complex, involving many difference aspects. These include, but are not limited to, the role of the government in appointing (and dismissing) members of the central bank governing board, the voting power (if any) of the government on the board, the degree to which the central bank is subject to budgetary control by the government, the extent to which the central bank must lend to the government, and whether there are clearly defined policy goals established in the central bank's charter. Most discussions have focused on two key dimensions of independence. The first dimension encompasses those institutional characteristics that insulate the central bank from political influence in defining its policy objectives. The second dimension encompasses those aspects that allow the central bank to freely implement policy in pursuit of monetary policy goals. Grilli, Masciandaro and Tabellini (1991) called these two dimensions ‘political independence’ and ‘economic independence’. The more common terminology, however, is due to Debelle and Fischer (1994), who called these two aspects ‘goal independence’ and ‘instrument independence’. Goal independence refers to the central bank's ability to determine the goals of policy without the direct influence of the fiscal authority. In the United Kingdom, the Bank of England lacks goal independence since its inflation target is set by the government. In the United States, the Federal Reserve's goals are set in its legal charter, but these goals are described in vague terms (for example, maximum employment), leaving it to the Fed to translate these into operational goals. Thus, the Fed has a high level of goal independence. Price stability is mandated as the goal of the European Central Bank (ECB), but the ECB can choose how to interpret this goal in terms of a specific price index and definition of price stability.

Instrument independence refers only to the central bank's ability to freely adjust its policy tools in pursuit of the goals of monetary policy. The Bank of England, while lacking goal independence, has instrument independence; given the inflation goal mandated by the government, it is able to set its
instruments without influence from the government. Similarly, the inflation target range for the Reserve Bank of New Zealand is set in its Policy Targets Agreement (PTA) with the government, but, given the PTA, the Reserve Bank has the authority to sets its instruments without interference. The Federal Reserve and the ECB have complete instrument independence.

Measuring independence

The most widely employed index of central bank independence is due to Cukierman, Webb and Neyapti (1991), although alternative measures were developed by Bade and Parkin (1988) and Alesina, Masciandaro and Tabellini (1991), among others. The Cukierman, Webb and Neyapti index is based on four legal characteristics as described in a central bank's charter. First, a bank is viewed as more independent if the chief executive is appointed by the central bank board rather than by the government, is not subject to dismissal, and has a long term of office. These aspects help insulate the central bank from political pressures. Second, independence is greater the more policy decisions are made independently of government involvement. Third, a central bank is more independent if its charter states that price stability is the sole or primary goal of monetary policy. Fourth, independence is greater if there are limitations on the government's ability to borrow from the central bank.

Cukierman, Webb and Neyapti combine these four aspects into a single measure of legal independence. Based on data from the 1980s, they found Switzerland to have the highest degree of central bank independence at the time, closely followed by Germany. At the other end of the scale, the central banks of Poland and the former Yugoslavia were found to have the least independence.

Legal measures of central bank independence may not reflect the actual relationship between the central bank and the government. In countries where the rule of law is less strongly embedded in the political culture, there can be wide gaps between the formal, legal institutional arrangements and their practical impact. This is particularly likely to be the case in many developing economies. Thus, for developing economies, it is common to supplement or even replace measures of central bank independence based on legal definitions with measures that reflect the degree to which legally established independence is honoured in practice. Based on work by Cukierman, measures of actual central bank governor turnover, or turnover relative to the formally specified term length, are often used to measure independence. High actual turnover is interpreted as indicating political interference in the conduct of monetary policy.

Empirical evidence

The 1990s saw many countries, both developed and developing, adopt reforms that increased central bank independence. This trend was strongly influenced by empirical analysis of the relationship between central bank independence and macroeconomic performance. Among developed economies, central bank independence was found to be negatively correlated with average inflation. The estimated effect of independence on inflation was statistically and economically significant. Based on data from the high inflation years of the 1970s, for example, moving from the status of the Bank of England prior to the 1997 reforms that increased its independence to the level of independence then enjoyed by the Bundesbank would be associated with a drop in annual average inflation of four percentage points.
The form of independence may also matter for inflation. Debelle and Fischer (1994) report evidence that it is the combination of goal dependence and instrument independence that produces low average inflation, although their empirical results were weak. Even if central bank independence leads to lower inflation, the case for independence would be greatly weakened if it also leads to greater real economic instability. However, little relationship was found between measures of real economic activity and central bank independence (Alesina and Summers, 1993). In other words, countries with more independent central banks enjoyed lower average inflation rates yet suffered no cost in terms of more volatile real economic activity. Central bank independence appeared to be a free lunch.

While standard indices of central bank independence were negatively associated with inflation among developed economies, this was not the case among developing economies. Developing countries that experienced rapid turnover among their central bank heads tended to experience high rates of inflation. This is a case, however, in which causality is difficult to establish; is inflation high because of political interference that leads to rapid turnover of central bank officials? Or are central bank officials tossed out because they can't keep inflation down?

The empirical work attributing low inflation to central bank independence has been criticized along two dimensions. First, studies of central bank independence and inflation often failed to control adequately for other factors that might account for cross-country differences in inflation experiences. Countries with independent central banks may differ in ways that are systematically related to average inflation. After controlling for other potential determinants of inflation, Campillo and Miron (1997) found little additional role for central bank independence.

Second, treating a country's level of central bank independence as exogenous may be problematic. Posen (1993) has argued strongly that both low inflation and central bank independence reflect the presence of a strong constituency for low inflation. Average inflation and the degree of central bank independence are jointly determined by the strength of political constituencies opposed to inflation; in the absence of these constituencies, simply increasing a central bank's independence may not cause average inflation to fall.

Theoretical models of independence

Central bank independence has often been represented in theoretical models by the weight placed on inflation objectives. When the central bank's weight on inflation exceeds that of the elected government, the central bank is described as a Rogoff-conservative central bank (Rogoff, 1985). This type of conservatism accorded with the notion that independent central banks are more concerned than the elected government with maintaining low and stable inflation. Rogoff’s formulation reflects a form of both goal independence – the central bank's goals differ from those of the government – and instrument independence – the central bank is assumed to be free to set policy to achieve its own objectives.

Because the central bank cares more about achieving its inflation goal, the marginal cost of inflation is higher for the central bank than it would be for the government. As a consequence, equilibrium inflation is lower.

One problem with interpreting independence in terms of Rogoff-conservatism is that Rogoff’s model implies that a conservative central bank will allow output to be more volatile in order to keep inflation
stable. Yet the empirical research finds no relationship between real fluctuations and measures of central bank independence.

An alternative way to model central bank independence is to view the central bank as having its own objectives, but the central bank must also take into account the government's objectives when deciding on policy. The central bank might have either a lower desired inflation target than the government or an output target that, unlike the government's target, is consistent with the economy's natural rate of output. If actual policy is set to maximize a weighted average of the central bank's and the government's objectives, the relative weight on the central bank's own objectives provides a measure of central bank independence. With complete independence, no weight is placed on the government's objectives; with no independence, all weight is placed on the government's objectives. If the objectives of the central bank and the government differ only in their desired inflation target, then the degree of central bank independence affects average inflation but not the volatility of either output or inflation. Such a formulation is consistent with the empirical evidence discussed above.

Often, theoretical approaches have not distinguished clearly between goal and instrument independence. Suppose independence is measured by the relative weight on the government's and the central bank's objectives. This can be interpreted as reflecting either goal dependence – the objectives of the central bank must put some weight on the goals of the government – or instrument dependence – the actual instrument setting diverges from what would be optimal from the central bank's perspective in order to reflect the government's concerns.

Independence and accountability

While many countries have granted their central banks more independence, the idea that central banks should be completely independent has come under criticism. This criticism focuses on the danger that a central bank that is independent will not be accountable. Although maintaining low and stable inflation is an important societal goal, it is not the only macroeconomic goal; monetary policy may have no long-run effect on real economic variables, but it can affect the real economy in the short run. In a democracy, delegating policy to an independent agency requires some mechanism to ensure accountability. For this reason, reforms have often granted central banks instrument independence while preserving a role for the elected government in establishing the goals of policy and in monitoring the central bank's performance in achieving these goals.

central limit theorems

Werner Ploberger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Central limit theorems describe the behaviour of distributions of sums of random variables. We start with the classical result of distributions of sums of independent random variables converging to the Gaussian (bell-curve) distribution. We describe the most important cases of convergence to Gaussian distributions (sums of martingale differences) as well as convergence to other distributions.

Article

At the end of the 17th century, the mathematician Abraham de Moivre first used the normal distribution as an approximation for the percentage of successes in a large number of experiments. Later on, Laplace generalized his results, but it took 20th century mathematics to give an exact and complete description of this subject. So let me now describe the modern approach. We assume that for each \( n \) we have given a sequence \( X_{1,n}, \ldots, X_{n,n} \) of random variables, which we assume to be independent. Then we want to ‘approximate’ the distribution of

\[
S_n = \sum_{i=1}^{n} X_{i,n}
\]
by a standard normal distribution, whose density equals

\[
\frac{1}{\sqrt{2\pi}} \int_A \exp\left(-\frac{x^2}{2}\right) dx.
\]

Let us denote by \( P(B) \) the probability of an event \( B \). If \( X \) is a random variable, than let us denote by \( E(X) \) its expectation. For \( A \subseteq \mathbb{R} \) let \( [X \in A] \) be the event that \( X \) takes a value into \( A \). Written in formal terms, we want to establish that

\[
\lim_{n \to \infty} P([S_n \in A]) = \frac{1}{\sqrt{2\pi}} \int_A \exp\left(-\frac{x^2}{2}\right) dx
\]

(1)

or

\[
\lim_{n \to \infty} E[f(S_n)] = \frac{1}{\sqrt{2\pi}} \int f(x) \exp\left(-\frac{x^2}{2}\right) dx.
\]

(2)

The first question we have to ask ourselves is the nature of the approximation. Clearly it is impossible to approximate the distribution of \( S_n \) for all sets. Consider the binomial distribution discussed above. In this case, each \( S_n \) can only take a finite number of values. Therefore the possible values for all \( S_n \) lie for all \( n \) in a countable set, which has zero probability under the normal distribution.

So we have to aim at a compromise: the smaller the class of sets \( A \) or functions \( f \), the more ‘convergent’ sequences \( S_n \) we have. The most successful compromise is the convergence in distribution of the random variables (or the weak convergence of the probability distributions). We postulate that (2) holds for all bounded, continuous functions \( f \). This requirement can be shown to be equivalent to postulating that (1) holds for all sets \( A \) so that the boundary of \( A \) (that is, the difference between closure of \( A \) and inner points of \( A \)) has zero probability under the limiting measure. So in our case, where the limiting distribution is normal, (1) holds if \( A \) is an interval \((a, b)\): the boundary consists of two points, namely \( a \) and \( b \). Equation (1) does not hold if, for example, \( A \) is the set of all rational numbers in \((0, 1)\): then the boundary equals \([0, 1]\), which obviously has non-zero probability under the normal distribution (see
It is noteworthy that there are many more equivalent ways to define convergence in distribution for unidimensional random variables; for example, convergence in distribution is equivalent to the convergence of the cumulative distribution functions to the cumulative distribution function of the limiting distribution in all points where the latter is continuous. Another well-known criterion is the convergence of the characteristic functions.

Now we are in a position to formulate our first main theorem, the central limit theorem (CLT) of Lindeberg and Feller (see Billingsley, 1995).

Suppose we have given a triangle array of random variables $X_{i,n}$, so that for each $n$ the $X_{i,n}$ are independent, not necessarily identically distributed. We furthermore have

$$EX_{i,n} = 0,$$

$$\sum_{i=1}^{n} \text{Var}(X_{i,n}) = 1.$$

Then the following two propositions are equivalent:

- The ‘Lindeberg’ condition: For all $\delta > 0$

$$\sum_{i=1}^{n} E\left(\frac{X_{i,n}^2}{|X_{i,n}|} I_{|X_{i,n}| > \delta}\right)$$

(L)

converges to zero.

- Our sums

$$S_n = \sum_{i=1}^{n} X_{i,n}$$
converge in distribution to a standard normal and the ‘Feller’ condition is satisfied:

$$\max_{1 \leq i \leq n} \text{Var}(X_{i,n}) \to 0.$$  (F)

It seems plausible to assume the Feller condition (F). It simply states that the maximal contribution of an individual $X_{i,n}$ to the variance of the sum gets arbitrarily small. This seems reasonable. The Lindeberg condition (L) which is necessary for our theorem is a little stronger. Not only the maximum, but the total contribution of the $X_{i,n}$ taking ‘large’ values to the variance of the sum, must vanish asymptotically!

It is quite easy to establish that (L) is fulfilled if

$$X_{i,n} = \frac{1}{\sqrt{n}} X_i$$  (3)

where the $X_i$ are independent and identically distributed. In the general case, a sufficient condition is the ‘Lyapunov condition’: for some fixed $\varepsilon > 0$ we have

$$\sum_{i=1}^{n} E\left(|X_{i,n}|^{2+\varepsilon}\right) \to 0.$$

So we need a little more than second moments to establish convergence to a standard normal. Practitioners often assume that the requirements of the theorems are fulfilled automatically. This assumption is quite dangerous. We need a little more than lack of outliers; the contribution to the variance of the largest values must be negligible.

This relation between higher moments and goodness of the approximation with a standard normal is extensive. Under the assumption of at least three absolute moments, the theorem of Berry–Esseen shows that in the case (3) of independent, identically distributed $X_i$ the maximal difference between the cumulative distribution functions of $S_n$ and the standard normal is $1/\sqrt{n}$. Related are ‘coupling’ results.
One can show that – possibly on a richer probability space – there exist exactly normally distributed random variables $U_n$. In particular, if the $X_i$ have a Laplace transform, then the ‘Hungarian construction’ allows one to construct $U_n$ so that the difference to $S_n$ is $O(\log(n) / \sqrt{n})$. If the $X_i$ ‘only’ have fourth moments, then it is easy (for the insider: use Skorohod embedding) to construct $U_n$ so that the difference to $S_n$ is of the order of $1 / 4\sqrt{n}$.

All these bounds are very interesting from the theoretical point of view. Playing around with numbers for $n$ with realistic sample sizes, one can easily see that the bounds found that way are unrealistic. Although these bounds cannot be improved, they are a little pessimistic. Nevertheless, they indicate when we venture into dangerous territory: a lack of fourth moments indicates a ‘slow’ convergence. So the normal approximation is a useful first-order approximation of the distributions of sums of random variables. To improve this approximation, various techniques are used. Since the 19th century, Edgeworth expansions have proved useful. Nowadays, however, cheap computing makes direct calculation of distributions by Monte Carlo simulation possible.

**Independent, non-normal limit theorems**

Let us define $X_{i,n}$ to be independent, identically distributed and taking the value of zero with probability $1-\lambda/n$ and one with probability $\lambda/n$ with some $\lambda > 0$. Now one has an easy example where the Lindeberg condition is not fulfilled. (For $\delta < 1$, $\sum_{i=1}^{n} E(X_{i,n}^2 | |X_{i,n}| > \delta) = \lambda$, since $X_{i,n}$ can take only the values 0 and 1). Nevertheless, it is well known that $\sum_{i=1}^{n} X_{i,n}$ converges in distribution to a Poisson distribution with intensity $\lambda$. So the normal distribution is not the only limiting distribution of sums of independent random variables. One can, however, show that the normal and the Poisson distribution and mixtures (with possibly an infinite number of components) of these distributions are the only possible limits of sums $S_n$ of independent, identically distributed random variables $X_{i,n}$. These limiting distributions are called ‘infinitely divisible’. A precise formula for the logarithm of the characteristic function is given by the formula of Levy–Khinchin.

We even have some analogon, some generalization of the normal distribution. The properly normalized sum of normally distributed random variables is normal again. Can we generalize this property? Let us assume that

$$X_{i,n} = a_n(X_i - b_n),$$

where the $X_i$ are independent and identically distributed, and the $a_n$ are scale factors, and let us assume that the distribution of the $S_n$ is identical to the distribution of the $X_i$. These distributions are called the ‘stable’ distributions. Their density is determined essentially by two parameters, traditionally called $\alpha$ and $\beta$. $\alpha$ determines the ‘tail behaviour’ and varies between 0 and 2, and $\beta$ determines the symmetry.
For $\alpha = 2$, we have the normal distribution, for $\alpha < 2$ the distributions are more heavily tailed: in general, one has only moments of order smaller than $\alpha$. There is no closed form for their densities in the general case, only the characteristic functions can be expressed by elementary functions. One special case ($\alpha = 1$) is the Cauchy distribution with density

$$
\frac{1}{\pi(1 + x^2)}.
$$

The index $\alpha$ determines the scale factors $a_n$: in general, one has $a_n = \frac{1}{n^\alpha}$.

Convergence of sums to stable distributions can be achieved in more general circumstances. In general, under certain conditions on the ‘tail’ of the $X_i$ (the probabilities exceeding ‘large’ values have to obey certain regularity conditions) the sums of the $X_{i,n}$ defined by (4) one can ensure convergence (see Ibragimov and Linnik, 1971).

**Central limit theorems for dependent random variables**

Many econometric applications involve sums of dependent random variables. Hence it is important to remove the requirement of independence. Traditionally, one tried to replace independence by some form of ‘mixing’.

Independence of two $\sigma$-algebras $\mathfrak{A}$ and $\mathfrak{B}$ can be defined in various ways. Usually one defines $\mathfrak{A}$ and $\mathfrak{B}$ to be independent if for all $A \in \mathfrak{A}$ and $B \in \mathfrak{B}$

$$
P(A \cap B) = P(A)P(B).
$$

Another usual definition is that for all $A \in \mathfrak{A}$

$$
P(A/\mathfrak{B}) = P(A),
$$

where $P(\cdot/\cdot)$ should denote the conditional probability. Consequently, one can measure the ‘degree of dependence’ of $\sigma$-algebras $\mathfrak{A}$ and $\mathfrak{B}$ by
or
\[
\alpha_{\mathfrak{A}, \mathfrak{B}} = \sup_{A \in \mathfrak{A}, B \in \mathfrak{B}} |P(A \cap B) - P(A)P(B)|
\]

or
\[
\psi_{\mathfrak{A}, \mathfrak{B}} = \sup_{A \in \mathfrak{A}} |P(A \cap B) - P(A)|.
\]

Suppose one has a process \(X_t\). Then one defines the ‘mixing coefficients’
\[
\alpha_k = \sup_t \alpha(\mathfrak{A} \sigma(X_t, X_{t+1}, \ldots), \mathfrak{A} \sigma(X_{t-k}, X_{t-1-k}, \ldots))
\]

or
\[
\psi_k = \sup_t \psi(\mathfrak{A} \sigma(X_t, X_{t+1}, \ldots), \mathfrak{A} \sigma(X_{t-k}, X_{t-1-k}, \ldots)).
\]

Typically, conditions like
\[
\sum \sqrt{\alpha_k} < \infty
\]

or
\[
\psi_k \to 0
\]

are sufficient conditions for a CLT. So the CLT remains valid for stationary processes if the random variables in questions get less and less dependent if the time difference gets larger and larger (Ibragimov
One of the most important applications is the CLT for martingale differences. A process $X_t$ is a ‘martingale difference’ if for all $t$

$$E(X_t / \mathcal{F}_{t-1}) = 0,$$

where $\mathcal{F}_{t-1}$ is an increasing sequence of $\sigma$-algebras which contain at least $X_{t-1}, X_{t-2}, \ldots$. Then we have a result perfectly analogous to the case of independent random variables.

Suppose we have given a triangle array $X_{t,T}$, $t=1, \ldots, T$, of martingale differences with $\sigma$-algebras $\mathcal{F}_{t-1}, T$ and the following two conditions are satisfied:

- the conditional Lindeberg condition

$$\sum_{t=1}^{T} E(X_{t,T}^2 | [X_{t,T} \geq \varepsilon] / \mathcal{F}_{t-1}, T) \to 0,$$

- the norming condition

$$\sum_{t=1}^{T} E(X_{t,T}^2 / \mathcal{F}_{t-1}, T) \to 1,$$

where the convergence should be understood to be in probability. Then

$$S_n = \sum_{i=1}^{n} X_{i,T},$$

converges in distribution to a standard normal distribution (Davidson, 1994; Hall and Heyde,
This limit theorem is one of the most important ones for applications in econometrics. It is relatively easily seen that derivatives of log-likelihood functions are martingale differences. Hence this theorem is instrumental in establishing the limit theorems for maximum likelihood estimators.

An easy consequence of the theorem is that for every (strictly) stationary, ergodic martingale difference $X$ with $\sigma^2 = E(X_t^2) < \infty$ we have an almost classical CLT:

$$\frac{1}{\sigma \sqrt{n}} \sum_{i=1}^{n} X_i$$

which converges in distribution to a standard normal.

Gordin's theorem

Martingale differences form a large class of processes. Unfortunately, however, this class is not sufficiently large for many important applications (martingale differences must be, for example, uncorrelated). As an alternative, one might use mixing conditions. These conditions are, however, hard to verify. They usually involve inequalities involving all events from the $\sigma$-algebras involved. Hence a theorem allowing for general, autocorrelated processes with conditions which are easy to verify is an important tool in theoretical econometrics. Such a result was found by Gordin in 1969. Hayashi (2000) demonstrates the versatility of the theorem.

Suppose we have a stationary, ergodic process $X_i, i \in \mathbb{Z}$ so that $E X_i^2 < \infty$. Assume that $\mathcal{F}_i$ are adapted $\sigma$-algebras (that is, $X_i$ are $\mathcal{F}_i$-measurable), and let

$$\varepsilon_i = E(X_i / \mathcal{F}_1) - E(X_i / \mathcal{F}_0).$$

Then let us assume that

$$\sum_{i=1}^{\infty} \sqrt{E \varepsilon_i^2} < \infty.$$
Then

$$\frac{1}{\sqrt{n}} \sum_{i=1}^{n} X_i$$

converges in distribution to a normal distribution with zero mean and variance $\sigma_{LT}^2$, where

$$\sigma_{LT}^2 = E \left( \sum_{i=1}^{\infty} \varepsilon_i \right)^2.$$

$\sigma_{LT}^2$ is usually called the ‘long-term variance’.

**Conclusion**

Almost all theorems about limit distributions of estimators and test statistics depend on central limit theorems. So it should not be surprising that central limit theorems and their generalizations are an active field of research. Especially, generalizations of the concept of convergence in distribution to more general spaces generate theorems, which are important from the theoretical as well as the practical point of view. Billingsley (1999) and Davidson (1994) give an introduction to these ‘functional limit theorems’.

central place theory; city hierarchy; increasing returns to scale; Krugman, P.; spatial impossibility theorem; urban agglomeration

Article

Central place theory is a descriptive theory of market area in a spatial context. Its definition, history, and relation to modern microeconomic theory are set out in this article. Central place theory is a collection of loosely related, informal, descriptive models of city size, city location, and market area based on the trade-off between increasing returns to scale in production and the cost of transport of goods from firm to home. Land markets are often absent. At its core, central place theory is an empirically motivated description of production in southern Germany. It is a remarkable empirical regularity in search of a formal theory; a better name would be ‘central place regularity’.

The beginnings of the theory are attributed to Christaller (1933), who first made detailed observations of urban hierarchies and then attempted to model them. The basic ideas put forward are that consumer population is distributed uniformly, while firms locate in cities. Cities form a hierarchy in that cities higher in the hierarchy produce all the goods that cities one level lower in the hierarchy produce, and one more. The ratio of market areas of a commodity produced only at a given level of the hierarchy (and
Central place theory: The New Palgrave Dictionary of Economics

above) to the market area of a commodity produced at the next lower level of the hierarchy (and above) is assumed to be constant, independent of the level in the hierarchy considered. Thus, the cities in a given area form a hierarchy where the size of a city's market area and the variety of commodities it offers are perfectly correlated. In graphical terms, the result is a collection of hierarchically ordered cities with the market areas of cities not at the same level of the hierarchy overlapping, but market areas of cities at the same level disjoint. Commodities characterized by low transport cost but high returns to scale are provided by a few cities high in the hierarchy. Commodities characterized by high transport cost but low returns to scale are provided by most cities. Lösch (1944) expanded on this theory. He postulated a homogeneous agricultural plane with farmers. Some turn to beer production, and face linear, downward sloping demand curves with choke prices, that is, prices above which the demand is for beer is zero. For a given price at the brewery, total delivered price increases with distance from the plant due to transport cost. In the plane with a uniform distribution of inebriated consumers or farmers, demand for a firm's beer is given by the volume of a cone centred at the brewery, with height given by the brewery's mill price and the slope of its sides determined by the demand curve and the cost of beer transport. With a marginal cost curve, equilibrium can be found. Unfortunately, the collection of bases of cones, namely, disks, does not partition the plane. So hexagons are used, forming a Teutonic triangulation of hierarchical hexagons. In this theory, the central places are the breweries. (St. Louis is a prime example.) One can view the theory as producing a complex of overlapping, ordered layers of hexagonal partitions of the plane corresponding to the market areas of cities in a hierarchy. Agriculture is the basis for and genesis of this structure.

The theory has developed beyond these basic descriptive models; see McCann (2001, ch. 2.7) for a nice summary and cites. Hartwick (2004) is the culmination of a line of research more in accord with optimizing behaviour, pricing, and trade theory that also relates the models to the rank-size rule. The reader should be cautious in interpreting this entire literature because equilibrium and efficiency are often confused, while the models tend to be mechanistic in nature as opposed to allowing agents to optimize in equilibrium. To the general economist, the theory will appear to be informal and imprecise. Paul Krugman (1995, pp. 38–41) criticizes central place theory, or ‘Germanic geometry’, for its lack of formal foundations, particularly regarding market structure and firm behaviour. This criticism applies even to the contemporary literature. (Paul Krugman is also credited with the first alliteration in this literature. This article only builds on the original contribution.)

Even if one is willing to overlook these defects, there is one further important flaw. Central place theory generally runs afoul of Starrett's spatial impossibility theorem; see Starrett (1978), Fujita (1986), and Fujita and Thisse (2002, ch. 2.3) for discussion. In essence, the impossibility theorem says that, in a closed economy with perfect and complete markets at all locations, location-independent utility and production functions, and no relocation cost, there is no competitive equilibrium where commodities are transported. Thus, if the assumptions are satisfied, either there is no equilibrium or in equilibrium agents and commodities are distributed uniformly among inhabited locations, and locations are autarkic. Central place theory apparently makes these assumptions, though due to its imprecision perhaps it doesn't. Naturally, although the literature considers consumer migration at times, the assumption of a uniform distribution of consumers could render the theorem inapplicable. I conjecture that it simply makes the existence of an (autarkic) equilibrium more likely. But this is probably not worth pursuing, as
location models that fix consumer locations in a uniform distribution can generate only cities without people. So where does this leave us? The modern theory of agglomeration, and thus the modern theory of central places, begins with the impossibility theorem. Its contrapositive tells us that, to generate models with non-trivial agglomeration at equilibrium, at least one of the hypotheses must be violated. Even then, equilibrium might not exist, or in equilibrium cities could collapse to a point or have agents spread uniformly. Models of non-trivial cities involve a very delicate balancing act between forces pulling agents together and forces pushing them apart. The New Economic Geography has provided one of several possible types of models capable of producing cities and even hierarchies of cities. Fujita and Mori (1997) and Fujita, Krugman and Mori (1999) generate a form of central place theory in a general equilibrium framework by employing imperfect competition and increasing returns at the firm level. Unfortunately, this type of model has many defects, as detailed in Berliant (2006), including a reliance on specific functional forms and indeterminacy: one equilibrium is selected from a continuum. Central place theory is not grounded in the analytical tools of modern economics, so it does not have firm foundations. Thus, it is difficult to build on central place theory, either theoretically or empirically. In my view, the future of central place theory is as a stylized fact to be explained by our models, much like the rank-size rule.

certainty equivalence

Xavier Freixas

Edited by Steven N. Durlauf and Lawrence E. Blume

Article

In order to take a decision in an uncertainty context, it is necessary, from a theoretical point of view, to build a model and specify all the consequences in every possible state of the world. In applied work this method is much too involved. Consequently, for applied purposes, it would be interesting to have a model where uncertainty is treated in such a way that the decision problems are as simple as the equivalent ones in a certainty framework. The identification of the conditions under which such an isomorphism between the optimal decisions under uncertainty and the optimal decisions in an equivalent certainty context holds is called the certainty equivalent problem.

Theil (1954) has been the first to point out the problem and to suggest a specific model in which the certainty equivalent property holds.

Theil imposes the following two assumptions: (i) the vector $x$ of instruments and the vectory $y$ of result variables are related by a simple equation

$$y = g(x) + S$$

(1)

where $S$ is a vector of random variables, that we can take to have a zero expected value without loss of generality. (ii) The decision-maker's objective function is quadratic and can be written as

$$u(x, y) = A(x) + \sum_{i=1}^{m} A_i(x) y_i + \frac{1}{2} \sum_{i=1}^{m} \sum_{j=1}^{m} A_{ij} y_i y_j$$

(2)
Using such a model it is straightforward to show that whenever the optimal solution to the problem of maximizing the expected utility under the constraint (1) exists, it is the same as the optimal solution to the equivalent certain problem:

\[
\begin{align*}
\text{Max } & u(x, y) \\
y = g(x)
\end{align*}
\]

This result is extended not only to the multiperiod problem but also to the case where the decision-maker receives more and more information as time elapses. The resulting stochastic problem is then more involved, but it is simply solved by use of dynamic programming, the optimal strategy in period \( t \) being a function of the previously observed signals \( \eta_{t-k} \):

\[\chi_t^* = x_t^*(\eta_1, \eta_2, ..., \eta_{t-1})\]

Again, the conditions for the first period solution to this problem to be the solution of the equivalent certain problem are very strong. As before, it has to be the case that the objective function is quadratic, but in addition the constraint relating instruments to results is restricted to be of the following type:

\[y = RX + S\]

where \( R \) is a matrix with some required specifications (namely, the value of the instrument variables of one period have no effect on the result variables of the preceding periods).

The conditions that guarantee the equivalence between the uncertainty problem and the certainty problem are so restrictive, that an alternative view of the problem has been suggested. Instead of setting restrictions on the parameters of the model, the uncertainty itself is restricted to be ‘small’. Formally, this is equivalent to consider an entire class of problems that can be ranked in their uncertainty as measured by a parameter \( \varepsilon \) and whose limit is the certain problem. The question is then to know under what conditions the solution to the limit of the random problems, that is equal to the one of the certain problem, is independent of \( \varepsilon \) to the first order, so that
This slightly different point of view is called the ‘first order certainty equivalence’ problem and has been dealt with by Theil (1957) and Malinvaud (1969). The very general conditions obtained by Malinvaud for the first order certainty equivalent to hold are (i) that the objective function is twice differentiable and (ii) that the optimal strategy is continuous with respect to the degree of uncertainty. If this condition holds, the optimal values of the instruments at time 1 are, to the first order approximation, independent of the degree of uncertainty. It is clear that this condition cannot be met if there are constraints on the future instrument variables, since this will bring in a kink. A particular and natural example of a framework where the first order certainty equivalence does not hold is when decisions are irreversible. As pointed out in Henry (1974), it is then the case that the value of the decision in the first period will affect the decision set in the following periods, and consequently, the use of the certainty equivalent would generate a systematic error.

The CES (constant elasticity of substitution) production function, including its special case the Cobb–Douglas form, is perhaps the most frequently employed function in modern economic analysis. Not only is the CES function used for the formal depiction of production technology, it is used as a convenient tool for empirical analysis as well. In addition to production theory, the CES function, more commonly known as the Bergson family of utility functions, is employed in utility theory.

**Ordinary CES production functions**

The simplest form of CES function utilized in production theory is the constant returns to scale type (Arrow et al., 1961):

\[
Y = (aK^{-\rho} + (1-a)L^{-\rho})^{-(1/\rho)}
\]

where \(Y\)=output, \(K\)=capital, \(L\)=labour, and the parameters \(T\), \(\alpha\) and \(\rho\) satisfy the conditions: \(T \geq 0\), \(0 \leq \alpha \leq 1\) and \(\rho \leq -1\). As is implied by its name, the elasticity of factor substitution between capital and labour for production function (1) is expressed as some constant value.

For any neoclassical production function \(Y = f(K, L)\), the elasticity of factor substitution between capital
and labour is defined as the proportionate change in the $K/L$ ratio ($k$) relative to the proportionate change in the marginal rate of factor substitution $r = f_L / f_K$ along a given isoquant curve, where $f_L = \partial Y / \partial L$ and $f_K = \partial Y / \partial K$ are the respective marginal products. That is,

\[
\sigma = \frac{d \log k}{d \log r} = \frac{f_K f_L (f_{KK} + f_{LL})}{KL (2 f_{KL} f_K f_L - f_K^2 f_{LL} - f_K^2 f_{KK})},
\]

where $\sigma$ represents the elasticity of substitution and $f_{KL}, f_{KK}$ and represent the cross and own derivatives of the respective marginal products.

Applying definition (2) to production function (1) we obtain:

\[
\sigma = \frac{1}{1 + \rho} \quad \text{or} \quad \rho = \frac{1 - \sigma}{\sigma}.
\]

Consequently, it is easy to see why $\rho$ is often referred to as the ‘substitution’ parameter. The $\alpha$ parameter in production function (1) is the ‘distribution’ parameter that permits the relative importance of capital and labour to vary in production. In the extreme case where $\sigma \to 0$ or $\sigma = 1$, the CES function (1) converges to the Cobb–Douglas form:

\[
Y = TK^\alpha L^{1-\alpha}.
\]

In this form, it is evident that $\alpha$ and $1 - \alpha$ are the production elasticities of capital and labour respectively. Under conditions of perfect competition, $\alpha$ and $1 - \alpha$ will also equal the respective relative income shares (or income distribution). The $T$ parameter in both production functions (1) and (4) is the ‘efficiency’ (or technical progress) parameter.

With the exception of its special case the Cobb–Douglas form, the ordinary CES production function is cumbersome and difficult to manipulate. However, the underlying expression for the marginal rate of factor (technical) substitution has a simple form and this is the primary reason for the popularity and wide use of this production function.
Homothetic and non-homothetic CES production functions

Any monotonic transformation of the ordinary CES production functions (1) belongs to a class of CES production functions called the homothetic class, that is,

\[
Y = F(f), \quad F' > 0,
\]

where

\[
f = \tau \left[ \beta K^{-\rho} + (1 - \beta)L^{-\rho} \right]^{-1/\rho},
\]

(5)

In addition to the class of homothetic CES production functions, there is a more general, and perhaps more meaningful, class of non-homothetic CES production functions. One can refer to the class of non-homothetic CES functions as the ‘general class’ of CES production functions as it contains the homothetic class as a special case.

The class of non-homothetic CES production functions is derived as a solution to the differential equation that defines a constant elasticity of factor substitution. However, unlike the case of the homothetic CES production functions where the marginal rate of factor substitution is (implicitly) assumed to be independent of either the output level and the process of technical change, the family of non-homothetic CES production functions explicitly assumes that output level and technical change will have some kind of impact on the factor input ratio.

The class of non-homothetic CES production functions can be expressed as follows (Sato, 1975):

\[
C_1(\gamma)K^{-\rho} + C_2(\gamma)L^{-\rho} = 1, \quad \rho = \frac{1 - \sigma}{\sigma}, \quad \sigma \neq 1,
\]

(6a)

\[
C_1(\gamma)\log K + C_2(\gamma)\log L = 1, \quad \sigma = 1,
\]

(6b)
where $C_1$ and $C_2$ are functions of the output level $Y$. When $C_1=aC_2$, where $a$ is a constant, we can express (6a) as

$$k^{-\rho} + aL^{-\rho} = \frac{1}{c_1(Y)} = b(Y)$$

or

$$Y = b^{-1}(k^{-\rho} + aL^{-\rho}).$$

Note that with the appropriate choice of $B$ and $a$, we can always express the above in the form of the ordinary CES production function. In general, the non-homothetic CES production functions are in an implicit form and can never be expressed in an explicit form.

**Classification of non-homothetic CES production functions**

The general class of non-homothetic CES production functions can be classified in a number of ways, depending on the specific purpose in mind. For example, it is well known that the ordinary CES production function belongs to the explicit and separable class of homothetic CES functions. In a similar fashion, we can derive an explicit and separable class of non-homothetic CES functions (Sato, 1974). Another way of classifying non-homothetic CES production functions is to consider the form of the underlying marginal rate of factor substitution function. However, the most precise way of classifying the family of non-homothetic CES production functions is to utilize Lie group theory.

**A historical note**

It was Arrow et al. (1961) who first utilized the ordinary CES production function expressed in (1) for the estimation of constant returns to scale aggregate production functions using cross-country data. Since then, the ordinary CES function and its variants have been widely applied in both theoretical and empirical work involving production behaviour. Prior to its application to production analysis, the ordinary CES function, was utilized in the study of demand as the Bergson family of utility functions (Samuelson, 1965). Earlier writers in growth economics, such as Dickinson (1955) and Solow (1956), used special cases of the CES function, such as $\sigma = 2$. In the field of mathematics, Courant (1959, vol. 1, pp. 557, 601) has used the explicit form of the ordinary CES function in conjunction with the so-called Jensen inequalities.
A published note by McElroy (1967) contains the first reference to the non-homothetic CES production family. However, it was not until later that Sato (1974) derived an explicit form of the non-homothetic CES production function. The application of Lie group theory to CES production functions was first presented in 1975. This work demonstrated that the ‘projective’ type of technical change with eight essential parameters can be used most effectively to classify the general non-homothetic CES family of production functions. This work is summarized in Sato (1981, ch. 5).

The Latin phrase 'ceteris paribus', which translates as 'other things the same', is much invoked by economists. Its popularity stems from its prominent use by Alfred Marshall (1920, pp. xiv–xv, 366–70), who invented the metaphor of 'the pound called Coeteris Paribus' – pound being used here in the same sense as in impoundment – in which are imprisoned 'those disturbing causes, whose wanderings happen to be inconvenient' (1920, p. 366).

The term 'ceteris paribus' has no clearly settled technical meaning among economists, so that an attempt to chronicle its usage would be both difficult and unrewarding. Instead, it seems preferable to distinguish the most important alternative ways in which the phrase might be employed, alluding only briefly to the pertinent literature. It is important to distinguish at the outset three broad ways in which the phrase might be used. These are:

- as a reminder that any practicable theory must take for granted the stability and continuance of certain background circumstances;
- as a warning, when using a theory predictively, that certain variations in circumstances admitted by the theory have been assumed not to occur;
- as an instruction to hold hypothetically constant some members of a set of necessarily covarying variables while changes in the others are contemplated.

For example, an analysis of the movement of a group of adjacent cooling towers during gales might (i) abstract from earthquakes, or (ii) hold constant ambient temperature while considering the effects of varying wind speed, or (iii) analyse the swaying of one tower in a high wind on the assumption that the other towers are perfectly rigid, even though they too must actually sway in a way that subtly alters the wind currents buffeting the first tower. In the language of econometric models, these three usages of...
‘ceteris paribus’ can be characterized as (i) a reminder that the model’s structure is assumed not to change, or (ii) a warning that certain exogenous variables are presumed to remain constant when others change, or (iii) an instruction to hold constant certain endogenous variables while varying others, even though this is not justified by any separability properties of the model’s structure.

The first two usages pose no difficulties. In each, the invocation of ceteris paribus merely serves as a reminder that a more comprehensive or elaborate analysis might have been attempted. The risk of earthquakes could have been incorporated into the analysis of cooling-tower stability at the price of added complexity. But a failure to do so is without methodological significance. The incidence of earthquakes is unlikely to be affected by any movement of the towers, so that the exclusion merely singles out a convenient stopping place on the inevitable trade-off between comprehensiveness and complexity. Analogously, in predicting with an econometric model it would be possible to make careful predictions of the changes in all exogenous variables that accompany a tax cut. But a failure to do so involves no logical inconsistency, and the resulting ceteris-paribus prediction of the tax cut's effects will still have substantive interest.

It is the third usage alone, with its implied logical inconsistency, which poses distinct difficulties of interpretation and methodological justification. To start with, the assertion that certain variables are mutually interdependent presumes knowledge, at least in principle, of a correct comprehensive theory in which these variables are endogenous. For economists, the requisite background theory has usually been that of Walrasian competitive general equilibrium. In such a context, the invocation of ceteris paribus in its third sense to freeze hypothetically certain endogenous variables (or, more generally, to treat them as if exogenous) can itself be given at least three alternative rationalizations.

1 Partial equilibrium analysis as an approximation

The focus here is on the demand–supply interactions in one market or a few closely interrelated markets as exogenous shifts occur, prices in all other markets being treated as hypothetically constant (or perhaps in some cases varied exogenously). Such a procedure is inconsistent with the supposed background general-equilibrium theory which implies that all prices vary interdependently. But it may give an adequate approximate representation of the particular markets being examined (see Viner, 1953, p. 199). This is more likely the weaker and more diffuse are connections to, and feedbacks from, markets outside the examined set. Smallness relative to the entire economy is usually helpful in this regard, but such questions have received surprisingly little detailed analysis.

2 Approach by successive approximation

Here the use of ceteris paribus restrictions is viewed as a necessary transitional step towards the evolution or understanding of a fully-comprehensive general-equilibrium theory. The limitations of human comprehension, its need to understand and test only one link of a complete chain at a time, calls for a piecemeal step-by-step progression from the crude but simple to the sophisticated but more complex, even though such a proceeding would appear illogical to an all-comprehending Cartesian intelligence. It should, however, be observed that this progression could well take place by starting with a highly aggregated general equilibrium model and successively reducing the degree of aggregation,
instead of by starting with a simple partial-equilibrium model and gradually expanding its coverage until general equilibrium is reached – as is Marshall’s clearly stated strategy (1920, pp. xiv–xv).

3. Illuminating thought experiment

Conceptual experiments which hold constant certain endogenous variables, or vary them arbitrarily, may perform a valuable heuristic role in aiding comprehension of the attainment and character of general equilibrium, even though they are not part of the theory's logical structure. Thus, the construction of Walrasian market excess demand functions, by the mental experiment of facing each individual with the same arbitrary price vector and then aggregating, is heuristically valuable despite the fact that all market excess demands must be zero in equilibrium. In part this heuristic value comes from pertinence to the disequilibrium meta theory in which any equilibrium theory must be embedded, a meta theory which might be visualized only vaguely and informally. Mental experiments of this type have been termed ‘individual’ or ‘ceteris paribus’ experiments by Patinkin, who contrasts them with ‘market’ or ‘mutatis mutandis’ experiments in which endogenous variables are always constrained to satisfy the requirements of the underlying general equilibrium structure (1965, pp. 11–12).

These three different ways of invoking ceteris paribus to freeze or ‘exogenize’ some endogenous variables may be contrasted briefly by saying that the first views partial-equilibrium theory as sometimes preferable to general-equilibrium theory, the second regards partial-equilibrium theory as an interim step towards general-equilibrium theory, and the third interprets ceteris-paribus experiments as heuristic aids sustaining general-equilibrium theory.

The partial-equilibrium approach is closely associated with Marshall, who popularized its use, although Cournot (1838) among others had employed it previously. But Marshall’s methodological discussion of the use of ceteris paribus restrictions arose in the narrower context of his time-period analysis, which is conducted within a framework already partial-equilibrium in character (1920, pp. 366–80). Considering a single industry (his example is fishing), he imprisons in the pound of ceteris paribus those variables, exogenous or endogenous, whose movement is very rapid or very slow compared with those whose equilibrium and comparative-static properties he wishes to explore. The aim is to gain rough insight into likely time paths, given that explicit dynamic analysis is not feasible (see Viner, 1953, p. 206).

The use, other than for frank approximations, of ceteris paribus assumptions which conflict with underlying general-equilibrium requirements (that is, the use of individual rather than market experiments) has been attacked as illogical or misleading by Friedman (1949) and Bailey (1954) in the context of demand functions, and by Buchanan (1958) more generally. A judicious assessment and summing up is provided by Yeager (1960).

Applications of ceteris paribus ideas to growth paths rather than stationary equilibria have been pioneered by Fisher and Ando (1962).

In closing, mention might be made of the classical notion of ‘disturbing causes’ as set out by J.S. Mill (1844, Essay V). Any deductive theorist who regards his assumptions as true, rather than mere means for generating refutable statements, must view his (valid) deductions as also true in the absence of disturbing causes not allowed for in his assumptions (see Keynes, 1891, pp. 204–13). Are such disturbing causes to be viewed as ruled out by a ceteris paribus assumption? According to Mill, they are in the statement of general economic theory (when, for example, other motives than the pursuit of
wealth are excluded) but not in its specific applications, when due allowance must be made \textit{ex ante} for all likely disturbing causes. Thus, the ruling out of disturbing causes is meant as nothing but a device to permit statement and development of a common theoretical skeleton which must be fleshed out whenever specific use is made of it.

Ceva, Giovanni (1647/48–1734)

Giancarlo Gandolfo

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Ceva, G.; Gresham's Law; mathematical economics; quantity theory of money

Article

Mathematician, hydraulic engineer and mathematical economist, Ceva was born in Milan in 1647 or 1648 and died in Mantua in 1734. He studied at the University of Pisa; later he obtained a post at Gonzaga's court in Mantua, where he became the chief technician and applied his mathematical skill to technical and administrative problems.

As a mathematician he is known for the theorem (1678) concerning the concurrency of the transverse lines from the vertices of a triangle, which is named after him; his work on fluvial hydraulics is summed up in *Opus hydrostaticum* (1728). His studies in economics are contained in a work of 1711, where he studied monetary problems. Here we find a statement of the quantity theory of money: *ceteris paribus*, the value of money varies inversely with its quantity and directly with the number of people. The latter assertion may seem odd, but it is not if we interpret ‘number of people’ as a proxy for the transaction variable in the quantity theory equation (as is implicit in Ceva’s Postulate II). We also find an independent statement of Gresham’s Law and a study of the problems of a plurimetallic standard. The interest of this work, however, does not lie in its economics, where no objectively new contributions are made, but in its methodological content and message. Ceva was the first to conceive, to state lucidly and to apply unhesitatingly the idea of *systematically* employing the mathematical method in economics as an indispensable tool with which to reason rigorously, to understand difficult and otherwise obscure phenomena and to put them in order. His analytico-deductive treatment, which proceeds by definitions, postulates, remarks, propositions, theorems and corollaries, is indeed the first example of mathematical economics as we now understand it.

Chalmers, Thomas (1780–1847)

D.P. O'Brien
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Chalmers, T.; Malthus's theory of population; overproduction; over-saving; Poor Law

Article

Chalmers was born in Anstruther, Fife, and died in Edinburgh. Though he was strongly attracted to mathematics and physics in his youth, he is famous as a theologian and economist and as an active worker in the field of poor relief. Appointed to a parish in 1803, he later moved to Glasgow, where he began a famous and influential experiment in the administration of poor relief through dividing up the large parish of St John into small units and relying on a large number of voluntary helpers. He left Glasgow to become Professor of Moral Philosophy at St Andrews in 1823; in 1828 he became Professor of Divinity at Edinburgh and in 1843 he was centrally involved in the famous ecclesiastical divisions which produced the Free Church.

Endorsing Malthus's theory of population, he argued fervently (and repetitively) that the answer to the problem lay in moral education which would, in turn, lead to moral restraint. He opposed the Poor Law: it stimulated population, and interfered with private charity, which, his Glasgow experience had convinced him, was more effective. His work on aggregate demand and gluts – he argued that there could be both overproduction and over-saving since aggregate demand could be diminished not increased in proportion to both production and saving – is generally regarded as following the work of Malthus; but the essence of the argument, in terms of his aggregate demand and employment-creating analysis of trade, is present in his 1808 pamphlet, and thus precedes Malthus's own concern with aggregate demand.

Chamberlin, Edward Hastings (1899–1967)

Robert E. Kuenne
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Chamberlin, E. H.; collusion; excess capacity; exploitation; firm, theory of; Harrod, R. F.; imperfect competition; industrial organization; large-group case; monopolistic competition; monopoly; oligopoly; product differentiation; Robinson, J. V.; Schlesinger, K.; specialization

Article

A major innovator in modern microeconomic theory, Chamberlin was born in La Conner, Washington, on 18 May 1899, and died in Cambridge, Massachusetts, on 16 July 1967. He received his Ph.D. from Harvard in 1927, became a full professor there in 1937, and occupied the David A. Wells chair from 1951 until his retirement in 1966. He edited the Quarterly Journal of Economics from 1948 to 1958.

Chamberlin's career exhibits a unity of professional purpose and thematic dedication over its more than 40-year length that is rare for modern theorists. Beginning with the start of his thesis research in 1925, its publication in 1933 as the seminal *Theory of Monopolistic Competition*, and continuing through eight editions, Chamberlin devoted his life to his vision of realistic market structures as mixtures of monopoly and competition. He opposed the alternative polar frameworks of pure competition and monopoly of the 1920s as unrealistic; proselytized for his merger of them at the level of the firm in both broad and narrow contexts; strove tirelessly (and rather stridently) to distinguished his concepts from Joan Robinson's similar constructs; and manned the academic ramparts in full echelon against all who sought either to criticize the concepts or, alternatively, take credit for their genesis.

In so doing, Chamberlin's broad contributions to microeconomic analysis were of fundamental and insufficiently acknowledged importance. His ‘large group case’ and revival of interest in oligopoly theory created the notion of market structure as a continuum between pure competition and monopoly with location dictated by numbers of firms and product differentiation. With his work he fathered modern industrial organization analysis by giving a theoretical core to what was previously institutional and anecdotal. He reoriented the interest of microeconomics from the industry to the firm, revealing the latter's target variables to include selling cost and product variation as well as price. And his frameworks led economists to comprehend the importance of differentiated oligopoly in developed economies through his emphasis upon product differentiation, his formalization of monopoly power as control over price, and his perception of the core feature of oligopolistic market structure as perceived mutual interdependence of decision making.

Monopolistic competition theory

In its generic sense, which Chamberlin stressed increasingly in his later career, monopolistically competitive market structures are those in which the firm feels the external compulsions of competitive forces tempered in varying degrees by a monopolistic power to price its product. Central to monopolistic competition in this wider sense is product differentiation, or the ability of the firm to distinguish its product in the preferences of consumers, where product is defined to include a complex of qualities in addition to those inherent in the physical good (for example, location, repair services, ambience and so on). The existence of differentiation (a) implies the possibility of selling costs, or costs aimed at adapting demand to the product (advertising, catalogues, discounts, and so on) as distinguished from production costs, or expenditures that adapt the product to demand, and (b) product variation, or the variability of the complex of qualities and attributes that characterize the firm's output in the mind of the consumer.

In his original presentation of monopolistic competition and into the 1940s, Chamberlin tended to identify it more narrowly with a specific market structure that isolated product
differentiation as its distinctive component. This was the *large-group case* with the ‘tangency solution’ as the firm's long-run equilibrium position, as shown in Figure 1. Each firm produces a slightly differentiated product which may be closely approximated by competing firms. Hence, a large number of close substitutes ensure that the firm's demand curve is only slightly tilted from the pure competitor's horizontal position. If, for simplicity, all firms are assumed to have identical cost functions and to share sales equally (the *symmetry* assumption) then competition will reduce profit to zero by equating average cost and price at a tangency of the demand curve $dd'$ and the average cost function $AC$. Where the tangency occurs marginal revenue $MR$ will equal marginal cost $MC$. Hence, at price $p^o$ and sales $x^o$ each firm will be maximizing its profits at zero and neither entry into nor exit from the industry will occur: no internal or external force will exist to upset the long-run status quo.

Figure 1
The firm's optimal solution in the large-group case
Despite Chamberlin's later disclaimers, there is little doubt that the large-group case was featured as the novel contribution of his theory, and it became identified with monopolistic competition theory. But from the beginning, Chamberlin did identify a second species in the generic theory: monopolistic competition caused by fewness of sellers of a homogeneous product. In the preface to the first edition of the *Theory* he included oligopoly in the concept of monopolistic competition. Oligopoly – he coined the word independently but later recognized its prior usage in 1914 by Karl Schlesinger – in the pure (that is, undifferentiated product) case formed the mirror image of the large-group case, with small rather than large numbers of sellers and undifferentiated rather than differentiated products. Surprisingly, given the centrality of product differentiation in his thought, he had little to say about differentiated oligopoly as a composite of the two purer cases of monopolistic competition – as late as 1948 the sixth edition of the *Theory* devoted only five pages to informal discussion of it – although he realized increasingly in his later work the prominent position it held in realistic market structures.

Chamberlin's contributions to the theory of pure oligopoly were noted above in listing his broader impacts on the field. More narrowly, they were not great advances. He ignored formal treatment of collusion and tended to urge that tacit collusion would lead to joint profit maximization for pure oligopoly and to a price solution intermediate between joint profit maximization and the large-group case for differentiated oligopoly. In his later, more informal, treatment of oligopoly, however, he asserted a general tendency toward 'live-and-let-live' limitations on oligopolistic rivalry.

But from the 1950s on, Chamberlin moved away from the large-group case as the featured form of monopolistic competition theory and shifted emphasis to oligopoly in its differentiated form. In part this was an aspect of his continuing desire to distance his theory from Joan Robinson's imperfect competition, in which she had independently developed the large-group case complete with tangency solution in the symmetry case. But, more importantly, the evolution of his thought reflected his increasing awareness that few market structures contained the uniform product competition implied by that solution. Rather, closer investigation of most realistic market structures with large numbers of sellers of slightly differentiated products revealed hierarchical clusters of oligopolistically competing firms. His book of essays (Chamberlin, 1957) reveals clearly his attempt to prevent monopolistic competition theory from being too closely identified with the large-group case.

Another aspect of this later effort was the playing down of his pioneering use of marginal revenue and marginal cost curves. In denying P.W.S. Andrews's assertion that full cost pricing was antithetical to monopolistic competition, Chamberlin asserted that it was integral to that body of analysis from the beginning, since profit maximization was never an exclusive motivation of the firm – as it was in Robinson's imperfect competition.

**Other microeconomic contributions**

An implication of the large-group equilibrium illustrated in Figure 1 is that firms would have long-run excess capacity in the sense that they would be operating at a production rate less than the rate associated with minimum average cost. This led to a dispute with Sir Roy Harrod, who seemed to believe that Chamberlin's results occurred because he was using short-run demand and cost curves in the large-group analysis. Harrod argued that businessmen would follow their long-run revenue and cost prospects and that excess capacity would not result. Chamberlin properly pointed out that his functions were long-run functions and that the long-run demand in Harrod's case did not attain the horizontality needed to eliminate excess capacity (Harrod, 1952, Essays 7, 8; Chamberlin, 1957, pp. 280–95; Kuenne, 1967, pp. 67–70). Later, Chamberlin argued that excess capacity also occurred in an industry when entrants flooded in irrationally even when profits disappeared (whose counter-argument was probably what Harrod had in mind) (Chamberlin, 1957, p. 290).

Chamberlin devoted a large portion of his writing to rationalizing the U-shaped average cost curve that was so fundamental to his market structures. Building upon the notion of the long-run average cost curve as the envelope of short-run average cost curves with fixed plants, he distinguished between using a fixed plant curve optimally in the short-run at its minimum-cost rate and producing a given rate of output optimally in the long-run by building an over-sized plant and using it at less than minimum cost capacity. Also, he denied that the rising portion of the long-run average cost curve was caused solely by management complexity or lumpy factors at higher output rates. In so doing, Chamberlin challenged the assertions of Knight (1921, pp. 98–9), Lerner (1944, pp. 165–7, 174–5), Stigler (1952, pp. 133, 202n.), and Kaldor (1934, p. 65n; 1935, p. 42) that, if all factors could be reduced to finely divisible units with (explicitly or implicitly assumed) constant efficiency, the average total cost would be constant as all product would be produced with optimal factor proportions. He argued that such factors would experience economies of scale as a function of factor-complex size owing to the ability to exploit specialization possibilities. These possibilities – $100 in capital might be concretized in ten shovels but $10,000 in capital might materialize as one back-hoe – permitted resource aggregates to become qualitatively different complexes with increased scale, rendering the notion of factor units with unchanged efficiency meaningless. The argument turns upon the semantics of constant efficiency units and the usefulness of the assumption, however, and was seen by most theorists to be non-illuminating and, as Chamberlin emphasized, tautological.
Two other contributions by Chamberlin are worthy of brief note. One was his destruction of Joan Robinson's notion of worker 'exploitation', because in non-purely competitive industries workers received marginal revenue product rather than marginal value product. Chamberlin demonstrated conclusively that the difference between the two was not received by any other factor, including the entrepreneur, but was experienced as an external revenue constraint by the firm. The second, quite different, contribution was Chamberlin's role as a founder of modern experimental market research by his publication of the results of mock market operations with his students.

The debate with Robinson

Chamberlin, like most microeconomic theorists of his generation, was thoroughly Marshallian in vision and methodology, and his innovations integrated neatly into the concerns of the post-Marshallian school. It was somewhat ironic, therefore, that Chamberlin found his major (and reluctant) opponent in Joan Robinson, as thoroughly Marshallian as himself. Chamberlin spent much of his professional life urging the fundamental divisions between his theory of monopolistic competition and Robinson's theory of imperfect competition. The basis of the distinction changed fundamentally over his career. In the earlier objections, Chamberlin perceived correctly that Robinson's aim was to implement Sraffa's suggestion that microeconomic theory be rewritten in terms of a general theory of monopoly (Robinson, 1933, p. v). In so doing, he urged, Robinson failed to achieve the true blending of monopoly and competition that his theory achieved. Robinson evolved the large-group case in every detail, but passed quickly over it in pressing on to her larger goal of creating a general theory of 'monopoly' in industries with more than one firm. To Chamberlin, who in this early period stressed the large-group case, her emphasis upon near-homogeneous commodities with some differentiation of sellers in the consumers' minds slighted the competition among differentiated products and resulted in an analysis of industry 'monopoly', very close to the one-firm monopoly of standard theory.

There was some truth in this, although Chamberlin was ungenerous to Robinson in interpreting her achievements, for in addition to her large-group case development she paralleled him in isolating selling costs and in defining two types of imperfect markets: (a) firms which were not alike in customers' preferences, and (b) oligopoly. But she saw the threat to the existence of the 'industry' that non-homogeneous products posed, and her overall goal needed that solid Marshallian construct. Chamberlin from the beginning was willing to abandon the concept and speak of 'product groups'.

However, as the large-group case came under criticism as incorporating too much of the purely competitive, and as oligopolistic structures received more attention in the literature, Chamberlin, as we have seen, shifted his ground and began to criticize Robinson for the opposite fault. The problem was, he now said, that imperfect competition failed to achieve the union of the competitive and the monopolistic because there was not enough monopoly content at the level of the firm. Implicitly, Robinson's large-group case was now focused upon for this fault, in comparison with his increasingly emphasized generic concepts that stressed oligopolistic elements. The profession has ignored Chamberlin's strictures as distinctions without meaningful differences, and quite properly rewarded both theorists for their innovations. But the goals of the theorists were different, and, in most instances, Chamberlin's greater stress upon product differentiation and variation, selling cost and oligopoly proved to be more seminal in their professional impact.

It was fortunate for the economics profession that the schoolboy Champernowne, a keen and able mathematician, was advised to read something in the school library to broaden his horizons: he chose Marshall's *Principles*.

David Champernowne was born on 9 July 1912 into an Oxford academic family. He was sent to school at Winchester and went from there as a scholar to King's College, Cambridge. While still an undergraduate he published his first paper (on ‘normal numbers’). Early contact with Dennis Robertson confirmed his previous interest in economics, and he was advised by J.M. Keynes to abandon his thoughts of becoming an actuary and switch to the Economics Tripos by taking his Part II Mathematics in one year rather than the normal two. He obtained firsts throughout in both subjects.

His academic career spanned the London School of Economics (1936–8) Oxford (1945–59), and Cambridge (1938–40 and 1959–78). During the war period he served with Lindemann as Assistant in the Prime Minister's Statistical Section (1940–1) and worked with Jewkes at the Ministry of Aircraft Production's Department of Statistics and Programming.

He proved to be a genuine pioneer both in economic theory and statistics. His King’s fellowship dissertation (submitted in 1936, but published 27 years later in the *Economic Journal*) laid the foundations for the application of stochastic process models to the analysis of income distributions; this work has been of importance in recent economic research on fat-tailed distributions and scaling laws. His pre-war interest in Frank Ramsey’s theory of probability led on to work at Oxford on the application of Bayesian analysis to autoregressive series (at a time when the Bayesian approach was decidedly unfashionable), and culminated in his major trilogy on *Uncertainty and Estimation* (1969). However although he is thought of today primarily as a theoretician, his flashes of technical insight were always been tempered with healthy doses of practical scepticism. This is evident in his early work with
Beveridge on the regional and industrial distribution of employment and unemployment. Champernowne acted as midwife to a number of major theoretical contributions over and above his own work. He provided an invaluable ‘translation’ to von Neumann's seminal paper on multisector growth. His role as behind-the-scenes expert at Cambridge over many theoretical issues is legendary: Joan Robinson acknowledged the assistance of his ‘heavy artillery’ in underpinning, and extending, her major work on capital and growth: A.C. Pigou's later writings on output and employment, Nicholas Kaldor's work on savings and economic growth models, and Dennis Robertson's *Principles* were all indebted to his intellectual influence.

He held Chairs at both Oxford and Cambridge, was director of the Oxford Institute of Statistics and was editor of the *Economic Journal*. He was elected Fellow of the British Academy in 1970.

chaotic dynamics in economics

Jess Benhabib
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A new literature in the 1980s studied the possibility that endogenous cycles and irregular chaotic dynamics resembling stochastic fluctuations could be generated by deterministic, equilibrium models of the economy, in particular in overlapping generations models and in models with infinitely lived representative agents. Other empirical studies attempted to identify whether various economic time series were generated by deterministic chaotic dynamics or stochastic fluctuations. While dynamic equilibrium models calibrated to standard parameter values can generate chaotic dynamics and endogenous cycles even under intertemporal arbitrage and without market frictions, definitive empirical evidence for chaos in economics has not yet been produced.

Keywords

arbitrage; chaos; chaotic dynamics in economics; endogenous cycles; equilibrium cycles; ergodic chaos; intertemporal arbitrage; overlapping generations model

Article

When a new literature in the 1980s showed that endogenous cycles and chaos can arise in equilibrium models in economics, it came as a surprise. The possibility of deterministic fluctuations, as opposed to fluctuations driven by exogenous stochastic shocks, had been noted in an earlier literature on business cycles, for example in the well-known multiplier-accelerator models, but not in equilibrium models of the economy with complete markets and no frictions (see for example Frisch, 1933, or Samuelson, 1939). Yet deterministic fluctuations in equilibrium models with predictable relative price changes should be ruled out by intertemporal arbitrage. Such considerations led to the rejection of regular endogenous cycles in favour of models whose fluctuations are driven by stochastic shocks. The new literature on chaotic dynamics showed that deterministic cycles and chaos were indeed possible under complete intertemporal arbitrage and without any market frictions, both in standard models of
overlapping generations and in calibrated models of infinitely lived representative agents (see for example Benhabib and Day, 1980; 1982; Benhabib and Nishimura, 1979; Grandmont, 1985; and Boldrin and Montrucchio, 1986). Of course, relative price fluctuations in such models had to be within the bounds allowed by the discount factor in order to be compatible with intertemporal arbitrage. (For an exploration of the relation between equilibrium cycles, chaos and discount rates in models with infinitely lived agents, see Benhabib and Rustichini, 1990; Sorger, 1992; Mitra, 1996; and Nishimura and Yano, 1996.) Furthermore, chaotic dynamics could exhibit not only deterministic endogenous cycles, but generate trajectories that are irregular, and that are statistically indistinguishable from stable linear stochastic AR1 processes (see Sakai and Tokumaru (1980)).

We can usually describe a dynamical system in discrete time as chaotic if it can generate cycles of every periodicity, where a sequence \( \{x_j\} \) is of period \( n \) if \( x_j = x_{j+n} \) but \( x_j \neq x_i \), for \( j < i < n - 1 \). In addition, this simple definition of chaos requires the existence of an uncountable number of initial \( x \) which give rise to bounded but aperiodic (not even asymptotically) sequences. For example the well-known hump-shaped function, \( 4x(1-x) \), when iterated, generates such chaotic dynamics. The kind of chaotic dynamics described above is usually referred to as ‘topological chaos’. If in addition we require that the set of initial conditions giving rise to aperiodic sequences are not simply uncountable but also have a positive (Lebesgue) measure, then we also have ergodic chaos. A useful sufficient condition to obtain topological chaos with a simple difference equation \( x_{t+1} = f(x_t) \), with \( f \) continuous and mapping a closed interval into itself, is the existence of some \( x \) such that \( f(f(f(x))) \leq x < f(x) < f(f(x)) \). (See Li and Yorke, 1975; for simple sufficient conditions for chaos in higher dimensions, see Diamond, 1976, or Marotto, 2005.) Note that this condition will be satisfied if the difference equation has a solution of period three. A particularly interesting feature of some dynamic systems that are chaotic is their sensitive dependence on initial conditions: initial conditions that are arbitrarily close can generate sequences that tend to diverge over time. Thus, small measurement errors in initial conditions may cause large forecasting errors, which may explain some of the difficulties associated with business-cycle forecasting.

The aperiodic but bounded trajectories that characterize chaos and exhibit sensitive dependence on initial conditions cannot continue to diverge for ever. They converge not to a point or a periodic cycle but to a bounded chaotic or ‘strange’ attractor. The dynamical system which induces the local separation and instability of the trajectories must eventually bend them back. The combination of local stretching and global folding generates the complex nature of the dynamics. Such dynamic behaviour is in fact a familiar theme in economics that highlights the self-correcting nature of the economic system. Shortages create incentives for increased supply; dire necessities give rise to inventions as the invisible hand guides the allocation of resources. An equally familiar theme is that of instability: the multiplier interacts with the accelerator, leading to explosive or implosive investment expenditures; self-fulfilling expectations give rise to bubbles and crashes. In combination, these two themes suggest a nonlinear system, somewhat unstable at the core, but effectively contained further out. The contribution of the new literature on chaotic dynamics starting in the early 1980s has been to demonstrate the compatibility of endogenous irregular fluctuations with equilibrium dynamics in economics.

For a very simple example of chaotic dynamics, consider a simple overlapping generations model where each generation lives two periods. The utility function of a generation born at \( t \) is \( U(c_0(t), c_1(t+1)) \),
where $c_0(t)$ is consumption when young and $c_1(t+1)$ is consumption when old. This generation faces a budget constraint $c_1(t+1) = w_1 + r(t)(w_0 - c_0(t))$, where $w_0$ is the endowment when young, $w_1$ is the endowment when old, and $r(t)$ is the rate of return on savings. The first order condition to the problem of maximizing utility subject to the budget constraint, on the assumption of interiority, yields

$$r(t) = \frac{U_1(c_0(t), c_1(t+1))}{U_2(c_0(t), c_1(t+1))}.$$  

Here $U_1$ and $U_2$ denote the derivatives of the utility function $U$ with respect to the first and second arguments. During each period $t$, market clearing requires that the sum of the endowments of the young and the old add up to the sum of their consumptions:

$$w_1 + w_0 = c_1(t) + c_0(0).$$

Now consider the quadratic utility function

$$U(c(t), c(t+1)) = ac_0(t) - 0.5b(c_0(t))^2 + c_1(t), 0 \leq c_0 \leq a/b,$n

and $a, b > 0$. If we substitute the first order condition into the budget constraint, and use the market clearing condition, the difference equation describing the dynamics is given by

$$c_1(t+1) = \alpha c_0(t)(1 - (b/a)c_0(t)).$$

Note that

$$c_0(t) \in (0, a/b) \text{ for all } c_0(0) \in (0, a/b),$$

provided $a \leq 4$. This difference equation will exhibit chaotic dynamics in $c_0$ for $a \in [3.53, 4]$, $b = a$. For example, if $a = 3.83$, the difference equation has a three-period cycle for $c_0(t) = 0.1561$, where $c_0(t+1) = 0.5096$ and $c_0(t+2) = 0.9579$. In this simple example utility saturates at $c_0 = a/b$, but the chaotic trajectories and those with a period greater than one never attain $b/a$, since if $c_0(t) = b/a$, $c(t+i) = 0$ for all $i = 1, 2, \ldots$. Another simple example of an exponential utility function that will generate chaotic dynamics in this simple overlapping generations model, for $a > 2.692$ and $w_1 > e^{a-1}$, is

$$U(c(t), c(t+1)) = \alpha e^{a+c_0(t)+w_0} - c_0(t) + c_1(t).$$

(See Benhabib and Day, 1982, s. 3.4.)

Techniques to empirically distinguish between data generated by non-chaotic stochastic systems and deterministic chaotic systems have been developed by physicists and mathematicians (see for example Eckmann and Ruelle, 1985). These techniques have been further refined into statistical tests for applications to economic data by Brock (1986) and Brock et al. (1996), among others. Very roughly, these methods exploit the idea that deterministic systems will generate trajectories that are of lower dimension than those generated by stochastic systems, which have more scattered trajectories. For example, if we consider a one-dimensional difference equation that generates chaotic dynamics, say

$$x_{t+1} = 4x_t(1 - x_t)$$

for initial $x_0 \in (0, 1)$, plotting $x_{t+1}$ against $x_t$ will yield a curve. By contrast, if the dynamics were generated by a linear or nonlinear stochastic system with noise, the same plot would produce a scatter of points, which could not be captured by a ‘relatively smooth’, one-dimensional line. By formalizing this idea, we may attempt to distinguish data generated by deterministic chaotic systems and by non-chaotic stochastic systems, even without explicit knowledge of the underlying economic system generating the data. In general, however, such a method is hard to apply because, unlike data generated by scientific experiments, economic time series are often not long enough. If the order of underlying dynamical system generating the data is high-dimensional, say of the order of five or higher, or alternatively if we can only observe the realizations of a subset of the variables of the underlying economic model, distinguishing between stochastically and chaotically generated data becomes very difficult. The difficulty of empirically identifying chaos in high dimensional economic systems may be particularly important if chaotic dynamics is more likely to be manifested in disaggregated sectoral or industry data whose components, because of resource constraints or other scarcities, can move in ways that partially offset one another's cyclic or irregular movements. It would therefore be fair to say that at
this point, while we know that standard dynamic equilibrium models with parameters calibrated to values often used in the literature may well generate chaotic dynamics, more definitive empirical evidence for chaos in economics has not yet been produced.

While it may be instructive to set the theories of endogenous economic fluctuations in opposition to the theories of fluctuations driven by stochastic shocks, in practice it is more helpful to consider endogenously oscillatory dynamics as complementary to stochastic fluctuations. In certain environments it may make little difference if endogenous mechanisms by themselves generate regular and irregular persistent fluctuations, or whether they give rise to damped oscillations that are sustained by stochastic shocks. On the other hand, if the underlying equilibrium system is subject to distortions and there is room for stabilization policy, correctly identifying the source of the fluctuations becomes much more important. (See for example Benhabib, Schmitt-Grohe and Uribe, 2002). Furthermore, recognizing the role of oscillatory dynamics may diminish our reliance on unrealistically large shocks to explain economic data, for example, in real business cycle theory.

Abstract

Charitable giving is a significant vehicle for providing needed goods and services around the world. In the United States, for example, charitable giving accounts for nearly two per cent of income. Moreover, the tax deduction for charitable giving is one of the oldest and most widely used tax policies in the US tax code. This article describes the known facts on charitable giving, how and why people give, and discusses the impacts of government policies on giving.

Keywords

altruism; charitable giving; charitable organizations; crowding out; estate tax; free rider problem; fund-raising; permanent income hypothesis; philanthropy; public goods; self-interest; tax deductibility; two-stage least squares; warm glow

Article

In 2005 charitable giving in the United States totalled over 260 billion dollars, or around 1.9 per cent of personal income, making it a significant fraction of the economy. Individual giving accounted for 77 per cent of this total, while foundations accounted for 12 per cent, bequests for 7 per cent, and corporations for 5 per cent (Giving USA, 2006). Almost 70 per cent of US households report giving to charity. While the United States typically has one of the largest and most extensively studied charitable sectors, other countries around the world also have significant philanthropy (Andreoni, 2001; 2006).

There are three sets of actors in markets for charitable giving, and understanding each and their relationships to each other is essential to an understanding of charity. The first set is the donors who supply the dollars and volunteer hours to charities. The second is the charitable organizations, that is, the demand side of the market. They organize donors with fund-raising strategies, and produce the charitable goods and services with the money and time donated. The third player is the government. Governments are involved in charities in a number of ways. In many countries, including the United
States, individual taxpayers may be able to deduct charitable donations from their taxable income. Governments also give directly to charities in the form of grants. The following highlights the most important and fundamental aspects of research on charitable giving.

**What motivates giving?**

Why would a self-interested agent give away a considerable fraction of his income, often for the benefit of complete strangers? Obviously, acting unselfishly must be in his self-interest. One model of this is that the public benefits of the charity enter directly into a giver's utility function, that is, charity is a privately provided public good. This approach is advanced by Warr (1982) and Roberts (1984), who show theoretically that, if giving is a pure public good, then we would predict that government grants to charities will perfectly crowd out private donations, meaning government spending is largely ineffective. Bergstrom, Blume and Varian (1986) develop this model further to provide a series of elegant derivations, including the (unrealistic) prediction that redistributions of income will be ‘undone’ if everyone gives to a public good. Andreoni (1988) pushes this model to its natural limits and shows that in large economies we would predict a vanishingly small fraction of people who will give to a public good, which is clearly contradicted by the statistics presented above.

For this reason, economists have felt more comfortable assuming that, in addition to caring about the total supply of charity, what could be called pure altruism, people also experience some direct private utility from the act of giving. While there are numerous models and justifications for such an assumption, they have often been gathered under the general (and slightly pejorative) term, the ‘warm glow’ of giving (Andreoni, 1989; 1990). In large economies, in fact, it is easy to show that this motive must dominate at the margin (Ribar and Wilhelm, 2002). The intuition is clear. If large numbers of others are collectively providing a substantial amount of charity, the incentive to free ride must be so overwhelming that the only remaining justification for giving is that there is some direct benefit to the act of giving.

The consequence of assuming a warm-glow motive is that we can treat individual donations as having the properties of a private good. When income is higher or when the price of giving is lower, we predict that individuals will give more.

**What is the impact of the tax deduction for charitable giving?**

Studies of the charitable deduction are aimed at understanding just how individual giving is responsive to changes in income and price. If \( t \) is the marginal tax rate faced by a giver, and if (in the United States) the person itemizes deductions, then the charitable deduction makes the effective price of a dollar of donations \( 1 - t \). The policy questions are how responsive is giving to the price, and is the policy successful in promoting additional giving.

Let \( g \) be the giving of the household. If the policy is effective, then the new giving received by the charity should exceed the lost revenue of the government, that is, total spending on giving will rise with the deduction. This means \( d(1-t)g/dt > 0 \), which holds if \( \varepsilon = [dg/d(1-t)]/[(1-t)/g] < -1 \). This means that the policy is effective if giving is price-elastic, \( \varepsilon < -1 \). Since the first studies on giving (Feldstein and Clotfelter, 1976), researchers have debated whether this ‘gold standard’ has been met.
Dozens of studies of this question have been undertaken. Most employ cross-sectional data, either from surveys about giving or from tax returns. Each of these data sources has advantages and weaknesses, and each presents special challenges for identification and estimation (see Triest, 1998, for a careful discussion). These studies are summarized by Clotfelter (1985), Steinberg (1990), and Andreoni (2006).

Prior to 1995, a consensus had formed that the income elasticity was below 1, typically in the range of 0.4 to 0.8, and that the price elasticity was below minus 1, generally in the range minus 1.1 to minus 1.3, thus meeting the gold standard. Only a few studies found giving was price-inelastic.

This consensus was upset by an important study of Randolph (1995). There are two important features of his analysis. First, he uses a panel tax returns rather than a cross section. Second, the period of his sample, 1979–89, spans two tax reforms. These reforms provide independent variation in price that can be helpful in identifying elasticities. Moreover, his instrumental variables analysis allows him to separate short-run and long-run elasticities. Contrary to the prior literature, he estimates a long-run price elasticity of only minus 0.51, meaning that the policy no longer satisfies the gold standard. Short-run elasticities, by contrast, are high, at minus 1.55. This means that givers are sophisticated at substituting giving from years of low marginal tax rates to years with high marginal tax rates. His analysis suggests that cross-sectional studies conflate short- and long-run elasticities and thus mislead policy analysts.

Auten, Sieg and Clotfelter (2002) challenged Randolph's results. They use a similar (although longer) panel of tax payers, but employ a different estimation technique. Their analysis capitalizes on restrictions placed on the covariance matrices of income and price by assumptions of the permanent income hypothesis. Their analysis again returns estimates to the consensus values, with a permanent price elasticity of minus 1.26. The sensitivity of the estimates to the estimation technique and the identification strategy has left the literature unsettled as to the true values of price and income elasticities.

**Giving by the very wealthy**

Most of the data available, for reasons of confidentiality, exclude the very wealthy. Yet, the richest 400 US tax filers in the year 2000 accounted for about seven per cent of all individual giving in that year. Auten, Clotfelter and Schmalbeck (2000) provide a fascinating analysis of wealthy givers drawn from income tax filings at the Internal Revenue Service. Among the most interesting findings is that giving as a percentage of income rises only modestly with income, up to about four per cent for those earning over 2.5 million dollars. However, the variance in giving rises sharply. The inference is that wealthy givers are ‘saving up’ for larger gifts. These larger gifts may allow them to exert some control over the charity, such as providing a seat on the board of directors, or may garner a monument, such as naming a university building after the donor.

In discussing the wealthy, one must also address the effects of the estate tax on giving. Bakija, Gale and Slemrod (2003) use 39 years' worth of federal estate tax filings to study the sensitivity of estate giving to the estate tax. They rely on variation in estate tax rates across states for identification and find that charitable giving from estates is extremely sensitive to the tax. They measure the price elasticity of estate giving to be around minus 2.0, while the ‘wealth elasticity’ is about 1.5. This indicates that the 2001 changes in US estate tax laws, which greatly reduce (and eventually eliminate) estate tax rates, can have huge impacts on giving.
Do government grants crowd out individual giving?

There are many studies on crowding out, and most show that crowding is quite small, often near zero, and sometime even negative (Kingma, 1989; Okten and Weisbrod, 2000; Khanna, Posnett and Sandler, 1995; Manzoor and Straub, 2005; and Hungeman, 2005). Payne (1998), however, noted that the government officials who approve the grants are elected by the same people who make donations to charities. Hence, positive feelings toward a charity will be represented in the preferences of both givers and the government. This positive relationship between public and private donations means that some of the prior estimates could be biased against finding crowding out.

Payne (1998) turns to two-stage least squares analysis to address this endogeneity. As an instrument for government grants she uses aggregate government transfers to individuals in the state, and finds that estimates of crowding out rise to around 50 per cent, which is significantly above the zero per cent crowding that comes when she applies prior techniques to her data. This is a significant new finding. None of this analysis, however, has accounted for the fact that government grants may also have an impact on the fund-raising of charities. Andreoni and Payne (2003) ask what happens to a charity's fund-raising expenses when it gets a government grant. Does it fall, and by how much? They look at 14-year panel charitable organizations and find there are significant reductions in fund-raising efforts by charities after receiving government grants. This raises the possibility, therefore, that grants crowd out fund-raising, which then indirectly reduces giving, and that this may be the actual channel through which 'crowding out' occurs.

Incorporating fund-raising into research on charitable giving

One of the exciting new challenges for research on charitable giving is accounting for the strategic actions of charities in the analysis. This typically means understanding how charities choose fund-raising strategies, and how givers respond. A theoretical literature has emerged to provide a framework for analysing fund-raising (see Andreoni, 2006, for a review). At the same time researchers have begun considering field and laboratory experiments on charitable giving. These studies look at the effectiveness of ideas proposed by the theoretical literature, and evaluate some of the standard practices of charities.

Rege and Telle (2004) and Andreoni and Petrie (2004) show in laboratory studies that the common practice of revealing the identities of givers, and reporting amounts given in categories (Harbaugh, 1998), can have positive impacts on donations. Soetevent (2005) shows similar social effects in a field experiment.

List and Lucking-Reiley (2002) use a field experiment to establish that when charities require a minimum amount of contributions before a new initiate can be pursued, having a ‘seed grant’ can be greatly effective (Andreoni, 1998), as can be guarantees of refunds in the event that the threshold of donations is not met (Bagnoli and Lipman, 1989).

Landry et al. (2006), explore the use of lotteries in raising money for charities (Morgan, 2000) in an actual door-to-door fundraising campaign. They find that lotteries increase giving, as expected. Perhaps surprisingly, however, they find that the physical attractiveness of the fundraiser has a significant affect
on the amounts raised, and that this was at least as important as any economic incentives offered.

Conclusion

Charitable giving has been one of the perennial topics for economists. It presents challenges for the theorists to understand the motives and institutions for giving, for policy analysts to measure and identify the effects of price and income, and for experimenters to explore innovations in the market for giving. As governments become increasingly reliant on private organizations to provide public services, and as charities become increasingly sophisticated at raising money and delivering needed services, understanding the relationships among the suppliers and demanders of charity will become essential for calculating the social costs and benefits of charitable institutions.

cheap talk

Vijay Krishna and John Morgan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Cheap-talk models address the question of how much information can be credibly transmitted when communication is direct and costless. When a single informed expert, who is biased, gives advice to a decision maker, only noisy information can be credibly transmitted. The more biased the expert is, the noisier the information. The decision maker can improve information transmission by: (a) more extensive communication, (b) soliciting advice from additional experts, or (c) writing contracts with the expert.

Keywords

cheap talk; communication equilibria; delegation principle; games with incomplete information; incentive contracts; revelation principle; signalling

Article

In the context of games of incomplete information, the term ‘cheap talk’ refers to direct and costless communication among players. Cheap-talk models should be contrasted with more standard signalling models. In the latter, informed agents communicate private information indirectly via their choices – concerning, say, levels of education attained – and these choices are costly. Indeed, signalling is credible precisely because choices are differentially costly – for instance, high-productivity workers may distinguish themselves from low-productivity workers by acquiring levels of education that would be too costly for the latter.

The central question addressed in cheap-talk models is the following. How much information, if any, can be credibly transmitted when communication is direct and costless? Interest in this question stems from the fact that with cheap talk there is always a ‘babbling’ equilibrium in which the participants deem all communication to be meaningless – after all, it has no direct payoff consequences – and as a result no one has any incentive to communicate anything meaningful. It is then natural to ask whether there are also equilibria in which communication is meaningful and informative.

We begin by examining the question posed above in the simplest possible setting: there is a single informed party – an expert – who offers information to a single uninformed decision maker. This simple model forms the basis of much work on cheap talk and was introduced in a now classic paper by Crawford and Sobel (1982). In what follows, we first outline the main finding of this paper, namely, that while there are informative equilibria, these entail a significant loss of information. We then examine various remedies that have been proposed to solve (or at least alleviate) the ‘information problem’.

The information problem

We begin by considering the leading case in the model of Crawford and Sobel (henceforth CS). A decision maker must choose some decision \( y \). Her payoff depends on \( y \) and on an unknown state of the world \( \theta \), which is distributed uniformly on the unit interval. The decision maker can base her decision on the costless message \( m \) sent by an expert who knows the precise value of \( \theta \). The decision maker's payoff is \( V(y, \theta) = - (y - \theta)^2 \), and the expert's payoff is \( U(y, \theta, b) = - (y - (\theta + b))^2 \), where \( b \geq 0 \) is a 'bias' parameter that measures how closely aligned the preferences of the two are. Because of the tractability of the 'uniform-quadratic' specification, this paper, and indeed much of the cheap talk literature, restricts attention to this case.
The sequence of play is as follows:

| Expert learns $\theta$ | Expert sends message $m$ | Decision maker chooses $y$ |

What can be said about (Bayesian-perfect) equilibria of this game? As noted above, there is always an equilibrium in which no information is conveyed, even in the case where preferences are perfectly aligned (that is, $\theta = 0$). In such a ‘babbling’ equilibrium, the decision maker believes (correctly it turns out) that there is no information content in the expert's message and hence chooses her decision only on the basis of her prior information. Given this, the expert has no incentive to convey any information – he may as well send random, uninformative messages – and hence the expert indeed ‘babbles’. This reasoning is independent of any of the details of the model other than the fact that the expert's message is ‘cheap talk’.

Are there equilibria in which all information is conveyed? When there is any misalignment of preferences, the answer turns out to be no. Specifically,

**Proposition 1:** If the expert is even slightly biased, all equilibria entail some information loss.

The proposition follows from the fact that, if the expert's message always revealed the true state and the decision maker believed him, then the expert would have the incentive to exaggerate the state – in some states $\theta$, he would report $\tilde{\theta} + b$.

Are there equilibria in which some but not all information is shared? Suppose that, following message $m$, the decision maker holds posterior beliefs given by distribution function $G$. The action $y$ is chosen to maximize her payoffs given $G$. Because payoffs are quadratic, this amounts to choosing a $y$ satisfying:

$$
\gamma(m) = E[\theta m]
$$

(1)

Suppose that the expert faces a choice between sending a message $m$ that induces action $y$ or an alternative message, $m'$, that induces an action $\gamma' > \gamma$. Suppose further that in state $\theta'$ the expert prefers $\gamma'$ to $y$ and vice versa in state $\theta < \theta'$. Since the preferences satisfy the single-crossing condition, $V_{\theta'} \geq V$, the expert would prefer $\gamma'$ to $y$ in all states higher than $\theta'$. This implies that there is a unique state $a$, satisfying $\theta < a < \theta'$, in which the expert is indifferent between the two actions. Equivalently, the distance between $y$ and the expert's 'bliss' (ideal) action in state $a$ is equal to the distance between action $\gamma'$ and the expert's bliss action in state $a$. Hence,

$$
a + b - y = \gamma' - (a + b)
$$

(2)

Thus, message $m$ is sent for all states $\theta < a$ and message $m'$ for all states $\theta > a$.

To comprise an equilibrium where exactly two actions are induced, one would need to find values for $a$, $y$, and $\gamma'$ that simultaneously satisfy eqs. (1) and (2). Since $m$ is sent in all states $\theta < a$ from eq. (1), $\gamma = \frac{a}{2}$. Similarly, $\gamma' = \frac{1+a}{2}$. Inserting these expression into eq. (2) yields

$$
a = \frac{1}{2} - 2b
$$

(3)
Equation (3) has several interesting properties. First, notice that \( a \) is uniquely determined for a given bias. Second, notice that, when the bias gets large \( (b \geq \frac{1}{4}) \), there is no feasible value of \( a \), so no information is conveyed in any equilibrium. Finally, notice that, when the expert is unbiased \( (b = 0) \), there exists an equilibrium where the state space is equally divided into ‘high’ \( (\theta > \frac{1}{2}) \) and ‘low’ \( (\theta < \frac{1}{2}) \) regions and the optimal actions respond accordingly. As the bias increases, the low region shrinks in size while the high region grows; thus, the higher the bias is, the less the information conveyed.

For all \( b < \frac{1}{4} \), we constructed an equilibrium that partitions the state space into two intervals. As the bias decreases, equilibria exist that partition the state space into more than two intervals. Indeed, Crawford and Sobel (1982) showed that:

**Proposition 2:** All equilibria partition the state space into a finite number of intervals. The information conveyed in the most informative equilibrium is decreasing in the bias of the expert.

If the expert were able to commit to fully reveal what he knows, *both* parties would be better off than in any equilibrium of the game described above. With full revelation, the decision maker would choose \( y = \hat{y} \) and earn a payoff of zero, while the expert would earn a payoff of \( -\beta^2 \). It is easily verified that in any equilibrium the payoffs of both parties are lower than this. The overall message of the CS model is that, absent any commitment possibilities, cheap talk inevitably leads to information loss, which is increasing in the bias of the expert. The remainder of the article studies various ‘remedies’ for the information loss problem: more extensive communication, delegation, contracts, and multiple experts.

**Remedies**

**Extensive communication**

In the CS model, the form of the communication between the two parties was one-sided – the expert simply offered a report to the decision maker, who then acted on it. Of course, communication can be much richer than this, and it is natural to ask whether its form affects information transmission. One might think that it would not. First, one-sided communication where the expert speaks two or more times is no better than having him speak once, since any information the expert might convey in many messages can be encoded in a single message. Now, suppose the communication is two-sided – it is a conversation – so the decision maker also speaks. Since she has no information of her own to contribute, all she can do is to send random messages, and at first glance this seems to add little. As we will show, however, random messages improve information transmission by acting as coordinating devices.

To see this, suppose the expert has bias \( b = \frac{1}{12} \). As we previously showed, when only he speaks, the best equilibrium is where the expert reveals whether the state is above or below \( \frac{1}{3} \). Suppose instead that we allow for *face-to-face* conversation – a simultaneous exchange of messages – and that the sequence of play is:

| Expert learns \( \theta \) | Expert and DM meet “face-to-face” | Expert sends “written report” | Decision maker chooses \( y \) |

> The following strategies constitute an equilibrium. The expert reveals some information at the face-to-face meeting, but there is also some randomness in what transpires. Depending on how the conversation goes, the meeting is deemed by both parties to be a ‘success’ or a ‘failure’. After the meeting, and depending on its outcome, the expert may send an additional ‘written report’ to the decision maker.

During the meeting, the expert reveals whether \( \theta \) is above or below \( \frac{1}{6} \); he also sends some additional messages that affect the success or failure of the meeting. If he reveals that \( \theta \leq \frac{1}{6} \), the meeting is adjourned, no more communication takes place, and the decision maker chooses a low action \( \hat{y}_L = \frac{1}{12} \) that is optimal given the information that \( \theta \leq \frac{1}{6} \).

If, however, he reveals that \( \theta > \frac{1}{6} \), then the written report depends on whether the meeting was a success or a failure. If the meeting is a failure, no more communication takes place, and the decision maker chooses the ‘pooling’ action \( \hat{y}_P = \frac{7}{12} \) that is optimal given that \( \theta > \frac{1}{6} \). If the meeting is a success, however, the written report further divides the interval...
\[ \left[ \frac{1}{6}, 1 \right] \] into \( \left[ \frac{1}{6}, \frac{5}{12} \right] \) and \( \left[ \frac{5}{12}, 1 \right] \). In the first sub-interval, the medium action \( y_M = \frac{7}{24} \) is taken and in the second sub-interval the high action \( y_H = \frac{17}{24} \) is taken. The actions taken in different states are depicted in Figure 1. The dotted line depicts the actions, \( \theta + \frac{1}{12} \), that are ‘ideal’ for the expert.

Figure 1
Equilibrium with face-to-face meeting
Notice that in state $\frac{1}{6}$, the expert prefers $y_L$ to $y_P$ ($y_L$ is closer to the dotted line than is $y_P$) and prefers $y_M$ to $y_L$. Thus, if there were no uncertainty about the outcome of the meeting – for instance, if all meetings were 'successes' – then the expert would not be willing to reveal whether the state is above or below $\frac{1}{6}$; for states $\theta = \frac{1}{6} - \varepsilon$, the expert would say $\theta \in \left(\frac{1}{6}, \frac{5}{12}\right]$, thereby inducing $y_M$ instead of $y_L$. If all meetings were failures, then for states $\theta = \frac{1}{6} + \varepsilon$, the expert would say $\theta < \frac{1}{6}$, thereby inducing $y_L$ instead of $y_P$.

There exists a probability $p = \frac{16}{21}$ such that when $\theta = \frac{1}{6}$ the expert is indifferent between $y_L$ and a $(p, 1 - p)$ lottery between $y_M$ and $y_P$ (whose certainty equivalent is labelled $y_C$ in the figure). Also, when $\theta < \frac{1}{6}$, the expert prefers $y_L$ to a $(p, 1 - p)$ lottery between $y_M$ and $y_P$, and when $\theta > \frac{1}{6}$, the expert prefers a $(p, 1 - p)$ lottery between $y_M$ and $y_P$ to $y_L$.

It remains to specify a conversation such that the meeting is successful with probability $p = \frac{16}{21}$. Suppose the expert sends a message $(\text{Low}, A_i)$ or $(\text{High}, A_i)$ and the decision maker sends a message $A_j$, where $i, j \in \{1, 2, \ldots, 21\}$. These messages are interpreted as follows. $\text{Low}$ signals that $\theta \leq \frac{1}{6}$ and $\text{High}$ signals that $\theta > \frac{1}{6}$. The $A_i$ and $A_j$ messages play the role of a coordinating device and determine whether the meeting is successful. The expert chooses $A_i$ at random and each $A_i$ is equally likely. Similarly, the decision maker chooses $A_j$ at random. Given these choices, the meeting is a

\[
\begin{align*}
\text{Success} & \quad \text{if} \quad 0 \leq i - j < 16 \text{ or } j - i > 5 \\
\text{Failure} & \quad \text{otherwise}
\end{align*}
\]

For example, if the messages of the expert and the decision maker are $(\text{High}, A_{17})$ and $A_5$, respectively, then it is inferred that $\theta > \frac{1}{6}$ and, since $i - j = 12 < 16$, the meeting is a success. Observe that with these strategies, given any $A_i$ or $A_j$, the probability that the meeting is a success is exactly $\frac{16}{21}$.

The equilibrium constructed above conveys more information than any equilibria of the CS game. The remarkable fact about the equilibrium is that this improvement in information transmission is achieved by adding a stage in which the uninformed decision maker also participates. While the analysis above concerns itself with the case where $b = \frac{1}{12}$, informational improvement through a 'conversation' is a general phenomenon (Krishna and Morgan, 2004a):

**Proposition 3:** Multiple stages of communication together with active participation by the decision maker always improve information transmission.

What happens if the two parties converse more than once? Does every additional stage of communication lead to more information transmission? In a closely related setting, Aumann and Hart (2003) obtain a precise but abstract characterization of the set of equilibrium payoffs that emerge in sender–receiver games with a finite number of states and actions when the number of stages of communication is infinite. Because the CS model has a continuum of states and actions, their characterization does not directly apply. Nevertheless, it can be shown that, even with an unlimited conversation, full revelation is impossible. A full characterization of the set of equilibrium payoffs with multiple stages remains an open qst.

**Delegation**

A key tenet of organizational theory is the ‘delegation principle’, which says that the power to make decisions should reside in the hands of those with the relevant information (Milgrom and Roberts, 1992). Thus, one approach to solving the information problem is simply to delegate the decision to the expert. However, the expert's bias will distort the
chosen action from the decision maker's perspective. Delegation this leads to a trade-off between an optimal decision by an uninformed party and a biased decision by an informed party.

Is delegation worthwhile? Consider again an expert with bias \( b = \frac{1}{12} \). The decision maker's payoff from the most informative partition equilibrium is \(-\frac{1}{36}\). Under delegation, the action chosen is \( y = \theta + b \) and the payoff is \(-\frac{1}{144}\). Thus delegation is preferred. Dessein (2002) shows that this is always true:

**Proposition 4:** If the expert's bias is not too large \((b \leq \frac{1}{4})\), delegation is better than all equilibria of the CS model.

In fact, by exerting only slightly more control, the decision maker can do even better. As first pointed out by Holmström (1984), the optimal delegation scheme involves limiting the scope of actions from which the expert can choose. Under the uniform-quadratic specification, the decision maker should optimally limit the expert's choice of actions to \( \forall \in [0, 1 - b] \). When \( b = \frac{1}{12} \), limiting actions in this way raises the decision maker's payoff from \(-\frac{1}{144}\) to \(-\frac{1}{162}\).

Optimal delegation still leads to information loss. When the expert's choice is 'capped', in high states the action is unresponsive to the state.

An application of the delegation principle arises in the US House of Representatives. Typically a specialized committee – analogous to an informed expert – sends a bill to the floor of the House – the decision maker. How it may then be amended depends on the legislative rule under effect. Under the so-called closed rule the floor is limited in its ability to amend the bill, while under the open rule the floor may freely amend the bill. Thus, operating under a closed rule is similar to delegation, while an open rule is similar to the CS model. The proposition above suggests, and Gilligan and Krehbiel (1987; 1989) have shown, that in some circumstances the floor may benefit by adopting a closed rule.

Contracts

Up until now we have assumed that the decision maker did not compensate the expert for his advice. Can compensation, via an incentive contract, solve the information problem? To examine this, we amend the model to allow for compensation and use mechanism design to find the optimal contract. Suppose that the payoffs are now given by

\[
U(y, \theta, t) = -(y - \theta)^2 - tV(y, \theta, b, t) = -(y - \theta - b)^2 + t
\]

where \( t \geq 0 \) is the amount of compensation.

Using the revelation principle, we can restrict attention to a direct mechanism where both \( t \) and \( y \) depend on the state \( \theta \) reported by the expert. Notice that such mechanisms directly link the expert's reports to payoffs – talk is no longer cheap.

Contracts are powerful instruments. A contract that leads to full information revelation and first-best actions is:

\[
t(\hat{\theta}) = 2b(1 - \hat{\theta})y(\hat{\theta}) = \hat{y}
\]

where \( \hat{\theta} \) is the state reported by the expert. Under this contract, the expert can do no better than to tell the truth, that is, to set \( \hat{\theta} = \theta \), and, as a consequence, the action undertaken in this scheme is the 'bliss' action for the decision maker. Full revelation is expensive, however. When \( b = \frac{1}{12} \), the decision maker's payoff from this scheme is \(-\frac{1}{12}\). Notice that this is worse than the payoff of \(-\frac{1}{36}\) in the best CS equilibrium, which can be obtained with no contract at all. The costs of implementing the fully revealing contract outweigh the benefits.

In general, Krishna and Morgan (2004b) show:

**Proposition 5:** With contracts, full revelation is always feasible but never optimal.

The proposition above shows that full revelation is never optimal. No contract at all is also not optimal – delegation is preferable. What is the structure of the optimal contract? A typical optimal contract is depicted as the dark line in Figure 2. First, notice that, even though the decision maker could induce his bliss action for some states, it is never optimal to do so. Instead, for low states (\( \theta < b \)) the decision maker implements a 'compromise' action – an action that lies between \( \theta \) and \( \theta + b \). When \( \theta > b \), the optimal contract simply consists in telling the truth.
of capped delegation.

Figure 2

An optimal contract, $b \leq \frac{1}{3}$
Thus far we have focused attention on how a decision maker should consult a single expert. In many instances, decision makers consult multiple experts – often with similar information but differing ideologies (biases). Political leaders often form cabinets of advisors with overlapping expertise. How should a cabinet be constituted? Is a balanced cabinet – one with advisors with opposing ideologies – helpful? How should the decision maker structure the ‘debate’ among her advisors?

To study these issues, we add a second expert having identical information to the CS model. To incorporate ideological differences, suppose the experts have differing biases. When both \( b_1 \) and \( b_2 \) are positive, the experts have like bias – both prefer higher actions than does the decision maker. In contrast, if \( b_1 > 0 \) and \( b_2 < 0 \), then the experts have opposing bias – expert 1 prefers a higher action and expert 2 a lower action than does the decision maker.

**Simultaneous talk**

When both experts report to the decision maker simultaneously, the information problem is apparently solved – full revelation is now an equilibrium. To see this, suppose the experts have like bias and consider the following strategy for the decision maker: choose the action that is the more ‘conservative’ of the two recommendations. Precisely, if \( m_1 < m_2 \), choose action \( m_1 \) and vice versa if \( m_2 < m_1 \). Under this strategy, each expert can do no better than to report \( \theta \) honestly if the other does likewise. If expert 2 reports \( \theta \), then a report \( \theta \) has no effect on the action. However, reporting \( m_1 < \theta \) changes the action to \( y = m_1 \), but this is worse for expert 1. Thus, expert 1 is content to simply tell the truth. Opposing bias requires a more complicated construction, but the effect is the same: full revelation is an equilibrium (see Krishna and Morgan, 2001b).

Notice that the above construction is fragile because truth-telling is a weakly dominated strategy. Each expert is at least as well off by reporting \( m_1 = \theta + b_1 \) and strictly better off in some cases. Battaglini (2002) defines an equilibrium refinement for such games which, like the notion of perfect equilibrium in finite games, incorporates the usual idea that players may make mistakes. He then shows that such a refinement rules out all equilibria with full revelation regardless of the direction of the biases. While the set of equilibria satisfying the refinement is unknown, the fact that full revelation is ruled out means that simply adding a second expert does not solve the information problem satisfactorily.

**Sequential talk**

Finally, we turn to the case where the experts offer advice in sequence:

Suppose that the two experts have biases \( b_1 = \frac{1}{18} \) and \( b_2 = \frac{1}{12} \), respectively. It is easy to verify (with the use of (2)) that, if only expert 1 were consulted, then the most informative equilibrium entails his revealing that the state is below \( \frac{1}{9} \), or between \( \frac{1}{9} \) and \( \frac{4}{9} \), or above \( \frac{4}{9} \). If only expert 2 were consulted, then the most informative equilibrium is where he reveals whether the state is below or above \( \frac{1}{3} \). If the decision maker were able to consult only one of the two experts, she would be better off consulting the more loyal expert 1. But what happens if she consults both? It turns out that, if both experts actively contribute information, then the decision maker can do no better than the following equilibrium.
Expert 1 speaks first and reveals whether or not the state is above or below $\frac{11}{27}$. If expert 1 reveals that the state is above $\frac{11}{27}$, expert 2 reveals nothing further. If, however, expert 1 reveals that the state is below $\frac{11}{27}$, then expert 2 reveals further whether or not it is above or below $\frac{1}{27}$. That this is an equilibrium may be verified again by using (2) and recognizing that, in state $\frac{1}{27}$, expert 2 must be indifferent between the optimal action in the interval $[0, \frac{1}{27}]$ and the optimal action in $[\frac{1}{27}, \frac{11}{27}]$. In state $\frac{11}{27}$, expert 1 must be indifferent between the optimal action in $[\frac{1}{27}, \frac{11}{27}]$ and the optimal action in $[\frac{11}{27}, 1]$. Sadly, by actively consulting both experts, the decision maker is worse off than if she simply ignored expert 2 and consulted only her more loyal advisor, expert 1. This result is quite general, as shown by Krishna and Morgan (2001a):

**Proposition 6:** When experts have like biases, actively consulting the less loyal expert never helps the decision maker.

The situation is quite different when experts have opposing biases, that is, when the cabinet is balanced. To see this, suppose that the cabinet is comprised of two equally loyal experts biases $b_1 = \frac{1}{12}$ and $b_2 = -\frac{1}{12}$. Consulting expert 1 alone leads to a partition $[0, \frac{1}{3}]$, $[\frac{1}{3}, 1]$ while consulting expert 2 alone leads to the partition $[0, \frac{2}{3}]$, $[\frac{2}{3}, 1]$. If instead the decision maker asked both experts for advice, the following is an equilibrium: expert 1 reveals whether $\theta$ is above or below $\frac{2}{9}$. If he reveals that the state is below $\frac{2}{9}$, the discussion ends. If, however, expert 1 indicates that the state is above $\frac{2}{9}$, expert 2 is actively consulted and reveals further whether the state is above or below $\frac{7}{9}$. Based on this, the decision maker takes the appropriate action. One may readily verify that this is an improvement over consulting either expert alone. Once again the example readily generalizes:

**Proposition 7:** When experts have opposing biases, actively consulting both experts always helps the decision maker.

Indeed, the decision maker can be more clever than this. One can show that, with experts of opposing bias, there exist equilibria where a portion of the state space is fully revealed. By allowing for a ‘rebuttal’ stage in the debate, there exists an equilibrium where all information is fully revealed.

Cheap talk

How to cite this article

The chemical industry is among the largest manufacturing industries; its products range from acids to intermediate chemicals such as synthetic fibres and plastics, and to final products such as soaps, cosmetics, paints and fertilizers. Perhaps as a result, the chemical industry is under-studied by economists, though not by economic and business historians (e.g., Hounshell and Smith, 1988).

The modern chemical industry has its origins in the discovery of synthetic dyes in Britain in the 1850s. German chemical firms such as BASF, Bayer and Hoechst soon dominated the production of synthetic dyestuffs and related organic compounds. The American chemical industry grew by exploiting the rich American natural resource endowments, initially using European technology. After the First World War, American firms, especially Du Pont, invested in R&D. The inter-war period saw rapid product innovation in synthetic fibres, plastics, resins, adhesives, paints, and coatings, based on polymer science. To succeed commercially, these products had to be produced cheaply, which meant large-scale production and, in turn, the development of chemical engineering. The Second World War marked a watershed. The chemical industry became closely linked with the oil industry, as many chemicals used petroleum-based inputs instead of coal by-products. The United States was the first country to develop a petrochemicals industry, mainly due to its abundant oil reserves, as well as wartime government programmes for aviation fuel and synthetic rubber.

The early advantage of the US chemical industry in petrochemicals was eroded as technologies diffused widely, first to Europe and Japan; and in the 1970s China, Taiwan and S. Korea emerged as leading producers. Increased competition, the oil shocks of the 1970s, and waning possibilities for product innovation together resulted in exit: larger, multi-product firms exited earlier, but larger plants closed later (Lieberman, 1990). In addition, firms reshuffled product portfolios so as to focus on fewer products but in more geographical markets (Arora and Gambardella, 1998). The restructuring took a heavy toll of
incumbents; and many familiar names such as Hoechst, Union Carbide, Ciba-Geigy, Sandoz, and American Cynamid have vanished. A number of interesting themes emerge, some of which have been studied by economists. Others remain as potentially rich veins to be mined.

**International competition:** Why did British firms fail to exploit the rich potential of organic chemistry despite a head start, access to cheap inputs (coal tar) and to the British textile industry, and a well-functioning capital market? Many explanations, none entirely persuasive, have been offered, including the alleged bias of the British financial system towards low risk-projects (Da Rin, 1998), the weak links between English universities and industry (Murmann and Landau, 1998), and inferior management (Chandler, 2005).

**Patents:** Overenthusiastic patent protection in the 1870s nearly killed the French dyestuff industry, while German firms strategically used patent protection (Arora, 1997). The confiscation of German patents and industrial property in Britain, France and the United States after both world wars was a setback to German firms but proved insufficient for the Americans and British to catch up. Systematic analysis of this natural experiment can shed light on the role of patents in shaping oligopolistic competition.

**Markets for technology:** Arrow (1962) observed that Du Pont appeared to have profited as much from innovations it had licensed from others as from its own products, perhaps reflecting imperfections in the market for technology. Yet technology licensing has been extensive in chemicals (Arora, Fosfuri and Gambardella, 2001). The market for technology dramatically changed industry structure, with accumulated production experience of incumbents insufficient to deter successful entry (Lieberman, 1989).

**Complementarities and industrial convergence:** After the Second World War, oil refining and the production of synthetic fibres and plastics came to share a common technical base. The convergence led to vertical integration by oil firms into chemicals and chemical firms into petrochemicals (Lieberman, 1991). Thanks to a market for petrochemical technology, the European chemical industry was able to switch to petrochemicals very rapidly, despite very substantial investments in coal-based technologies.

**Division of labour and vertical industry structure:** Specialized engineering firms, which arose to provide plant construction and design services to chemical firms, led the way in diffusing petrochemical technologies worldwide (Freeman, 1968). This competition prodded even large chemical firms such as Union Carbide to give licences to others, further diffusing technology and promoting entry (Arora, Fosfuri and Gambardella, 2001). The chemical industry thus provides a clear example of the benefits of vertically disintegrated industry structures in promoting entry and competition.

The enduring lesson of the history of the chemical industry for economists is the important role of firms – their history and their capabilities – which largely explains why some countries dominated the industry for such long periods. But that history is also a strong reminder to that, in the end, even the mightiest firms must eventually bow to market forces.

Chenery, Hollis B. (1918– 1994)

Shantayanan Devarajan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Hollis Burnley Chenery was born in Richmond, Virginia, in 1918. He received his Ph.D. at Harvard University, worked for the Marshall Plan in Europe, taught at Stanford University, served as Assistant Administrator of the US Agency for International Development before joining the World Bank in 1970 for a distinguished, 13-year career there. He returned to Harvard as a professor in 1983. He died in 1994.

Keywords

Chenery, H. B.; comparative advantage; computable general-equilibrium models; development economics; development strategy; economic development; foreign aid; poverty alleviation; total factor productivity; World Bank

Article

Hollis Burnley Chenery was the consummate development economist. He defined the contours of the field with his ground-breaking research on patterns of development and development strategy. He developed tools that helped translate research into policy, and, as Vice-President for Development Policy at the World Bank, he helped shift the focus of development economics from a narrow one of economic growth to the alleviation of poverty.

Patterns of development

In the tradition of Kuznets and Denison, Chenery was interested in how economies grow, whether there were systematic patterns in the process of development. His 1960 paper in the American Economic Review, ‘Patterns of Industrial Growth’, grew into a decade-long research project with Moshe Syrquin culminating in their 1975 book, Patterns of Development, 1950–1970. Many of the patterns that Chenery and Syrquin found are received wisdom today: as countries grow, the share of agriculture in GDP
declines, and the shares of industry and services increase; and overall GDP growth is typically accompanied by an increase in total factor productivity (TFP) growth. Chenery and Syrquin were the first to document these patterns, using the statistical techniques available at the time, for a large number of countries in the modern era. Their work has led to Chenery–Syrquin ‘norms’ (interestingly, a word they never used) whereby countries could benchmark their progress in the development process. They were also aware of the limitations of this approach, identifying for example the differences between large countries and small ones, work that has been extended by Perkins and Syrquin (1989). The observed pattern of TFP growth has been questioned by, among others, Young (1995) and is still a topic of vigorous debate.

Development strategy

In contrast with the recent work on cross-country growth (see Barro, 1991), the Patterns work was silent on what countries could do to grow faster. Chenery answered this question in a series of major pieces on development strategy. He entered the debate between outward- and inward-looking development strategies in his 1961 American Economic Review paper, ‘Comparative Advantage and Development Policy’. While countries should only produce those goods in which they have a comparative advantage, Chenery conjectured that comparative advantage in certain goods could be developed through careful investment policies. Chenery's notions saw a resurgence in the 1980s in the Brander–Spencer (1985) and other models of policy-induced comparative advantage. Of course, policies to create comparative advantage have to be carefully designed, especially because public investment has economy-wide impacts, as Chenery showed in his 1959 book with Peter Clark, Interindustry Economics.

Chenery's thinking on development strategy evolved over time. He became convinced that a country's underlying economic structure – the functioning of its labour and capital markets, its resource endowments – influenced the choices it could make in trying to create ‘dynamic comparative advantage’. Using case studies, cross-country analysis and model-based analysis, he distilled this work in his 1984 book with Sherman Robinson and Syrquin, Industrialization and Growth: A Comparative Study.

Structure also determines how foreign aid affects the economy, as Chenery showed in his ‘two-gap’ model (see Chenery and Strout, 1966; Chenery and Bruno, 1962). Ex ante, an economy may be foreign-exchange-constrained or fiscally constrained. Since foreign aid is both foreign exchange and resources to the government, its impact depends on which constraint is binding. An extended version of this simple model became the workhorse model of aid agencies such as the World Bank. It saw a resurgence during the debt crises of the 1980s. It has also been criticized for neglecting the role of prices and incentives (see Easterly, 1999), although it can be shown that, as long as domestic and foreign capital are imperfect substitutes, most of the results of the two-gap model survive in a fully specified, intertemporal, general-equilibrium model.

Tools

Building on his work on the interdependence of investment decisions, Chenery and his collaborators pioneered the development of multisectoral models for investment planning, collected in his co-authored

book, *Studies in Development Planning*. This work saw applications in various planning agencies, notably in India. Recognizing the limitations of linear programming approaches, Chenery encouraged the development of computable general-equilibrium (CGE) models at the World Bank and in universities. Today, CGE models are commonly used to inform policy in developing and developed countries, although they too have their limits (see Devarajan and Robinson, 2005).

**Redistribution with growth**

Arriving at the World Bank in 1970, Chenery proceeded to establish the first, and eventually one of the most influential, research programmes in economic development. In addition to producing academic-quality research, Chenery's group helped shape Bank policies. In 1974, Chenery and his associates published *Redistribution with Growth*, a seminal book that, while recognizing the need for direct action to alleviate poverty (especially since the high growth of the 1960s had not significantly reduced poverty), showed that wealth redistribution can and should be consistent with the promotion of economic growth. Chenery's approach has been the leitmotif of the World Bank's (and indeed most development agencies') strategy since then.

Chevalier, Michel (1806–1879)

P. Bridel

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Chevalier, M.; free trade; Leroy-Beaulieu, P. P.; liberalism; Rossi, P. L. E.; Saint-Simon, C. H.; Walras, L.

Article

Born in Limoges, 13 January 1806; died in Paris, November 1879. Undoubtedly one of the most eminent 19th-century French economists, Chevalier belongs to that most typical brand of engineer-economists. First in his class (major) at the Ecole Polytechnique in 1830 and member of the Corps des Mines as an economist, Chevalier came very early under the spell of Saint-Simon's utopian doctrine. From his early editorship of the Saint-Simonian newspaper Le Globe (1830–2) and his subsequent sentence to a year in jail (for 'outrage to morals' for publishing advanced ideas on the liberation of women, sexual liberty and the need for communal life) to a made-to-measure niche as economic adviser to Napoleon III and 'éminence grise' to the Second Empire business and banking establishment, Chevalier applied his brilliant mind to various current problems and policy issues without managing, however, to escape completely from the Saint-Simonian mystique. His main claim to fame, the Anglo-French Treaty of 1860 (the Cobden–Chevalier Treaty), an important if short-lived interruption in the general protectionist policy of France, is one of the best illustrations of these twin components of Chevalier's approach to economics and economic policy: weak on the analytics and very strong on the factual analysis with a touch of Saint-Simonian idealism.

Together with public works, cheap bank credit and education, free trade is one of the articles of faith he took over from the Saint-Simonian doctrine. Chevalier returned to these issues throughout his life (notably in his penetrating analysis of the American economy and banking system in the early 1830s which earned him later the nickname of 'Economic Tocqueville'). Binding these various elements with a quasi-philosophical concept of association (as the cornerstone of social order), Chevalier suggests a broad theory of economic growth which he considered flexible enough to be applied to different times and countries.

His Saint-Simonian antecedents and his extensive travelling (to England, Egypt and foremost to the
United States) rendered Chevalier suspicious of all ‘absolutist’ economic theory. In fact, in his most technical chapters (particularly on money) Chevalier never digs beneath the surface of things and contributes very little, if anything, to analytic economics. His only systematic work, his *Cours* (1843; 1844; 1850) delivered at the Collège de France offers little more in the field of theory than a lengthy (and flat) apology for Say’s brand of ‘vulgar’ liberalism. With Rossi, his predecessor, and Leroy-Beaulieu, his successor at the Collège de France, Chevalier was in fact largely responsible for introducing and perpetuating in academic circles the liberal orthodoxy that was to bar Walras from getting an appointment in the 1860s and that dominated French economics for so long that as late as 1939 Keynes could still quip about its lack of ‘deep roots in systematic thought’ (1939, p. xxxii).

Chicago School (new perspectives)

Ross B. Emmett

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

M. W. Reder's entry on the Chicago School closed with the claim that the final chapter of the School's history was about to end. Chicago economics has changed, but it has also stayed the same. Each of the four movements of recent Chicago economics are rooted in common themes of the tradition. As well, our interpretation of economics at Chicago has evidenced both continuity and change. Historians are examining the history of the institutional structure of Chicago economics, as well as the histories of specific fields at Chicago (labour, economic history, quantitative analysis) and finding both change and continuity in the tradition.

Keywords

Article

The history of Chicago economics remains a story of continuity and change. M.W. Reder closed the entry on the Chicago School in the first edition of The New Palgrave (and reproduced in this edition) with the claim that the final chapter of the School's history was about to end. Perhaps he was right: the apex of the School's influence on public policy – the presidency of Ronald Reagan – ended in 1988. By that time key figures in the School's history had retired, become inactive, left the University of Chicago, or died. Milton Friedman retired in 1977 and moved to the Hoover Institution at Stanford University, where he was eventually joined by Aaron Director (linchpin of the early Chicago law and economics movement) and George Schultz (former dean of the University of
Chicago's Graduate School of Business and Secretary of State under President Reagan); he died in late 2006. Arnold Harberger stepped down as chair of the Economics Department in the early 1980s and moved to UCLA shortly thereafter, following the previous departure of long-time graduate advisor H. Gregg Lewis to Duke in 1977. T.W. Schultz, former department chair, was largely inactive as a scholar by the late 1970s; his student and collaborator for many years, D. Gale Johnson, retired in the early 1980s. In international economics, Robert Mundell left the university in the early 1970s and Harry Johnson died in 1979. Of the early leaders, only George Stigler (industrial organization) and Ronald Coase (law and economics) remained active at Chicago, although both were retired.

But it would be a mistake to see the 1980s as the final chapter of the Chicago School. Four major movements in Chicago economics since 1980 are captured in the awarding of more recent Nobel Prizes. Gary Becker was awarded the prize for his work in the new home and social economics. Robert Lucas won for developments in empirical macroeconomics. Merton Miller was joined by former Chicago researcher Harry Markowitz for their development of finance theory. And James Heckman won the prize for the development of microeconometrics. Alongside these scholars (Miller died in 2000, but the others remain active), the next generation of Chicago economists is making a place for itself. Both Thomas Sargent and Lee Hansen have won the new Erwin Plein Nemmers Prize for significant contributions to new modes of analysis in economics, and Kevin Murphy and Steven Levitt have won the coveted John Bates Clark medal from the American Economic Association.

Each of the four recent movements within Chicago economics – finance, empirical macroeconomics, the new home economics, and microeconometrics – are rooted in common Chicago themes: the application of price theory, the development of methods for the quantitative analysis of social problems, and the notion that economics is an applied policy science. The Chicago approach rests on a three-legged stool which combines an appreciation for the ‘simple’ analytics of Marshallian price theory (as Reder observes, a constant at Chicago since the early 1930s), the development of quantitative tools as expressed in Friedman's classic article (1953) on ‘positive economics,’ and the Becker–Stigler prescription to focus attention on the elements of the constraint set, rather than changes in values and preferences, in the explanation of human behaviour (see Becker, 1976; Stigler and Becker, 1977). Once combined, this three-legged methodological stool provided a stable foundation for the continued expansion of the scope of social scientific problems that Chicago economists have addressed (Becker, 1981; Becker and Murphy, 2000; Levitt and Dubner, 2005). Economic imperialism it may be, but Chicago economists argue that it is the only basis upon which a true social science can be built (see Lazear, 2000).

Yet Reder's claim that the book on Chicago economics was about to close was right at least in one regard. Up to the mid-1970s, Chicago economists were an embattled minority (albeit growing in numbers and influence) of the economics profession. After the early 1980s, Chicago was no longer embattled, or even a minority. Its central ideas are still alive, but they are no longer the notions of a contrary-minded small group of scholars; in antitrust, law and economics, monetary theory, labour, finance and applied microeconomics, they comprise a position that has been widely adopted. Chicago economics today is part of the discipline's mainstream; indeed, in some sub-fields it has defined the mainstream. Success outside the confines of Chicago has also changed the School itself: since 1980, Chicago economics has gradually accommodated itself to the common standards of the discipline. Finally, the role of the Chicago School themes within the university has also been rendered more complicated by the remarkable expansion of the Graduate School of Business and the Law School as
centres of Chicago-style economic, legal and public policy analysis.

Change and continuity in Chicago economics

The 1980s were a period of transition in Chicago economics, in several regards. For most of the period from the late 1940s until the early 1980s, the department of economics was chaired by either T. W. Schultz, D. Gale Johnson or Arnold Harberger; the required price theory course (ECON 301) was taught by either Milton Friedman, Harberger or Gary Becker, and required thorough familiarity with the canon of Chicago price theory – the theory texts of Knight (1933), Friedman (1962), Stigler (1966), Becker (1971), and Alchian and Allen (1969); and the other required first-year course was titled ‘money’ (not macroeconomics). The continuity in leadership was disrupted in the early 1980s (just as it had been 30 to 40 years earlier by the departures of Jacob Viner, Oskar Lange and the Cowles Commission, and the retirement of Frank Knight), as the early luminaries retired and passed responsibility on to the next generation (although Becker still shares some of the teaching in ECON 301). But a successful programme is not built around individual scholars, even if they are luminaries like Friedman, Stigler, and Becker. Chicago's success, even in the period from the 1940s to the 1980s, is misunderstood if it is interpreted simply as the product of the unique cluster of scholars that it managed to attract (compare Van Overtveldt, 2007, with Emmett 1998). In the early 1950s, the economics department replaced the traditional lone-scholar model of graduate education and faculty research with a workshop model that created an educational environment for graduate students and faculty members more closely akin to a scientific laboratory within which students and faculty pursued a collaborative intellectual project. While the Chicago model is reasonably well-known today and emulated, it was quite unique in the post-war period, and is central to Chicago's success. After passing the core examinations in price theory and money at the end of the first year, students not only continued to take courses but also associated themselves with a workshop (most workshops were open, so students often attended more than one; but each student was primarily associated with one workshop). Faculty were also associated with at least one workshop, and frequently defined the workshop's style: Friedman's money workshop; Stigler's industrial organization workshop; Fogel and McCloskey's economic history workshop; Harberger's Latin American finance workshop; and Coase's law and economics workshop. In the early years no common model had been established, and the workshops varied significant. Eventually, most workshops adopted the ‘Chicago rules’: the workshop met once per week, papers were distributed beforehand and therefore assumed to have been read, and presenters knew that discussion of the paper might begin as soon as five minutes into their presentation. Most of the workshop time was spent dissecting the paper's thesis, method, and data. Because the pattern of discussion was repeated every week in a dozen or more workshops, students and faculty became quite adept at working within Chicago's rules, applying Marshallian price theory to a wide range of policy-relevant topics. By the early 1980s, the number of economics workshops in the department, the Graduate School of Business, and the Law School was approaching 20. Today, in 2006, it still numbers in the teens.

The transition of key personnel in the early 1980s, therefore, did not affect the structure of the research and educational enterprise which supports the Chicago School. However, it did have an impact on the nature of the research and education of Chicago economists. By the end of the 1980s, the texts which comprised the canon of Chicago price theory lost their pride of place in the reading lists for ECON 301.
At about the same time, the ‘money’ course (ECON 302) became a study of ‘income, employment and the price level’ built around standard Walrasian general equilibrium models that characterize macroeconomic analysis in most economics programmes. As well, the development of more sophisticated econometric models and techniques came to play a larger role in economic research at Chicago. ‘Quantitative methods’ was added as a core examination that all students had to pass in order to continue beyond the first year. In short, Chicago economics today looks a lot like economics everywhere else (in part, of course, because Chicago’s approach is taught elsewhere and other programmes have created collaborative research environments like the Chicago workshops), although there remains a distinct Chicago ‘flavour’ that distinguishes it from MIT, Harvard, Berkeley and Yale, if not from Stanford, UCLA and Washington.

Change and continuity in the interpretation of Chicago economics

Even as the contemporary evolution of Chicago economics continues to involve both continuity and change, our understanding of the history of Chicago economics has also evidenced both continuity and change. Reder's original essay was constructed on a model of Chicago economics which placed a small group of key individuals and their ideas at the centre of the School; one could envision his essay as an examination of concentric circles emanating out from the inner circle that started with Viner and Knight and then included Friedman, Stigler and Becker. While not rejecting Reder's model entirely, historians have begun to construct a story of the development of Chicago economics that complicates the model significantly. Three aspects of Chicago School historiography can be highlighted to illustrate the direction of contemporary historical research on the School, and indicate the potential for further research. First, the transition from the Chicago economics of the inter-war period to the Chicago School of the 1950s and 1960s involved several significant changes. The elements of continuity that Reder emphasized remain – the pre-eminent role of price theory, for example – but discontinuities have crept in. Daniel Hammond's recent work on Milton Friedman's early career provides a glimpse into how that transition influenced even one of the mainstays of Chicago economics. Arguing against the continuity thesis about Chicago price theory articulated by Philip Mirowski and Wade Hands (1998), Hammond shows that Friedman had as much in common with NBER-style statistical work as he did with Knight's Chicago approach (Hammond, 2005; see also Hammond, 2008, and Rutherford, 2008) In fact, even Friedman's famous methodological essay may be more a statement of his experiences with the NBER and the Statistical Research Group at Columbia University (associated with Harold Hotelling) than any earlier Chicago economist. In more recent work, Mirowski and Rob van Horn (2008) argue that, whatever the continuities of Chicago's price theoretic tradition are, the Chicago School of the 1950s and 1960s was shaped more by new research projects initiated in the effort to define a new liberalism to in the Cold War period than it was by the classical liberalism of the Knight–Simons agenda in the 1930s and 1940s (see also Amadae, 2003). Thus, while the Chicago School of Friedman and company should not be seen as a totally new tradition, historical reconstructions of their work have opened the door to further exploration of continuities and potential discontinuities between ‘old’ and ‘new’ Chicago. We have already seen the second aspect of contemporary historical reconstruction in the earlier discussion of the institutional framework of the Chicago School. Rather than seeing individual scholars and their ideas transforming modern economics (as suggested even recently by Van Overveldt, 2007),
contemporary historiography suggests that the intellectual success of the School was built upon a unique research infrastructure, focused in the workshops. Constructing the history of the workshops involves investigating the support network they developed, ranging from private foundation funding to international connections for research and students. Mirowski and van Horn (2008) focus on the role of the Volcker Fund, but other foundations and external research organizations like the Ford Foundation, Rockefeller Foundation (which funded many activities across the University of Chicago from its inception), Earhart Foundation, and the RAND Corporation participated in supporting Chicago's research infrastructure. In terms of international connections, much has been said of the role of the ‘Chicago boys’ in Chile, who set the groundwork for economic liberalization in Latin America and elsewhere, but were appointed to their positions by General Pinochet (Valdez, 1995; Barber, 1995). However, the institutional history of the Chile connection, which goes back to the early 1950s with an educational exchange between the University of Chicago and the Catholic University in Chile, has yet to be completely told. And we also do not have any histories of Chicago's other international research and student connections, including the equally unique relationship with the Hebrew University in Jerusalem and the University of Tel Aviv, despite the fact that Chicago was one of the few American academic institutions that welcomed Jewish scholars.

The third aspect of the Chicago School points toward two potential areas of research which would deepen the type of historical work illustrated above, while also providing insight into the degree of continuity and change within the School. Neither of these areas of research has made significant inroads into contemporary research. The first is the story of the integration of econometric developments at Chicago into the story of Chicago economics (as opposed to their place in the econometric literature). How did we go from Friedman and Stigler to Heckman, Hansen, and Levitt? Was it just Chicago accommodating itself to the mainstream of the discipline, as is often suggested? Did Zvi Griliches and the development of quantitative analysis in agricultural economics play a role? Or Gregg Lewis and Albert Rees and labour economics? Did a quiet revolution go on at Chicago in the fields outside the core exams that gradually changed the School as a whole? These stories need to be examined in greater detail (see Kaufman 2008, for the history of Chicago labour economics in this regard). Second, the Chicago School's laissez-faire reputation is offset by the fact that a large portion of its graduates have gone into public service both in the United States and elsewhere. Harberger alone can count approximately 20 former students who have become central bank governors and ministers of finance. And countless Chicago students staff national and international economic ministries, commissions, and other organizations. If Chicago economists do believe that economics is a policy science, then the history of their interaction with policy, both as policy advocates and as policymakers, needs to be incorporated into our history. Again, what we do know about this history is piecemeal or quite general (for a start in the right direction; see Banzhaf, 2008).

The new perspectives on Chicago economics open the door to both reconstructing the story of the Chicago School and to extending that story forward to the present. While Reder may have been premature to suggest the School's demise, both the reconstruction of its history and the story of its recent developments suggest both continuity and change.

Chicago School

M.W. Reder

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article deals with the history and main protagonists of the Chicago School from c. 1930 to 1985. The two main beliefs of members of the School are (a) that neoclassical price theory can explain observed economic behaviour, and (b) that free markets efficiently allocate resources and distribute income, implying a minimal role for the state in economic activity. Chicagoans maintain that no opportunity for arbitrage gains goes unexploited, and subscribe to the efficient markets hypothesis. Their ‘disciplinary imperialism’ leads them frequently to challenge conventional wisdom by applying price theory to seemingly non-economic topics.

To identify a Chicago School of economics requires some demarcations, both of ideas and persons, that may not be universally accepted. Justification for these decisions must be heuristic; that is, they facilitate the story to be told. But it is not denied that there may be alternative accounts that would entail different demarcations. In this account, the ‘Chicago School’ is and has been centred in the University of Chicago’s Economics Department from about 1930 to the present (1985). However, it is convenient to define the School so as to include many members of the large contingent of economists in the Graduate School of Business and the group of economists and lawyer-economists in the Law School. Largely because of the intellectual loyalty of former students, the influence of the Chicago School extends far beyond the University of Chicago to the faculties of other universities, the civil service, the judiciary and private business. Moreover, this influence is not confined to the United States.

To restrict the retrospective horizon of the School to 1930 implies exclusion of a number of famous economists who had been on the University of Chicago faculty before that time; for example, Thorstein Veblen, Wesley C. Mitchell, J.M. Clark, J. Laurence Laughlin, C.O. Hardy. However, none of these shared the intellectual characteristics that have typified members of the Chicago School as defined here. In a nutshell, the two main characteristics of Chicago School adherents are: (1) belief in the power of neoclassical price theory to explain observed economic behaviour; and (2) belief in the efficacy of free markets to allocate resources and distribute income. Correlative with (2) is a tropism for minimizing the role of the state in economic activity.

Before discussing these characteristics in detail, let me give a brief historical account in which it is convenient to divide the history of the School into three periods: (1) a founding period, in the 1930s; (2) an interregnum, from the early 1940s to the early 1950s; and (3) a modern period, from the 1950s to the present.

During the founding period, the Chicago Economics Department contained a wide diversity of views both on methodology and public policy. Institutionalist views were well represented among the senior faculty, and institutionally oriented students constituted a large part of the graduate student population. Among the prominent Institutionals were the labour economists H.A. Millis and (one side of) Paul H. Douglas; the economic historians John U. Nef and C.W. Wright, and Simeon E. Leland, a Public Finance specialist and long-time department chairman.

Like other social science departments at Chicago, economics was actively engaged in developing the (then) embryonic ‘quantitative techniques’. The leading figures in quantitative methods were Henry Schultz, a pioneer student of statistical demand curves, who taught the graduate courses in mathematical economics and mathematical statistics, and Paul Douglas who was (during the 1920s and 1930s) a leader in the estimation of and the measurement of real wages and living costs.

However, it is generally agreed that the progenitors of the Chicago School were Frank H. Knight and Jacob Viner. These two scholars shared an intense interest in the history of economic thought and both were, broadly speaking, devotees of neoclassical price theory. However, their intellectual styles and temperaments were quite different, and their personal relations were not close. Apart from his interest in the history of thought, Viner was primarily an applied theorist working on problems in international trade and related issues in monetary theory. Knight's work was focused on the conceptual underpinnings
of neoclassical price theory, and his main concerns were to clarify and improve its logical structure. Temperament and intellectual focus combined to make Knight a formidable critic, both of ideas and their protagonists. This led to a good deal of friction between him and both Douglas and Schultz. Personalities aside, Knight was strongly averse to the quantification of economics and was very outspoken on this, as on most other matters. (For further details, see Reder, 1982, pp. 362–5.) By contrast, Viner was rather sympathetic to the aspirations of ‘quantifiers’, though sceptical of their prospects for success, at least in the near future. Viner’s sympathy for quantitative work was prompted by the strong empirical bent of his own research, although friendship for Douglas and Schultz may also have been involved. On the other hand, Knight's purely theoretical studies of capital theory, risk, uncertainty, social costs, and so on, generated neither need for empirical verification nor exposure to research that might have offered it. As a result, Knight's relations with Douglas and Schultz were ridden with conflict, and theoretical disagreements with Viner spilled over into barbed comments to graduate students and kept personal relations (between Knight and Viner) from becoming more than merely correct (Reder, 1982, p. 365).

What Knight and Viner had in common was a continuing adherence to the main tenets of neoclassical price theory and resistance to the theoretical innovations of the 1930s, Monopolistic Competition and Keynes's *General Theory*. This theoretical posture paralleled an antipathy to the interventionist aspects of the New Deal and the full employment Keynesianism of its later years. Viner, who was actively consulting the government throughout the period, was much less averse to New Deal reforms than Knight and his protégés. However, there was a sharp contrast between the views of Knight and Viner, on the one hand, and those of avowed New Deal supporters such as Douglas, Schultz and some of the Institutionalists.

As a result of the division of faculty views, on both economic methodology and public policy, the graduate student body was exposed to a diversity of thought patterns and did not exhibit a great degree of conformity to any particular one. But despite their many disagreements, an effective majority of the Chicago faculty concurred in a set of degree requirements (for the PhD) that stressed competence in the application of price theory. These requirements were quite unusual in the 1930s and the process of satisfying them exercised a great influence in forming a (common) view of the subject among the students, in which price theory was of major importance.

The most important of the requirements was that all PhD candidates, without exception, pass preliminary examinations in both price theory and monetary theory. These examinations were difficult and attended with an appreciable failure rate. Even on second and third trials, there was a non-negligible probability of failure, with the result that some students were (and are) unable to qualify for the doctorate. For most students, the key to successful performance on the examinations was mastery of the material presented in relevant courses, especially the basic price theory course (301) and study of previous examinations.

For over half a century, the need to prepare for course and preliminary examinations, especially in price theory, has provided a disciplinary–cultural matrix for Chicago students. Examination questions serve as paradigmatic examples of research problems and ‘A’ answers exemplify successful scientific performance. The message implicit in the process is that successful research involves identifying elements of a problem with prices, quantities, and functional relations among them as these occur in price theory, and obtaining a solution as an application of the theory.

Although the specific content of examination questions has evolved with the development of the science,
the basic paradigm remains substantially unchanged: economic phenomena are to be explained primarily as the outcome of decisions about quantities made by optimizing individuals who take market prices as data with the (quantity) decisions being coordinated through markets in which prices are determined so as to make aggregate quantities demanded equal to aggregate quantities supplied.

Of course, students vary in the degree to which they assimilate price theoretic ideas to their thought processes, and resistance to these ideas was probably greater in the 1930s than later. Nevertheless, regardless of their special field of interest, all students were compelled to absorb and learn to use a considerable body of economic theory. In the 1980s these skills are very widespread, but in the 1930s they were rarely found and served to distinguish Chicago-trained PhD’s – especially in applied fields – from other economists.

Despite the common elements of their training, as in other institutions, doctoral students tended to identify themselves with one or another particular faculty member, usually their dissertation supervisor. Thus each of the major figures in the department was associated with a cluster of advanced students. One such cluster, associated with Knight in the mid-1930s, became of very great importance in the history of the Chicago School. Key members of this cluster were Milton Friedman, George Stigler and W. Allen Wallis. The group established close personal relations with two junior faculty members, Henry Simons and Aaron Director, who were also protégés of Knight. Another member of the group was Director’s sister, Rose, who later married Milton Friedman.

It was this group that provided the multigenerational linkage in intellectual tradition that is suggested by the term ‘Chicago School’. Although they admired Knight, and were devoted to him, the intellectual style of Friedman, Stigler, et al. was very different from Knight's. They were thoroughgoing empiricists with a distinct bias toward application of quantitative techniques to the testing of theoretical propositions. In their empirical bent and concern with ‘real world’ problems, they were much closer to Viner than to Knight, but, whatever the reason, they identified with the latter.

Partly because of his important role in the teaching of theory to undergraduates and (less well-prepared) beginning graduates, in the 1930s and until his untimely death in 1946, Henry Simons exercised an important influence on Chicago students. But he is remembered mainly for his essays on economic policy (collected in Simons, 1948) which constituted the principal statement of Chicago laissez-faire views during this period.

Simons's view had a distinctly populist flavour that is absent from those more recently associated with Chicago economics. For example, he favoured use of government power to reduce the size of large firms and labour unions. Where such policies would lead to unacceptable losses of efficiency (e.g. ‘natural monopolies’), Simons favoured outright public ownership. In sharp contrast to more recent Chicago statements on the matter, Simons emphatically supported progressive income taxation to promote a more egalitarian distribution of income (Simons, 1938).

Finally, Simons proposed a requirement of 100 per cent reserves against demand deposits and restriction of Federal Reserve discretion in monetary policy in favour of fixed rules designed to stabilize the price level (Simons, 1948). In this he was the direct forbear of Chicago monetarism, as later developed by Friedman and Friedman's students.

Historically, Friedman, Stigler and Wallis were both the intellectual and the institutional heirs of Knight and Viner. The story of Chicago economics would be less convoluted if the succession had been a matter of the older generation appointing their best students to succeed them. But it was not that simple. On the eve of World War II there was great concern, within the Economics Department and (probably)
in the central administration as well, that Chicago had none of the leading figures in the new theoretical developments of the period; that is, in nonperfect competition and Keynesian macroeconomics. To rectify this, in 1938, they appointed Oscar Lange as assistant professor. In addition to his credentials as a contributor to the literature of Keynes's *General Theory*, especially its relation to general equilibrium theory, Lange was a leading participant in the current debate on the possibility of market socialism and its (alleged) advantages relative to laissez-faire capitalism in terms of efficiency. Further, he had made a number of contributions to mathematical economics and was able to provide backup support for Henry Schultz in that subject area, and in mathematical statistics as well.

As an outspoken and politically active socialist, Lange's views were diametrically opposed to laissez-faire. That he managed to stay on friendly terms with virtually all of his colleagues was a testimonial both to his own tact and to their tolerance of dissent. Of course, it was no accident that the principal socialist in the Chicago tradition should have been a market socialist.

Within a few months of Lange's appointment, Henry Schultz was killed in an automobile accident and Lange became the sole mathematical economist in the Chicago department. Within a year the loss of Schultz was compounded by the partial withdrawal of Douglas from academic life to pursue a political career. Still further, with the outbreak of World War II, Viner became increasingly involved in Washington and, ultimately, in 1945, he resigned to accept an appointment at Princeton.

As a result of these losses, the Department had to be rebuilt. The process of reconstruction began during the war years, with Lange taking a leading role. He was very anxious to recruit colleagues who were leaders in current theoretical developments, especially in mathematical economics. Failing to obtain his first choice, Abba Lerner, he readily accepted Jacob Marschak and, for a short period, collaborated with the latter in making further appointments both to the Department and to the Cowles Commission, which had located at the University of Chicago in 1938. The collaboration ended abruptly in 1945 when Lange resumed Polish citizenship to become ambassador to the United States and, subsequently, to fill many other high positions in the socialist government of Poland.

During the war years, T.W. Schultz was attracted from Iowa State. A leading figure in agricultural economics, Schultz soon became chairman, a position from which he exercised much influence for over two decades. In addition to Schultz, in 1946 the Department acquired Lloyd Metzler to teach international trade and a number of younger theorists and econometricians associated mainly with the Cowles Commission. Whatever was the intention, these appointments served as a counterweight to the more or less contemporaneous appointments of Friedman (to the Economics Department) and Wallis (to the Business School).

There then ensued a struggle for intellectual pre-eminence and institutional control between Friedman, Wallis and their adherents on one side, and the Cowles Commission and its supporters on the other. The struggle persisted into the early 1950s, ending only with the partial retirement of Lloyd Metzler (due to ill health) and the departure of the Cowles Commission (for Yale) in 1953. While not monolithic, the Chicago economics department that emerged from this conflict had a distinctive intellectual style that set it apart from most others.

In positive economics, this style involves de-emphasizing the role of aggregate effective demand as an explanatory variable and stressing the importance of relative prices and ‘distortions’ thereof. In economic policy, it involves stressing the beneficial effects of allowing prices to be set by market forces rather than by government regulation. In an important sense, ‘Chicago economics’ in the 1950s and 1960s was simply an extension of the ideas of the Knight coterie of the 1930s. Indeed, some of the key
figures – notably Friedman, Stigler and Wallis – of that group were leading Chicago economists in the later period as well. Moreover, they were consciously concerned with explicating the continuity of the tradition and preserving it (see below).

The close personal relations of the members of the Knight coterie, maintained for over a half century, has reinforced the strong common elements in their idea-systems and made it easy to ignore the (important) points of disagreement, both among themselves and with others. As already mentioned, Friedman, Stigler and Wallis, like most Chicago economists of their own and subsequent cohorts, believe strongly in use of statistical data and techniques for testing economic theories. In this they differ from Knight, Simons, James Buchanan, Ronald Coase (1981) and a significant minority of other economists associated with Chicago, either as graduate students or faculty, who believe (on various grounds) that the validity of an economic theory lies in its intuitive appeal and/or its compatibility with a set of axioms, rather than in the conformity of its implications with empirical observation.

A second disagreement concerns the consistency of policy advocacy in any form, with the methodology applied in positive economics. (The most influential general description of this methodology is chapter 1 of Friedman, 1953.) This methodology recommends that explanations of economic behaviour be based on a model of (individual) decisions of resource allocation (among alternative uses) designed to maximize utility subject to the constraints of market prices and endowments of wealth. Market prices are presumed to be set so as to equate quantities supplied with those demanded, for all entities traded.

As traditionally applied by neoclassical economists with a predilection for laissez faire, this methodology coexists with advocacy of government policies designed to promote that objective. But in the late 1960s one group of Chicago economists led by Stigler (who had returned to Chicago in 1958 as Walgreen Professor in both the Economics Department and the Business School) began to apply the tools of economic analysis to the investigation of the determinants of political activity, especially government intervention in resource allocation. Thus study of the regulatory and taxing activities of the state became directed not simply at demonstrating their adverse effects upon economic efficiency, but primarily to explaining their occurrence as an outcome of the operation of ‘political markets’ for such activities.

So analysed, interventions traditionally viewed as efficiency impairing, such as tariffs, require reinterpretation. An individual's resources include not only his command over goods and services acquired through conventional markets, but also his political influence (however measured).

Government interventions are considered to be endogenous outcomes of a political-economic process, reflecting the political as well as the economic wealth of decision making units, and not as aberrations of an exogenous state (e.g. see Stigler, 1982). So viewed, criticism of political outcomes is no more warranted than criticism of the expenditure behaviour of sovereign consumers; both are outcomes of the free choice of resource owners.

This is not to suggest that the ‘political economy’ wing among Chicago economists has become indifferent to laissez faire. On the contrary, opposition to government intervention (e.g. regulation) among Stigler and his allies is quite as strong as it ever has been. During the past decade many economists and lawyers at some time affiliated with the Law and Economics group at Chicago have been prominent advocates of deregulation. However, tension between advocacy of reform, and positive analysis of the political process through which reform must be achieved, presents a continuing existential problem to the heirs of the Chicago tradition. Although they are well aware of the problem, thus far they have refrained from divisive dispute and treat exercises in political advocacy as a
consumption activity by those engaged.

Political science is only one of the fields into which Chicago economics has expanded during the past quarter century. Beginning in the early 1940s and accelerating in the last two decades under Richard Posner's leadership, the economic analysis of legal institutions has become an important area of research both for economists and for legal scholars. Further, using the theory of labour supply as a point of departure, the economic analysis of the family has become an important part of the study of population, marriage, divorce and family structure. This development has challenged sociological and psychological modes of explanation in fields that had long been considered provinces of these other disciplines. Still further, the theory of human capital has had a major impact on the study of education.

It is convenient to date the ‘disciplinary imperialist’ phase of the Chicago School as beginning in the early 1960s and continuing to the present. However, its roots go back into the 1930s; since that time there has been, at least in the oral tradition, a tropism for application of the tools and concepts of price theory to (seemingly) alien situations, and for taking delight in confronting conventional wisdom with the results. Correlatively, there has been a strong tendency to resist explanations of behaviour that do not run in terms of utility maximization by individual decision-makers coordinated by market clearing prices. However, until well into the 1950s, the disciplinary imperialist aspect of the Chicago paradigm was overshadowed by the struggle to defend the integrity of neoclassical price theory from the attacks of Keynesians at the macro level and the attempts of various theorists of nonperfect competition to provide alternatives at the micro level. The counterattack on the *General Theory* produced a revival of neoclassical monetary theory in a refined and empirically implemented form; this revival is associated with the work of Milton Friedman (1956).

The struggle to re-establish the competitive industry as the dominant model for explaining relative prices was led by Stigler (1968, 1970), and generated much of the theoretical and empirical literature of the field of Industrial Organization. Both in Industrial Organization and Money-Macro, the earlier debates continue, with Chicago-based participants being identifiable as partisans of the standpoints of Friedman and Stigler a quarter of a century ago. However, in the 1970s and 1980s the topics related to these debates have been forced to share centre stage with newer subjects.

The expansion of Chicago economics beyond the traditional boundaries of the discipline began in the middle and late 1950s; two early examples were H.G. Lewis's application of price theory to the ‘demand and supply of unionism’ (Lewis, 1959) and Gary Becker's dissertation on racial discrimination (Becker, 1957). These were followed in the 1960s and 1970s by a number of others, as already mentioned. Many of these are more or less straightforward applications of conventional price theory to new problems. However, the analysis of time as an economic resource (Becker, 1965) has led to important improvements in the theory of household behaviour.

The analysis of time is also related to a methodological tendency to reject differences in tastes (including attitudes, opinions and beliefs in ‘tastes’) as a source for explanations of cross-individual differences in behaviour (Stigler and Becker, 1977; Becker, 1976). The rejection is based on the contention that (1) seeming differences of taste are usually reducible to differences of cost and (2) statements about cost differences are much more amenable to empirical test. While this methodological principle has met with resistance, at Chicago as elsewhere, it is reflected in a great deal of ongoing research, especially where cost of time is an important variable.

A separate path of disciplinary expansion has arisen in the field of Finance. Whether, prior to the 1960s,
this field was a province of Economics, is a point that it is convenient to bypass. But unquestionably, prior to the theoretical developments initiated by Modigliani and Miller's famous paper (1958) on the (non) relation of stock prices and dividends, the theory of price. Subsequent developments have completely reversed that situation, so that in the mid-1980s, the ‘capital asset pricing model’ has become an integrating matrix for the theories of security prices, asset structure of the firm, and, via the study of executive compensation, wages.

The dominant idea underlying these developments is that, save for transaction costs, on average no opportunity for arbitrage gains goes unexploited. One implication of this is the proposition that there is ‘no free lunch’; another implication is that no specifiable algorithm can be found that will enable a resource owner to utilize publicly available information to predict movements of asset prices well enough to gain by trading. The latter implication is tantamount to the ‘hypothesis of efficient markets’. While not formally identical with rational expectations, efficient markets will support any behaviour conforming to rational expectations, but will be compatible with other models of expectations only where one or another set of correlated forecast errors (across individuals) is assumed. Moreover, so long as expectations are rational, and regardless of how they are generated, there is no way in which variables operating through expectations can improve upon the neoclassical explanation of relative prices and quantities. This obviates any need for augmenting economic theory by variables reflecting psychological or sociological factors that operate upon individual decision-making via expectations. Obviously, such a theory of expectations is strongly supportive of the claims of economic theory in interdisciplinary competition.

The interrelated ideas of rational expectations and efficient markets originated at Carnegie-Mellon in the work of Muth (1961) and Modigliani and Miller (1958) rather than at Chicago. However, their consonance with the Chicago paradigm is such that they have found a home in the Chicago Business School under the leadership of Miller and his students, and (since the mid-1970s) in the Economics Department under Robert Lucas, rather than in their place of origin. While the claim of Chicago to be the primary locus for research in these fields is a strong one, it is a claim more subject to challenge than analogous claims in some other fields.

Yet a third Chicago innovation of the late 1950s is the ‘Coase Theorem’ (Coase, 1960). In essence this theorem states that, ignoring transaction costs, if there is any reallocation of goods, claims, rights (especially property) or alteration of institutions that – after making compensating side payments to losers – increases the utility of everyone, said reallocation will occur. If rationality is a maintained hypothesis and transaction costs are negligible, the theorem becomes a tautology. Thus the empirical content of the theorem will vary inversely with the importance attributed to transaction costs, which serve as a conceptual receptacle for all forces bearing upon decision-making other than those explicitly incorporated in the theory of price. To consider the Coase Theorem empirically important is to believe that transaction costs and departures from rationality are unimportant.

Put differently, the Coase Theorem suggests that the real world tends towards a position of Pareto optimality. Of course, for given tastes and technology, there may be a different Pareto optimum for each distribution of wealth. Therefore, to the extent that the distribution of wealth is exogenous and has important behavioural consequences, the predictive implications of both Pareto optimality and the Coase Theorem are less salient. Thus the rise in influence of the Coase Theorem at Chicago has more or less paralleled a decline in the marked concern with income distribution that existed in the 1930s and 1940s, especially in the work of Henry Simons (Reder, 1982, p. 389).
When objects of exchange are taken to include legislation and other political variables, the Coase Theorem strongly suggests that the forces of decentralized decision-making that govern production and exchange also control changes in laws and institutions. Thus belief in the Coase Theorem is – or should be – conducive to political passivity. Nevertheless, not all Chicago economists are politically quiescent. But with few exceptions, they are generally conservative, though with considerable differences in shading and intensity of belief, and in taste for political controversy. Probably these differences parallel differences in the degree to which they accept economic explanations of political behaviour. Perhaps the most common characteristic of Chicago economists is distrust of the state. This distrust, together with the belief that, given time, voluntary exchange will usually generate truly desirable reforms, acts as a powerful brake on wayward impulses to improve society through political action.

The saga of the Chicago School is at once the story of the evolution of a set of ideas – a paradigm – and of a particular institution with which its leading protagonists have been associated. In this essay I have emphasized certain central theoretical ideas and historical events to the exclusion of detailed coverage of applied work and mention of the individuals responsible for it. However, it is the association of these central ideas with an identifiable, multigenerational group of individuals located at a particular institution that justifies the title of this article. Many of the key individuals in this history – Director, Friedman, Stigler, Wallis – are still alive, intellectually active and in close touch with their successors on the Chicago faculty. This continuity, both of personalities and ideas, is a distinctive feature of the intellectual tradition called the Chicago School.

In the mid-1980s the vitality of this tradition is threatened more by the growing acceptance of many of its key ideas than by resistance to them. A quarter century ago, Chicago economics was distinguished by its emphasis on the importance of competition and money supply. Arguably, in 1985, these views and their extensions have become mainstream economics, leaving the story of the Chicago School as a nearly closed episode in the history of economic thought. While such an argument may prove valid, it is too soon to tell.

Child health is a major indicator of the direction and well-being of society. It is a significant factor predicting health and productivity in adult life, and the health of adults in turn affects the well-being of the next generation of children. The most important outstanding issues include determining the most cost-effective investments in child health, explaining the relationship between health and socio-economic status over the life course, and finding the interventions that are most effective in breaking the inter-generational cycle of ill health and poverty. As children are economic actors in their own right, their well-being is worthy of study.

Article
Child health and mortality are of interest to economists for three reasons. First, they are important indicators of the success or failure of government policy. Second, children's health has long-term impacts on their health and productivity as adults. Third, there is increasing recognition that children are economic actors in their own right. Hence, their well-being is worthy of study.

The most common model of child health is one in which health is ‘produced’ by families using health ‘inputs’ (Grossman, 2000). Examples of inputs include the goods and services families buy to improve child health. Families maximize an inter-temporal utility function subject to the production function, prices, and budget constraints. Inputs are valued only because of their effect on health. Children start with a ‘health endowment’ that depreciates over time in the absence of health inputs. Public policy
affects either the price of inputs or the form of the production function. The model predicts that child health will be influenced by the price of health inputs. The inter-temporal nature of the model highlights the idea that health inputs are investments with long-term payoffs.

Studies of children in developing countries often focus on the ‘production’ of mortality rates, nutrient intakes, height, weight and other objective measures. In contrast, studies of children in richer countries often focus on the utilization of medical care. But health care is only one input into the production of child health, and it is not the most important. Improvements in standards of living, advances in knowledge about disease and hygiene, and public health measures such as improved sanitation have done more to improve child health in the past 150 years than even the most spectacular advances in personal medical care (Preston, 1977). Today, accidents and violence, rather than disease, are the major killers of young children in wealthy countries after the first year of life (UNICEF, 2001).

### Measures of child health

Health is multidimensional and difficult to measure. Mortality and parent-reported health fall at two ends of a spectrum. Mortality is an objective but narrow measure. In countries with high death rates, child mortality is a relatively sensitive indicator of economic and social conditions. For example, in Zimbabwe mortality among children under five years old increased from 80 to 126 per 1,000 live births between 1990 and 2003 as the economic crisis deepened (United Nations Common Database). In countries with lower child mortality rates, the relationship between economic conditions and mortality may be masked by the effects of economic cycles on fertility. For example, some recent papers demonstrate that in developed countries poorer people have fewer children during economic downturns so that the average health of infants increases (see, for example, Lleras-Muney and Dehejia, 2004). The relationship between mortality and economic conditions is also masked by strong underlying downward trends in mortality due to technological advances.

A typical survey question eliciting parent reports about child health asks respondents to rate child health on a scale of 1 to 5. An advantage of this measure is that it applies to all children. A disadvantage is that parent reports may be biased. For example, sick parents are more likely to report sick children. Parents are also often asked about limitations on children's activities (for example: Did a health problem prevent school attendance?) and about the presence of chronic conditions. These questions have the advantage of being more specific, but capture only one dimension of health and also suffer from potential biases (Baker, Deri and Stabile, 2004; Strauss and Thomas, 1996).

In between are anthropometric measures such as birthweight, height, weight, height for age, and body mass index (Martorell and Habicht, 1986). Anthropometrics are objective measures that apply to large numbers of children. But, like mortality, they may not be sensitive measures in healthy populations. For example, American children are unlikely to be stunted (low height for age) and are increasingly likely to survive low birthweight (less than 2,500 grams) without significant impairments. American children are increasingly likely to be obese, however, suggesting that body mass index is likely to become a more important health indicator in the future.

A fourth class of measures involve ‘risky behaviours’ such as precocious or dangerous sexual activity, involvement in crime or victimization, use of handguns, and use of alcohol, tobacco, and illegal drugs. Given the importance of accidents and violence among children, these are important questions. But the
stigma associated with these activities makes it likely that they will be under-reported. Also, risky behaviours may or may not lead to poorer health. Unfortunately, the actual health effects of many behaviours are very poorly reported. For example, there is little information available about injuries that do not lead to deaths.

Some surveys include clinical assessments of children's health by doctors or other trained professionals in addition to some of the information about economic status that is usually collected in social surveys. Examples include the British birth cohort studies, the American National Health and Nutrition Examination Surveys, the World Bank's Living Standards and Measurement Surveys and the Indonesia Family Life Survey. Some of the most interesting work being done in this area involves measures of children's genetic make-up. Caspi et al. (2002) show, for example, that New Zealand men with a specific genetic marker were more likely to be violent adults, but only if they had been maltreated as children. Given the broad range of health outcomes, researchers should look at a range of outcomes and carefully consider whether the chosen ones are likely to be affected by the phenomena under study.

Health care utilization

The human capital model makes a clear distinction between health and health inputs. In the model, parents care about health rather than health inputs. Yet this distinction is often blurred. Williams and Miller (1992, p. 991) state that ‘One of the most impressive aspects of health policy implementation [in Europe is] that the programs were put in place not because of extensive documentation on cost effectiveness, but out of a value system that cherishes equity in health care.’ The underlying assumption is that all health care produces health. Yet the market for health care is plagued with imperfections. Some care is likely to be superfluous, for consumption rather than investment purposes, or even injurious.

Models of physician-induced demand show that asymmetric information can lead to excessive consumption of medical services if physicians take advantage of their superior information to ‘sell’ services that patients do not need (Pauly, 1980; Dranove, 1988). There may be considerable scope for inducement in the market for children's health care. Many child treatments are inexpensive but have a high clinical value when they are warranted, so parents perceive a low cost set against a potentially high benefit. The availability of insurance compounds the problem by further reducing costs to parents. Researchers should focus on measures of utilization that have a clear benefit. Whether or not a child visited a doctor in a year and whether a child is immunized are good examples. Measures such as the number of hospitalizations are problematic since many hospitalizations could be prevented with appropriate outpatient care. Some recent work focuses on ‘preventable hospitalizations’ as a measure of inadequate utilization of care (Casanova and Starfield, 1995).

Health as an investment

Child health affects adult health. Poor health in childhood also lowers future utility through its effects on future wages and labour force participation (Currie and Madrian, 1999) and through its effects on schooling. Currie (2005) provides a survey of literature linking several specific health conditions to cognitive outcomes and schooling achievement.
Using data from the 1999 Panel Study of Income Dynamics, James Smith (2005) shows that a retrospective self-reported question about health during childhood is remarkably predictive of future outcomes. Comparing siblings, he finds that those who were in excellent or very good health earn 25 per cent more as adults. Currie (2000) surveys some of the many studies that find positive associations between cognitive test scores and anthropometric measures of health such as birthweight, weight, height, head circumference, and the absence of abnormalities in children of various ages. More recently Currie and Moretti (2005) have shown that differences in birthweight between sisters are predictive of differences in education and median income in the zip code of residence at the time the sisters deliver their own children many years later.

But low birthweight is only one of a number of health shocks that low-income children are more likely to experience (Newacheck, Hughes and Stoddard, 1996). Case, Lubotsky and Paxson (2002) show that the gap in health status between rich and poor US children widens as children age. Currie and Stabile (2003) replicate this finding using Canadian data, and argue that the widening gap reflects the greater frequency of negative health shocks among poor children. The comparison between the United States and Canada suggests that public health insurance is not sufficient to shield children from the negative health consequences of poverty (since Canada has universal insurance). However, in Britain the gap between rich and poor children is smaller than in North America and does not widen as children age (Currie, Shields and Price, 2004). This suggests that some other aspect of the social safety net may be responsible for protecting child health in Britain.

Poor children are more likely than rich children to suffer from mental health problems (Currie, 2005, 2002). Mental health problems account for the largest share of days lost due to health problems in the United States. Many mental health conditions have their roots in childhood, but the relationship between mental health and child outcomes has been largely ignored in economics. Currie and Stabile (2005) investigate the relationship between symptoms of Attention Deficit Hyperactivity Disorder Activity disorder (ADHD) and educational attainment using US and Canadian panel data. We find large negative effects even in rich sibling-fixed effects models. Other research has shown that childhood behaviour problems predict negative future outcomes (cf. Gregg and Machin, 1998). The prevalence and potential economic importance of child mental health problems suggest that more work is warranted.

**Policy and child health**

It is easy to justify government intervention in the market for health care. In addition to asymmetric information between patients and providers, there are other informational problems. For example, imperfect information in the market for insurance can lead to market failure. And although parents make most decisions about child health inputs, these decisions have consequences for society. Parents who do not take account of externalities may not provide the optimal level of care for their children (cf. Kremer and Miguel, 2004). Finally, the health sector accounts for a large and growing share of the economy, and the government is already the major player in the health care markets in most countries, including the United States.

Policies can be divided into those that intervene in the market for health care and those that affect health through other means. Public health insurance is the most prominent example in the first category. It is
difficult to study the impact of universal health insurance because there is only a single ‘before/after’ comparison. But over the late 1980s and early 1990s, the United States greatly expanded its public health insurance coverage of pregnant women and children. Forty per cent of US births are now covered by public insurance. The expansion took place at an uneven rate across states, yielding a potential source of identification.

The effects of this expansion of insurance coverage are surveyed in Gruber (2003). It reduced infant and child mortality, increased utilization of preventive care, and reduced preventable hospitalizations among children. But increases in coverage also increased the inappropriate use of care (for example, increased rates of Caesarean section). And some who took up public health insurance would have had private health insurance in the absence of the expansions. Hence, public health insurance improves child health, but does not necessarily result in efficient service delivery.

Health care utilization is only one input into health production. Other inputs such as a healthy lifestyle and the avoidance of injury are arguably much more important. Government policy has a large role to play in affecting many health inputs beyond health care. A few examples follow. Pollution is likely to be more harmful to children than to adults both because they are still developing and because of their small size. Hence, any policy that affects the environment may affect child health. For example, Chay and Greenstone (2003) show that the recession of the early 1980s reduced infant mortality. Currie and Neidell (2005) show that reductions in carbon monoxide pollution in California over the 1990s (largely due to cleaner vehicles) saved at least 1,000 infant lives.

Child obesity is a growing problem that threatens future health. The potential role for government ranges from the provision of information (for example, revising the ‘healthy food pyramid’ to reflect the most recent nutritional knowledge) to regulation (for example, eliminating Coke machines in schools). The government plays a similar role with respect to discouraging children from using alcohol and tobacco, though in these examples government also directly controls the price of the products through taxation. A good deal of research documents the relationships between prices, advertising, and youth consumption of tobacco and alcohol. But we know much less about the effectiveness of newer policies aimed at curbing obesity (see Gruber, 2001).

Although injuries remain a major cause of death, the incidence of accidental death has declined dramatically since the 1970s, especially in the United States (UNICEF, 2001). Glied (2001) argues that the decline is due to improvements in education resulting in increased use of, for example, bicycle helmets and seat belts. But many products, including cars, cribs, and medicine bottles, are much safer than they used to be. Is this a result of random technical innovation, government mandates, or fear of lawsuits? Similarly, trauma care has improved greatly. So there are many possible explanations for the reduction in mortality.

While health affects education, maternal education affects child health. Currie and Moretti (2003) find that increases in the availability of colleges increased women’s education, leading to better infant health outcomes. Hence, there is an inter-generational payoff to government investments in education that leads to ‘increasing returns’ to investments in education (Rosensweig and Wolpin, 1994).

Finally, as discussed above, poor children are more likely than rich children to suffer virtually all forms of health insult. Hence, improving health is a goal of general poverty alleviation programmes such as public housing and income maintenance.
Summary

Child health is an important indicator of the direction and well-being of society. Health in childhood is one of the more important factors predicting health and productivity in adult life, and the health of adults will in turn affect the well-being of the next generation of children.

Many policies have impacts on child health. Some simple improvements in data collection efforts could have a large research payoff in terms of identifying these impacts. These include: allowing the release of geographical identifiers so that health data can be merged to other data; the inclusion of family income and demographics in health data-sets; and the collection of more objective measures of child health.

What are the most interesting outstanding questions? First, what are the most cost-effective investments in child health? Second, what explains the relationship between health and socio-economic status over the life course? And third, what interventions are most effective in breaking the inter-generational cycle of ill health and poverty?

child labour

Kaushik Basu
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

According to latest available estimates, somewhere between 14 to 18 per cent of all children between the ages of 5 and 14 years in the world are labourers. The causes of child labour are many but the primary one is poverty, since for most parents sending children to work is an act of desperation. The availability of decent schools and the provision of small incentives, such as school meals, can help limit child labour. Hence, the best policy response is to improve conditions on the adult labour market, provide better schooling and, on rarer occasions, use legal interventions.

Keywords

child labour; education; household production; Industrial Revolution; poverty

Article

According to the International Labour Organization (ILO, 2002) there were 186 million child labourers in the world in 2000, that is, children between the ages of 5 and 14 years doing regular economic work. This implies a ‘participation rate’ (the number of labouring children as percentage of all children of that age group) of 15.5 per cent. Of these, 111 million were engaged in ‘hazardous work’. But by 2004 the number was down to 166 million – a participation rate of 13.7 per cent – and the number of children in hazardous work was down to 74 million. Some details and regional distribution estimates are available in Hagemann et al. (2006), but (at the time of writing) these new numbers are yet to be absorbed and analysed.

It is a truism that the incidence of child labour is hard to estimate, both because it is often illegal and so respondents would not proffer information too readily and because the work is usually in the informal sector where record keeping is weak. Not surprisingly, there are other estimates of child labour, higher and lower. According to the UNICEF (2006), which collates data from different sources from 1998 to 2004, the participation rate is 18 per cent.
These data sources have both upward and downward biases along different dimensions. Domestic work that is done in one's own household is usually recorded very poorly or not at all. But we have micro evidence that in poor regions children, especially girls, do huge amounts of work in their homes, ranging from fetching wood to hazardous work like cooking over open fires. Indirect evidence for this comes from the gender breakdown of child labour. According to ILO data, boys do more labour than girls; their participation rates are respectively 15.9 per cent and 15.2 per cent. But detailed micro studies that try to include heavy domestic work, such as that by Cigno and Rosati (2005, ch. 5), show that girls tend to do 30 per cent more work than boys. Hence, there is a downward bias in the macro numbers mentioned above.

On the other hand, one source of upward bias comes from ‘work’ being equated with doing more than one hour of work in the ‘reference period’, and from the fact that for most studies the reference period is one week. It is arguable that children who answer ‘yes’ because they barely satisfy that cut-off ought not to be classified as child labourers.

The reason for not becoming too weighed down by these statistical debates is that, no matter how one measures it and, as a consequence, whether the participation rate turns out to be 14 per cent or 18 per cent, it is easy to agree that the incidence of child labour is unacceptably high. In a world with as much opulence as ours there should not be so many children working and that too in grinding poverty and in intolerable working conditions.

This raises the question of the causes of child labour and the appropriate policy response. The primary cause is poverty. Well-off parents living in the same nation and under the same laws as poor ones almost never send their children to work. Hence, a child's non-work (whether this be leisure or schooling) is a luxury good. Sufficiently poor parents cannot afford this. This was called the ‘luxury axiom’ in Basu and Van (1998), and there is ample empirical evidence for it (see discussion in Ray, 2000; Basu and Tzannatos, 2003; Edmonds and Pavnick, 2005). But there are other causes as well. There are parents on the borderline of poverty, who, if they knew that there were decent schools in the area and/or that their children would get a square meal in school, would take the children out of labour and send them to school. Hence, the provision of schooling and, ideally, having some added incentives for sending children to school can make a large difference to the incidence of child labour (Ravallion and Wodon, 2000; Bourguignon, Ferreira and Leite, 2003).

The presence of other determinants is also evident from the fact that the location of a child in the rural–urban spectrum affects the probability of the kind and amount of work the child is likely to do. This was always believed to be true. There were commentators at the time of the Industrial Revolution in Britain who argued that the alleged increase in child labour was really not an increase but a shift of child labour from agriculture to industry and a dramatic change in the nature of work (see Horrell and Humphries, 1995, for discussion). Contemporary, casual evidence seems to support this. And a recent empirical study of child labour in Nepal (Fafchamps and Wahba, 2006) formally confirms for the first time that urban proximity matters in a significant way. Children who live in or close to cities participate significantly less in labour and have a higher incidence of schooling than their rural counterparts. The health effects of these two kinds of child labour – agrarian and industrial – remain to be investigated systematically. Work in factories can be in dark and dank settings; on the other hand, agricultural work can mean exposure to not just the elements but also to pesticides and fertilizers. The net effects of these deserve investigation.
Given the multiplicity of causes, one has to be careful about the policy response to child labour. It is no surprise that, despite attempts by the British government from 1802 till the mid-19th century to deter child labour through a series of Factory Acts, the participation rate remained consistently and intolerably high. Indeed, the participation rates in Britain in the first half of the 19th century were higher than those found in today’s China or India. Likewise in the USA, despite a variety of legislative measures starting in 1837 in Massachusetts, the incidence of child labour remained high and in fact continued to rise till the end of the 19th century.

While there is no final word on policy, we know that some measures are likely to be more effective than others. Ameliorating poverty, improving adult labour market conditions and providing better schooling, as already discussed, can have a significant effect. The law – bans and fines – can also play a role but should be used with caution and after empirical tests of whether the context deserves such measures. It has been argued (see Basu and Van, 1998; Dessy and Pallage, 2001; Emerson and Souza, 2003) that the labour market can in different ways (such as the general equilibrium impact on market wages, coordination with technology and intergenerational dynamics) give rise to multiple equilibria. That is, the market, left to itself, can settle into different grooves; for instance, one with no child labour and another with a high participation rate. In such a case, if the economy settles into the latter equilibrium, a ban can be an effective tool. Otherwise a ban can lead children labouring in factories to worse outcomes, such as starvation or prostitution. Minimally, in such situations the law has to be combined with complementary interventions to ward off the extreme poverty and deprivation that can arise as a side effect of its implementation.

The second son of Richard Child, a London merchant, Sir Josiah Child was born in 1630 and enjoyed a highly successful merchant career during which he amassed a considerable fortune. His business ventures, which included the provisioning of Navy ships, led to his appointment as Deputy to the Navy's Treasurer at Portsmouth in 1655 and he became Mayor of that city in 1658. He was appointed a director of the East India Company in 1674, and with the exception of 1676 he was re-elected to a directorship in every subsequent year until his death. In 1681 he was elected governor of the company and established a close relationship with the Crown. Following the Revolution of 1688, and in response to mounting attacks on his conduct of company affairs, he relinquished some of his active management responsibilities.

Child's claim to recognition as an economist rests on his Brief Observations concerning Trade and Interest of Money, first published in 1668 and reissued (anonymously) in expanded form as A Discourse about Trade in 1690 and again as A New Discourse of Trade (with Child's name on the title page) in 1693. The work summarizes the views he presented to the Council of Trade appointed by the King in 1668 (following the appointment of a Select Committee on the State of Trade by the House of Commons in the preceding year) and to a similar House of Lords Committee in 1669. Among the reasons for the mercantile supremacy of the Dutch, he cites the establishment of banks and the widespread use of transferable bills of exchange, which he strongly argued should be adopted in England. He argued for a reduction of the legal maximum rate of interest from six to four per cent (referring to this as 'my old theme'), claiming that the lower rate of interest in the Netherlands was 'the causa causans of all the other causes of the riches of that people'. He saw the beneficial effects on trade of a lower cost of money capital, but he did not discuss, as did John Locke at the same time, the relation between a legally established rate of interest and the rate established by natural market forces. Child's argument that the beneficial effect of lower interest rates would cause 'all sorts of labouring...
people that depend on trade (to be) more constantly and fully employed’ took up the then widespread concern with the employment problem and he concluded: ‘it is our duty to God and nature so to provide for and employ the poor’. A significant discussion of the question of the poor and a scheme for their relief and employment is included in Chapter II of the Discourse of Trade. Notwithstanding his scattered observations that appear to support free trade principles and his assertion of the principles of competitive markets, Child was an exponent of monopoly when it suited his and the East India Company's advantage. He recognized the need to export bullion if that gave rise to further export trade opportunities. But his work abounds in arguments for trade restrictions in specific cases, such as those requiring the transportation of traded commodities in English vessels and requiring that colonial trade should be conducted only with England, thereby emphasizing the domestic employment-creating effects of the colonies. He stands as a latter-day mercantilist rather than an analytical anticipator of the laissez-faire doctrines of genuine and generalized freedom of trade.

childcare

David M. Blau

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The market for childcare and the role of the government in the childcare market have grown enormously as mothers of young children have entered the labour force in very large numbers. Economists have made important contributions to understanding many aspects of childcare. This article focuses on (a) the effect of the price of childcare on labour force participation of mothers of young children, (b) the effect of childcare and early childhood interventions on children, and (c) the rationale for and effects of government involvement in childcare. Fruitful avenues of additional research are suggested.

Article

The market for childcare in advanced economies has grown enormously in response to the dramatic increase in labour force participation by mothers of young children. In 1950 12 per cent of married women in the United States with children under age six were in the labour force, compared to 63 per cent in 2000. Labour force participation of single mothers with children under six has also increased rapidly, reaching 65 per cent in 2000. As the market has grown, the role of the public sector in subsidizing, regulating, and providing childcare has increased substantially. One-third of all expenditure on childcare and preschool in the United States is financed by government subsidies or by direct provision of services. The public sector plays an even larger role in childcare in many European countries. Three aspects of childcare have received the most attention from economists: (a) the effect of the price of childcare on labour force participation of mothers, (b) the effect of childcare and early childhood interventions on child development, and (c) the rationale for and effects of government
involvement in childcare. Childcare is interpreted broadly here to include care provided by someone other than a child's parent either to facilitate employment of parents or to enhance child development. Blau and Currie (2006) summarize the findings of 20 studies that estimate the elasticity of maternal labour force participation with respect to the price of childcare. The estimates vary widely across studies, but studies that account for the availability of informal unpaid childcare options usually estimate relatively small elasticities, in the range of –.09 to –.20. These studies use a multinomial choice framework that allows for the possibility that a mother can work without using paid childcare. Use of unpaid childcare by family members, relatives, and others is very common. The relatively small elasticity estimates suggest that a price increase induces substitution of informal unpaid childcare for paid care, dampening the sensitivity of maternal employment to the price of childcare. Some evidence suggests that the price elasticity is larger in absolute value for lower-wage women. This evidence confirms that childcare costs are a significant but not major barrier to employment of mothers. The evidence also implies that childcare subsidies increase work incentives of mothers, a finding confirmed by a small number of studies that directly analyse the impact of subsidy programmes on employment.

An important concern about childcare is that low-quality care could be harmful to the development of young children. Conversely, high-quality care may help compensate children from low-income families for the disadvantages of growing up in poverty. The effect of childcare on child development has traditionally been the domain of developmental psychology, but in recent years economists have contributed to this literature, noting its similarities to the ‘education production function’ literature for school-age children.

The quality of childcare can be characterized by ‘structural’ features such as the size of the group in which care is provided, the ratio of adult caregivers to children, and the education and specialized training of providers. Alternatively, direct observation of the developmental appropriateness of the care received by children can be made by trained observers using standardized instruments. These ‘process’ measures of quality are more proximate determinants of child development than are the structural features.

The small amount of evidence available suggests that higher-income parents do not choose higher-quality childcare on average: among users of day-care centres, there is no systematic relationship between family income and the quality of childcare used, if other factors are controlled for (Blau, 2001). This is true whether the quality of care is measured by structural characteristics or process measures. This suggests that parents are either unable to discern the quality of care, or unwilling to pay the additional cost associated with higher-quality care, or both.

Several random assignment demonstration projects have evaluated the impact of high-quality preschool programmes for disadvantaged children (see reviews in Blau, 2001, and Blau and Currie, 2006). The results show that such programmes have delivered substantial long-run benefits to the participants and society: lower school dropout rates, higher earnings, fewer out-of-wedlock births, and lower public expenditures on welfare, criminal justice, and special education. Benefit-cost calculations show that these interventions have a very high social rate of return. This evidence is compelling, but it is based on very intensive and costly programmes that are of exceptionally high quality and are targeted at highly disadvantaged children. It is unclear whether childcare of moderately high quality provides positive but proportionately smaller developmental benefits, or whether there exists a threshold of quality below which benefits are negligible. It is also unclear how the quality of childcare affects children who are not highly disadvantaged. In non-experimental studies that follow children over time, higher-quality
childcare is associated with better developmental outcomes in the short run (one to three years). However, it remains uncertain to what extent this is a causal impact. Recent studies that control for many other potentially confounding factors find that the quality-development association is smaller than in models with fewer controls, but remains significantly different from zero.

Two main arguments have been used to rationalize a role for government in the childcare market. The arguments are based on attaining economic self-sufficiency, and childcare market imperfections. On self-sufficiency, childcare subsidies might help low-income families achieve economic self-sufficiency, defined as being employed and not enrolled in welfare programmes. Self-sufficiency is a desirable goal because it may inculcate a work ethic and generate human capital through on-the-job training and experience. These arguments explain why many childcare subsidies require employment or work-related activities such as education and training. Subsidies for childcare and other work-related expenses paid to employed low-income parents may cost the government more today than would cash assistance. But these subsidies could result in increased future wages and hours worked and lower lifetime government support than the alternative of cash assistance both today and in the future. This argument has nothing to do with the effects of childcare on children, and there are few restrictions on the quality of childcare that can be purchased with employment-related childcare subsidies. However, evidence on wage growth of low-skill workers suggests that wages grow only modestly with experience, too slowly to lift low-skill workers out of poverty (Gladden and Taber, 2000). Middle and upper-income families are generally not at risk of going on welfare, so it is not obvious that there is an economic rationale for subsidies for their employment-related childcare expenses.

As for market imperfections, the imperfections that are often cited are imperfect information available to parents about the quality of childcare, and positive external benefits to society generated by high-quality childcare (Walker, 1991). Imperfect information exists because consumers do not know the identity of all potential suppliers, and the quality of care offered by any particular supplier is not fully known. A potential remedy for the first problem is government subsidies to resource and referral agencies to maintain comprehensive and accurate lists of suppliers. The second information problem arises because consumers know less about product quality than does the provider, and monitoring the provider is costly to the consumer. This can lead to moral hazard and/or adverse selection. The limited evidence available suggests that parents are not well-informed about the quality of care in the arrangements used by their children. Childcare subsidies targeted at high-quality providers could induce parents to use higher-quality care.

The externality argument is a standard one that closely parallels the reasoning applied to education. High-quality childcare leads to improved intellectual and social development, which in turn increases school readiness and completion. This reduces the cost to society of problems associated with low education: low earnings, unstable employment, crime, drugs, teenage childbearing, and so forth. If parents are not fully aware of these benefits, or account for only the private and not the social benefits, then they may choose childcare of less than socially optimal quality. This argument could rationalize subsidies targeted to high-quality providers, such as Head Start, a US programme aimed at enhancing cognitive and social development of low-income children.

As this discussion implies, childcare policy can be used to facilitate employment of mothers and enhance development of young children. There is likely to be a trade-off between these goals because higher-quality care is more expensive. There is not a political agreement in the United States to spend enough to achieve both goals, or on which goal should have the highest priority. This is due in part to
conflicting views on the proper role of the government in a domain that was mainly left to families until the last quarter of the twentieth century. But it also reflects lack of knowledge about the magnitudes of important parameters that affect the costs and benefits of alternative policies. Economists could make significant contributions to knowledge by careful empirical studies that produce reliable estimates of such parameters. The following issues seem important and well-suited to analysis by economists. Despite a large number of studies, there is considerable uncertainty about the magnitude of the elasticity of maternal employment with respect to the price of childcare. A careful sensitivity analysis could help resolve this uncertainty. Research on the price-responsiveness of low-income mothers would be especially useful. Consumer demand for quality in childcare is not well-understood, and new research could be valuable. Research on the take-up decisions of families eligible for childcare subsidies would be useful in order to determine the likely effectiveness of different forms of subsidies. New research on the supply of childcare would be useful. Subsidies to consumers may bid up the price of childcare, and it is important to be able to quantify such effects. It would also be useful to examine the quality supply decisions of providers, in order to determine how responsive the supply of high-quality care might be to subsidies.

Abstract

Although pre-modern China possessed rich ideas pertaining to economic matters, they were not separated from the discourse of morality and politics. Even in the late 20th century, Chinese thinking, often unconsciously, reflected traditional ideas. Liberal economics missed the chance to guide the modernization of China. Marxian economics established its monopoly under the reign of the Communists. However, China had Marxian economists who supported its gradualist transition to a market economy. In the 1990s, the task of guiding economic reforms in China was handed over to a new generation of economists who absorbed ‘Western’ (non-Marxian) economics.

Article

Economics in China has not been able to disassociate itself from politics. The Chinese word for economy or economics, Jingji, is the abbreviation of Jingshi (or Jingguo) Jimin, which means ‘ruling the society or state and saving the people’. In traditional Chinese learning, this is a generalized concept that covers almost the entire range of a state's administrative activity. However, the viewpoint implied in this word is that of the rulers or administrators and not that of individuals engaging in economic activity on their own account.

The quest for wealth and the control of morality
Policies oriented towards the attainment of ‘wealth and power’ had appeared already in ancient China, the Eastern Chou Period (722–256 BC), when the rule of Chou dynasty became in title alone and powerful vassal lords struggled with each other for leadership, which was based on the power of their feudal states. A crucial insight pertaining to economic growth that emerged during this period was that fostering the material welfare of the people was a precondition for a strong state. The famous saying ‘Man will care about honour and disgrace only when he has enough clothing and food’ is attributed to Guan Zhong (730–645 BC), the prime minister of a ducal state. He implemented policies that would bring stability to people's lives; these policies included the promotion of agriculture, monopolizing salt and iron, state intervention in the public distribution system, maintenance of a balanced budget and the consolidation of taxation and military services. Practical policies were further developed by many politicians in the Warring States Period (475 –221 BC). These became part of the arsenal of policy measures adopted by the administrators of the unified state of successive dynasties from the Qin (221–206 BC) to the Qing (AD 1644–1911). A text named after Guan, Guan Zi, was compiled in the Western Han Period (206 BC–AD 8). This contains detailed discussions of the practical economic policies of ancient China.

In ancient China, before the unification by the Qin, political control over merchants was not strict. Wealthy merchants in the pre-Qin period were vividly described in Records of the Historian (‘Shiji’). The editor–historian, Sima Qian (145–87 BC) clearly favoured a liberal economic policy that permitted the innovative activities of talented merchants.

**Competitive schools in ancient China**

Confucius (551–479 BC) also recognized the quest for wealth as a natural human trait. However, he stressed that the teachings of morality (Ren) should control the quest for wealth. According to him, superior men can understand and adhere to the virtues of righteousness and benevolence in their deeds, while inferior men (common people) cannot. The former belong to the ruling class and the latter are the ones who are ruled, who must be guided by the former. Confucius stressed the educational effect of a ruler on the people's perception of societal order. He was opposed to the levying of heavy taxes and unnecessary state intervention, since that might jeopardize the common man's standard of living. He maintained that a peaceful and fair reign of a virtuous ruler fosters allegiance. As long as people follow the basic order of society, the wealth of the state emerges as a spontaneous result of the growth in the population.

Meng Ke (c. 390–c. 305 BC), whose name is often mentioned together with Confucius, strictly excluded the consideration of material benefits from the political discourse of superior men. During his first meeting with the king of Liang, Meng declared that he spoke only of ‘righteousness’ (Yi) and not of ‘benefits’ (Li). However, he also stated that the dominance of ‘righteousness’ presupposes the maintenance of a ‘permanent property’ of the people in order to secure the morality of the people (Mencius).

Mo Di (c. 468–c. 367 BC) and his School (Mohists) grounded their altruistic teaching on the extended approval of ‘benefits’. They believed that economic transactions are acts of ‘mutual benefit’, which will eventually support the doctrine of ‘universal love’. From a utilitarian viewpoint, they regarded righteousness as a material benefit; this is in clear contradiction with the Confucians. Mohists further advocated a ban on war and simple burial. Apparently, this School originated from the craftsmen who
China, economics in: The New Palgrave Dictionary of Economics

were not entirely integrated into the social hierarchy existing in the pre-Qin period. Legalists such as Shang Yang (c. 390–338 bc) and Han Fei (c. 310–238 bc) differed from the Confucians with respect to the measures to be adopted for guiding people. They stressed the effective control of people by the strict enforcement of punishment. They prioritized agricultural production and considered manufacturing and commerce as tertiary activities. The Legalists were prepared to collaborate with princes and politicians who sought to enhance the wealth and power of their states.

Omnipotent state vs. virtuous reign

Ancient China was unified by the Qin dynasty, which had adopted the policies of Legalists. The first emperor of the Qin (221–206 bc) suppressed Confucians who criticized his reign as measured against the criterion of virtuous ruler. However, under the following dynasty, the Han, Confucianism established its position as the state orthodoxy, which continued until the end of the Qing dynasty. Still, a Legalist direction survived in the pragmatic mentality and policies of administrative bureaucracy. Thus, Chinese political history witnessed repetitive conflicts between the moralistic direction of Confucianism and the bureaucratic administration in the direction of Legalists.

One of the most noteworthy debates was the dispute on salt and iron (81 bc), in which San Hongyoung (152–80 bc) – the finance minister of the Western Han dynasty – had to defend his policy against the criticism of Confucian scholars. In order to compensate for the deficit in the state finance caused by an expansionary policy, San extended the state monopoly of salt and iron and introduced a state-managed storage and distribution system. Such a system could be legitimized if it was successful in guaranteeing the nationwide provision of necessaries and a stabilization of their prices. However, coupled with a heavy tax burden, San's system made a devastating impact on the nation. Confucian scholars voiced the dissatisfaction of the people and pressed for the abolition of San's system.

A similar constellation appeared in the dispute around the economic reforms of Wang Anshi (1021–86). Wang's attempt to consolidate public finances by suppressing the annexation of lands by rich families and establishing a strict taxation system was opposed by traditional scholars, who were in alliance with the richer families.

Apart from the taxation and market control, Chinese administrators showed their expertise in the area of currency. They are the first to have issued paper money (Jiao Zi) in the 11th century. The Yuan dynasty (1271–1368) adopted the idea of inconvertible notes in its monetary system. The paper currency ordinance of 1287 drafted by Ye Li (1242–92) contained sound measures to maintain the value of paper money in relation to the regularly inspected silver reserve fund. This paper currency system of the Yuan dynasty exerted a certain influence over the currency system of other countries through the commercial networks under the grand Mongolian rule.

The demand for equalization

Support for equality is another persistent trait of traditional Chinese economic thought. The equalization of land and wealth was a typical demand raised by numerous peasant rebellions. The Taiping Rebellion (1851–64) put into effect an equal distribution of land, and the rural revolution under Mao Zedong's (1893–1976) directive displayed a similar kind of egalitarianism. However, the ideal of equality in the distribution of wealth can also be found in Confucian classics. Confucius himself remarked that rulers
must worry ‘not about the scantiness of wealth but its inequality of distribution’ since ‘there will be no feeling of poverty under equal distribution’ (Analects). Here, equality is appreciated with respect to its ability to maintain harmony and tranquillity among the ruled. Meng Ke also proposed an egalitarian Jin land system, in which peasants, who were allotted equal amounts of land, jointly cultivated public land for the sake of generating public finance. This proposal was revived several times by reformist politicians as well as by egalitarian rebels.

A vision of an egalitarian ideal society, the Great Harmony (Datong), where neither private property nor egoistic interests exist, is mentioned in the Confucian classic Li Ki. Xiaokang, a society in which the people are guided by order and institutions is not an ideal but a second best, suited to the age of a civilized society. However, towards the end of the Qing dynasty, Kang Youwei (1858–1927), a reformist politician and scholar, revived the ideal of the Great Harmony to regenerate the whole nation.

Preconditions for Chinese modernization

The nationwide examination system for the recruitment of government officials was established under the Sui dynasty (581–618) and continued until 1905. Based on the Confucian orthodoxy, it moulded the thought of Chinese intellectuals over a millennium. However, Confucian orthodoxy was not totally exempt from change. In addition to the ideas that had emerged in the ancient period, it absorbed heterogeneous ideas from other intellectual schools of thought, such as Buddhism and Taoism. The effect of the development of a rationalistic Neo-Confucianism guided by Zhu Xi (1130–1200) and the emergence of the countervailing school of Wang Yangmin (1472–1528), which introduced an inner integrity to Confucianism, are interesting issues that need to be further researched. Towards the end of the Ming dynasty (1368–1644), these developments promoted a critical attitude towards the traditional order of the empire. Huang Zongxi (1610–95) and Wang Fuzhi (1619–95) developed a utilitarian concept of hierarchy based on the private property and self-interest of the people. Further, the diffusion of the teaching of Wang Yangmin (Xinxue) that stressed purity of mind nourished the morality of the merchants (Yu, 1987). However, these developments were not sufficient to modernize the Chinese intellectual tradition from within. The landlord class that recruited state officials through a nationwide examination formed the ruling alliance of the society. Merchants had no other option but to join this alliance as subordinate participants. However, the intellectual legacies of old China were preconditions for the Chinese to cope with the modernization that was initially forced on them by external forces.

Introduction of Western economics

It was the publication by Wei Yuan (1794–1857) of the Geography of the Maritime Countries (1843) that initiated the movement among Chinese intellectuals of learning from the West. However, Western economics was not introduced until two decades later. Using H. Fawcett's A Manual of Political Economy as a textbook, W.A.P. Martin, an American Christian missionary, began a course on policies for the wealth of nations at a government school in Beijing in 1867. Later, in 1883, this course was translated and published in Shanghai under the same title. A second significant contribution pertaining to the translation of Western economics was that of a British missionary, J. Edkins, who translated W.S. Jevons's Primer of Political Economy into Chinese. This translation was published in 1886 with the
Chinese title, *Policies for the Wealth of Nations and Support of People*. Fawcett and Jevons were neither mercantilists nor interventionists. However, both Chinese titles suggest that the Chinese people of this period regarded Western economics as a policy measure to strengthen the state.

Between 1901 and 1902, Yan Fu (1853–1921) published the translation of Adam Smith's *Wealth of Nations* in Shanghai under the title *Elements of Wealth* (‘Yuan Fu’). In his commentary on this translation, Yan clearly stated that the principles of economics advocate free competition, are against state intervention and limit the scope of state involvement in those tasks that are not suited for the private sector. However, most Chinese intellectuals, including Yan himself, accepted the theory of liberal economics because of its contribution to the recovery of the power of the nation (Schwartz, 1964).

However, the principles of liberal economics do not appear to have contributed much to the modernization of China. Late 19th-century reformers had to fight against the obsolete bureaucracy of the Qing dynasty. As was typical of revolutions in the 20th century, the social dimension of the Chinese revolution increased in significance with the passage of time. Democrats and liberals worked together on the cultural front of the 4 May Movement (1919). However, this collaboration soon broke down, since democrats shifted their position to that of Communist revolutionaries and began to attack liberals as ‘bourgeois intellectuals’.

The ideology of Western socialists and social reformers was introduced by Sun Yatsen (1866–1925) through his ‘Three People's Doctrines’. Sun regarded Western capitalism as the root cause of the social problems in the West and searched for an alternative route towards economic development for China. He recognized Henry George's idea of land nationalization and the German socialist idea of capital regulation. After experiencing the state of anarchy that followed the Xinhai Revolution (1911), he sympathized with the Russian Revolution and led his Nationalist Party, the Guomindang, in cooperation with the Communists.

**Period of the Republic of China**

Despite continued struggles among the warlords and an unstable security environment in both domestic as well as external affairs, the period of the Republic of China (1912–49) marked the emergence of economic academism in China. Most of the renowned universities of today originated in this period, and specialized economists, some of whom were educated in the United States, Europe and Japan, began to teach there. There were 16 Chinese publications on economics in the decade following Yan's translation of Adam Smith's *Wealth of Nations*; this number increased to 20 between the 1911 revolution and the 4 May Movement. It further increased to 228 in the decade following 1919 and to 1,116 after 1929 (Shanghaishi, 2005, pp. 114–15).

The Chinese Economic Society was established in 1923, and after a decade its membership amounted to c. 600. In 1930, it launched the quarterly journal *Jinngjixue Jikan* in Shanghai. Ma Yinchu (1882–1982), a Ph.D. holder from Columbia University who had taught economics at Beijing University since 1915, was its president. He served the Guomindan government as its economic advisor and published his views on the currency problems, banking and public finance in China. The Chinese economists of this period actively participated in policy discussions, such as the currency reforms of 1936, financial problems and industrial development plans. However, it was the problem of agriculture that most concerned Chinese economists. A large-scale
research project in rural economy headed by Chen Hansheng (1897–2004) gave birth in 1933 to the Research Forum in Chinese Rural Economy. This forum gathered a membership of about 500 members and trained economists who continued their research activity in the post-1949 period. The most prominent member among them was Xue Muqiao (1904–2005), who edited *Rural China* (*Zhongguo Nongcun*) from 1934.

Social scientists influenced by Marxism eagerly discussed the nature of existing Chinese society (1929–1931). This debate contained a political element since those who supported the Chinese Communist Party (CCP), which was founded in 1921, regarded Chinese society to be a semi-feudal and semi-colonized society, whereas the Trotskyists emphasized the dominance of the capitalistic elements. Such debates on the nature of Chinese social history and its periodization (1931–3) and on the Asiatic mode of production continued in the field of economic history.

**Marxist monopoly under the PRC**

The People's Republic of China (PRC) started in 1949 with the programme of the ‘New Democracy’ that was to be based on the alliance between Communists and democrats from all sections of the society. The government requested non-resident Chinese scholars to participate in the reconstruction of China. Ma Yinchu, who was exiled to Hong Kong as a result of a dispute with the Guomindang government, returned to take over as the president of Beijing University. Initially, several of his colleagues were those who had been educated in American universities. Thus, in the beginning of the PRC, universities in China had non-Marxian economists on their staff. However, the socialist reconstruction of academic system based on the Soviet–Russian model, and the intensifying confrontation with the United States, soon deprived ‘bourgeois economists’ of freedom. Abridged translations of Russian textbooks pertaining to Marxian economics became the standard education materials. In 1957, when the CCP declared a liberal policy towards intellectuals with the appealing phrase ‘Let a hundred flowers blossom’, Ma proposed his idea of population restraint to the People's Congress of the PRC. This offended Mao Zedong's positive view of population growth. The ensuing continuous attacks on ‘Malthus in China’ signalled the expulsion of non-Marxian ideas from the academic world under the PRC.

According to the original concept of the New Democratic Economy, the development of capitalism in China, except for ‘monopoly capital’, was to be welcomed as the basis for initiating future socialist transformations. However, in 1953 the success of the agrarian reforms motivated Mao to practise ‘the solution to the problem of ownership’. Through the socialization of the ownership of the means of production, a Soviet Russian-type of planned economy was established in the sectors of industry and commerce during 1953–6. This was followed by the establishment of people's communes in the rural areas in 1958.

**Reform economists in China**

The first criticism levelled against a centrally planned economy also emerged in the years of ‘Let a hundred flowers blossom’. In 1956 and 1957, Sun Yufang (1908–83) proposed an economic model of decentralization with the use of profit targets in the management of manufacturing sector. Sun was a Marxian economist who had studied in Moscow. He grounded his proposal on the validity of the ‘law of value’ in a socialist economy, which is distinguished from the ‘law of market’. In this respect, the views
of Gu Zhen (1915–74) were more progressive, in that he openly criticized the abolition of the market mechanism under socialism. During the wave of the Anti-Rightist Struggle that occurred during the latter half of 1957, Sun and Gu were labelled ‘revisionist’ and ‘bourgeois rightist’ respectively. Chinese economists were aware of the shortcomings of a Russian-type planned economy and the need for reform. However, the ideological rejection of the ‘material interest’ as a tool of ‘revisionists’ prevented the introduction of reforms in the management system of state-owned enterprises (SOEs). Ideological politicians stuck to the appeal to ‘spiritual incentive’. Reforms were then directed towards an administrative decentralization, in which powers and benefits were divided among various administrative organs.

It was only after the declaration of the end of the Great Cultural Revolution (1966–1976) and with Deng Xiaoping (1904–1997) taking over the leadership of China that the damage caused by excessive decentralization and the need for management reforms were seriously taken into consideration. After the strategic decision of the CCP for economic reforms and an ‘open door’ policy, China implemented various policies such as the creation of special economic zones and township and village enterprises as well as the approval of private enterprises and households contracting in agriculture. Under the concept of the ‘planned commodity economy’ (1984), the market economy was theoretically subordinate to the planned economy. The existence of private sectors was legitimizad by the theory of the ‘early stage of socialism’ (1987). At last, in the 1990s, by the definition of the ‘socialist market economy’ (1992), the private sector was clearly approved as the main and normal element of Chinese socialist economy.

A group of veteran economists, namely, Xue Muqiao, Du Rensheng (born 1913), Yu Guangyuan (born 1915), Liao Jili (1915–93), Lieu Guogang (born 1923), and others contributed to the transformation of the concept of ‘socialist economy’. In the early 1980s, they re-examined the orthodox and heterodox texts of Marxism, studied reform economics of former socialist eastern European countries, and endeavoured to draw conclusions from the empirical research on agriculture and manufacture sectors. They formed the ‘theory of the socialist commodity economy’.

After Mao's death and the end of the Great Cultural Revolution, academic economists soon regained their energy. The Chinese Academy of Social Sciences (CASS) was established in 1977. The oldest Shanghai Economics Society, whose origin can be traced back to 1950, resumed its activities in 1978. In the same year, the Chinese Research Forum of Overseas Economics was established and began to work for the diffusion of the ‘Western’ (non-Marxian) economics among Chinese economists.

In the 1980s, Chinese economists recovered their communications with the world community of economists. The government invited renowned Western economists to academic conferences pertaining to the economic reforms in China. It began to send young people to the graduate courses of top Western universities, and encouraged them to assimilate advanced analysis of modern economics. By the mid-1990s, China already had a group of talented economists who could analyse economic reforms in China in a manner similar to the Western (non-Marxian) economists. In the fields of research, economic teaching, and policymaking, the activities of non-Marxian economists became more significant with each passing year. Thus, the monopoly of the Marxian economists was broken.

**Present situation of economics in China**

The ideological/political control exercised by the CCP over Chinese intellectuals had been considerably reduced at the outset of the 21st century. Economists in China can now keep themselves abreast of the
latest developments in the field of economics. However, the following three features are noteworthy when compared with economics in other countries.

The first is the peculiar position of Marxian economics in China. At present, it is clear that Marxian economics is just a sub-area in the whole gamut of research activities undertaken by Chinese economists. It is therefore symbolic that the Marxian economists organized themselves into a society named the Chinese Forum for the Study of Capital (founded in 1981). However, Marxian economics still influences society by two privileged routes. One is that Marxian economics continues to be an obligatory course of political economy (Zhengzhi Jingjixue) in most Chinese universities. It is virtually a part of the political education imposed on academicians. The other route is the ideological function for the ruling CCP. The CCP needs Marxian economists to defend its policy on ideological grounds.

The second noteworthy feature of Chinese economics is the focus on institutional economics and political economy. Leading economists of the post-Great Cultural Revolution generation such as Lin Yifu (born 1952) and Fan Gang (born 1953) adopted the framework of institutional economics. Lin attributed the success of the Chinese economy after the implementation of the ‘open door’ policy to the switch of the development strategy and the institutional reforms accompanying it. Fan provided an analysis of the incremental reforms in China by applying the public choice approach. The theories pertaining to modern institutional economics – transaction cost theory, property rights theory, contract and corporate governance theory, and comparative institutional analysis – are widely accepted by Chinese economists.

Lastly, a new divide between the supporters of the prevailing liberal policy and its critics emerged in 2004, and a debate between these two groups has continued since then. First, Lang Xianping (born 1956), a professor at the Chinese University in Hong Kong, attacked managers of the firms whose stocks were newly listed on the stock market. They were charged with smuggling national property by the application of various techniques such as management buyouts. His attack on the privatization policy encouraged economists who were concerned about the increasing inequality in society and diminishing state intervention. They criticized over-hasty privatization and demanded a policy that would enhance the level of equality in society. They stressed the need to implement reforms in the field of social policy, and rejected the unconditional integration of the Chinese economy within the global market. Liberal economists, who stressed efficiency, rebutted them. Another group of economists declared themselves as taking a middle-of-the-road position. The government is said to have attentively followed the debate.

Chinese economic reforms

Loren Brandt and Thomas G. Rawski
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Why did China's modest reforms unleash an enormous boom? Three decades of socialist planning created vast untapped potential. China captured this potential by focusing on ‘big reforms’ linked to incentives, markets, prices, mobility, openness and competition. Advances in these areas created sufficient momentum to overcome the drag associated with remaining distortions and institutional shortcomings. China's political economy, which incorporates substantial local autonomy, facilitated experimentation that repeatedly identified feasible reform paths. Because China's political economy delivers undesirable outcomes along with rapid growth, and because China's success is linked to unique historical circumstances, the beneficial outcomes associated with Chinese policies and institutions may be limited in time and space.

Keywords

agricultural productivity; China, economics in; Chinese economic reform; collectivization; decentralization; dual price system; planning; rural–urban migration; socialist market economy (China); Cultural Revolution (China); Great Leap Forward (China)

Article

Since the late 1970s, China's economic performance has astonished the world. Official figures show that, after adjusting for inflation, China's GDP grew at an annual rate of 9.7 per cent between 1978 and 2006, and at a rate of 8.4 per cent in per capita terms (Yearbook, 2006, p. 60; National Bureau of Statistics, 2006). By 2006, the Chinese economy, measured in terms of purchasing power parity, was the world's second largest, behind only the United States: per capita incomes, measured on the same basis, rose from 324 dollars to 5,772 dollars between 1978 and 2004 (Heston, Summers and Aten, 2006). China's new dynamism includes a major shift towards intensive growth, with productivity change, which had contributed negatively to Chinese growth between 1957 and 1978, accounting for 40 per cent of overall
Reform began in the late 1970s. The impetus for modifying the plan system came from two sources: general awareness that China's neighbours were running far ahead in the economic sphere, and stagnation of living standards, especially China's persistent problems with food supply. The initial objective was to improve economic results under the system of central planning.

**Initial reform efforts**

Not surprisingly, early reform efforts focused on agriculture. Starting in 1978, household cultivation swiftly replaced collective tillage as the norm in China's vast farm sector, as hundreds of millions voted with their feet to abandon collective farming, the central feature of the people's communes. Introduction of the household responsibility system meant that farmers could claim the fruits of extra effort for themselves. This brought an immediate multiplication of work effort, which was further encouraged by modest relaxation of restrictions on marketing and price flexibility, and by a considerable increase in procurement prices (Sicular, 1995). The result was a sudden upsurge of farm production and productivity (Lin, 1992). With the expansion of food supply, millions of farmers no longer needed to work the land and so began to move into non-farm employment. Improved diets raised the energy levels and hence the productivity of formerly undernourished villagers. Relaxation of efforts to enforce local self-sufficiency in favour of historic patterns of crop specialization, along with new opportunities to diversify into animal husbandry, horticulture, and aquaculture, also contributed to steep gains in farm output (Lardy, 1983).

The response to agricultural reform quickly spread beyond the farm sector. Rural factories, which had enjoyed a brief boom during the Great Leap Forward of 1958–60 (a massive and chaotic push to organize villagers into communes and to transfer rural labour into steel and other industries), suffered considerable retrenchment during the 1960s, and then expanded rapidly during the 1970s. Following the revival of agriculture, collectively owned rural industry, now fortified by greater access to the cities, rising rural incomes, increased supplies of agricultural inputs, and throngs of job-seekers, bounded ahead. In addition, new freedom encouraged a wide range of non-farm self-employment and family businesses. The resulting shift out of farming initiated what eventually became a massive exodus of labour from the countryside.

The explosive response to rural reform spurred officials to press forward with urban initiatives focused on ‘enlivening’ state-owned enterprises. While these early measures achieved only limited progress towards their main objective, they benefited rural and urban collective industry by opening new markets as well as new sources of materials, subcontracting opportunities, and technical expertise.

As the influence of markets, price flexibility, and mobility expanded, a separate strand of reform began to move China's isolated system towards greater participation in international trade and investment. China's leaders agreed to establish four tiny ‘special economic zones’ in the southern provinces of Guangdong and Fujian. Initial operations in these zones seemed directionless and inconsequential, but the arrival of ethnic Chinese entrepreneurs, most from Hong Kong and Taiwan, turned the zones into drivers of regional and eventually national growth. This novel combination of low-cost Chinese labour with the market knowledge and entrepreneurial capabilities of overseas Chinese businessmen gradually developed into an export bonanza that nudged China towards its subsequent embrace of economic globalization.
Although the limited extent of domestic reform restricted the initial response to growing openness, the buoyant prosperity of the new zones prompted cities along the coast, and eventually across the nation to clamour for access to the same tax, legal, and regulatory concessions that had powered their growth. China's initial reforms focused on limited changes directed at specific sectors. These changes proved sufficient to accelerate growth despite the continued importance of state ownership, price controls, material-balance planning, and other key features of the socialist system. Early reform was particularly successful in removing long-standing constraints formerly imposed by limited availability of food and of foreign exchange.

Further reforms: expanding the cage

During this period, China's gathering boom encouraged a growing array of jurisdictions, constituencies, and interest groups to pursue the advantages enjoyed by reform participants, including expanded managerial autonomy and access to the special economic zones. The image of China's economy as a caged bird advanced by Chen Yun, an economic specialist within the leadership group, illustrates the underlying economic thinking (Lardy and Lieberthal, 1983). Chen argued that expanding the cage (reform) allows the bird to beneficially spread its wings; an overlarge cage threatens loss of control – thus the slogan ‘planned economy as the mainstream, market allocation as a supplement’.

Implementation of the dual price system, which partitioned allocation of most commodities into plan and market components and allowed the distribution of after-plan residuals at increasingly flexible prices, stands as the central policy achievement of this period. The expansion of market transactions began to whittle away at long-standing barriers to mobility, which had restricted the transfer of labour, capital, commodities and ideas across administrative boundaries, with negative consequences for growth of output and productivity.

Developments in the international sphere, including the continued growth of foreign trade, the northward spread of special zones, and the expansion of foreign direct investment, now involving multinational corporations as well as overseas Chinese entrepreneurs, extended the impact of market forces. The growth of cross-border transactions and the increased presence of foreign business operations on Chinese soil intensified pressures for contract arbitration, codification of urban land-use rights and other legal and institutional reforms needed to facilitate new activities.

The main impact of these reforms fell on flows – of labour, commodities, profits, and new investments. New entrants to the workforce, for example, including college graduates, were increasingly left to find their own positions, rather than receiving job assignments from local labour bureaus. Existing stocks, including assets or employees of extant firms, especially in the state sector, were not yet exposed to the full impact of market forces. Mergers appeared, but only on a microscopic scale. Despite the enactment of bankruptcy legislation, floundering companies rarely disappeared. Nor did redundant workers face the sack, although the ‘optimal labour programme’, which invited managers to identify essential and surplus workers, foreshadowed the mass layoffs of the late 1990s.

Economic reforms since 1992: towards a ‘socialist market economy’

The brief recession, triggered by efforts to quell inflation during the late 1980s, together with the anti-
reform backlash and pullback of foreign investment that followed the June 1989 suppression of popular unrest, slowed both growth and reform. The setback, however, was short. Deng Xiaoping's call for expanded reform during his southern tour of 1992, together with the Communist Party's 1992 decision to pursue a socialist market economy with Chinese characteristics gave fresh impetus and as well as new direction to economic reform.

The Party's 1992 decision replaced vague ideas of ‘doing better’ with a clear reform objective: a market economy in which the eventual role of the state will resemble the current circumstances of major economies such as those of France or Japan: macroeconomic management; regulation of health, environment, and so on; and strategic planning, with other functions explicitly assigned to the sphere of market determination.

Although the 1992 decision is a statement of principle rather than a description of reality, the ensuing 15 years witnessed decisive strides towards market outcomes, which we summarize in terms of four major shifts:

1. **From plan to market**: price liberalization extended beyond the substantial achievements of the first reform decade: despite significant exceptions (energy, credit, foreign exchange) supply and demand now determine most prices (Li, 2006, pp. 104–7). The growing influence of market forces brought a considerable (but incomplete) hardening of budget constraints, even in the state sector. Market pressures compelled the dismissal of more than 50 million workers, most from state-owned factories. Mergers and acquisitions extended the reach of market pressures to much of China's capital stock. Barriers to the free flow of labour and goods continue to recede, and migrant workers have begun to attain normal citizenship rights in China's cities and towns. Growing expansion of wage differentials and of income inequality reflect the new prominence of market outcomes.

2. **From village to town and city** and from agriculture to industry and services. The primary sector's GDP share dropped from 27.9 per cent in 1978 to 11.8 per cent in 2006. Following the departure of 150–200 million villagers from the land, survey data indicate that the primary sector's labour force share has declined from 69.2 per cent in 1978 to 31.8 per cent in 2004 (National Bureau of Statistics, 2006; Yearbook, 2006, p. 58; Brandt, Hsieh and Zhu, 2008).

3. **From public to private ownership**. At the start of reform, the public sector (including collectives) held nearly all China's fixed capital. The growth of private business, while rapid in percentage terms, started from a tiny base. It was only from the late 1990s that the non-public sector, swollen by the privatization of rural collective enterprises, the transfer of (mostly small and medium) state-owned firms into private hands, and the rapid expansion of direct foreign investment, began to take on a prominent role in the national economy. The share of state-owned firms in industrial output fell from 81 per cent to 55 per cent between 1980 and 1990, and to 15–35 per cent in 2005/6 (depending on the treatment of state shareholdings; see National Bureau of Statistics, 2006; Perkins and Rawski, 2008). The pace of change has accelerated: by 2003, the private sector's GDP share had risen to 59.2 per cent (OECD, 2005, p. 125). The state sector's share in industrial output and non-farm employment during 2004/5 declined to 15.2 and 13.1 per cent (Yearbook, 2006, p. 505; Brandt, Hsieh and Zhu, 2008). Following lengthy reform efforts China's major banks and financial firms have begun to sell partial ownership stakes to overseas
