Radner (1972) establishes the existence of an asset market equilibrium (for either nominal or real assets), assuming an exogenously given bound on short sales. Such a constraint is unsatisfactory because if the constraint is binding then the equilibrium depends on an arbitrarily given, perhaps not economically meaningful, bound. For economies in which all assets are nominal, Cass (1984), Werner (1985) and Duffie (1987) show that short sale bounds are not necessary. The case of real assets is more subtle, because the possibilities for wealth transfer may depend on commodity spot prices. Suppose, for example, that trading takes place today and tomorrow, that there are two possible states – rainy and sunny – of the world tomorrow, and that there are only two assets, one promising delivery of (the value of) one bushel of wheat in each state, the other promising delivery of (the value of) one bushel of corn in each state. If the ratio of the price of wheat to the price of corn is different in the rainy state than in the sunny state, then the dividends of these assets are linearly independent, and the market is complete; if the ratio of the price of wheat to the price of corn is the same in the rainy state as in the sunny state, then these assets are collinear and the market is incomplete. In the former case, the space of wealth patterns that can be achieved by trading assets is two-dimensional; in the latter case, it is one-dimensional. In particular, consumers’ budget sets are discontinuous functions of commodity spot prices. (For financial assets, dividends are by definition independent of prices, so this phenomenon cannot arise.) As Hart (1975) shows, this phenomenon leads to examples in which no equilibrium exists. However, Duffie and Shafer (1985; 1986) show that equilibrium does exist for generic values of the parameters. (The proof...
uses degree theory, because familiar arguments based on the Kakutani fixed point theorem are not
applicable. Elegant fixed point proofs were later discovered by Hussein, Lasry and Magill, 1990, and
argument.) For more complicated assets, such as options, equilibrium may fail to exist for an open set of
parameters (Ku and Polemarchakis, 1990). The volume by Magill and Quinzii (1996) presents an
excellent extended discussion and bibliography.
The incomplete markets model is attractive in part because it provides a framework in which to model
and address many interesting economic phenomena and questions. For instance:

- When asset markets are incomplete, equilibrium commodity allocations need not be Pareto
  optimal. Indeed, Geanakoplos and Polemarchakis (1986) show that equilibrium commodity
  allocations will typically fail to be even constrained optimal: a social planner could improve
  welfare of all participants, even if constrained to use only existing asset markets to transfer
  wealth.
- Enlarging the set of available assets increases trading opportunities, so it is tempting to believe
  that it improves welfare. A surprising example due to Hart (1975) shows that enlarging the set of
  available assets may make everyone worse off; Elul (1995) and Cass and Citanna (1998) show
  that the possibility of such Pareto worsening is a robust phenomenon.
- By definition, the dividends of financial assets are independent of commodity spot prices – but
  the purchasing power of these dividends may depend on price levels. In a market with only
  financial assets, there is nothing to connect price levels in one date-event to price levels in
  another, so equilibrium asset prices and purchasing power are generally indeterminate; this leads
  to robust indeterminacy of equilibrium prices and consumptions as well (Balasko and Cass, 1989;
  Geanakoplos and Mas-Colell, 1989). For real assets, the purchasing power of dividends is
  independent of price levels, and equilibrium prices and consumptions are generically determinate
  (Geanakoplos and Polemarchakis, 1986).
- Default is suggestive of disequilibrium and inefficiency. Dubey, Geanakoplos and Shubik (2005)
  show, to the contrary, that default is compatible with equilibrium and may in fact promote
  welfare. Zame (1993) uses a similar framework to underscore the positive role played by default
  in expanding the effective span of assets when markets are incomplete.

A recurring theme in the study of asset markets is the importance of re-trading long-lived assets. The
power of frequent trading underlies both the celebrated option-pricing formula of Black and Scholes
(1973) and portfolio insurance (Leland, 1980). (Cox, Ross and Rubinstein, 1979, present a more easily
understood discrete time version.) In a general discrete time model, Kreps (1982) argues that, if the
number of long-lived assets is at least as great as the degree of uncertainty from one date-event to the
next, then it will generically be possible to replicate any wealth pattern by frequent trading of a few long-
lived assets. In particular, asset market equilibrium will, in this circumstance, coincide with complete
markets equilibrium. Duffie and Huang (1985) identify an appropriate of Kreps's spanning condition in
the continuous time setting (the setting most used in finance) and proves the corresponding
generalization of Kreps's dynamic completeness result.
In an infinite-horizon setting, the existence of equilibrium when markets are incomplete requires ruling out the possibility of perpetual borrowing to pay each period's debts; the ‘right’ conditions (which may be expressed as transversality conditions, as limits on short sales, or as debt constraints) were identified (independently) by Magill and Quinzii (1994), Levine and Zame (1996) and Hernandez and Santos (1996).

The infinite-horizon setting is of particular interest because of its connection with asset-pricing. Mehra and Prescott (1985) show that historical returns on equity (stocks) cannot be reasonably explained within a complete-markets, infinite-horizon, asset-pricing model in the style of Lucas (1978). US data, (real) returns on safe assets (such as Treasury bills) are about one per cent and returns on equity are about seven per cent. With reasonable choices for time preference and risk aversion, the model suggests that returns on safe assets should be about two to three per cent and that returns on equity should be about three to four per cent; even extreme specifications of risk aversion do not yield an equity premium (that is, a rate of return on equity in excess of the return on safe assets) above two per cent. For overviews see Kocherlakota (1996) and Cochrane (2001).

A plausible objection to the complete markets assumption made by Mehra and Prescott is that labour income is not readily tradable; however, computationally tractable models with plausible parametrizations of untradable labour income do not appear to deliver a substantially higher equity premium (Telmer, 1993; Lucas, 1994; Heaton and Lucas, 1996). On the other hand, Constantinides and Duffie (1996) show that an arbitrary equity premium can be generated if enough income is untradable. More precisely, given an aggregate income process and any system of asset prices that are consistent with time preference, there is a distribution of untradable income for which the given prices constitute an equilibrium. The argument of Constantinides and Duffie relies on individual shocks that are permanent; whether that assumption is necessary and whether the true distribution of labour income (or other untradable income) is sufficient to generate the observed equity premium is a subject of considerable interest (Levine and Zame, 2002; Cogley, 2002; De Santis, 2005).

An interesting alternative explanation for the divergence of observed asset prices from theoretical predictions is that markets are complete but participation is not. Alvarez and Jermann (2000), building on a model of Kehoe and Levine (1993), explore the implications for asset pricing of an environment in which imperfect enforcement generates endogenously incomplete participation. See also incomplete markets.

Infinitely many commodities

The description of a commodity includes its physical characteristics and the date, location and state of the world at which it will delivered. If time is modelled as continuous or the horizon is modelled as infinite, if uncertainty is modelled by the use of an infinite state space, or if commodities are modelled as having a continuous range of possible characteristics, then the number of commodities will be infinite. Examples include:

- the use (especially in macroeconomics and asset pricing) of $\mathcal{C}^\infty$ (the space of bounded sequences) to model of consumption and trade over an infinite time horizon (Bewley, 1972;
general equilibrium (new developments): The New Palgrave Dictionary of Economics

Lucas, 1978; Mehra and Prescott, 1985);

- the use (especially in finance) of $L^2(\Omega, F, P)$ (the space of random variables with finite mean and variance on some probability space $(\Omega, F, P)$) (and related spaces) to model choice and asset trading under uncertainty (Black and Scholes, 1973; Merton, 1973; Duffie and Huang, 1985);

- the use of $C[0, T]$ (the space of continuous functions on the interval $[0, T]$) or $L^\infty(\mathbb{R}^+)$ (the space of bounded functions on the non-negative real numbers) to model consumption and trade in a continuous-time framework (Gabszewicz, 1968; Bewley, 1972); and

- the use of $M(K)$ (the space of (signed) measures on some space $K$ of commodity characteristics) to model finely differentiated commodities (Mas-Colell, 1975; Dixit and Stiglitz, 1977; Hart, 1979; 1985a; 1985b; Jones, 1984).

The Arrow–Debreu–McKenzie framework is powerful because it can be applied in many different economic environments, so it is natural to look for an extension of this framework which applies in the models above (and hopefully in many others).

In looking for such an extension, several problems arise. The most obvious problem is that neither budget sets nor feasible sets need be compact (in the given topology); thus the existence of optimal choices is immediately in doubt. An approach that avoids this difficulty, and is quite generally applicable, is to make use of the fact that most infinite dimensional vector spaces admit many topologies. For example, $L^\infty = L^\infty(\mathbb{R}^+)$ admits a norm topology (where $\|f\|$ is the essential supremum of $|f|$), but it also admits two weaker topologies that arise from viewing $L^\infty$ as the space of continuous linear functionals on $L^1 = L^1(\mathbb{R}^+)$ (the space of integrable functions on $\mathbb{R}^+$): $\sigma(L^\infty, L^1)$ (the weak topology) is the weakest vector space topology on $L^\infty$ for which $L^1$ is the space of continuous linear functionals, and $\tau(L^\infty, L^1)$ (the Mackey topology) is the strongest vector space topology for which $L^1$ is the space of continuous linear functionals. The weak topology is weaker than the Mackey topology which is in turn weaker than the norm topology (Dunford and Schwartz, 1957). The applicability to equilibrium analysis comes from three facts:

1. (i) in the weak topology, closed and bounded sets are compact;
2. (ii) convex sets that are closed in the Mackey topology are also closed in the weak topology;
3. (iii) for preference relations, continuity in the Mackey topology can be interpreted as impatience.

In view of (iii), Mackey continuity of preferences is an economically meaningful and natural assumption; in view of (ii), preferences that are convex and Mackey continuous are also weakly upper semi-continuous; in view of (i), such preferences admit optimal choices whenever feasible sets are closed and bounded. (This interplay between topologies is a familiar functional-analytic theme.)

The second problem that arises is that sensible-looking preference relations may not admit supporting prices. When the commodity space is finite-dimensional and preferences are convex, the separation theorem guarantees that a supporting price at a consumption bundle $x$ can be constructed as a linear functional separating $x$ from the set $p(x)$ of bundles strictly preferred to $x$. When the commodity space is infinite dimensional, the separation theorem only guarantees the existence of a linear functional
separating $x$ from $p(x)$ in case $p(x)$ has non-empty interior. In many spaces, this is problematical because the positive cone (the most natural consumption set) has empty interior, whence, *a fortiori*, the strictly preferred set also must have empty interior.

Mas-Colell (1986) shows by example that supporting prices need not exist, and identifies a class of preferences for which supporting prices *do* exist. Say that a preference relation defined on the positive cone $X_+$ of some commodity space $X$ is *uniformly proper* if there is some vector $v \in X_+$ and some open cone $C$ containing $v$ such that for each $x \in X_+$ every bundle in $(x - C) \cap X_+$ is strictly dis-preferred to $x$. (The non-existence of supporting prices may be interpreted as unboundedness of marginal rates of substitution; uniform properness may be interpreted as a bound on marginal rates of substitution.)

For commodity spaces that are topological vector lattices (ordered topological vector spaces in which every pair of elements have an infimum and a supremum and in which the lattice operations are continuous), Mas-Colell shows that uniform properness is the crucial additional assumption needed to guarantee the existence of competitive equilibrium for exchange economies with a finite number of agents. Mas-Colell (1986) and Zame (1987) extend the existence theorem to include production economies, introducing (necessary) additional conditions that bound marginal rates of transformation as well as marginal rates of substitution. Mas-Colell and Richard (1991) offer a different proof that makes weaker assumptions by focusing more on the lattice structure of the price space and less on the lattice structure of the commodity space; this is important in a number of applications. Mas-Colell and Zame (1991) and Aliprantis, Brown and Burkinshaw (1989) provide good surveys of the existence theorems, including discussion of a number of different proof strategies.

A surprising aspect of the analysis in the infinite dimensional setting is that it relies heavily on the order structure of the commodity and prices spaces and on the assumption that consumption sets coincide with the positive cone of the commodity space, which play no role in the finite dimensional setting. That the order structures should play an important role is suggested by Aliprantis and Brown (1982), but a foreshadowing can already be seen in Bewley (1972). In that paper, the role of the order structure is not to guarantee the existence of equilibrium, but to guarantee the existence of equilibrium with economically meaningful prices (that is, prices in $\mathcal{E}^1$ rather than in the full dual of $\mathcal{E}^\infty$). Bewley's argument rests on the possibility of decomposing a socially feasible bundle dominated by the social endowment into a sum of individually feasible bundles dominated by individual endowments. That this is possible is a consequence of the *Riesz decomposition property*, which holds when the commodity space is a vector lattice and consumption sets are the positive cone, but not for general commodity spaces or consumption sets. The arguments used by Mas-Colell to construct prices that support a Pareto optimal allocation, and by Yannelis and Zame (1986) to provide estimates on supporting prices, make similar use of the Riesz decomposition property and so again require that the commodity space be a lattice. For explorations of equilibrium theory when assumptions on the order structure are relaxed, see Aliprantis, Tourky and Yannelis (2001) and Aliprantis, Florenzano and Tourky (2005). See also functional analysis.

**Hidden information and hidden actions**

The standard model of competitive markets treats an environment in which all agents are equally
informed about economically relevant parameters, and has nothing to say about environments in which agents are asymmetrically informed – but even casual observation suggests that the latter environments are more common than the former. That asymmetric information can have an enormous impact on market outcomes is pointed out forcefully in Akerlof’s (1970) seminal discussion of used-car markets. Because sellers typically have private information about their own cars, such markets display adverse selection: low-quality cars are offered for sale more readily than are high-quality cars, so the quality distribution of cars offered for sale at a given price will be skewed downward in comparison with the overall distribution of cars in the market. As a result, market outcomes may be less efficient than in the case where all information is public; in extreme situations, only autarkic outcomes (no trade) may obtain, even though every potential buyer values every car more than its original owner. Adverse selection arises in many other markets as well. Potential borrowers may know more about their creditworthiness than do potential lenders, owners/operators of a productive firm may know more about its future profitability than potential investors, and potential buyers of insurance may know more about their accident or health risks than do potential sellers of insurance. In the insurance context, Rothschild and Stiglitz (1976) argue that adverse selection may become so important that equilibrium does not exist. (But Rothschild and Stiglitz use a mixed, and not strictly price-taking, notion of equilibrium.) The work of Akerlof makes it clear that asymmetric information may matter for market outcomes; the work of Rothschild and Stiglitz makes it clear that asymmetric information may matter for the way we model markets as well. Following these seminal contributions, a large literature has sought to integrate asymmetric information with general equilibrium modelling of competitive markets. Central issues in this literature include: which models are appropriate for which kinds of asymmetric information? Does the operation of the market reveal information? If so, how? And how much? Radner (1968) develops a model of an environment in which agents learn their private information (modelled as an information partition over true states of the world) and make contingent trades before the true state of the world occurs. In this model, private information acts as a constraint on choices: each agent can choose only among state-contingent consumption bundles that are measurable with respect to his/her private information; call such bundles private. A Walrasian expectations equilibrium consists of economy-wide prices and private consumption bundles for each agent such that each agent’s bundle is optimal among private, budget-feasible consumptions, and markets clear in each state of the world. If free disposal is permitted, standard conditions guarantee that Walrasian expectations equilibrium exists. For these environments, Walrasian expectations equilibrium can be justified as a descriptive theory in much the same way that Walrasian equilibrium is justified for symmetric information environments: as the limit of a cooperative solution. For these asymmetric information environments, the appropriate cooperative notion, the private core, consists of private allocations (vectors of private consumption choices) which have the property that no coalition can construct an improving private allocation, using only its own resources (Yannelis, 1991; Allen, 1994; 2003. Aliprantis, Tourky and Yannelis (2001), Einy, Moreno and Shitovitz (2003) and Hervés-Beloso, Moreno-Garcia and Yannelis (2005) show that versions of Debreu and Scarf’s (1963) core convergence theorem and Aumann's (1964) core equivalence theorem obtain for the private core and Walrasian expectations equilibrium. For environments in which trade takes place after the true state of nature occurs but before it is publicly known, agents may use their own private information and draw inferences from market activities, such
as prices (Radner, 1979). A *rational expectations equilibrium* consists of a (state-dependent) price function and an allocation such that each agent's state-dependent consumption bundle is measurable with respect to the join of his or her own information and the information in prices, each agent optimizes among measurable budget-feasible bundles, and markets clear in each state of the world. A simple example (Kreps, 1979) shows that some simple economies do not admit any rational expectations equilibrium. However, for generic specifications of economic parameters (endowments, information and preferences or utility functions) there is always a rational expectations equilibrium in which all information is fully revealed (Allen, 1981). In the presence of noise, such as uncertainty about aggregate endowments, equilibrium may be partially, but not fully, revealing (Admati, 1991). Rational expectations equilibrium forms the theoretical basis of a cornerstone of finance, the *efficient markets hypothesis*, which asserts that all information is revealed in prices.

An alternative view of rational expectations equilibrium, as a rest point of a rational, but imperfect, learning process, is offered by Anderson and Sonnenschein (1985). In their framework, each agent has an exogenously given (linear) model of the world and the economy, and chooses parameters of the model to best fit the observed data. At equilibrium (a rest point of the process of fitting parameters to data), each agent's model is best fitting but not necessarily correct. At such an equilibrium, agents may not have learned everything, but they have learned all that is possible for them to learn, given their models. Bossaerts (2002) addresses the econometric implications of this kind of rational, but imperfect, learning process.

A criticism of rational expectations equilibrium is that it does not address the mechanism through which agents obtain their private information. This seems an important omission because, if all information were to be revealed by prices, there would seem to be no incentive for agents to acquire information in the first place, especially if acquiring information is costly (Grossman and Stiglitz, 1980). A second criticism of rational expectations equilibrium is that extracting information from prices seems to require agents to have a great deal of information about the economy (including information about other agents); when equilibrium is fully revealing, for example, agents must be able to invert the map from states of the world to equilibrium prices. Perhaps the most serious criticism of rational expectations equilibrium is that it provides no process by which information gets into prices. If agents use information in prices in forming their demands, how do those demands influence prices? If demands do not influence prices, where do prices come from?

A very fruitful approach to the revelation of private information takes as its starting point the observation that private information gives rise to incentive problems: if private information is valuable, agents may not wish to take actions that reveal that private information. However, incentive problems may not matter much if agents are *informationally small*. (A new-car variation of Akerlof's familiar used-car market provides an intuitive idea of what it means to be informationally small. Suppose that all cars have the same true quality, unknown to both buyers and sellers, but that sellers receive noisy signals of this common quality. If there are many sellers, and sellers' signals are conditionally independent, then the marginal amount of information revealed by the signal of a given seller is small. Put differently: in an economy with many sellers, each seller's signal has little effect on the true posterior information about quality.) This idea can be formalized in a number of different ways. For instance, Gul and Postlewaite (1993) and McLean and Postlewaite (2002) describe classes of environments for which allocations close to competitive allocations are incentive compatible in large replications. McLean and
Postlewaite (2005) define an incentive-compatible core and show that incentive compatible core allocations in replica economies are close to competitive allocations of the full information economy provided that agents are informationally small. Forges, Heifetz and Minelli (2001) prove a related convergence result in a different formulation that includes lotteries. Prescott and Townsend (1984a; 1984b) pioneered an approach that treats certain kinds of private information and incentive issues within the standard general equilibrium paradigm. Prescott and Townsend model shocks (hidden information) as affecting preferences. Incentive problems (moral hazard) arise in guaranteeing that agents who experience a particular shock should have no incentive to misrepresent themselves as having experienced a different shock; these incentive constraints are incorporated into consumption sets. Two unusual aspects of the model is that objects of choice are lotteries over consumption bundles and that prices are linear in probabilities but not necessarily in consumption. Competitive equilibria exist and are Pareto optimal within the class of allocations that satisfy the incentive constraints. (Allowing for lotteries guarantees that consumption sets and preferences are convex, so that familiar Arrow–Debreu existence results can be applied. It does not seem commonly observed that, in the continuum of agents framework Prescott and Townsend adopt, convexity of consumption sets and preferences is not necessary to guarantee the existence of an equilibrium.)

If enforcement of contractual arrangements is imperfect, then issues of moral hazard and adverse selection arise in financial markets as well. Borrowers may choose to default on promises (moral hazard) and borrowers who are poor risks or less affected by sanctions are more likely to default than are borrowers who are good credit risks (adverse selection). Surprisingly, neither of these interferes with the existence equilibrium, provided that deliveries on asset promises are pooled (Dubey, Geanakoplos and Shubik, 2005). The most familiar pooled financial instruments are collateralized mortgage obligations, which are pools of individual mortgages. Pooling mortgage deliveries spreads the default risk across all lenders; absent pooling, each lender would face the idiosyncratic risk that individual borrowers default against them. Although default is suggestive of deadweight losses, allowing for default may be Pareto-improving when markets are incomplete, because it expands the effective span of available assets (Dubey, Geanakoplos and Shubik, 2005; Zame, 1993).

Bisin et al. (2002) argue that, if all trade – even trade for commodities – is carried out through contracts, and deliveries on all contracts are pooled, then both adverse selection and moral hazard can be accommodated within almost standard general equilibrium models. (The assumption that deliveries on commodity contracts are pooled would seem natural for orange juice, but not for used cars; the assumption that deliveries on financial contracts are pooled would seem natural for collateralized mortgage obligations but not for individual mortgages.) Dubey and Geanakoplos (2002) use a similar idea to reformulate the insurance economy of Rothschild and Stiglitz (1976) and argue that an equilibrium always exists.

All of the work described above considers either economies in which individuals consume by themselves and production (if any) is of the standard Arrow–Debreu–McKenzie type. A growing literature treats economies in which individuals consume and/or produce in small groups (teams or firms). Prescott and Townsend (2006), Rahman (2005) and Song (2006) treat general equilibrium models with team production. Output is a function of observable investment and unobservable effort, which creates a moral hazard problem. Working in the tradition of Prescott and Townsend, these papers...
find institutional arrangements that permit the decentralization of incentive-efficient configurations. When production is deterministic and utility is transferable, the requisite institutions include contract arbitrageurs and Lindahl (personalized) prices for team membership; when production is stochastic and utility is not transferable, public randomization devices and assets whose payoffs depend on the distribution of idiosyncratic uncertainty are required as well.

Zame (2005) takes a different approach, adding hidden information and hidden actions to the clubs framework of Ellickson et al. (1999; 2006). In that model, firm output and individual utility depend on skills and actions of other agents, which are unobservable and uncontractable; thus there is scope for both adverse selection and moral hazard. Moreover, because output within firms depends on action profiles, agents are subject to idiosyncratic risk. The set of firms that form and the contractual arrangements that appear, the assignments of agents to firms, the prices faced by firms for inputs and outputs, and the incentives to agents are all determined endogenously at equilibrium. Agents choose consumption – but they also choose which firms to join, which roles to occupy in those firms, and which actions to take in those roles. Agents interact anonymously with the (large) market, but strategically within the (small) firms they join. The model accommodates moral hazard, adverse selection, signalling and insurance. Equilibrium allocations may be incentive efficient and even Pareto ranked.

general equilibrium

Lionel W. McKenzie

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Unlike partial equilibrium theory, general equilibrium theory treats as constant only non-economic influences and embraces all sales and purchases of all agents involved in exchanges. It implies that all subsets of agents are in equilibrium and that all individual agents are in equilibrium. The development of a formal general equilibrium theory in mathematical terms was initiated in the 19th century by Walras, who moved from a model of an exchange economy to an equilibrium with production. It was completed in the 1950s by McKenzie, who formalized Walrasian theory, and by Arrow and Debreu, who formalized Hicksian theory.

Article

General equilibrium theory is in contrast with partial equilibrium theory where some specified part of an economy is analysed while the influences impinging on this sector from the rest of the economy are held constant. In general equilibrium the influences which are treated as constant are those which are considered to be noneconomic and thus beyond the range of economic analysis. Of course, this does not guarantee that these influences will in fact remain constant when the economic factors change, and the usefulness of economic analysis for predictive purposes may depend on to what degree influences treated as noneconomic are really independent of the economic variables.
The institution whose phenomena are the primary subject matter of economic analysis is the market, made up of a group of economic agents who buy and sell goods and services to one another. In partial equilibrium theory the group of agents may be confined to those who are involved in one industry, either buying or selling its product or buying or selling the materials and productive services used in making its product. However, in general equilibrium theory all the agents involved in exchanges with each other should ideally be included and all their sales and purchases should be allowed for. However, it may happen that the activities of many agents are only treated in the aggregate and the list of goods and services may be reduced by aggregation. The aggregation of agents and commodities into a few categories is especially important when general equilibrium theory is applied to special areas of public policy such as the government budget, money and banking, or foreign trade. Much of the theory developed for these subjects is general equilibrium theory in aggregated form.

The general equilibrium implies that all subsets of agents are in equilibrium and in particular that all individual agents are in equilibrium. The conscious development of a formal general equilibrium theory stated in mathematical terms seems to have been inspired by a formal theory of the equilibrium of the individual consumer faced with a given set of trading opportunities or prices. This theory was developed by the marginal utility, or neo-classical, school of economists in the third quarter of the 19th century, independently, by Gossen (1854), Jevons (1871), and Walras (1874–7), who used mathematical notations, and by Menger (1871) who did not. The step was taken in the most effective way by Walras.

**The equilibrium of an exchange economy**

Walras assumed that the utility derived from the consumption of a good was given as a function of the amount of that good alone that was consumed and independent of the amounts consumed of other goods. He also assumed that the first derivative of the utility function was positive and decreasing up to a point of satiation when one exists. He then gave a rigorous derivation of the demand for a good by a consumer from the maximization of utility subject to a budget constraint. The demand functions give the equilibrium quantities traded by the consumer as a function of market prices. As Walras saw, this is a crucial step in the development of a general equilibrium theory for an economy. It has remained in a generalized form the cornerstone of general equilibrium theory since Walras.

The simplest problem of general equilibrium arises in the theory of the exchange economy without production. In this economy the budget constraint of the trader is established by his initial stocks and the list of prices. Then the individual demand function represents the equilibrium of the single trader in face of a given price system. The market demand function is the sum of the individual demand functions, and the equilibrium of the market occurs at a price for which the sum of demands, including offers as negative demands, is equal to 0 for each good, or, if free disposal is allowed, is not positive for any good. This idea was expressed in classical economic theory by the equality of supply and demand in each market, but its expression in a set of equations to be satisfied by the list of equilibrium prices was due to Walras, although Cournot (1838) had foreshadowed the Walrasian analysis in his discussion of the international flow of money and Mill (1848) in his discussion of foreign trade.

Suppose there are $n$ goods to be traded and there are $m$ traders. Let $W_i^h$ be the quantity of the $i$th good held initially by the $h$th trader. Let $u^h(x)$ where $x=(x_1,\ldots,x_n)$ be the utility to the $h$th trader of possessing
the quantities $x_1, \ldots, x_n$, of the $n$ goods traded. Then the $h$th trader is in equilibrium at the prices $p=(p_1, \ldots, p_n)$ and the quantities $x^h$ if $u^h(x)$ is a maximum at $x^h$ over all values of $x$ which satisfy
\[
\sum_{i=1}^{n} p_i x_i \leq \sum_{i=1}^{n} p_i \omega_i^h.
\]
If smoothness and concavity conditions are met by the utility function, and the goods are divisible, the maximizing $x$ will be unique and will define a function $f^h(p)$ over an appropriate price domain. Since the set of commodity bundles $x$ at which the utility function is maximized does not change when the prices $p$ are multiplied by a positive scalar, this function will satisfy $f^h(\alpha p) = f^h(p)$ for $\alpha > 0$.

The market demand function is $f(p) = \sum_{\ell=1}^{m} f^\ell(p)$. Then the market equilibrium for a trading economy is given by a price vector $p$ and an allocation of goods $(x^1, \ldots, x^m)$ such that $x^h = f^h(p)$ and $\sum_{\ell=1}^{m} x^\ell = \sum_{\ell=1}^{m} \omega^\ell$, or, assuming free disposal, $\sum_{\ell=1}^{m} x^\ell \leq \sum_{\ell=1}^{m} \omega^\ell$. The first condition expresses the equilibrium of the individual trader and the second condition is the equality of supply and demand. Thus there are $n$ scalar equations $\sum_{\ell=1}^{m} f^\ell(p) = \sum_{\ell=1}^{m} \omega^\ell$ to determine the $n$ equilibrium prices $p_i$. The given data are the consumer tastes, expressed in the utility functions $u^h$, and the initial stocks of goods $\omega^h$.

It is clear that the market demand function satisfies the homogeneity condition $f(\alpha p) = f(p)$ for $\alpha > 0$. Thus equilibrium prices are only determined up to multiplication by a positive number. This reflects the fact that the equilibrium of the consumer is not affected if prices are multiplied by $\alpha$ and market equilibrium is the simultaneous equilibrium of all consumers at the same prices. It is often convenient to adopt some normalization of prices. Walras chooses a good whose price is known to be positive in equilibrium and gives this good, which he calls the numeraire, the price 1. Another convention which is useful when free disposal is assumed, so that prices are necessarily non-negative, is to choose $p$ such that $\sum_{i=1}^{n} p_i = 1$. Then the domain of definition for the demand functions may be taken to be all $p$ such that $p_j \geq 0$ and $\sum_{i=1}^{n} p_i = 1$.

There is an analogy between the equilibrium of the trading economy and the equilibrium of mechanical forces. Indeed, one of the inspirations for the theory of Walras appears to have been a treatise on statics by Poinsot (1803, 1842). According to the principle of virtual work an infinitesimal displacement of a mechanical system, which is at equilibrium under the stress of forces and subject to constraints, does no work. In the economy at equilibrium an infinitesimal displacement of the allocation of goods $(x^1, \ldots, x^m)$ cannot increase the utility of one trader unless it reduces the utility of another. This is an easy implication of the fact that utility is maximized over the budget constraint, provided no one is saturated. This means that a new allocation to a trader cannot preserve his utility level if its value at the equilibrium prices falls. On the other hand, the utility level of a trader cannot increase unless his allocation becomes more valuable at the equilibrium prices. But then the new allocations $x^{h'}$ would satisfy
\[
\sum_{h=1}^{m} \sum_{i=1}^{n} p_i x_i^{h'} > \sum_{h=1}^{m} \sum_{i=1}^{n} p_i \omega_i^{h'}.
\]
which is impossible since the total allocation cannot exceed the total supply of goods. Indeed, if each trader holds all goods in his equilibrium allocation and the utility functions are differentiable, which implies that goods are divisible, an infinitesimal reallocation would have no effect on utility levels if it has no effect on the levels of individual budgets. This property of market equilibrium was first recognized by Pareto (1909), and an allocation of goods with the property that no displacement of it can benefit one consumer unless it harms another is said to be Pareto optimal. The implication from competitive equilibrium to Pareto optimality requires that no consumer be locally satiated. It is also true that a Pareto optimal allocation may be realized as a competitive equilibrium given an appropriate distribution of initial stocks but the conditions are more severe. The first general theorems were proved by Arrow (1951).

**Equilibrium with production**

The next step in developing the general equilibrium of an economy is to introduce production under the condition that the output matures without a lapse of time. This step was taken by Walras, who introduced linear activities which list the quantities of productive services required to produce one unit of a good. There may be many alternative activities for the production of any given good and a choice is made among them in order to minimize the cost of production at given market prices. Let \( z = (z_1, \ldots, z_r) \) be a list of quantities of productive services and let \( g^i(z), i = 1, \ldots, n \), be production functions for the \( n \) goods. Since linear activities are assumed, the production functions will satisfy \( \alpha g^i(z) = g^i(\alpha z) \). In particular, we may consider the unit isoquant or the set \( A_i \) such that \( g^i(z) = 1 \) for \( z \) in \( A_i \). Then the activities which minimize cost at given prices \( q \) are represented by production coefficients \( a^i(q) \), contained in \( A_i \), where \( q^i a^i(q) \leq q^i z \) for \( z \) in \( A_i \). Equilibrium in the production sector is given by price vectors \( p \) and \( q \) and activity vectors \( a^i(q) \) where \( p_j \leq \sum_j q_j a^i_j(q) \) for all \( i \) and equality holds if the \( i \)th good is produced.

In an equilibrium of the production sector any quantities \( y \) of outputs may be produced provided quantities \( z \) of productive services are available where \( z_j = \sum_i a^i_j(q) \). In order to include the productive sector in a market equilibrium the utility functions of consumers must be extended to include productive services among their arguments. They may be written \( u^h(x, z) \). If we reinterpret \( x_i \) as the quantity of a good traded rather than the quantity consumed, the initial stocks may be suppressed. This is convenient since it is not clear how initial stocks of labour services can be specified. Then the individual consumer is in equilibrium given prices \( p \) and \( q \) for goods and productive services when the quantities traded \((x^h, z^h)\) maximize \( u^h(x, z) \) over all \((x, z)\) such that \( \sum_i p_i x_i - \sum_i q_i z_i \leq 0 \). The maximizing quantities need not be unique in general, so it is necessary to represent demand by a correspondence that takes a set of trades as its value and write \((x^h, z^h) \in \mathcal{F}^h(p, q)\) when \((x^h, z^h)\) is a maximizer given prices \( p \) and \( q \).

As before, market equilibrium is achieved when all economic agents are in equilibrium at the same prices and supply is equal to demand. Since risk is not present in this economy, the productive services
involved in organizing production need not be given a distinguished role. Activities may be treated as conducted by the whole set of owners of the productive services involved in them. Then if it should happen that \( p_i > \sum_{j=1}^{r} q_j a_j^i(q) \) for the \( i \)th good, there will be an opportunity for some owners of productive services to earn larger returns producing the \( i \)th good than those prevailing generally as given by \( q \). Thus productive services will leave other activities and flow to this activity, so equilibrium does not obtain for owners of productive services. This equilibrium now requires, on the one hand, equilibrium of each economic agent as consumer of goods and provider of productive services, that is, \((x^h, z^h) \in f^h(p, q)\), and, on the other hand, equilibrium of each economic agent as a participant in production, that is, \( p_i \leq \sum_{j=1}^{r} q_j a_j^i(q) \), with equality if the \( i \)th good is produced. However, market equilibrium also requires that

\[
\sum_{h=1}^{m} z_j^h = \sum_{j=1}^{r} x_j^h a_j^i(q),
\]

that is, the supply of productive services must equal the quantities needed to produce the quantities of goods demanded. As before, if surplus productive services may be freely disposed of, the equality in the last equation may be replaced by an inequality.

The demand functions \( f^h_{n+j}(p, q) \) and the supply functions \( f^h_{n+j}(p, q) \) express the equilibrium of the household sector. Therefore, the relation

\[
\sum_{j=1}^{r} p_i f^h_{n+j}(p, q) = \sum_{j=1}^{r} q_j f^h_{n+j}(p, q)
\]

holds for all values of \( p \) and \( q \) in the price domain. Let \( x_i \) be the amount of the \( i \)th good produced and let \( z_j \) be the amount of the \( j \)th factor used in production. Then equilibrium in the production sector implies that

\[
\sum_{i=1}^{n} p_i x_i = \sum_{j=1}^{r} q_j x_j = \sum_{j=1}^{r} q_j z_j.
\]

Let \( f(p, q) = \sum_{h=1}^{m} f^h(p, q) \). Then household equilibrium implies

\[
\sum_{j=1}^{n} p_i f^h_{n+j}(p, q) = \sum_{j=1}^{n} q_j f^h_{n+j}(p, q).
\]

Let excess demand for a good be \( e_i(p, q) = f^h_{n+j}(p, q) - x_i \), and excess demand for a productive service be \( e_{n+j}(p, q) = z_j - f^h_{n+j}(p, q) \). Then equilibrium in the production and household sectors together implies that

\[
\sum_{j=1}^{n} p_i e_i(p, q) + \sum_{j=1}^{n} q_j e_{n+j}(p, q) = 0,
\]

or the value of excess demand is zero whatever price system is set. This relation is referred to as Walras's Law.

If there is free disposal, prices must be non-negative. Otherwise, disposal would be profitable. Also with free disposal the condition for equilibrium of the market is \( e(p, q) \leq 0 \). Then Walras's Law immediately implies \( p_i e_i(p, q) = q_j e_{n+j}(p, q) = 0 \), and if any good or productive service is in excess supply in equilibrium, its equilibrium price must be 0. This might be termed Wald's Law, since he made crucial use of it in the first rigorous proof that equilibrium exists in a competitive economy (Wald, 1935, 1936a).

A production sector composed of activities with single outputs is the model used by Walras, who was responsible for the first fully developed general equilibrium theory. The natural generalization of this
model is to introduce more than one output. Then the \( k \)th activity is represented by an output vector \( b^k = \left( b^k_1, \ldots, b^k_r \right) \) and an input vector for productive services \( a^k = \left( a^k_1, \ldots, a^k_r \right) \). Assume that activities may be replicated and are independent of each other. Then if \((a^k, b^k)\) is a possible input-output combination for the \( k \)th activity, so is \((\alpha a^k, \alpha b^k)\) where \( \alpha \) is any non-negative integer. Indeed, if all inputs and outputs are divisible it is possible for \( \alpha \) to take as its value any real number.

This model of the production sector which embraces the transformation of productive services into goods and services is due to Walras in the context of a theory of general equilibrium. It is convenient to think of the market as held periodically to arrange for the delivery of goods and services over a certain basic period of time. This view of the market, which is also a device of Walras, leads to a theory of temporary equilibrium. The theory was further elaborated by Hicks (1939) and in recent years by other authors. In order to explain the demand and supply of products and productive services in the periodic market it is necessary to introduce some assumptions on the formation of expectations for the prices which will prevail in future markets. The simplest assumption is that the prices arrived at in one market are expected to prevail in future markets. This type of expectation formation is sometimes referred to as static expectations. Walras usually appears to assume static expectations. Hicks introduced a notion of elasticity of expectations to allow expectations of future prices to depend on the change of prices from one temporary equilibrium to another. In recent work analysis has proceeded upon more general assumptions, using various formal properties of dependencies between past prices and expected prices.

A quite different approach to expectations which enjoys much current popularity is to assume that expectations are correct, at least in a stochastic sense. The rationale of this approach is that any persistent bias in forecasts of future prices implies that there are unexploited opportunities for profit from further trading which eventually should be recognized.

The model of the production sector as a set of potential linear activities was subsequently used by Cassel (1918) in a simplified Walrasian model which preserved the demand functions and the production coefficients but which did not deduce the demand functions from utility functions or preferences. The model was generalized to allow joint production in a special context by von Neumann (1937). It was given a thorough elaboration and analysis in a model where intermediate products are introduced explicitly by Koopmans (1951). In the Walrasian picture intermediate products were eliminated through the combination of activities so that activities were described as transforming productive services directly into final products whether consumer goods and services or capital goods. However, such a description of the economy depends for its relevance on prices which do not change from one temporary equilibrium to another, so that the choice of activities is not changing.

In the general linear model of production it is no longer adequate to treat the choice of activities as a process of cost minimization given the price vectors \( p \) and \( q \). Cost minimization must be replaced by the condition that no activity may offer a profit and no activity which is used in competitive equilibrium may suffer a loss. This is exactly the condition ‘\( \text{'ni benefice ni perte'} \)’ which Walras used to define equilibrium in production, initially in a model with fixed coefficients of production. However, this condition was first used in a general production model by von Neumann, so it might be termed von Neumann's Law for an activities model of production. Koopmans explored the relation between efficient production and von Neumann's Law. He established an equivalence between the proposition that an output is efficient and the proposition that prices exist such that von Neumann's Law is satisfied when the activities used are those needed to produce this output. Moreover, if each good or service is either
desired in unlimited quantities or freely disposable the prices must be non-negative. Thus under these demand and supply conditions any competitive equilibrium must include an efficient output from the production sector. The activities approach to the production sector of a competitive economy was used by Wald and then by McKenzie (1954) in proofs of existence for competitive equilibrium. It was also used by Scarf (1973) in an algorithm for finding a competitive equilibrium given the technology, the resources, and the demand functions.

An alternative model of the production sector emphasizes the productive organization or firm rather than the activities or technology. A set of actual or potential firms is given and each firm is endowed with its own set of possible input-output combinations. The set of possible input-output combinations achievable by the economy, independently of resource availabilities, is the sum of the sets of input-output combinations achievable by the firms. The condition for equilibrium in the production sector is that each firm maximizes its profits, that is, the value of the input-output combination over its production possibility set, given the prices of inputs and outputs. This view of production was explicit in a partial equilibrium context in Cournot. It was at least implicit in the work of Marshall (1890) and Pareto, and became quite explicit in a general equilibrium context in the work of Hicks (1939) and Arrow and Debreu (1954).

In the Hicksian model a firm is associated with each economic agent who is a consumer and who may be a worker and owner of resources, but who also may be an entrepreneur. As an entrepreneur he owns a possible production set based on his personal characteristics and perhaps some other non-marketed resources. Of course, most of these individual enterprises will be inactive. A difficulty with this model is that it seems unrealistic to treat the entrepreneur as a profit maximizer unless all the resources which he himself supplies have market prices so that they could equally well be bought by him from the market or sold by him to the market. But if that is the case we are back to the concept of the entrepreneur used by Walras and it seems more realistic to refer to activities, which are impersonal, rather than to individual enterprises.

In the model of Arrow and Debreu, which is the first complete general equilibrium model in which the existence of equilibrium was rigorously proved, the production sector is made up of firms which are described as joint stock companies. Each firm has a production possibility set based on resources which it owns and the ownership of the firm is spread in a prescribed way over a set of consumers. The production sector is in equilibrium when each firm has chosen an input-output combination from its production possibility set which maximizes profit at the market prices. Since the outputs of one firm may be inputs of another and the resort to integrated activities which convert productive services directly into products is not available in a model based on firms, it is convenient to distinguish inputs from outputs by signs rather than by lists. Let \( Y_j \) denote the production possibility set of the \( j \)th firm, and let \( y = (y_1, \ldots, y_n) \) denote an element of this set. There are \( n \) goods and services in the economy, and \( y_i < 0 \) denotes an input, while \( y_1 > 0 \) denotes an output. Let \( y^j \) be the input-output vector of the \( j \)th firm. Then equilibrium in the production sector requires that the condition \( p \cdot y^j \geq p \cdot y \) for all \( y \in Y_j \) holds for all \( j \), where \( j \) indexes the set of firms, and \( p \) is the market price vector.

The Arrow–Debreu approach to the production sector involves a major difficulty. It is not well adapted to handle the formation of new firms and the dissolution of old ones. If firms are based on the assembly of a set of resources jointly owned by the shareholders, it becomes critical to give the principle which underlies such an assembly. If the firm's resources are priced and traded, so the firm's production may be
treated like an activity, there is no difficulty since von Neumann's Law may be applied. Otherwise, the rules governing the entry and exit of firms are unclear. The problem is similar to the general problem of coalition formation in the theory of cooperative games.

A formal model

A formal model of the competitive economy, presented in the form of a series of axioms, was developed in the 1950s. It was intended that the axioms should be interpretable to apply to real economic systems, albeit in some approximate sense. However, as a formal mathematical model the implications of the axioms could be developed independently of the applications. The selection of axioms was influenced by the possibility of making useful interpretations, but also by the facility with which results can be derived.

Two closely related sets of assumptions were developed. One, developed primarily by McKenzie (1959), is a formalization of the Walrasian theory and uses a linear model of production. The other, developed primarily by Arrow and Debreu, is a formalization of the Hicksian theory where the production sector is described as an assembly of firms. On the side of consumers and the market there are no significant differences at a fundamental level, although there are sometimes differences of approach. A history of the problem of existence of equilibrium for the formal models may be found in Weintraub (1983).

In the fully developed McKenzie model (see McKenzie, 1981) two assumptions are made for the consumption sector, two for the production sector, and two assumptions relate the consumption and production sectors. On the consumption side there is a finite number $m$ of consumers indexed by $h$, and each consumer has a set $X_h$ of trades which are feasible for him. There are $n$ goods and the sets $X_h$ are contained in $\mathbb{R}^n$, the $n$ dimensional Euclidean space. The convention is used that quantities supplied by consumers are negative and quantities received by consumers are positive. The consumer has preferences defined on $X_h$ by a correspondence $P_h$. The preference correspondence $P_h$ takes as its value at $x \in X_h$ the subset of $X_h$ each of whose members is preferred to $x$. This subset may be empty. The assumptions on the consumers which hold for all $h$, are.

1. $(1)$ $X_h$ is convex, closed and bounded below.
2. $(2)$ $P_h$ is open valued relative to $X_h$ and lower semi-continuous. Also $x$ is not in convex hull $P_h(x)$.
   Convexity of $X_h$ implies that a good is divisible if someone can consume it in more than one quantity. $X_h$ bounded below means that the consumer is not able to supply an indefinite quantity of any good.
   Closedness and boundedness are needed to provide compact feasible sets.
   On the production side there is an activities model with no limitation on the number of activities. The activities are linear and give rise to a possible production set $Y$ contained in $\mathbb{R}^n$. If $y \in Y$, the negative components of $y$ denote quantities of inputs and the positive components denote quantities of outputs. The assumptions on $Y$ are.
3. $(3)$ $Y$ is a closed convex cone.
4. $Y \cap \mathbb{R}^n_+ = \{0\}$. $\mathbb{R}^n_+$ is the set of non-negative vectors in $\mathbb{R}^n$.

That $Y$ is a convex cone is equivalent to the production set being generated by linear activities. It means that if $y$ and $y'$ are producible, that is, elements of $Y$, then $\alpha y + \beta y'$ is also producible, that is, an element of $Y$, for any non-negative numbers $\alpha$ and $\beta$. Thus producible goods are divisible. Closedness is needed for the compactness of the feasible set. Assumption (4) is not restrictive. It is a recognition that goods which are never scarce are irrelevant to problems of economizing.

Finally two assumptions relate the consumption sector and the production sector. Let $X$ be the total possible consumption set, that is, $X = \sum_{h=1}^{m} X_h$. The first relation is

5. (5) relative interior $X \cap \text{relative interior } Y \neq \emptyset$.

Here the relative interior of a set is relative to the smallest linear subspace that contains it. This assumption insures that someone has income at any price vector which is consistent with equilibrium in the production sector, that is, satisfies von Neumann's Law. The second relation is an assumption that the economy is irreducible. Let $I_1$ and $I_2$ refer to nonempty subsets of consumers such that $I_1 \cup I_2$ includes all consumers and $I_1 \cap I_2 = \emptyset$. Let $X^1 = \sum_{h \in I_1} X_h$, and similarly for $I_2$. Let $\overline{X}_h$ be the convex hull of $X_h$, and the origin of $\mathbb{R}^n$. The irreducibility assumption is

6. (6) however $I_1$ and $I_2$ may be selected, if $x^1 = y - x^2$ with $x^1 \in X^1$, $y \in Y$ and $x^2 \in \overline{X}_2$, then there is also $\overline{y} \in Y$ and $w \in \overline{X}_2$, such that $\overline{x}^1 = \overline{y} - x^2 - w$ and $\overline{z} \in P(x^h)$ for all $h \in I_1$.

Assumption (6) guarantees that everyone has income if anyone has income. The meaning of having income is that the consumer is able to reduce his spending at the market price vector below the cost of his allocation and remain within his possible consumption set $X_h$.

Competitive equilibrium is defined by a price vector $p$, an output vector $y$, and vectors $x^1, \ldots, x^m$ of consumer trades. There is equilibrium in the production sector if von Neumann's Law holds, that is:

1. (I) $y \in Y$ and $p \cdot y = 0$, and for any $\overline{y} \in Y$, $p \cdot \overline{y} \leq 0$.

When $y$ satisfies (I) it is not possible for the owners of inputs to withdraw them from activities where they are being used and employ them in other activities, whether in use or not, so that the receipts from the resulting outputs allow some inputs to earn larger returns while none of them earns less. This is the same condition for equilibrium in production that was given by Walras, or, for that matter, by Adam Smith (1776).

There is equilibrium in the consumer sector if the $x^h$ satisfy

2. (II) $x^h \in X_h$ and $p \cdot x^h \leq 0$, and $p \cdot z > 0$ for any $z \in P_h(x^h)$, $h = 1, ..., m$.

When $x^h$ satisfies condition (II), there is no preferred bundle of goods, including goods or services that are supplied by the consumer, which is available to him under his budget constraint. This is essentially the same condition used by Walras, except that he assumed that preferences could be represented by a strictly concave utility function. Thus he is able to refer to
maximization of the utility function over the budget set uniquely at \( x^h \).

Finally, there is market equilibrium when

\[ \sum_{h=1}^{m} x^h = \gamma. \]

This is the condition that markets clear which was used by Walras.

If there is free disposal, Wald's Law may be derived directly from equilibrium in the production sector. The possibility of free disposal is recognized by the inclusion of disposal activities in the production cone, that is, an activity \( y^i \) for \( i = 1, \ldots, n \) which has \( \lambda^i = -1 \) and \( \lambda^j = 0 \) for \( j \neq i \). The condition \( p \cdot \lambda^j \leq 0 \) implies that \( p_i \geq 0 \) must hold. Then if disposal occurs the condition \( p \cdot \lambda^j = 0 \) implies that \( p_i = 0 \).

On the basis of Assumptions 1 through 6 it is possible to prove that a competitive equilibrium exists. This was first achieved in a model with assumptions for the demand sector put directly on preferences, in the manner of Walras, by Arrow and Debreu. At the same time McKenzie proved existence for a model with assumptions put on the demand functions rather than directly on preferences. Also McKenzie assumed a linear technology rather than a set of firms. This was a generalization of a model of Wald in which joint production was absent and the very special assumption was made that the market demand functions satisfied the weak axiom of revealed preference. The weak axiom says if \( x \) is demanded at \( p \) and \( x' \) at \( p' \), then \( p \cdot x \leq p \cdot x' \) implies that \( p' \cdot x < p' \cdot x \). This is a consistency requirement on choice under budget constraints. Wald's assumption was a deep insight. He anticipated the statement of this principle by Samuelson (e.g. 1947) who applied it to the demand of the individual consumer to derive most of the propositions of demand theory. Wald showed that the weak axiom assumed for the market leads to uniqueness of equilibrium. Subsequently it was shown by Arrow and Hurwicz (1958) that the weak axiom is implied by the assumption that all goods are gross substitutes.

They also proved that the weak axiom confined to a comparison of choices between the equilibrium prices and other prices implies the global stability of a process of price adjustment in which the prices of goods are increased if excess demand exists and lowered if excess supply exists. Wald (1936b) wrote another paper on equilibrium in an exchange market which used assumptions closer to those of Arrow and Debreu, but this paper unfortunately was lost.

The only important distinction between the approach of Arrow and Debreu (see Debreu, 1962) and the approach expressed in Assumptions 1 through 6 is the use of a set of firms rather than a set of activities to generate the production set. Mathematically, through the introduction of entrepreneurial factors the approaches can be reconciled. However, the intentions of the two approaches are quite different. The linear model is intended to represent free entry into any line of production by cooperating factors, however organized in a legal sense, where economies of scale are sufficiently small to allow approximate linearity to be achieved by the multiplication of producing units. The lumpiness which is present is compared to that resulting from goods which are in fact indivisible, although they are treated as divisible. This leads to a reasonable approximation to real markets only if units are small compared with the levels of trade. This view of the competitive economy is consistent with the analysis of Marshall as well as Walras. Of course, it has to be recognized that in real economies some sectors cannot be approximated in this way. However, when linearity becomes a bad approximation to the production sector, convexity has in all likelihood become an equally bad approximation to the
production sets of firms. Recently an explicit modelling of the approach of the firms economy to the activities economy has been given by Novshek and Sonnenschein (1980). They use the model of quantity adjusting firms developed in a partial equilibrium context by Cournot to find an equilibrium for the firms economy. Then they let the firm size shrink and show that the Walrasian equilibrium of an activities economy is approached in the limit.

Two interpretations of the formal model

Two basic interpretations of the general equilibrium model were described by Hicks and referred to as the spot economy and the futures economy. The spot economy is a market held on ‘Monday’ at which all transactions are arranged that involve delivery during the ‘week’. This is the economy described by Walras. The equilibrium of the spot economy is called temporary equilibrium in the modern literature. Some effort has been devoted to an analysis of the path followed by such an economy through a succession of temporary equilibria. The role of expectations in the spot economy is critical, as Hicks recognized.

The futures economy on the other hand has a single market in which all future transactions are negotiated at once. Hicks does not treat this economy in detail, but turns to a sequence of spot markets with trading that is guided by expectations. In the futures economy goods available in different periods would be treated as different goods, so that the number of goods would be finite only if the economic horizon is finite. If there is perfect foresight the futures economy is a reasonable alternative and there is not reason why markets should reopen. However, when the future is uncertain and the available futures contracts are for sure delivery, or at least do not exist in sufficient variety to take account of all contingencies, there is no assurance that the contracts entered into will remain desirable or indeed can be executed. For this reason Hicks chose to do a dynamic analysis of a sequence of temporary equilibria in the main body of his work.

In order to avoid the problem of the feasibility of plans and the need to reopen markets, Debreu (1959) following a lead of Arrow (1953) introduced a specification of goods by the event in which they are made available. The set of events would have to discriminate all the circumstances that might make delivery impossible or undesirable, so there would be no motive for traders to reopen markets. Despite this complexity, it is a consistent model which may have relevance to the real world. In order to keep the set of goods finite they assume a finite horizon and a finite set of events, in addition to assuming a finite list of goods in terms of location and physical characteristics.

With this interpretation of the formal model there is no room for borrowing and lending since payments are cleared only once, at the beginning of time. Uncertainty is present since there is no assumption that the event realized at any future time is known. Rather it will be revealed when the time arrives. There is no reason for spot markets to arise since the transactions which have been made for the future event that is revealed are the ones each trader desired at the prices paid in those circumstances. Thus if a spot market were opened no transactions would take place.

Of course it is idealization to suppose that all relevant events could be described in advance, or, if they could, that it would be feasible to establish markets discriminating between them. An alternative is to use a succession of markets in which temporary equilibria are established while some trading in futures contracts takes place. However, the limiting cases of the pure spot economy or the pure futures economy...
have an analytical tractability that the mixed cases lack and for this reason they remain of great
importance.

**Temporary equilibrium**

Once a sequence of markets is contemplated, rather than a single comprehensive market, plans for future
trades become relevant and, therefore, expectations of the prices at which they can be made. Also money
stocks and loans become useful in making financial preparations for the trading that is planned. Also, if
there may be forward trading as well as spot trading, arbitrage is possible, and speculative trading arises
which expresses disagreement among consumers about probable price levels on future spot and forward
markets.

These complications were handled by Walras without an explicit analysis of demand by consumers for
goods in the future using utility functions in which these goods appear. Rather he reduces the demand
for future goods to a demand for assets in general which would provide the means for future purchases.
On the other hand, he carefully distinguishes between stocks of goods and their services, and the
investments of the consumer are treated as if they were made directly in the stocks of goods whose
services are sold to the entrepreneurs, or directly to consumers in the case of services of consumer goods.
The spirit of this analysis is to choose a period short enough that it is not too great a distortion of reality
to suppose that all trades for this period can be concluded in advance as in the Arrow–Debreu model for
the entire horizon, but the forms of industrial organization are abstracted from, so that attention may be
concentrated on the productive activities and the ultimate beneficial owners of the resources whose
services are used in them. Also to give the future some role in the decisions of the consumers but not a
role requiring detailed analysis, Walras assumed that present market prices are expected to persist. In
contrast, Hicks and Arrow–Debreu deal explicitly with intertemporal planning by firms and consumers.
In a succession of markets this allows Hicks to analyse the effects of changes in expectations on the
present market prices and the plans of agents.

The theory of Walras provides the most complete and detailed model of temporary general equilibrium
that has ever been given, an impressive performance since it was also the first formal model of general
equilibrium. He was able to deal with money, production, lending, and capital accumulation, and in his
model an interest rate, price levels, and prices of capital goods and their services are all determined. He
showed that the system was not over determined, and probably not under determined either, in that the
number of independent functional relationships and the number of economic quantities to be determined
are equal. He was not able to give a proof that an equilibrium in non-negative real variables exists for his
model. However, proofs have since been given for simplified versions of it.

A fundamental difference between temporary equilibrium and equilibrium over a horizon is that part of
the consumers’ demand for goods in the temporary equilibrium is intended for investment rather than for
consumption within the period while in the economy of the classical existence theorem consumers’
demand is entirely aimed at consumption within the horizon. This raises two problems. One is to
distinguish between resources devoted to this period's consumption and resources reserved for the
support of consumption in future periods. The other is to explain how the decision to reserve a certain
quantity of resources for future use is made. Walras went further to make the distinction between current
and future use than any of his successors. They, on the other hand, have done much more analysis of the
relation between investment and expectations. The Walrasian assumption on expectations was usually to
project the prices arrived at in the current market into the future. This assumption is only appropriate for a stationary, or a steadily progressive, state of the economy. Of course, it has often been remarked that it is only in these conditions that expectations are likely to be correct.

Walras distinguished between consumption goods and services which are consumed in one use and consumption goods which are in effect capital goods providing consumer services, that is, having more than one use. Among the consumption goods which serve as capital goods he included consumption goods which are held in stocks to provide, as Walras put it, services of availability. Thus part of a person's income for a period may be invested in new stocks of consumer goods as well as in capital goods which are intended for use in productive activities. By the same token some of the productive activities which occur may occur in the household rather than in the factory, and these should satisfy the same profit conditions as the productive activities that occur in the firms.

The Walrasian approach to temporary equilibrium is entirely appropriate only to steady states where underlying circumstances, technology, tastes, and resources are constant, perhaps with capital stocks and population expanding at uniform rates. Then the comparative statics that can be done is a comparison of different steady states. On the other hand, in the Hicksian model where expectations of price changes are allowed, it is possible to consider the effect on the temporary equilibrium of changes in price expectations which need not duplicate changes in current prices. However, the approach of Walras allows him to ignore the consumer's portfolio problem and treat the consumer as only making a saving decision, since all assets of equal value are treated as indifferent with equal rates of return after allowing for depreciation and insurance costs. When there is uncertainty, the treatment of all assets as indifferent in this fashion is not justified even by the mean variance theory of portfolio selection. The variances and covariances of asset returns must be taken into account. Thus Walras's theory of investment requires that expectations be held with certainty, although he only explicitly assumes certainty within the horizon of a single period, after allowing for fully insurable risks.

There are two features of the Walrasian theory of investment which are quite effective, even by modern standards. One is the analysis of the demand for money. Money is needed during the period to make payments which are planned in advance and the cost of this money service is simply the interest on a loan of that amount for the period. This is very close to the treatment of the demand for money for transactions purposes in modern theory. The demand for money as an asset is merged with the general demand for assets, since any net money balance at the end of the period will be expected to be lent at the current interest rate for the next period, either to others or implicitly to oneself. This represents a cash balance approach to monetary theory where cash balances are only wanted for transactions purposes. It leads to a strict quantity theory of the price of money in terms of other goods in comparisons between steady states.

The second effective feature of Walras's theory of investment is the recognition that the cost of investment goods will depend on the level of investment, since in the general equilibrium high levels of investment will raise the prices of the productive services needed to produce investment goods and thus the prices of the investment goods themselves. In this way the Walrasian theory takes account of the distinction between the marginal efficiency of investment and the marginal efficiency of capital familiar in the Keynesian literature, as well as the modern notion of the cost of adjustment resulting from an increase in the level of investment.

The two main deficiencies of the Walrasian theory of temporary equilibrium are its lack of an analysis of the demand for assets in general in terms of the future consumption streams that the assets are expected...
to support and the expected utility they promise to yield, and its lack of an analysis of the demand for particular assets in terms of the distribution of their expected returns.

The neglect of future plans for consumption in determining current demand was addressed by Hicks. He did not suppose that consumers make detailed plans but that they form vague plans and expectations of future prices, which still allow some comparative statics methods to be applied in estimating the effect on current demand of changes in current or future expected prices. Since firms are recognized explicitly in Hicks's model, they are also represented as making plans for future inputs and outputs in the light of price expectations, which in his case can be identified with the expectations of individuals who become entrepreneurs. The equilibrium of such a model in one period is a set of prices for all the goods and services traded in the market of that period such that the demand for each good or service, including any contract for future delivery that happens to be traded, equals the supply.

Hicks assumes that each consumer and each firm in its planning applies actual or expected interest rates to discount expected future prices to the present so that the problem of maximizing utility for the consumer, or present value for the firm, does not differ, in principle, from the static problem. However, he must assume that agents are risk neutral or in any case that distributions of prices may be replaced by single prices, or certainty equivalents. Thus he is no more able than Walras to analyse how the value of an asset is influenced by the distribution of its returns. But he is able to consider how changes in current prices influence expected future prices, when expected future prices do not necessarily change by the same amounts. This may be the most significant advance made by Hicks beyond Walras, together with the corollary of planning by firms and consumers for a future that involves expected prices changes.

**Expectations in temporary equilibrium**

A natural way to generalize the Hicksian model and one which has been followed in recent years, for example, by Grandmont, is to impute to each trader an expectation function which gives a probability distribution over future prices, and perhaps over other relevant variables, both market and environmental, as functions of previous values taken by the same variables. Then assuming that each trader has a criterion by which he can choose an optimal trade plan given his expectations, he will determine an excess demand as a function of current prices. Then equilibrium is achieved if there is market clearing at the current prices. Since in the Walrasian or Hicksian model there are two kinds of traders, consumers and entrepreneurs or firms, criteria must be found for each kind of trader.

The criterion for the consumer is rather easily arrived at. It is assumed that each consumer has a von Neumann-Morgenstern utility function, so that any current trade can be evaluated in terms of the expected utility which it makes possible. The utility in turn is derived from the utility of the various possible consumption streams multiplied by their probabilities of occurrence. Of course, these consumption streams and their probabilities logically underlie the expected utilities but they cannot be known to the consumer in detail. The probability distribution on consumption streams is induced by the probability distribution on prices and environmental variables, together with the current trade of the consumer and his plans for future trades, which are in turn contingent on the prices and environmental variables realized in the future. As Hicks points out the consumer may only try to plan levels of spending and certain large expenditures for the future. Particular price expectations will affect these plans and current spending, in total as well as on specific items. What is needed for the theory is to
general equilibrium: The New Palgrave Dictionary of Economics

express consumer's demand finally as a function of current prices so that the condition of market clearing will characterize equilibrium prices. The logic of this analysis is entirely compatible with the methods of Walras, given stationary conditions for tastes, technology, and resources. In simple models it can be spelled out in detail.

On the other hand, there is little agreement on an appropriate criterion for the firm. The difficulty arises that the firm is usually owned by many consumers whose preferences and probability beliefs differ. The consumer does not own capital goods directly but only stock in firms. Moreover, the firms make investment plans and plan their dividend streams in considerable independence of their owners. Walras abstracts from these difficulties in his formal development by two means. First, he treats the consumer as the owner of capital goods which are rented to the entrepreneur. Second, he values the capital goods on the assumption that prices of productive services, interest rates, depreciation rates, and insurance rates will be constant in the future. Given the prices of the productive services arbitrage in the market for capital goods results in a uniform ratio between the net rental of the capital goods, or the prices of their productive services less depreciation and insurance charges, and the prices of the capital goods. In Walras's notation $P_k = p_k / (i + \mu_k + \nu_k)$ where $k$ indexes capital goods, $P_k$ is the price of the capital good, $p_k$ is the price of its service, $i$ is the interest rate per period, $\mu_k P_k$ is the depreciation change per period, and $\nu_k P_k$ is the insurance charge per period. In equilibrium the consumer will be indifferent between capital goods in making investments since they all promise equally attractive returns. This also applies in a similar way to investments in circulating capital or in loans.

Hicks adapts the Walrasian viewpoint to a model in which expectations are point valued but not static by imputing to the entrepreneur, who now owns the capital goods, a plan of inputs, including initial stocks, and outputs, including terminal stocks, whose values are discounted back to the present. Then the entrepreneur chooses a plan with the largest discounted value. In this case the firm achieves maximum value in the eyes of its owner. Radner (1972) adapts the Hicksian viewpoint to a model in which point estimates of future prices are not a sufficient basis for decisions. In a temporary equilibrium model his approach imputes to each firm a von Neumann-Morgenstern utility function over alternative dividend streams. This would imply an expected utility for alternative investments in the current period in the same way that the utility of alternative consumption plans implies expected utility for current spending by the consumer.

On the other hand, by use of the stock market it is possible to bring consumers into the decision-making of firms. The firm's criterion is then to choose a plan of production and investment which leads to a maximum value for its shares on the stock market. It can be argued that if the firm chooses a plan which fails to maximize its value in the stock market the stock market will not be in equilibrium, since there is a profitable arbitrage opportunity for someone to buy controlling interest in the firm and revise its planning.

Existence theorems for temporary equilibrium have been proved in many special cases, particularly for trading economies where production does not enter and the number of periods is taken to be finite. Typically the method of proof parallels a method of proof for the model with complete markets, that is, appropriate continuity properties for individual, and thus market, excess demand functions are proved for the goods and services, and the futures contracts, if any, which are traded in the current period. The application of a fixed point theorem completes the proof that a price system exists which results in market clearing, that is, puts each excess demand function equal to zero. However, some special
problems do arise. Consider a market at the start of period 1 when there are two periods and a second market will be held at the start of period 2. There is uncertainty about the endowment of period 2 and about the spot prices of the second market. All goods are perishable. Suppose there is trading in contracts for current delivery and in forward contracts for delivery in the second period. Let $x^n_h$, $x^2_h$ be the vectors of goods and services delivered to the $h$th consumer in periods 1 and 2 respectively. Denote by $w^n_1$, $w^n_2$ the vectors of endowments for the $h$th consumer in periods 1 and 2 respectively. Let $\psi^h(p_1, q_1)$ be the expectation function of the $h$th consumer, that is, the value of $\psi^h$ is a probability distribution of $(w^n_1, p_2)$, where $p_1$ and $p_2$ are the vectors of spot prices in periods 1 and 2, while $q_1$ is the vector of forward prices in period 1 for sure delivery in period 2. There is a finite set of goods and services in each period and a finite number of consumers each of whom holds positive initial stocks in the first period. The possible consumption sets are $\chi^1_1 = \mathbb{R}^{n_1}_+$ and $\chi^2_h = \mathbb{R}^{n_2}_+$, the positive orthants of the respective commodity spaces. The following assumptions are made for the consumer.

1. (1) There is a concave and monotone utility function $u^h$ of von Neumann-Morgenstern type, that is, preferences over trades in the first period may be determined by taking the sum of the utilities of the resulting consumption vectors weighted by these probabilities of occurrence.
2. (2) The expectation function $\psi^h(p_1, q_1)$ is continuous in an appropriate sense.
3. (3) For every $(p_1, q_1)$, $\psi^h(p_1, q_1)$ gives probability 1 to the set of $(w^n_1, p_2)$ for which $p_2$ is positive.
4. (4) The support of $\psi^h$ is independent of $(p_1, q_1)$. The convex hull of the projection of the support of $\psi^h$ on the second period price space has a non-empty interior $\Pi^h$.

With these assumptions a necessary and sufficient condition for the existence of competitive equilibrium is that the intersection $\Pi$ of the $\Pi^h$ not be empty. In other words there must be an open set of spot prices in the second period which all traders believe to have a positive probability of occurrence. Then, if the forward prices $q_1$ lie in $\Pi$ and $p_1$ and $q_1$ are positive, excess demand is well defined. Let $D$ be the set of $(p_1, q_1)$, satisfying these conditions. As $(p_1, q_1)$ converges to the boundary of $D$, excess demand diverges to $\infty$. This happens because preferences are monotone and for $q_1$ outside $\Pi$ unlimited arbitrage becomes profitable to some trader. These results were reached by Green (1973). It should be noted that point expectations are not consistent with the assumption that $\Pi$ is not empty, unless all traders expect the same prices next period. However, $\Pi$ might not be needed to bound short sales if other considerations limit the commitments that will be accepted in view of the likelihood that they can be fulfilled.

Money in temporary equilibrium

There is little difficulty in introducing money into the temporary equilibrium model. It must be
recognized that money serves in at least two capacities, to facilitate exchange, and as an asset with its
own prospects for losing or gaining value relative to other goods. In addition it may serve as a
numeraire, in terms of which prices are stated. In its capacity as an asset in a market with uncertainty,
money may contribute to a diversified portfolio. On the other hand, in its capacity to facilitate exchange
money balances will affect the cost of making transactions and thus the stream of consumption which is
realizable from given resources. Given his context, where risks are assumed to be insurable, Walras is
particularly clear in his treatment of money. If some good other than money serves as numeraire, the
price of the service of availability of money is written by Walras as \( p_m \), and the price of money itself as
\( P_m \). Then as for any asset the ratio of the net rental to the asset price is equal to the interest rate or
\( \frac{p_m}{P_m} = i \). Thus if money serves as the numeraire, \( P_m = 1 \) and \( p_m = i \).
Although his analysis seems somewhat artificial because uninsurable risks are absent, Walras indicates clearly how cash balances may contribute to productive efficiency and to consumer utility.

If attention is concentrated on the asset role of money, so that the transaction role is neglected, it may be shown that the assumption of static expectations may lead to the absence of equilibrium for the current period. Static expectations imply that the relative prices of present and future goods cannot be changed. Therefore, price changes leading to inter-temporal substitution are prevented. Only the wealth effects of price changes have free play since price level decreases raise the value of the money stock and conversely for increases. However, as Grandmont (1983) has demonstrated, these real balance effects may be insufficient to equate supply and demand. For example, if there is excess demand for current goods, this excess demand may not be eliminated by increases in the current price level which are accompanied by equally large increases in the future price level. In a trading economy the effect of the price increases is to reduce the wealth of the traders toward the endowment point \((w(1), w(2))\) in a two period model. Suppose there is only one good, which is perishable, and money is the only store of value. Then if the marginal utility of the current endowment exceeds the marginal utility of the second period endowment for all traders, the price of the good cannot rise high enough to reduce current demand to the current endowment. The same dilemma may arise when the Hicksian elasticity of expectations is equal to one, even though expected prices do not equal current prices.

Grandmont considers a model of this type where trading in futures contracts is excluded so that point expectations do not cause difficulties. It is a trading economy in which consumers receive an endowment of perishable goods in each period of their lives and an initial money stock in the first period. In the current period they maximize a utility function of consumption over the remaining periods of life (assuming the life span to be known) subject to budget constraints of the form
\[
p_t x_t + m_t = p_t w_t + m_{t-1},
\]
where future prices \( p_t \) are equal to functions \( \psi_t \) of present prices \( p_1 \). He assumes

1. (1) The utility function \( u^h(x_1, \ldots, x_{n(h)}) \) is continuous, increasing, and strictly quasi-concave for every \( h \).
2. (2) The endowments \( w_t^h \) are positive for all \( h \) and \( t, 1 \leq t \leq n(h) \).
3. (3) Total money stock \( M = \sum_{h} m_{t^h} \) is positive.

He then proves that the temporary monetary equilibrium exists, that is, money prices are well defined, if
every agent's price expectations $u_t^h$ are continuous and, for at least one agent, who will be living in the next period and who has a positive money stock, price expectations are bounded away from 0 and $\infty$. In Grandmont's opinion this result leaves the existence of temporary equilibrium ‘somewhat problematic’. However, it seems quite inappropriate to deal with a money which has no role to play in facilitating transactions. Grandmont and Younes (1972) have studied general equilibrium in a model similar to the model just described except that lifetimes are taken to be infinite and utility functions are separable by time period, that is $u_t^h(x_1, \ldots) = \sum_{t=1}^{\infty} \delta_t u_t^h$ for $0<\delta<1$. Also money is now assigned a role in transactions, that is, only part of the proceeds of sales in the current period can be used to finance purchases in this period. Thus in each period there is both a budgetary constraint, as before and, in addition, a liquidity constraint, which may be written in simplest form as

$$p_t(x_t - w_t) + \leq m_t + k p_t(x_t - w_t), \quad \text{where for any vector } z \text{ we write } z_i^+ = \max(z_i, 0) \text{ and } z_i^- = \max(-z_i, 0), \quad \text{and } 0<k<1.$$ Thus the fraction $k$ of receipts from sales can be used to buy goods in the current period. This fraction could be allowed to vary by consumer and by good. The constraint on purchases is entirely in the spirit of Walras. It is an explicit modelling of a need for liquidity that he left implicit in his account.

In order to prove that a monetary equilibrium exists an assumption to bound expected prices is made which is very similar to the previous assumption for this purpose, and also very similar to the assumption made by Green to obtain existence of temporary equilibrium in a non-monetary economy with futures trading. The assumption is that the set of expected prices, over a finite planning horizon, that result from all possible choices of current prices, which are assumed positive, lie in a compact subset of the set of positive future prices. Then if all consumers have continuous expectations which satisfy this assumption, and the assumptions of the previous model are also met, there will exist a temporary equilibrium in this case also. Indeed, the case $k=1$, where the liquidity motive is lacking, can be allowed.

In the second model where money has a transactions role expectations are described as depending on past prices as well as current prices, which leads inelastic price expectations to be more plausible. It also gives plausibility to correct foresight in states of stationary equilibrium over sequences of periods. Grandmont and Younes (1973) prove that the stationary equilibria of the model are not Pareto optimal. However, they can be made Pareto optimal by use of a lump sum tax to reduce the quantity of money by a factor equal to the discount factor for utility. It is then proved that a continuum of such equilibria exists to sustain any Pareto optimal allocation, since the price level falls by the same factor, and it is not worthwhile to reduce a money stock, even if it is in excess of transaction requirements. Moreover, if the tax rate is set slightly too high, the consumer will always wish to increase his real balances and no stationary equilibrium will exist. Grandmont and Younes are not able to prove that an exact stationary equilibrium exists for a fixed money stock, although a near equilibrium exists if the discount factor is near 1.

In addition to proofs of existence and non-optimality for monetary equilibria, Grandmont and Younes show that the quantity theory holds between stationary equilibria, that is, if $p$ and $m_h$, $h = 1, \ldots, m$, provide a stationary equilibrium, then $\lambda p$ and $\lambda m_h$ also provide one. This is the conclusion of Walras as well. On the other hand, the stationary equilibria of a monetary economy will differ from the stationary equilibria of a barter economy unless $\delta = 1$. This is apparent from the fact that the barter
Economy's equilibria are Pareto optimal and the monetary economy's equilibria are not, unless $\delta = 1$. Thus the simple 'classical dichotomy' does not hold.

Equilibrium over time

In addition to temporary equilibrium Hicks considered the possibility of equilibrium over time, in the sense that the expectations held by traders in one market about prices on future markets are realized when those future markets are held. However, when there is uncertainty it is not clear what is meant by the realization of expectations. If expectations take the form of a non-atomic probability measure over future prices, any vector of prices within the support of the measure is as likely as any other, that is, it has zero probability. Nor does the Hicksian trick of replacing the probability distribution by a representative price, depending on the trader, avoid the difficulty, since the representative price is not typically a statistic of the price distribution, such as the mean or the mode. Thus even if all traders held the same expectations in the sense of a probability distribution for prices, they would not have the same representative prices except by the chance that their circumstances and their risk preferences also coincide.

A way to resolve this dilemma was provided by Radner (1972). His solution is a type of perfect foresight. All traders hold the same point expectations for prices with certainty, contingent on the event in which the market is held. Only a finite number of dates are allowed and only a finite number of events may occur in each. From the viewpoint of a given market the relevant elementary events are the possible sequences of states of nature that may occur up to the horizon. For any such sequence the traders expect correctly a corresponding sequence of prices. This does not lead to a grand initial market in which all future exchanges are arranged because the set of forward commitments which are actually available in the market is a small subset of all those associated with future events. For example, it may be that most commodities are traded for sure delivery and only one commodity (money or the numeraire) is traded on a contingent basis (insurance). It should be noted that this construction does not depend on any agreement between traders on the probabilities of the alternative events. Thus the expectation functions which were introduced in the discussion of temporary equilibrium would not be likely to be the same for different traders.

In this setting the trader plans a sequence of consumptions contingent on the events in which they occur and also a sequence of trades on the markets which are open. Spot markets are open for all commodities at all dates but only a small subset of the possible markets in forward contracts may be open at any particular date. In any case since the number of dates and states of nature and thus of elementary events is finite, only finitely many prices will arise.

Let $X_h$ be the consumption set of the $h$th consumer. Let $M$ be the set of elementary date-events pairs. A consumption-trade plan for the $h$th consumer is a pair $(x^h, z^h)$ where $x^h_m$ is the consumption planned for $m \in M$ and $z^h_m$ is the trade planned for $m \in M$. Let $\Gamma_h(p)$ be the set of feasible plans for $h$, given prices $p$. In particular, $(x^h, z^h)$ in $\Gamma_h(p)$ implies that consumption $x^h_m$ plus net deliveries $z^h_m$ due at $m$ are not greater than resource endowments $w^h_m$ for each $m$ and the budget constraint $p_m z^h_m$ holds at each $m \in M$.

Let $\gamma_h(p)$ be the set of plans in $\Gamma_h(p)$ which are optimal for $h$. An equilibrium of plans and price
expectations (including current prices which are known) is given by plans \((x^h, z^h)\) and expected prices \(p\) such that \((x^h, z^h)\) is in \(\gamma^h(p)\) for each \(h\), that is, the plans are preferred at the expected prices, and the sum \(\sum_{m} z^h_m\) of commitments at each \(m\) is non-negative, and the value of commitments \(p_m \sum_{h} z^h_m = 0\) at each \(m\), that is, Walras's Law holds. In such a purely trading economy for perishable goods with a finite set of dates and events and under assumptions of the usual kind on preferences, and positive endowments which lie in the interior of consumption sets, Radner proves that an equilibrium exists.

It is not difficult to bring production into this setting if firms are introduced with fixed production plans and with shares which are traded on a stock exchange. The ownership of a share of a firm can be equated to the ownership of a share of its output, including the end of the period capital stock. The output of a firm at any date would depend on the event, and the function relating this output to the events would be known by traders, just as future prices of goods are known, contingent on events. Now, in addition to goods prices, share prices are foreseen in each event at each date with certainty. As before the number of dates and events is finite.

A feature of this model not present in the trading model is that consumers do not own the resources of the firms as individual goods but as proportions of the batch of goods that firms hold. The consumer can buy and sell goods forward by means of long and short positions in the stock market but the trade he arranges by these means for one event at the next date determines his trade for all other events at that date. Thus spot markets still may offer useful alternatives, quite aside from the practical difficulties of physically dissolving the firm. Of course, given the presence of spot markets, dissolution of the firms is not needed if the value of the firm equals or exceeds the value of its resources.

If one tries to go further to specify how the production and trading plans are arrived at, a major problem arises of setting the objectives of the firm. Hicks solves this problem by assuming that the production plan chosen would have the maximum discounted value among those available. This value could be calculated since expectations were single-valued and interest rate, actual or expected, could be used in arriving at present values. Moreover, firms were treated like single proprietorships. In the modern literature firms have sometimes been assigned utility functions defined on the streams of profits.

Another suggestion is to suppose that the firm adopts the plan that maximizes the value of its shares on the stock market. This would seem to be the approach most in accord with other parts of general equilibrium theory. However, it encounters the difficulty that the judgement of the management and the judgement of the market on the probability of different events may not coincide. If this difference of judgement exists, the market solution would be for the firm to be purchased through a takeover by those who value its potential most highly and the management displaced. Markets which work in this way would correspond quite well to the original Walrasian model.

Various results on the existence of a general equilibrium have been reached with special models of production by firms. One theorem of Radner extends the existence of an equilibrium of plans and price expectations to this context. His assumptions are:

1. (1) Consumers satisfy the usual conditions on convexity, non-satiation, and positive endowments.
2. (2) Consumers own the shares of firms and each consumer owns shares in every firm.
3. (3) Producers have closed, convex production sets with free disposal. The total production set satisfies the condition that the negative of a producible vector of commodities is not producible.
4. (4) Each firm has a continuous, strictly concave utility function on profit streams.
With these assumptions he does not achieve a full existence theorem because the model is not well adapted to handle the entry and exit of firms. What may happen is that some firms show an excess supply of shares in some events and dates. Then since the firms are treated like partnerships with unlimited liability, negative share prices might be justified at this point. In any case the questions of entry and exit of firms is one that the Arrow–Debreu model also fails to deal with. The theorem proved by Radner only finds a ‘pseudo-equilibrium’ where the value of total excess supply (of shares) is minimized.

In the foregoing discussion it has been assumed that only a subset, possibly small, of the potential Arrow–Debreu markets is open. It is possible to justify the selection of markets which are open by postulating costs for carrying out transactions. If the markets which are open are given, the previous equilibria may be supported by assigning infinite transactions costs to the lost markets and zero costs to the open ones. Otherwise the open markets will be endogenous to the general equilibrium. In the analysis of markets with transaction activities which consume resources the same convexity or linearity assumptions have been used as for the production technology. Then it is not difficult to prove existence of equilibrium under assumptions of the usual sort.

**Rational expectations**

It has been implicitly assumed in the preceding discussion of temporary equilibrium that the traders have the same information available. If this is not the case the complication arises that the equilibrium price may convey information. For example, in the market for umbrellas if some traders have the benefit of weather forecasts and some do not, a high price based on the demand of informed traders will signal to uninformed traders that rain is expected. Then all traders are informed and an equilibrium price must be consistent with fully informed demand.

A difficulty arises if it happens that the utilities of consumers depend on events in contrary ways, that is, uninformed consumers use umbrellas to ward off sun and informed traders to ward off rain. Then price will be higher if rainy weather is expected by informed traders but if uninformed traders perceive this and become informed, the high price may not appear and a fully informed market may not show a price difference depending on the weather forecast. But then no information is transmitted so the weather forecast cannot be read out of equilibrium prices. The conclusion is that no equilibrium is possible. However, the result requires an exact balance in the effects of rain and sun on the two sets of traders, so it is unlikely to hold. More robust examples of nonexistence were given by Green (1977) and Kreps (1977). The idea of the discontinuity was first proposed by Radner (1967).

A rational expectations equilibrium is said to exist if there is a function \( \phi \) mapping states of the world into equilibrium prices which is invertible, that is, \( \phi^{-1} \) exists, mapping prices, from a normalized set, into states of the world. It is clear that such a function will exist if the equilibrium price which appears when all traders are fully informed is uniquely determined by the elementary event, and the relation is one to one. It is also clear, given a finite set of elementary events, that the correspondence of prices to elementary events will be one to one in all but exceptional cases. Then the equilibrium is said to be revealing. But the price function of a revealing full information equilibrium is a price function that provides a rational expectations equilibrium. This observation is due to Grossman (1981). The situation is more complicated when the possibility is recognized that spending resources will allow
An infinite horizon

In the Arrow–Debreu model of general equilibrium there are a finite number of periods, a finite number of locations, a finite number of events, and a finite number of commodity types, so the number of distinct goods when all these grounds for distinguishing goods have been recognized is still finite. The principal objection to the restriction to a finite number of goods is that it requires a finite horizon and there is no natural way to choose the final period. Moreover, since there will be terminal stocks in the final period there is no natural way to value them without contemplating future periods in which they will be used. The finiteness of the number of locations and commodity types is achieved by making a discrete approximation to a continuum, and perhaps the finiteness of the number of states of nature can also be viewed in this light. But in the case of time, a discrete approximation by periods still leaves a denumerable infinity of dates.

There are two principal models in which an infinite number of goods appear. In one model there is a finite number of infinitely lived consumers. Such a consumer may be considered to represent a series of descendants stretching into the indefinite future, so that consumers alive in the present period have an interest in the goods of all periods. The other model has an infinite number of consumers, but only a finite number of them are alive in any period. This model is called the overlapping generations model. It was first proposed and explicitly analysed by Samuelson (1958).

A model of general competitive equilibrium with a finite number of consumers and an infinite number of commodities was first presented in rigorous form by Peleg and Yaari (1970). They assumed the number of commodities to be denumerable. This is a basic case since a noncompact but separable commodity space can be approximated arbitrarily closely with a denumerable set of commodities in the same sense that a compact commodity space can be approximated by a finite set of commodities. This assumes that a sensible neighbourhood system can be defined in the commodity space, as Debreu does for the dimensions of location and time with places and periods.

Peleg and Yaari present a trading model without production. The commodity space $s$ is the space of all real sequences. In order to discuss continuity the space must be given a topology, in this case, the product topology. Thus a sequence of points converges if it converges in every coordinate, that is, $x^s \to x$, $s = 1, 2, \ldots$, if $x^s(i) \to x(i)$ for $i = 0, 1, \ldots$. The space is presented as a sequence of real numbers but by grouping terms it may equally well represent a sequence of vectors, for example, commodity bundles occurring in successive time periods. The $h$th trader has an initial stock $w^h$, where $w^h \in s$ and a preference relation $\succeq h$, which is reflexive, transitive, and complete on $s_+$, the set of nonnegative sequences. Strict preferences $\succ h$ is defined by $x \succ h y$ if $x \succeq h y$ and not $y \succeq h x$.

Peleg and Yaari prove an existence theorem for this economy on the following assumptions.

1. (1) Desirability. If $x \succeq h y$, then $x \succeq h y$.
2. (2) Strong convexity. If $x \neq y$ and $x \succeq h y$, then $\alpha x + (1 - \alpha) y \succ h y$ for $0 < \alpha < 1$.
3. (3) Continuity. The two sets \{$y \in h x$\} and \{$x \succeq h y\$} are closed.
4. (4) Positivity of total supply. Let $\mathcal{W} = \sum_{h=1}^{m} \mathcal{W}_h$. Then $\mathcal{W} > 0$.

A price system is a real sequence $\pi > 0$ which satisfies $\sum_{i=0}^{\infty} \pi(i) \mathcal{W}_h(i) < \infty$, that is, the value of the initial bundles is finite. This implies that $\pi(i) \mathcal{W}_h(i)$ converges to 0 as $i \to \infty$. A competitive equilibrium is given by $(x_1, \ldots, x_m, \ldots)$ such that $\mathcal{W}$ is a price system, $\sum_{i=0}^{\infty} \pi(i) x_h(i) \leq \sum_{i=0}^{\infty} \pi(i) \mathcal{W}_h(i)$, for each $h$, and $\sum_{i=0}^{\infty} \pi(i) x(i) \leq \sum_{i=0}^{\infty} \pi(i) \mathcal{W}_h(i)$ implies $x_h \succeq h^x$. Peleg and Yaari prove that a competitive equilibrium exists.

It is clear from their discussions, and it has become even clearer in subsequent work, that the use of a topology such that, in the context of an infinite horizon interpretation of the model, impatience is implied by continuity of preferences is the crucial assumption for a proof of existence. That the product topology implies impatience may be seen in the following way. If $x \succeq h^x$ then by continuity there is a neighbourhood $U$ of $x$ such that $z \in U$ implies $z \succ h^y$. However, a neighbourhood $U$ is defined by $|z(i) - x(i)| < \varepsilon$ for a finite number of coordinates where the remaining coordinates are free. Thus given $y \succeq h^x$, there must exist $N > 0$ such that $z(i) = x(i)$ for $i \leq N$ and $z(i) = 0$ for $i > N$, and $z \succ h^y$. These conditions are met if the preference order is representable by a separable utility function which is the sum of periodwise utilities discounted back to the present at a constant rate per period, and these utilities are continuous and uniformly bounded. Such a utility function is a common way of expressing impatience.

A model of general competitive equilibrium which allows for production where there is an infinite number of commodities was first presented in a rigorous form by Bewley (1972). A preference relation $\succeq_h$ is assumed for each consumer as in Peleg and Yaari. We will describe Bewley's model for the case of a sequence of periods with an infinite horizon where $N_1$ is the finite set of commodities available in the $t$th period. Then the set of all commodities is

$$M = \bigcup_{t=1}^{\infty} N_t.$$

It is assumed that $M = M_c \cup M_p$ where $M_c$ and $M_p$ are disjoint and $M_c$ contains the consumption goods. Bewley confines attention to the commodity space $l_\infty$ of bounded sequences of real numbers. Let $K_c = \{x \in l_\infty | x(i) = 0 \text{ for not } i \in M_c, x(i) \geq 0 \text{ for } i \in M_c\}$, and similarly for $K_p$. Let $\bar{K}_c$ have the same definition as $K_c$ except that $x(i) > \varepsilon > 0$ for all $i \in M_c$ for some given $\varepsilon$. Bewley's existence theorem holds for a weaker notion of continuity than that of componentwise convergence, but we will stay with the definition used by Peleg and Yaari for the sake of simplicity. Then the assumptions on the consumer sector are

1. (1) The consumption sets $\mathcal{X}_h = K_c - \mathcal{W}_h$ where $w_h$ is the endowment of the $h$th consumer.
2. (2) The sets \( \forall Y \preceq h x \) and \( \forall x \succeq h Y \) are closed. Also \( \forall Y \succeq h x \) is convex.

3. (3) \( M_c \) is not empty and for each \( h \), if \( x \in X_h \) and \( y \in K_c \), then \( x + y \succeq h x \).

The production sector is defined by means of production sets \( Y_t \) which convert inputs belonging to \( N_{t-1} \) into outputs belong to \( N_t \). The \( Y = \sum_{t=1}^{\infty} Y_t \) The assumptions on the production sector are:

4. (4) \( Y \) is a convex closed cone with vertex at 0.

5. (5) If \( w \in l_{\infty} \), then \( Y + w \cap l_{\infty} \) is bounded.

6. (6) If \( y \in Y \), then \( y^n \in Y \) where \( Y^*_t = Y_t \) for \( t = 0, \ldots, n \), and \( Y^*_t = 0 \) for \( t > n \).

7. (7) \( -K_p \subset Y \)

Assumption (4) means that each \( Y_t \) is a linear activities model as Walras assumed. Assumption (5) excludes unbounded production from given inputs. Assumption (6) allows production to end at any time with free disposal of the final outputs. Assumption (7) allows free disposal of all goods other than consumption goods.

In addition there is one assumption which relates the consumption sector and the production sector.

8. (8) For each consumer \( h \), there exists \( \bar{x}_h \in X_h \) and \( \bar{y}_h \in Y \) such that \( \bar{y}_h(i) - \bar{x}_h(i) > \epsilon > 0 \) for all \( i \) and some \( \epsilon > 0 \).

Assumption (8) protects consumer income in the sense that the consumer is not reduced to the subsistence level in equilibrium. That is to say, there are cheaper consumption bundles within this consumption set at equilibrium prices. An equilibrium is an allocation \( (x_1, \ldots, x_m, y) \) and a price sequence \( \pi = (\pi(0), \pi(1), \ldots) \) where \( \pi(i) \) is non-negative for all \( i \) but different from zero for some \( i \), which satisfy the conditions:

1. (I) \( \forall y \in Y \) and \( \pi z = 0, \pi z \leq 0 \) for all \( z \in Y \). The profit condition.

2. (II) \( x_h \in X_h \) and \( \pi x_h = 0 \), all \( h \), and \( z \succeq h x_h \) implies that \( \pi z > \pi x_h \). The demand condition.

3. (III) \( \sum_{h=1}^{m} x_h = y \). The balance condition.

On the basis of the assumptions Bewley is able to prove that an equilibrium exists where the price system \( \pi \in l_1 \), that is, \( \sum_{i=0}^{\infty} \pi(i) < \infty \). This represents a generalization of the classical existence theorem in the form given by McKenzie to the case of denumerably many commodities, retaining the assumption of a finite number of consumers. The argument is stated in terms of an infinite horizon and a finite number of goods in each period, but the original theorem is more general and applies to the case of uncertainty with an infinite number of events as well as to models with a continuum of commodities. The continuum of commodities may arise from a variation in the physical properties of the goods and services.

Overlapping generations
In the overlapping generations model of general equilibrium the number of consumers as well as the
number of commodities is infinite. However, at any given time the number of both is finite. While the
model with a finite number of infinitely lived consumers treats the consumers who are living as if their
lives were extended into the indefinite future by the lives of their descendants, in the classical
overlapping generations model bequests are neglected and each generation is assumed to be interested
only in its own consumption.

The first rigorous analyses of an overlapping generations model in a general equilibrium setting were
done by Balasko, Cass and Shell (1980) and by Wilson (1981). They treat an exchange model in which
all goods perish in each period, and each consumer receives an endowment in each period. They assume
that each consumer lives for two periods. However, this assumption is not essential. What is essential is
that lifetimes are finite in length and some of the people alive at any date have lifetimes which overlap
the lifetimes of some people who are born later than they.

The formal model makes these assumptions.

1. (1) In each period \( t \) \((t=1, 2, \ldots)\) there is an arbitrary, finite number of perishable commodities
\( n'_t \geq 1 \).
2. (2) Each consumer \( h=1, 2, \ldots \) lives for two periods. At the start of period \( t \) an arbitrary but finite
number of consumers is born with indices \( h \in G^t \).
3. (3) Consumption sets \( X_h = R^{n_h(0)}_+ \) for \( h \in G^0 \) the consumers alive when the economy begins and
\( X_h = R^{n(t)}_+ \times R^{n(t+1)}_+ \) for \( h \in G^t, t \geq 1 \). Write \( x_h = x'_h \) for \( h \in G^0 \) and \( x_h = (x_h(t), x_h(t+1)) \)
for \( h \in G^t \).
4. (4) Each consumer has a utility function, \( u_h(x(1)) \) for \( h \in G^0 \) and \( u_h(x(t), x(t+1)) \) for \( h \in G^t \).
Utility functions \( u_h \) are continuous, quasi-concave, and without local maxima.
5. (5) Each consumer receives an endowment, \( w_h = w_h(1) \) for \( h \in G^0 \) and
\( w_h = (w_h(t), w_h(t+1)) \) for \( h \in G^t \). For each \( h \), \( w_h \geq 0 \) and \( w_h \neq 0 \).
6. (6) The economy is inter-temporally irreducible. Let \( I(t) = \{h| h \in G^s \text{ for } 0 \leq s \leq t\} \). Then there
exists a sequence \( t_u \to \infty \) with the following property. Given any allocation \( x=(x_1, x_2, \ldots) \) and \( I_1 \)
\((t_u) \) and \( I_2(t_u) \neq \varnothing \), with \( I_1(t_u) \cap I_2(t_u) = \varnothing \), and \( I_1(t_u) \cup I_2(t_u) = I(t_u) \), there exist \( \nu_h \geq 0 \) for
\( h \in I_1(t_u) \) and \( x'_h \geq 0 \) for \( h \in I_2(t_u) \), such that \( \sum_{h \in I_1(t_u)} x_h(t_u) = 0 \) when \( \sum_{h \in I_1(t_u)} w_h(t_u) = 0 \), for
\( 1 \leq i \leq n'_t, \ 1 \leq t \leq t_u + 1 \), and

\[
\sum_{h \in I_2(t_u)} x'_h \leq \sum_{h \in I_1(t_u)} (w_h + \nu_h) + \sum_{h \in I_2(t_u)} w_h.
\]

Moreover, \( u_h(x_h) \geq u_h(x_h') \) for all \( h \in I_2(t_{\mu}) \) with the strict inequality for some \( h \).

Assumption (6) is the irreducibility assumption of McKenzie adapted to economies made up of the consumers born by the period \( t_{\mu} \). It says that it is always possible to increase the welfare of the second subgroup if the scale of the endowment of the first subgroup is increased.

Let \( p=(p(1), p(2), \ldots) \) where \( p(t) \in R^n(t) \). Then the pair \((x, p)\) is a competitive equilibrium if

1. (I) For all \( h, u_h(x_h) \) is maximal over all \( z_h \) such that
   \[
   p(t)z_h(t) + p(t+1)z_h(t+1) \leq p(t)w_h(t) + p(t+1)w_h(t+1) \quad \text{if} \quad h \in G^t, \quad t \geq 1, \text{ and}
   \]
   \[
   p(1)z_h(1) \leq p(1)w_h(1) \quad \text{if} \quad h \in G^0, \quad \text{where} \quad z_h \geq 0.
   \]

2. (II) \( \sum_{h \in G^t} x_h(t) \leq \sum_{h \in G^t} w_h(t) \) with equality if \( p_i(t) > 0 \), where the summation is over \( h \in G^t \cup G^{t-1} \), \( 1 \leq i \leq M(t) \) and \( t \geq 1 \).

Condition (I) is the usual demand condition and condition (II) is the balance condition. Balasko, Cass and Shell (1980) prove that the six assumptions listed imply the existence of a competitive equilibrium. They show that the artificial assumptions on birthdates and lifetimes are irrelevant by a redefinition of the period. They also conjecture that the introduction of production and consumption sets of the usual classical type, which are closed, convex, and bounded below, would cause no major difficulties.

Wilson (1981) treats an economy which may contain both finite lived and infinite lived consumers and which may be specialized to either. He also allows intransitive preferences. He uses a somewhat simpler version of irreducibility and proves existence in an exchange economy where the number of goods in each period is finite in two circumstances (1) when the consumers are all finite lived and (2) when a finite subset of infinite lived consumers own a positive fraction of the endowment in all but a finite number of periods. If preferences are transitive and strictly convex, the competitive equilibrium is also Pareto optimal. Thus Wilson's results contain the theorems on existence of Bewley and Balasko, Shell, and Cass as special cases while also providing conditions in the model sufficient for Pareto optimality.

A striking difference between the competitive equilibria of economies where the number of consumers is finite, and the competitive equilibria of economies with overlapping generations and an infinite horizon, where the number of consumers is infinite, is that with perfect foresight the former equilibria are also Pareto optima while the latter need not be. This is the major point emphasized by Samuelson in his initial paper. The most general theorem proving that competitive equilibria are Pareto optima even when the number of commodities is infinite provided that the number of consumers is finite is due to Debreu (1954). Under some additional smoothness conditions on utility and boundedness conditions on prices and allocations Balasko and Shell (1980) prove that the allocation \( x \) of a competitive equilibrium is Pareto optimal if and only if \( \sum_t (1 / ||p(t)||) = \infty \). This is a condition which had already been shown to characterize efficiency in neoclassical production economies by Cass. It is clear that \( \lim \inf (||p_{t+1}|| / ||p_t||) = r \leq 1 \) implies that the condition for Pareto optimality is satisfied since the sums dominate \( \sum_t (1 / r^t) \) which diverges. Intuitively, for a stationary economy if the interest rates are asymptotically non-negative, the competitive equilibria will be Pareto optimal, or if the economy is growing, if the interest rates exceed the growth rate, Pareto optimality follows.
Limitations of the analysis

As mentioned in the beginning the claim of the theories described as general equilibrium theories to be ‘general’ is qualified by the set of conditions considered to be constant. Walras as well as most subsequent theorists classified the constant factors as tastes, technology, and resources, including population. However, all three of these categories have been treated by some economists as responding, in ways amenable to analysis, to market variables. These studies have usually been confined to a few variables and have usually been partial equilibrium in character, although the classical school of economists included population as a major variable in models of economic development. Their models are comprehensive but lack the market equilibrium analysis of the general equilibrium theories, whose inspiration appears to have been found in the marginal utility theory of consumer demand. Similarly, tastes have sometimes been modelled to depend on past consumption or advertising, and technology has been modelled to depend on research and development spending and on the rewards to innovation. Also natural resources, in terms of resources known to exist, are often treated as responding to prices.

From this perspective general equilibrium theory is a partial theory of economic affairs with a special set of *ceteris paribus* assumptions. The variables which are left free are chosen because they lend themselves to a particularly elegant theory in terms of consumer demand under budget constraints and producer supplies with profit conditions where these constraints and conditions are established by prices equating demand and supply. This was the vision of Walras, perhaps guided by the theory of static equilibrium of mechanical forces which he found in Poinsot.

Another direction of abstraction in general equilibrium theory in its classic expressions has been to ignore the effects of processes which do not pass through the market. In particular each consuming unit is described as interested only in its own consumption in the theory of Pareto optimality and as uninfluenced in its choices by the choices made by other households. Similarly, the production possibilities of one firm or process are treated as independent of the productive activities of other firms. Some attempts have been made to incorporate these effects in the general equilibrium models but not with complete success. In particular there is not a good theory of existence when consumer possibility sets or production sets are affected by levels of consumption and production.

The convexity assumptions which have appeared in general equilibrium models from the time of Walras are often not good approximations of reality though they are depended on for many of theorems of the subject, such as the theorems on existence and Pareto optimality. However, there is a theory of approximate equilibria and of limiting results as the size of the market increases relative to the participants which does something to bridge the gap between theory and fact.

Finally, the assumption that the market participants take prices as independent of their actions fails to describe many markets, and describes very few exactly. Nonetheless, this assumption may be useful for a theory that embraces all markets, whose special features cannot be described in detail. It may, that is, give a good approximation to the working of the economy as a whole. Also it is useful for its implications for optimality, a point which was perceived, albeit through a glass darkly, by Walras. The proper notion was later found by Pareto.

Just as the model does not accommodate monopoly easily, government does not fit in well. A chief difficulty arises from its compulsory features which allow it to extract resources by force rather than by voluntary agreement. Government is not easily described either as a producer selling services, or as a
voluntary organization performing acts of collective consumption, though in ways it resembles both. Voluntary societies also do not fit perfectly in the scheme of producers and households though the disparity is less, since they must meet their expenses from contributions by the membership who will not contribute unless the services of the society to them are worth the dues they pay.

Properties of general equilibrium

Walras set the major objectives of general equilibrium theory as they have remained ever since. First, it was necessary to prove in any model of general equilibrium that the equilibrium exists. Then its optimality properties should be demonstrated. Next it should be shown how the equilibrium would be attained, that is, the stability of the equilibrium and its uniqueness should be studied. Finally, it should be shown how the equilibrium will change when conditions of demand, technology, or resources are varied, the subject now called comparative statics. He contributed to all these lines of research. Walras's arguments for existence are not conclusive but he did contribute a basic principle, that the model should be neither underdetermined nor overdetermined. That is, the number of independent equations to be satisfied and the number of variables to be determined should be equal. Some critics saw right away that this equality did not ensure a meaningful solution to the equation system, for example, that the solution to such an equation system is not guaranteed to be real. The question was not taken up seriously until the 1930s and the first rigorous treatment was given by Wald (1935, 1936b). Then in the 1950s more complete solutions on neo-classical assumptions were found by Arrow and Debreu (1954), McKenzie (1954) and Nikaido (1956).

In the discussion of models of general equilibrium that have been given above, the first requirement has been a set of assumptions from which existence could be inferred. This approach to the subject was begun in the papers of Wald and von Neumann, presented to the colloquium of Karl Menger (mathematician and son of Carl Menger, the neoclassical economist) in Vienna in the 1930s. The optimality that Walras claimed for competitive equilibrium, under conditions of certainty, except for insurable risk, did not seem to go beyond individual maximization of utility in face of an equilibrium price system. However, Pareto gave a genuinely social definition that the allocation of goods and services in a competitive equilibrium is such that no reallocation is possible with some consumer better off unless some consumer is made worse off. In fact, Walras seemed to be groping for the same definition and his arguments may be slightly extended to establish Pareto's proposition.

As noticed in the earlier discussion of markets with certainty, Pareto optimality is implied by maximization of preference under budget constraints and von Neumann's law, or maximization of profit given the technology. The former implies that an allocation which improves one consumer's position and harms none must, given local non-satiation for all consumers, be more valuable at equilibrium prices while the latter implies that no more valuable allocation is achievable. This argument depends on the finiteness of the value of the goods in the economy. Otherwise the impossibility of a more valuable allocation is not meaningful. Thus when the horizon is infinite and the discount factor is too large, for example, equal to 1 if the economy is stationary, or in general greater than or equal to the reciprocal of the growth rate, Pareto optimality may fail in competitive equilibrium, as Samuelson showed. Also there is no reason to expect Pareto optimality, in an exact sense, when some markets are missing, a very likely eventuality when there is uncertainty and goods must be traded on every possible contingency to provide
complete markets.

A second theorem on Pareto optimality asserts that any Pareto optimum can be realized as a competitive equilibrium. This theorem requires assumptions which are similar to those leading to existence, in particular, assumptions providing local non-satiation for some consumers and convexity of the preferred sets and the feasible set. Moreover, when the number of goods is infinite as in the case of an infinite horizon an additional condition is needed to give the existence of the prices. This condition may be that the sum of consumers’ preferred sets has an interior or that the production set has an interior. In the case of the product topology and free disposal by consumers the preferred sets will have interiors if the periodwise utility functions are continuous and bounded (see Debreu, 1954). Finally it was shown by Arrow (1953) that in order for the Pareto optimal allocation to maximize preference over the budget set rather than only to minimize the cost of achieving a given preference level, it is useful to assume that \( x_i \), the consumption set of the \( i \)th consumer, contains a point which is cheaper than the allocation he receives, for \( i = 1, \ldots, m \).

The stability theory for general equilibrium has been largely devoted to the stability of the Walrasian tâtonnement, or process of groping for equilibrium prices through a process of price revision according to excess demand. That is, prices rise or fall depending on whether excess demand is positive or negative. In the tâtonnement there is no trading until equilibrium prices have been reached. The most convincing theorems concern local stability and the dominant assumption leading to local stability is that the market excess demand function satisfies the weak axiom of revealed preference between the equilibrium price and any other price in a sufficiently small neighbourhood of the equilibrium price. That is, if \( \bar{p} \) is an equilibrium price and \( e \) is the excess demand function, \( p \cdot e(\bar{p}) - p \cdot e(p) \leq 0 \) implies \( p \cdot e(\bar{p}) - \bar{p} \cdot e(p) < 0 \). Since \( \bar{p} \) is an equilibrium price, \( e(\bar{p}) = 0 \), and \( p \cdot e(p) = 0 \) by Walras’s Law. Therefore, the condition holds and we may conclude that \( \bar{p} \cdot e(p) > 0 \). The weak axiom for the market may be expected to hold if the net income effect of price changes is small.

Consider the price revision process given by \( \frac{d p_i}{d t} = \dot{p}_i = e_i(p), \ for \ i = 1, \ldots, n - 1, \) where the \( n \)th good is numeraire so \( \dot{p}_n \equiv 0 \). Then consider the function \( |p(t) - \bar{p}|^2 \), the square of the distance from the equilibrium price vector to the price vector at time \( t \). We derive

\[
\frac{d}{dt} (|p(t) - \bar{p}|^2) = 2 \sum_{i=1}^{n} (p_i - \bar{p}_i) \dot{p}_i = 2 \sum_{i=1}^{n} (p_i - \bar{p}_i) e_i < 0,
\]

using the weak axiom of revealed preference and Walras’s Law. Thus the distance of \( p(t) \) from \( \bar{p} \) constantly falls, or \( p(t) \to \bar{p} \) as \( t \to \infty \). Since locally the rate of price change can be equated to excess demand for any continuous tâtonnement by choice of units, this is a general argument. Since the assumption of gross substitutes (\( e_{ij} < 0 \) for \( i \neq j \) and \( e_{ij} = \partial e_i(p)/\partial p_j \) implies the weak axiom, and the assumption of a negative definite Jacobian \( [e_{ij}], \ i, j = 1, \ldots, n - 1, \) at equilibrium is equivalent to the weak axiom locally, the weak axiom is a dominant condition for local stability. All global stability results are very special and relatively unconvincing.
A rigorous treatment of the stability problem for the tâtonnement was given by Arrow and Hurwicz (1958) and Arrow, Block and Hurwicz (1959). A stability theory which allows for trading was given by Hahn and Negishi (1962). These theories do not allow for speculative trading although profitable arbitrage opportunities would be likely to exist for any speculator who correctly inferred what the price revision process was. The stability of the tâtonnement was conjectured by Walras, to be the normal case for economies with many goods and essentially correct arguments were given by Walras for the case of exchange economies with two goods. He recognized and illustrated the case of locally unstable equilibria in the two goods case.

Finally, as Walras saw, it may be possible through a general equilibrium analysis to determine the effect of changes in the exogenous factors, resources, technology, or tastes, on the economic variables in equilibrium. This is analogous to the effect of a change in the constraints on the equilibrium of mechanical forces, an analogy with which Walras would have been familiar from the book of Poinsot. In the case of the exchange of two commodities Walras derives some simple and correct results for comparative statics just as he does for stability. He observes that an increase in the marginal utility of a good or a reduction in its supply will raise its price. In drawing this inference from his demand and offer curves he confines himself to stable equilibria as the only equilibria of interest.

Hicks used the comparative static result of Walras in a market with many goods to define stability of equilibrium. Samuelson (1947) pointed out that stability of equilibrium, where stability is given a dynamic interpretation as in a continuous tâtonnement, may imply comparative static results as a general principle. However, the straightforward generalization of Walras is the use of conditions which are sufficient to imply stability as a basis for deriving theorems on comparative statics. The most interesting theorem may be that derived from the revealed preference assumption at equilibrium.

Suppose that $\bar{\epsilon}(\bar{p}) = 0$ but excess demand changes so that the new excess demand function $\bar{\epsilon}_i'(\bar{p}) = \bar{\epsilon}_i(\bar{p})$ for $i \neq 1$ or $n$ and $\bar{\epsilon}_1'(\bar{p}) = \delta_1 < 0$ while $\bar{\epsilon}_n'(\bar{p}) = \delta_n > 0$. Let $n$ be numeraire. This change can be arranged by taking $\delta_n$ of the $n$th good from some holder and compensating him with $\delta_1$ of the first good. Suppose that the new equilibrium price is $p$, or $\bar{\epsilon}'(\bar{p}) = 0$. By Walras's Law $\bar{p} \cdot \bar{\epsilon}'(\bar{p}) = 0$ and by the assumption of revealed preference $p \cdot \bar{\epsilon}'(\bar{p}) > 0$. Thus $(\bar{p} - p) \cdot \bar{\epsilon}'(\bar{p}) < 0$, or $(\bar{p}_1 - p) \delta_1 < 0$, or $\bar{p}_1 - p > 0$. Any good falls in price when the excess demand for the numeraire rises at the expense of that good (see Allingham, 1975).

A type of stability has been proved for competitive equilibrium over time which concerns the path of equilibrium prices over real time rather than the path of disequilibrium prices over virtual time, that is, the time of the tâtonnement. It was shown by Negishi (1960) that there is a social welfare function associated with a competitive equilibrium which is maximized in the equilibrium over feasible allocations. Suppose each consumer has a concave utility function which is given by a discounted sum of periodwise utilities. Then the social welfare function which is maximized is also a discounted sum of periodwise utilities equal to a weighted sum of the individual utilities. Then using results from turnpike theory for optimal capital accumulation it has been shown by Bewley (1982) that the competitive equilibrium allocations converge over time to the allocations of a stationary competitive equilibrium whose capital stocks and allocations are the same as those of the unique optimal stationary path of capital accumulation given the social welfare function. The utility functions and the production
functions are assumed to be strictly concave and the discount factors are the same for all consumers and sufficiently near 1. However, these conditions may be relaxed.

Comparative static and comparative dynamic results have been derived from stability conditions in the context of optimal capital accumulation, which is equivalent to competitive equilibrium over time with a representative consumer. We may say that an optimal stationary path of capital is regular if an increase in the discount factor implies an increase in the value of capital stocks at initial prices. Then there are sufficient conditions for local stability of the optimal stationary path which imply that the path is regular. Similar dynamic results may be achieved for non-stationary paths as well (see Araujo and Scheinkman, 1979). It may be possible to extend these results to Bewley-type economies.

**How to cite this article**

Economists have come to use the term ‘general purpose technology’ (GPT) to describe technological advances that pervade many sectors, improve rapidly, and spawn further innovations. This article addresses the concept of a GPT by example, showing the extent to which electricity and information technology might qualify as members of this special class of inventions, as opposed to more ordinary ones.

Keywords
diffusion of technology; electricity; general purpose technologies; growth, models of; information technology and economic growth; innovation; intertemporal substitution; patents; productivity growth; skill premium; technical change

Economists have long been interested in how technological change affects long-run growth and aggregate fluctuations, yet it remains most often treated as incremental in nature, adding only a trend to standard growth models. History tells us, however, that such change can appear in bursts, with flurries of innovative activity following the introduction of a new core technology. This observation leads economists to reserve the term ‘general-purpose technology’ (GPT) to describe fundamental advances that drive these flurries, which in turn transform both household life and the ways in which firms conduct business. Over the past 200 years or so, steam, electricity, internal combustion, and information technology (IT) seem to have served as GPT-type technologies. They affected entire economies. Earlier, the very ability to communicate in writing and later to disseminate written information via the printed page also appears to fit well into the idea of a GPT.

The notions that GPTs differ from the more incremental refinements that occur in between their arrivals and that they represent real-side shocks that permanently change the nature of production and preferences provide the basis of a potentially useful way to organize thinking about long-run economic fluctuations and growth. But to support such a view with anything more than casual observation, it is necessary to establish criteria for determining just what features a technology must possess in order to be a GPT rather than a more ordinary invention. This article defines GPTs in terms of a number of tangible criteria, and then uses two candidate GPTs, electrification and IT, to demonstrate how identification of a GPT might proceed. Attention then turns to other indicators that may signal the start of a GPT era.

Dating a GPT's arrival

Associating a point in time with a GPT’s ‘arrival’ depends on what exactly one means by this term. If defined with a measure such as, in the case of electrification, attaining a one per cent share of horsepower in the manufacturing sector, then some time around 1895 might be appropriate. This coincides roughly with the start-up of the world's first large scale hydroelectric power facility at Niagara Falls, New York, in 1894. It would be reasonable to argue, however, that electricity arrived earlier, perhaps in 1882 when Thomas Edison brought the first centralized electricity system online at the Pearl Street station in lower Manhattan. For IT, it is true that mainframe computers had existed for two decades before the invention of the 4004 chip in 1971, and had even been used to project the winner of the 1952 US presidential election. Yet, if measured by the attainment of a one per cent share in the
industrial sector's stock of equipment, 1971 remains the most likely candidate for dating IT's 'arrival'.
Whether electricity and IT arrived in 1895 and 1971, respectively, or some time prior to these dates, one characteristic noted by David (1991) is that neither delivered productivity gains immediately. Indeed, productivity growth as measured by output per man-hour seems to have been relatively high in the 1870s, when steam was the dominant power source for industry, but fell as electrification arrived in the 1880s and 1890s. It was only in the period after 1915, which also saw the diffusion of secondary motors and the widespread establishment of centralized power distribution systems, that measured productivity numbers began to rise. (This can be seen in the series for output per man-hour in the non-farm business sector from US Census Bureau, 1975, Series D684, p. 162.) Further, Intel's 1971 invention of the 4004 microprocessor (the key component in the first generation of personal computers), if taken to be the start of the IT era, did not reverse the decline in productivity growth that had begun more than a decade earlier.

Identification of a new core technology as a GPT

Once the arrival date of a new technology has been established, identification of that technology as a GPT can proceed by considering characteristics associated with its diffusion. One set of criteria, proposed by Bresnahan and Trajtenberg (1995), suggests that a GPT should have the following three characteristics:

1. **Pervasiveness**: the GPT should spread to most sectors.
2. **Improvement**: the GPT should get better over time and, hence, should keep lowering the costs of its users.
3. **Innovation spawning**: the GPT should make it easier to invent and produce new products or processes.

Most technologies possess each of these characteristics to some degree, and therefore a GPT cannot differ qualitatively from them. But the extent to which technologies have all three characteristics should determine which ones are likely to be GPTs.

For example, both electrification and IT were pervasive, and so might qualify as GPTs under the first criterion, yet had quite different absorption paths across sectors. Figure 1 shows the shares of total horsepower electrified in manufacturing sectors at ten-year intervals from 1889 to 1954 in percentile form, with the shaded area highlighting the period of electricity's most rapid diffusion. Figure 2 shows the spread of IT, measured as the share of IT equipment in the capital stock at the two-digit standard industry classification level. The striking difference between the two figures is that electricity diffused uniformly across sectors while the adoption of IT was not as widespread. On this count, then, electricity would be the stronger GPT candidate.

Figure 1
Shares of electrified horsepower by manufacturing sector in percentiles, 1890–1954. **Source**: DuBoff (1964, Tables E-II and E-12–12e).
Figure 2
Presumably, the second characteristic – improvement – would show up in a decline in prices associated with the technology, an increase in quality, or both. How much a GPT improves can therefore be measured by how much cheaper a unit of quality gets over time. If the new technology is embodied in capital and begins to account for an increasing share of the net capital stock, capital should on the whole be getting cheaper faster during a GPT era, but especially capital that is tied to the new technology.

Figure 3 plots the price of the components of the aggregate capital stock tied to the two GPTs. Because deflators for electrically powered capital are not available in the first half of the 20th century, the figure compares the declines in relative price of electricity itself with the quality-adjusted price of computers, both relative to the consumption price index. The use of the left-hand scale for electricity and the right-hand scale for computers underscores the extraordinary decline in computer prices since 1960 relative to electricity. While electricity prices fall by a factor of 10, the computer price index falls by a factor of 10,000!

Figure 3
Price indices for products of two ‘GPT eras’, 1895–2000. Sources: The quality-adjusted price index for IT is formed by joining the ‘final’ price index for computer systems from Gordon (1990, Table 6.10, col. 5, p. 226) for 1960–78 with the pooled index developed for desktop and mobile personal computers by Berndt, Dulberger and Rappaport (2000, Table 2, col. 1, p. 22) for 1979–99. Electricity prices are averages of all electric energy services in cents per kilowatt hour from US Census Bureau (1975, series S119, p. 827) for 1903, 1907, 1917, 1922, and 1926–70, and from the US Census Bureau, Statistical Abstract of the United States, for 1971–89. For 1990–2000, prices are US city averages (June figures) from the US Bureau of Labor Statistics. Both indices are set to 1,000 in the first years of the samples (that is, 1903 and 1960).
It can be said that the electricity index, being the price of a kilowatt hour, understates the accompanying technological change because it does not account for improvements in electrical equipment, and especially improvements in the efficiency of electrical motors. Based on the price evidence in Figure 3, however, both electricity and computers might qualify as GPTs, with computers clearly more revolutionary.

With respect to the ability to generate further innovation, it is reasonable to assume that any GPT will affect all sorts of production processes, including those for invention and innovation. Some GPTs will be biased towards helping to produce existing products, others towards inventing and implementing new ones. Electricity and IT have both helped reduce the costs of making existing products, and they both spawn innovation. The 1920s especially saw a wave a new products powered by electricity, and the computer is now embodied in many new products as well. But the evidence suggests that IT has contributed more to furthering innovation.

In particular, patenting should be more intense after a GPT arrives and while it is spreading due to the introduction of related new products. US patent data confirm this, showing two surges in the annual number of invention patents issued per capita from 1890 to 2000 – one between 1900 and 1930, and the other after 1977. At the same time, the surge during the IT period was stronger than that observed during electrification. Interestingly, the slow rate of patenting during the Second World War years and the acceleration immediately thereafter suggests that there is some degree of intertemporal substitution in the release of new ideas away from times when they might be more difficult to popularize and towards times better suited for the entry of new products.

Of course, patent data may reflect fluctuations in the number of actual inventions or may simply reflect changes in the law that raise the propensity to patent. The distinction is important because, over longer periods of time, patents may reflect policy rather than invention. Kortum and Lerner (1998) analyse this question and find that the surge of the 1990s
was worldwide, but not systematically related to country-specific policy changes, and they conclude that technology was the cause of the surge.

**Other characteristics of GPTs**

In addition to the three basic qualities of a GPT, there are other, less direct signals implied by various theoretical models that deal with GPTs. These models predict the following:

1. **New ideas should come to market faster.** If a new technology has the potential for large productivity gains, firms will spend less time perfecting ideas associated with the new technology in order to realize the gains sooner (see, for example, Jovanovic and Rousseau, 2001).

2. **Entry, exit and mergers should rise.** New technologies may require some relocation of assets from firms that are unable to adopt them effectively to others with managements better equipped for their deployment (see, or example, Jovanovic and Rousseau, 2002).

3. **Young and small firms should do better.** The ideas and products associated with the GPT will often be brought to market by new firms. The market share and market value of young firms should therefore rise relative to old firms.

4. **Stock prices should initially fall.** The value of old capital should fall in anticipation of the new and more productive technology. How fast it falls depends on the way that the market learns of the GPT's arrival (see, for example, Hobijn and Jovanovic, 2001).

5. **Interest rates and the trade deficit should be affected.** The rise in desired consumption relative to output should cause interest rates to rise or the trade balance to worsen.

6. **The skill premium should rise.** If the GPT is not user-friendly at first, skilled people will be in greater demand when the new technology arrives, and their earnings should rise compared with those of the unskilled.

The available evidence suggests that predictions 1–3 hold for both the electrification and IT eras, but that a stock market decline (4) occurred only at the start of the IT period. Interest rates (5) rose in both eras, but the electrification period was associated with a trade surplus due to the First World War. It also appears that the skill premium (6) has risen over the IT period, but evidence of a rise in the electrification era is weaker.

To sum up, based upon the criteria chosen and the available evidence, both electricity and IT were pervasive, improving, and innovation-spawning, and thus seem to qualify as GPTs. At the same time, electricity was more pervasive, affecting sectors faster and more evenly than IT, while IT improved more dramatically, with computer prices falling more than 100 times faster than the price of electricity. IT also seems to have generated more innovation than electricity, and the initial productivity slowdown was also deeper in the IT era. All this would lead one to regard IT as the more ‘revolutionary’ GPT.

This is not to say that the differences between electrification and IT, or indeed between any two candidate GPTs, are unimportant. At the same time, the GPT paradigm emphasizes the commonalities, namely, that technological progress is uneven, that it does entail the episodic arrival of new core technologies, and that these GPTs bring on turbulence and lower growth early on and higher growth and prosperity later. Interestingly, the IT era has already outlasted that of electrification, but even six decades after what Field (2003) has called the ‘most technologically progressive decade of the century’ (that is, the 1930s), electricity has yet to become obsolete. Given the multitude of firms and households that have not quite yet adopted IT, its continuing price decline and the widespread increases in computer literacy among children and adults worldwide suggest that perhaps the most productive period of this GPT still lies ahead.

generalized method of moments estimation

Lars Peter Hansen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Generalized method of moments estimates econometric models without requiring a full statistical specification. One starts with a set of moment restrictions that depend on data and an unknown parameter vector to be estimated. When there are more moment restrictions than underlying parameters, there is family of such estimators. The tractable form of the large sample properties of this family facilitates efficient estimation and statistical testing. This article motivates the method, presents some of the underlying statistical properties and discusses implementation.

calibration; central limit theorems; Gauss–Markov theorem; generalized method of moments; identification; instrumental variables; Lagrange multipliers; law of large numbers; likelihood; martingales; maximum likelihood; rational expectations models; sequential estimation; statistical inference; stochastic discount factor models; Wald test

Article

1 Introduction

Generalized method of moments (GMM) refers to a class of estimators constructed from the sample moment counterparts of population moment conditions (sometimes known as orthogonality conditions) of the data generating model. GMM estimators have become widely used, for the following reasons:

1. GMM estimators have large sample properties that are easy to characterize. A family of such estimators can be studied simultaneously in ways that make asymptotic efficiency comparisons easy. The method also provides a natural way to construct tests which take account of both sampling and estimation error.
2. In practice, researchers find it useful that GMM estimators may be constructed without specifying
the full data generating process (which would be required to write down the maximum likelihood estimator.) This characteristic has been exploited in analysing partially specified economic models, studying potentially misspecified dynamic models designed to match target moments, and constructing stochastic discount factor models that link asset pricing to sources of macroeconomic risk.

Books with good discussions of GMM estimation with a wide array of applications include: Cochrane (2001), Arellano (2003), Hall (2005), and Singleton (2006). For a theoretical treatment of this method see Hansen (1982) along with the self-contained discussions in the books. See also Ogaki (1993) for a general discussion of GMM estimation and applications, and see Hansen (2001) for a complementary article that, among other things, links GMM estimation to related literatures in statistics. For a collection of recent methodological advances related to GMM estimation, see the journal issue edited by Ghysels and Hall (2002). While some of these other references explore the range of substantive applications, in what follows we focus more on the methodology.

2 Set-up

As we will see, formally there are two alternative ways to specify GMM estimators, but they have a common starting point. Data are a finite number of realizations of the process \( \{x_t: t=1, 2, \ldots \} \). The model is specified as a vector of moment conditions:

\[
Ef\left(x_t, \beta_0\right) = 0
\]

where \( f \) has \( r \) coordinates and \( \beta_0 \) is an unknown vector in a parameter space \( \mathbb{P} \subset \mathbb{R}^k \). To achieve identification we assume that on the parameter space \( \mathbb{P} \)

\[
Ef\left(x_t, \beta\right) = 0 \text{ if, and only if } \beta = \beta_0.
\]

The parameter \( \beta_0 \) is typically not sufficient to write down a likelihood function. Other parameters are needed to specify fully the probability model that underlies the data generation. In other words, the model is only partially specified.

Examples include:

1. (a) linear and nonlinear versions of instrumental variables estimators as in Sargan (1958; 1959), and Amemiya (1974);
2. (b) rational expectations models as in Hansen and Singleton (1982), Cumby, Huizinga and Obstfeld.
3. (c) security market pricing of aggregate risks as described, for example, by Cochrane (2001), Singleton (2006) and Hansen et al. (2007);

4. (d) matching and testing target moments of possibly misspecified models as described by, for example, Christiano and Eichenbaum (1992) and Hansen and Heckman (1996).

Regarding example (a), many related methods have been developed for estimating correctly specified models, dating back to some of the original applications in statistics of method-of-moments-type estimators. The motivation for such methods was computational. See Hansen (2001) for a discussion of this literature and how it relates to GMM estimation. With advances in numerical methods, the fully efficient maximum likelihood method and Bayesian counterparts have become much more tractable. On the other hand, there continues to be an interest in the study of dynamic stochastic economic models that are misspecified because of their purposeful simplicity. Thus moment matching remains an interesting application for the methods described here. Testing target moments remains valuable even when maximum likelihood estimation is possible (for example, see Bontemps and Meddahi, 2005).

2.1 Central limit theory and martingale approximation

The parameter dependent average

\[ g_N(\beta) = \frac{1}{N} \sum_{t=1}^{N} f(x_t, \beta) \]

is featured in the construction of estimators and tests. When the law of large numbers is applicable, this average converges to the \( Ef(x_t, \beta) \). As a refinement of the identification condition:

\[ \sqrt{N} g_N(\beta_0) \Rightarrow \text{Normal}(0, V) \]  

(2)

where \( \Rightarrow \) denotes convergence in distribution and \( V \) is a covariance matrix assumed to be nonsingular. In an iid data setting, \( V \) is the covariance matrix of the random vector \( f(x_t, \beta_0) \). In a time series setting:

\[ V = \lim_{N \to \infty} NE \left[ g_N(\beta_0) g_N(\beta_0)' \right], \]

(3)
which is the long-run counterpart to a covariance matrix. Central limit theory for time series is typically built on martingale approximation (see Gordin, 1969; Hall and Heyde, 1980). For many time series models, the martingale approximators can be constructed directly and there is specific structure to the $V$ matrix. A leading example is when $f(x_t, \beta_0)$ defines a conditional moment restriction. Suppose that $x_t, t=0,1,\ldots$ generates a sigma algebra $\mathcal{F}_t$, $E[|f(x_t, \beta_0)|^2] < \infty$ and

$$E[f(x_t+\epsilon, \beta_0)|\mathcal{F}_t] = 0$$

for some $\epsilon \geq 1$. This restriction is satisfied in models of multi-period security market pricing and in models that restrict multi-period forecasting. If $\epsilon = 1$, then $g_N$ is itself a martingale; but when $\epsilon > 1$ it is straightforward to find a martingale $m_N$ with stationary increments and finite second moments such that

$$\lim_{N \to \infty} E[|g_N(\beta_0) - m_N(\beta_0)|^2] = 0,$$

where $|\cdot|$ is the standard Euclidean norm. Moreover, the lag structure may be exploited to show that the limit in (3) is

$$V = \sum_{j=-\ell+1}^{\ell-1} E[f(x_t, \beta_0) f(x_{t+j}, \beta_0)'].$$

(4)

(The sample counterpart to this formula is not guaranteed to be positive semidefinite. There are a variety of ways to exploit this dependence structure in estimation in constructing a positive semidefinite estimate. See Eichenbaum, Hansen and Singleton, 1988, for an example.) When there is no exploitable structure to the martingale approximator, the matrix $V$ is the spectral density at frequency zero.

$$V = \sum_{j=-\infty}^{\infty} E[f(x_t, \beta_0) f(x_{t+j}, \beta_0)'].$$

(4)
2.2 Minimizing a quadratic form

One approach for constructing a GMM estimator is to minimize the quadratic form:

$$b_N = \arg \min_{\beta \in \mathcal{P}} g_N(\beta)' W g_N(\beta)$$

for some positive definite weighting matrix $W$. Alternative weighting matrices $W$ are associated with alternative estimators. Part of the justification for this approach is that

$$\beta_0 = \arg \min_{\beta \in \mathcal{P}} E_f(x_t, \beta)' W E_f(x_t, \beta).$$

The GMM estimator mimics this identification scheme by using a sample counterpart. There are a variety of ways to prove consistency of GMM estimators. Hansen (1982) established a uniform law of large numbers for random functions when the data generation is stationary and ergodic. This uniformity is applied to show that

$$\sup_{\beta \in \mathcal{P}} |g_N(\beta) - E[f(x_t, \beta)]| = 0$$

and presumes a compact parameter space. The uniformity in the approximation carries over directly the GMM criterion function $g_N(\beta)' W g_N(\beta)$. See Newey and McFadden (1994) for a more complete catalogue of approaches of this type.

The compactness of the parameter space is often not ignored in applications, and this commonly invoked result is therefore less useful than it might seem. Instead, the compactness restriction is a substitute for checking behaviour of the approximating function far away from $\beta_0$ to make sure that spurious optimizers are not induced by approximation error. This tail behaviour can be important in practice, so a direct investigation of it can be fruitful. For models with parameter separation:

$$f(x, \beta) = X h(\beta)$$

where $X$ is an $r \times m$ matrix constructed from $x$ and $h$ is a one-to-one function mapping $\mathcal{P}$ into subset of $\mathbb{R}^m$. 
there is an alternative way to establish consistency (see Hansen, 1982 for details). Models that are either linear in the variables or models based on matching moments that are nonlinear functions of the underlying parameters can be written in this separable form.

The choice of \( W = V^{-1} \) receives special attention, in part because

\[
N g_N(\beta)' V^{-1} g_N(\beta) \Rightarrow \chi^2(r).
\]

While the matrix \( V \) is typically not known, it can be replaced by a consistent estimator without altering the large sample properties of \( b_N \). When using martingale approximation, the implied structure of \( V \) can often be exploited as in formula (4). When there is no such exploitable structure, the method of Newey and West (1987b) and others can be employed that are based on frequency-domain methods for time series data.

For asset pricing models there are other choices of a weighting matrix motivated by considerations of misspecification. In these models with parameterized stochastic discount factors, the sample moment conditions \( g_N(\beta) \) can be interpreted as a vector of pricing errors associated with the parameter vector \( \beta \). A feature of \( W = V^{-1} \) is that, if the sample moment conditions (the sample counterpart to a vector pricing errors) happened to be the same for two models (two choices of \( \beta \)), the one for which the implied asymptotic covariance matrix is larger will have a smaller objective. Thus there is a reward for parameter choices that imply variability in the underlying central limit approximation. To avoid such a reward, it is also useful to compare models or parameter values in other ways. An alternative weighting matrix is constructed by minimizing the least squares distance between the parameterized stochastic discount factor and one among the family of discount factors that correctly price the assets. Equivalently, parameters or models are selected on the basis of the maximum pricing error among constant weighted portfolios with payoffs that have common magnitude (a unit second moment). See Hansen and Jagannathan (1997) and Hansen, Heaton and Luttmer (1995) for this and related approaches.

### 2.3 Selection matrices

An alternative depiction is to introduce a selection matrix \( A \) that has dimension \( k \times r \) and to solve the equation system:

\[
A g_N(\beta) = 0
\]

for some choice of \( \beta \), which we denote \( b_N \). The selection matrix \( A \) reduces the number of equations to be solved from \( r \) to \( k \). Alternative selection matrices are associated with alternative GMM estimators. By relating estimators to their corresponding selection matrices, we have a convenient device for studying simultaneously an entire family of GMM estimators. Specifically, we explore the consequence of using alternative subsets of moment equations or more generally alternative linear combinations of the moment
equation system. This approach builds on an approach of Sargan (1958; 1959) and is most useful for characterizing limiting distributions. The aim is to study simultaneously the behaviour of a family of estimators. When the matrix $A$ is replaced by a consistent estimator, the asymptotic properties of the estimator are preserved. This option expands considerably the range of applicability, and, as we will see, is important for implementation.

Since alternative choices of $A$ may give rise to alternative GMM estimators, index alternative estimators by the choice of $A$. In what follows, replacing $A$ by a consistent estimator does not alter the limiting distribution. For instance, the first-order conditions from minimizing a quadratic form can be represented using a selection matrix that converges to a limiting matrix $A$. Let

$$D = E \left[ \frac{\partial f(x_t, \beta_0)}{\partial \beta} \right].$$

Two results are central to the study of GMM estimators:

$$\sqrt{N}(b_N - \beta_0) \approx -(AD)^{-1}A\sqrt{N}g_N(\beta_0)$$

(5)

and

$$\frac{1}{\sqrt{N}}g_N(b_N) \approx \left[ I - D(AD)^{-1}D \right] \sqrt{N}g_N(\beta_0).$$

(6)

Both approximation results are expressed in terms of $\sqrt{N}g_N(\beta_0)$, which obeys a central limit theorem, see (2). These approximation results are obtained by standard local methods. They require the square matrix $AD$ to be nonsingular. Thus, for there to exist a valid selection matrix, $D$ must have full column rank $k$. Notice from (6) that the sample moment conditions evaluated at $b_N$ have a degenerate distribution. Pre-multiplying by $A$ makes the right-hand side zero. This is to be expected because linear combinations of the sample moment conditions are set to zero in estimation.

In addition to assess the accuracy of the estimator (approximation (5)) and to validate the moment conditions (approximation (6)), Newey and West (1987a) and Eichenbaum, Hansen and Singleton (1988) show how to use these and related approximations to devise tests of parameter restrictions. (Their tests imitate the construction of the likelihood ratio, Lagrange multiplier and the Wald tests familiar from likelihood inference methods.)
Next we derive a sharp lower bound on the asymptotic distribution of a family of GMM estimators indexed by the selection matrix $A$. For a given $A$, the asymptotic covariance matrix for a GMM estimator constructed using this selection is:

$$\text{cov}(A) = (AD)^{-1}A\Sigma A'(D'A')^{-1}.$$ 

A selection matrix in effect over-parameterizes a GMM estimator, as can be seen from this formula. Two such estimators with selection matrices of the form $A$ and $BA$ for a nonsingular matrix $B$ imply

$$\text{cov}(BA) = \text{cov}(A)$$ 

because the same linear combinations of moment conditions are being used in estimation. Thus without loss of generality we may assume that $AD = I$. With this restriction we may imitate the proof of the famed Gauss–Markov Theorem to show that

$$D'V^{-1}D \leq \text{cov}(A)$$

(7)

and that the lower bound on left is attained by any $\tilde{A}$ such that $\tilde{A} = BD'V^{-1}$ for some nonsingular $B$. The quadratic form version of a GMM estimator typically satisfies this restriction when $W_N$ is a consistent estimator of $V^{-1}$. This follows from the first-order conditions of the minimization problem.

To explore further the implications of this choice, factor the inverse covariance matrix $V^{-1}$ as $V^{-1} = \Lambda'\Lambda$ and form $\Delta = \Lambda D$. Then

$$V^{-1}D(D'V^{-1}D)^{-1}D'V^{-1} = \Lambda' [\Delta(\Delta')^{-1}\Delta'] \Lambda.$$ 

The matrices $\Delta(\Delta'\Delta)^{-1}\Delta'$ and $I - \Delta(\Delta'\Delta)^{-1}\Delta'$ are each idempotent and
The first coordinate block is an approximation for \( \sqrt{N} \Lambda g_N(\beta_0) \) and the sum of the two coordinate blocks is \( \sqrt{N} \Lambda g_N(\beta_0) \). Thus we may decompose the quadratic form

\[
N [g_N(\beta_0)]' V^{-1} g_N(\beta_0) = N [g_N(\beta_0)]' V^{-1} g_N(\beta_0) + N [g_N(\beta_0)]' V^{-1} D' V^{-1} D^{-1} D' V^{-1} g_N(\beta_0).
\]  

where the two terms on the right-hand side are distributed as independent chi-square. The first has \( r \) degrees of freedom and the second one has \( r-k \) degrees of freedom.

### 3 Implementation using the objective function curvature

While the formulas just produced can be used directly using consistent estimators of \( V \) and \( D \) in conjunction with the relevant normal distributions, looking directly at the curvature of the GMM objective function based on a quadratic form is also revealing. Approximations (5) and (6) give guidance on how to do this.

For a parameter vector \( \beta \) let \( V_N(\beta) \) denote an estimator of the long-run covariance matrix. Given an initial consistent estimator \( b_N \), suppose that \( V_N(b_N) \) is a consistent estimator of \( V \) and

\[
D_N = \frac{1}{N} \sum_{t=1}^{N} \frac{\partial f(x_t, b_N)}{\partial \beta}.
\]

Then use of the selection \( A_N = D_N' [V_N(b_N)]^{-1} \) attains the efficiency bound for GMM estimators. This is the so-called two-step approach to GMM estimation. Repeating this procedure, we obtain the so-called iterative estimator. (There is no general argument that repeated iteration will converge.) In the remainder of this section we focus on a third approach, resulting in what we call the continuous-updating estimator. This is obtained by solving:

\[
\min_{\beta \in \mathcal{P}} l_N(\beta).
\]
Let $b_N$ denote the minimized value. Here the weighting matrix varies with $\beta$.

Consider three alternative methods of inference that look at the global properties of the GMM objective $L_N(\beta)$:

1. (a) $\{\beta \in \mathbb{R}: L_N(\beta) \leq C\}$ where $C$ is a critical value from a $\chi^2(r)$ distribution.
2. (b) $\{\beta \in \mathbb{R}: L_N(\beta) - L_N(b_N) \leq C\}$ where $C$ is a critical value from a $\chi^2(k)$ distribution.
3. (c) Choose a prior $\pi$. Mechanically, treat $-\frac{1}{2}L_N(\beta)$ as a log-likelihood and compute

$$\frac{\exp\left[-\frac{1}{2}L_N(\beta)\right] \pi(\beta)}{\int \exp\left[-\frac{1}{2}L_N(\beta)\right] \pi(\beta) d\beta}.$$

Method (a) is based on the left-hand side of (8). It was suggested and studied in Hansen, Heaton and Luttmer (1995) and Stock and Wright (2000). As emphasized by Stock and Wright, it avoids using a local identification condition (a condition that the matrix $D$ have full column rank). On the other hand, it combines evidence about the parameter as reflected by the curvature of the objective with overall evidence about the model. A misspecified model will be reflected as an empty confidence interval.

Method (b) is based on the second term on right-hand side of (8). By translating the objective function, evidence against the model is netted out. Of course it remains important to consider such evidence because parameter inference may be hard to interpret for a misspecified model. The advantage of (b) is that the degrees of freedom of the chi-square distribution are reduced from $r$ to $k$. Extensions of this approach to accommodate nuisance parameters were used by Hansen and Singleton (1996) and Hansen, Heaton and Luttmer (1995). The decomposition on the right-hand side of (8) presumes that the parameter is identified locally in the sense that $D$ has full column rank, guaranteeing that the $D' V^{-1} D$ is nonsingular. Kleibergen (2005) constructs an alternative decomposition based on a weaker notion of identification that can be used in making statistical inferences.

Method (c) was suggested by Chernozhukov and Hong (2003). It requires an integrability condition which will be satisfied by specifying a uniform distribution $\pi$ over a compact parameter space. The resulting histograms can be sensitive to the choice of this set or more generally to the choice of $\pi$. All three methods explore the global shape of the objective function when making inferences. (The large sample justification remains local, however.)
4 Backing off from efficiency

In what follows we give two types of applications that are not based on efficient GMM estimation.

4.1 Calibration-verification

An efficient GMM estimator selects the best linear combination among a set of moment restrictions. Implicitly a test of the over-identifying moment conditions examines whatever moment conditions are not used in estimation. This complicates the interpretation of the resulting outcome. Suppose instead there is one set of moment conditions for which we have more confidence and are willing to impose for the purposes and calibration or estimation. The remaining set of moment conditions are used for the purposes of verification or testing. The decision to use only a subset of the available moment conditions for purposes of estimation implies a corresponding loss in efficiency. See Christiano and Eichenbaum (1992) and Hansen and Heckman (1996) for a discussion of such methods for testing macroeconomic models.

To consider this estimation problem formally, partition the function $f$ as:

$$f(x, \beta) = \begin{bmatrix} f[1](x, \beta) \\ f[2](x, \beta) \end{bmatrix}$$

where $f[1]$ has $r_1$ coordinates and $f[2]$ has $r-r_1$ coordinates. Suppose that $r_1 \geq k$ and that $\beta$ is estimated using an $A$ matrix of the form:

$$A = [A_1 \ 0],$$

and hence identification is based only on

$$A_1 Ef[1](x, \beta) = 0.$$

This is the so-called calibration step. Let $b_N$ be the resulting estimator.

To verify or test the model we check whether $Ef[2](x, \beta)$ is close to zero as predicted by the moment implication:
$$ E f^{[2]}(x_t, \beta_0) = 0. $$

Partition the matrix $D$ of expected partial derivatives as:

$$ D = \begin{bmatrix} D_1 \\ D_2 \end{bmatrix} $$

where $D_1$ is $r_1$ by $k$ and $D_2$ is $r - r_1$ by $k$. Here we use limit approximation (6) to conclude that

$$ \sqrt{N} g_N^{[2]}(b_N) \approx \left[ -D_2(A_1 D_1)^{-1} A_1 \right] \sqrt{N} g_N(\beta_0), $$

which has a limiting normal distribution. A chi-square test can be constructed by building a corresponding quadratic form of $r - r_1$ asymptotically independent standard normally distributed random variables. (When $r_1$ exceeds $k$ it is possible to improve the asymptotic power by exploiting the long-run covariation between $f^{[2]}(x_t, \beta_0)$ and linear combination of $f^{[1]}(x_t, \beta_0)$ not used in estimation. This can be seen formally by introducing a new parameter $\gamma_0 = E[f^{[2]}(x_t, \beta)]$ and using the GMM formulas for efficient estimation of $\beta_0$ and $\gamma_0$.)

4.2 Sequential estimation

Sequential estimation methods have a variety of econometric applications. For models of sample selection see Heckman (1976), and for related methods with generated regressors see Pagan (1984). For testing asset pricing models, see Cochrane (2001, chs 12 and 13).

To formulate this problem in a GMM setting, partition the parameter vector as

$$ \beta = \begin{bmatrix} \beta^{[1]} \\ \beta^{[2]} \end{bmatrix} $$

where $\beta^{[1]}$ has $k_1$ coordinates. Partition the function $f$ as:
where $f [1]$ has $r_1$ coordinates and $f [2]$ has $r-r_1$ coordinates. Notice that the first coordinate block only depends on the first component of the parameter vector. Thus the matrix $d$ is block lower triangular:

$$D = \begin{bmatrix} D_{11} & 0 \\ D_{21} & D_{22} \end{bmatrix}$$

where

$$D_{ij} = E \left[ \frac{\partial f [i] (x_t, \beta_0)}{\partial \beta [i]} \right].$$

A sequential estimation approach exploits the triangular structure of the moment conditions as we now describe. The parameter $\beta_0^{[1]}$ is estimable from the first partition of moment conditions. Given such an estimator, $b^{[1]}_N, \beta_0^{[2]}$ is estimable from the second partition of moment conditions. Estimation error in the first stage alters the accuracy of the second stage estimation, as I now illustrate.

Assume now that $r_1 \geq k_1$. Consider a selection matrix that is block diagonal:

$$A = \begin{bmatrix} A_{11} & 0 \\ 0 & A_{22} \end{bmatrix}$$

where $A_{11}$ has dimension $k_1$ by $r_1$ and $A_{22}$ has dimension $k-k_1$ by $r-r_1$. It is now possible to estimate $\beta_0^{[1]}$ using the equation system:
or a method that is asymptotically equivalent to this. Let \( b_N^{[1]} \) be the solution. This initial estimation may be done for simplicity or because these moment conditions are embraced with more confidence. Given this estimation of \( \theta_0^{[1]} \), we seek an estimator \( b_N^{[2]} \) of \( \theta_0^{[2]} \) by solving:

\[
A_{22} g_N^{[2]} \left( b_N^{[1]} , \theta_0^{[2]} \right) = 0.
\]

To proceed, we use this partitioning and apply (5) to obtain the limiting distribution for the estimator \( b_N^{[2]} \). Straightforward matrix calculations yield,

\[
\sqrt{N} \left( b_N^{[2]} - \theta_0^{[2]} \right) \approx - \left( A_{22} D_{22} \right)^{-1} A_{22} \left[ - D_{21} (A_{11} D_{11})^{-1} A_{11} I \right] \sqrt{N} g_N (\theta_0).
\]

(9)

This formula captures explicitly the impact of the initial estimation of \( \theta_0^{[1]} \) on the subsequent estimation of \( \theta_0^{[2]} \). When \( D_{21} \) is zero an adjustment is unnecessary.

Consider next a (second-best) efficient choice of selection matrix \( A_{22} \). Formula (9) looks just like formula (5) with \( A_{22} \) replacing \( A \), \( D_{22} \) replacing \( D \) and a particular linear combination of \( g_N (\theta_0) \). The matrix used in this linear combination 'corrects' for the estimation error associated with the use of an estimator \( b_N^{[1]} \) instead of the unknown true value \( \theta_0^{[1]} \). By imitating our previous construction of an asymptotically efficient estimator, we construct the (constrained) efficient choice of \( A_{22} \) given \( A_{11} \):

\[
A_{22} = g_{22} (D_{22}) \left[ - D_{21} (A_{11} D_{11})^{-1} A_{11} I \right] \left[ - \left[ D_{21} (A_{11} D_{11})^{-1} A_{11} \right]^\prime \right]^{-1}
\]

\[
\left[ - D_{21} (A_{11} D_{11})^{-1} A_{11} \right]^{-1}
\]
for some nonsingular matrix $B_{22}$. An efficient estimator can be implemented in the second stage by solving:

$$
\min_{\beta} g_N^{[2]}(b_N^{[1]}, \beta [2])' W_N g_N^{[2]}(b_N^{[1]}, \beta [2])
$$

for $V_N^{[2]}$ given by a consistent estimator of

$$
V_N^{[2]} = \left( -D_{21}(A_{11}^{-1}A_{11})^{-1}A_{11} \right) V \left( -D_{21}(A_{11}^{-1}A_{11})^{-1}A_{11} \right)^{-1}
$$

or by some other method that selects (at least asymptotically) the same set of moment conditions to use in estimation. Thus we have a method that adjusts for the initial estimation of $\beta^{[1]}$ while making efficient use of the moment conditions $E T^{[2]}(x_t, \beta) = 0$.

As an aside, notice the following. Given an estimate $b_N^{[1]}$, the criterion-based methods of statistical inference described in Section 3 can be adapted to making inferences in this second stage in a straightforward manner.

5 Conditional moment restrictions

The bound (7) presumes a finite number of moment conditions and characterizes how to use these conditions efficiently. If we start from the conditional moment restriction:

$$
E[f(x_t+\hat{\beta}, \beta_0)|\mathcal{F}_t] = 0,
$$

then in fact there are many moment conditions at our disposal. Functions of variables in the conditioning information set can be used to extend the number of moment conditions. By allowing for these conditions, we can improve upon the asymptotic efficiency bound for GMM estimation. Analogous conditional moment restrictions arise in cross-sectional settings.

For a characterizations and implementations appropriate for cross-sectional data, see Chamberlain (1986) and Newey (1993), and for characterizations and implementations in a time series settings see Hansen.
generalized method of moments estimation: The New Palgrave Dictionary of Economics (1985; 1993), and West (2001). The characterizations are conceptually interesting but reliable implementation is more challenging. A related GMM estimation problem is posed and studied by Carrasco and Florens (2000) in which there is a pre-specified continuum of moment conditions that are available for estimation.

6 Conclusion

GMM methods of estimation and inference are adaptable to a wide array of problems in economics. They are complementary to maximum likelihood methods and their Bayesian counterparts. Their large sample properties are easy to characterize. While their computational simplicity is sometimes a virtue, perhaps their most compelling use is in the estimation of partially specified models or of misspecified dynamic models designed to match a limited array of empirical targets.

How to cite this article

Many government programmes transfer resources between different population groups. Programmes to provide retirement and health security levy taxes on workers to finance transfers to retirees. Initiating or expanding such programmes often redistributes wealth across generations by altering their lifetime tax burdens. Although standard budget measures such as national debt and deficits do not fully reflect them, such public intergenerational redistributions could substantially affect different generations' economic choices. Generational accounting measures the size of prospective net tax burdens facing different generations under current government tax and expenditure policies. It also analyses how those fiscal burdens would change under alternative policies.

Article

Before the 1990s, studies of the distributional impact of fiscal policies distinguished between groups according to their income, wealth or consumption at a point in time but not according to their life-cycle stage. Feldstein (1974) first pointed out the possibility of implementing large resource transfers across generations even under balanced government budgets. Nevertheless, notions about the impact of fiscal policies across generations remained limited to a presumed positive association between larger budget deficits and larger tax burdens on future generations. Auerbach, Gokhale, and Kotlikoff (1991) developed generational accounting, a method for estimating
the economic impact of fiscal policy on different cohorts – including future ones – distinguished by birth year and gender. With rapidly ageing populations in developed countries and growing costs of social insurance programmes that redistribute resources from younger to older generations, the demand for evaluating the intergenerational effects of government fiscal policies increased considerably. As a result, generational accounting is now used as a fiscal-analysis tool in dozens of countries.

Generational accounting (GA) is a method of estimating prospective per capita lifetime net tax burdens that different cohorts would face under existing fiscal policies. ‘Prospective’ means that fiscal burdens are evaluated over cohorts’ remaining lifetimes; ‘net tax’ means that government transfers are subtracted from taxes; and ‘lifetime’ indicates that future dollar flows are actuarially discounted back to the present and aggregated into a summary measure of the fiscal burden in present value. Changes in the GAs of different cohorts arising from changes in government tax and spending policies measure fiscal policy-induced changes in those cohorts’ lifetime resources.

**Generational accounting method**

Under current (year t) policies, the present discounted value of the government's projected purchases of goods and services ($PVG_t$) must be paid for out of the government's current net financial wealth ($NW_t$), the present value of net tax payments by living generations ($PVL_t$), and the present value net tax payments by future-born cohorts ($PVF_t$). In this government intertemporal budget constraint,

$$PVG_t = NW_t + PVL_t + PVF_t,$$

$NW_t$ is calculated as the sum of past budget surpluses – which would be negative if past budgets mostly accrued deficits. The government's real assets, such as land, roads, buildings and public parks, are not included because that would require inclusion of a compensating term on the left-hand-side of eq. (1) – the rental cost of the services those real assets provide.

For calculating $PVL_t$, official government projections of annual aggregate taxes and transfers are first distributed across officially projected populations using profiles of tax payments and transfer receipts by age and gender obtained from the latest available micro-data surveys. Per capita taxes and transfers for years beyond the government projection horizon are obtained by growing the terminal year's per capita values at the labour productivity growth rate underlying official aggregate projections.

Next, each living cohort's GA is calculated by actuarially discounting its projected net taxes per capita using cohort-specific mortality projections and an assumed rate of discount. Because fiscal dollar flows are more volatile than returns on government bonds but less volatile than private capital returns, an intermediate rate of interest is used. Multiplying each cohort's GA by its year-t population and aggregating across all cohorts yields $PVL_t$.

$PVG_t$ is calculated by projecting government purchases of goods and services – such as administrative and judicial services, defence, and infrastructure – at current levels per capita using official population
projections, and discounting those amounts back to year $t$. The term $PVF_t$ in eq. (1) is calculated as a residual.

Both $PVL_t$ and $PVG_t$ are calculated by projecting fiscal flows under unchanged policies. $PVL_t$ equals the present value of net taxes that cohorts alive in year $t$ would pay collectively if their fiscal treatment remained unchanged throughout their lifetimes. $PVG_t$ indicates the size of the bill in present value for providing public goods and services at current levels for ever. To maintain the current fiscal treatment of living generations and current public goods and service levels for ever, the present value cost that future generations must pay equals $PVG_t - PVL_t - NW_t$.

Thus, generational accounting reveals the fiscal burden that future generations collectively face under current government fiscal policies. That burden does not necessarily equal the government’s outstanding debt: $-NW_t$.

Estimating per capita fiscal burdens facing future-born generations requires knowing how it would be distributed among them. Generational accounting assumes, hypothetically, an equal distribution of the residual fiscal burden except for an adjustment for productivity growth. If we ignore gender differences for simplicity, the GA facing those born in year $t + 1$ is calculated as

$$GA_{t+1} = \frac{(PVG_t - PVL_t - NW_t)(1 + r)}{\sum_{s=t+1}^{\infty} N_s \left[ (1 + g) / (1 + r) \right]^{s-(t+1)}}$$

(2)

Here, $r$ represents the discount rate; $g$ represents labour productivity growth; $s$ represents future cohorts' birth years; and $N_s$ represent their population sizes. In eq. (2), the residual fiscal burden in present value as of period $t + 1$ is divided by the weighted sum of the population of future-born persons with weights based on $r$ and $g$. The discount rate, $r$, is included in the weighting scheme to account for the differences in the timing of net tax payments by different future-born cohorts. Such weighting ensures that people born in period $s > t + 1$ pay lifetime net taxes that are $(1 + g)^{s-(t+1)}$ times larger than those paid by persons born in period $t + 1$.

**Generational accounts for the United States**

By using projections from the Budget of the US government for fiscal year 2005 (with $t =$ fiscal year 2004), applying a five per cent discount rate, and calculating US dollar amounts in constant 2004 dollars, $PVG_t$ is estimated to be $26.8$ trillion; $NW_t$ equals $-4.4$ trillion; and $PVL_t$ equals 4.9 trillion. That leaves future generations to collectively pay $26.3$ trillion.

Table 1 shows GAs for selected US male and female cohorts with $t =$ fiscal year 2004. They exhibit a standard life-cycle pattern: older cohorts face negative GAs – they receive benefits on net – and younger ones face positive GAs. Younger women have smaller GAs than men because of their lower labour-force participation and earnings. Very young cohorts with many years to go before paying taxes face
considerably smaller GAs because of discounting. Older women receive larger net benefits in present value than older men despite their lower prior labour-force activity because they live longer and receive social insurance benefits based on their male spouses’ earnings. The GA for those born in 2005 (year $t +1$) equals $333,200 per capita – considerably larger than that for 2004-newborns.

**Lifetime net tax rates and generational balance**

Alternatively, fiscal burdens can be represented as *lifetime net tax rates* ($LNTR$) that different generations would face under the given assumptions. For future generations, $LNTR_f = GA_s / PVE_s$, for all $s > t$, where $PVE_s$ represents the present value as of period $s$ of projected (pre-tax) labour earnings per capita for the cohort born in period $s$. Future labour earnings per capita are projected in a manner similar to that used for projecting taxes and transfers. Equation (2)'s distribution rule implies that both lifetime net taxes and lifetime earnings grow at the same rate for successive cohorts, implying that $LNTR_f$ applies to all future cohorts.

An important generational accounting concept is that of *generational balance*. It is derived by comparing the lifetime net tax rate facing year-$t$ newborns, $LNTR_t = GA_t / PVE_t$, with $LNTR_f$. Note that $LNTR_t$ is based on current tax and transfer policies extended throughout the lifetime of year-$t$ newborns whereas $LNTR_f$ is a hypothetical rate imputed for future generations based on an equal growth-adjusted distribution of the residual fiscal burden across future-born cohorts. A finding of $LNTR_t < LNTR_f$ would show current policy as being generationally out-of-balance – one that levies a smaller $LNTR$ on current newborns than would be required of future ones on average to balance the government's books. Thus, a policy that is generationally out of balance is also unsustainable.

Calculations based on the GAs shown in Table 1 reveal that US fiscal policy is considerably out of generational balance as of fiscal year 2004. The present value of lifetime earnings for males born in 2004 is estimated to be $562,000, making $LNTR_{2004}$ equal to 18.5 per cent. For future-born cohorts, $LNTR_f$ equals 58.2 per cent. Continuing existing tax and spending laws for living generations would require future generations to bear fiscal burdens that are more than three times larger on average.
If current policy is out of generational balance (that is, if $LNTR_t < LNTR_f$), GA machinery can also be used to calculate alternative policy changes that would restore generational balance. This exercise reveals the policy trade-offs involved in moving from a generationally out-of-balance policy to one that is balanced.

A large initial generational imbalance requires a large fiscal adjustment. Restoring generational balance to US fiscal policy via income tax hikes would require average income tax rates to be 39 per cent larger. That is, federal income tax revenues that according to the US Congressional Budget Office (2006) amounted to 8.6 per cent of GDP in 2004 would have to be immediately and permanently increased to 11.9 per cent of GDP. Alternatively, federal discretionary outlays would have to be reduced immediately and permanently by 67 per cent.

**Criticisms of generational accounting**

Generational accounting has been subject to several criticisms. First, it measures the direct net costs of taxes and transfers but excludes the benefits derived from government public goods and service purchases. If the benefits from some purchases accrue much later, the average GA facing future generations may not accurately reflect their fiscal treatment under current policies. Second, generational accounting does not factor in the costs and benefits from government insurance provision. These two criticisms indicate that generational accounting is not a ‘utility measure’ of the impact of fiscal policies on different generations. However, dynamic simulation studies suggest that changes in GAs correspond reasonably well to welfare gains and losses arising from policy changes.

Third, generational accounting ignores dynamic economic responses when estimating policy adjustments for restoring generational balance. However, its ‘static’ estimates constitute lower bounds of the required adjustments. For example, increasing income taxes would normally reduce labour supply and require a larger tax hike to achieve generational balance.

Fourth, to qualify as ‘budget concepts’ fiscal measures must show the implications of keeping policies unchanged. However, the generational balance measure employs a hypothetical policy for future generations. Gokhale and Smetters (2003) provide alternative fiscal and generational imbalance measures that do not involve hypothetical policies.

Fifth, generational accounting discounts future fiscal flows using a common discount rate whereas taxes and transfers may be subject to different degrees of policy and economic uncertainties. And sixth, it may be appropriate to use different discount rates for different cohorts because they face different risks. However, generational accounting studies include sensitivity analyses under alternative assumptions, including alternative discount rates.

**Final remarks**

It is important to note that generational accounting tracks only the redistributive impact of government fiscal policies. It does not include the impact of private bequests and *inter vivos* gifts. In theory, private intergenerational transfers may substantially or fully offset government transfers. However, the weight of evidence, at least for the United States, suggests that such offsets are quite small.

A chief lesson from the generational accounting literature is that the frequently cited aggregate cash-
flow measures of fiscal policy – such as the size of national debt and annual budget deficits – are uninformative and, indeed, may mislead policymakers about the true distributional and economic implications of current fiscal policies and policy changes.

To the extent that traditional deficit and debt measures miss significant policy-induced intergenerational redistributions – with potentially large effects on agents' economic choices such as consumption and labour supply – generational accounting calculations can provide useful information to policymakers and the public.

Generational accounting is also likely to prove useful in further economics and public-policy research. For example, generational accounts could be combined with other elements of wealth – human, non-human and private pension wealth – on a cohort basis to estimate whether changes over time in the cohort-distribution of resources are related to changes in cohort saving and labour force participation. Generational accounts could also be used to calculate changes in the degree of cohort wealth annuitization for examining the extent of insurance against uncertain longevity.

In many countries, government programmes for providing insurance to the public against various types of economic risks are financially unsustainable. Uncertainty about prospective changes in taxes and transfers for correcting those fiscal imbalances constitute a major source of risk for households. Analyses using generational accounting may help in better understanding the extent to which government fiscal policies mitigate or exacerbate the economic risks facing different generations.

Bibliography

**How to cite this article**

Genovesi was born near Salerno and died at Naples: he took holy orders in 1736. In 1741 he taught metaphysics at the University of Naples. He was intimately acquainted with Bartolomeo Intieri, who induced him to follow Broggia and Galiani in the study of economics; and when, in 1754, by the advice of Intieri and with funds' liberally supplied by him, the teaching of economics, then termed mechanics and commerce, was established at Naples, Genovesi was called to the chair. He was ‘the most distinguished and the most moderate of all Italian mercantilists.●…●Commerce was for him not an end only, but also a means by which the products of industry at large were brought to the right market. He, moreover, distinguished between useful commerce which exported manufactured goods and brought back in return raw material, and harmful commerce which exported raw material and imported foreign goods; he also insisted that useful commerce calls rather for liberty than for protection, while upon harmful commerce the strictest embargo should be laid, or at least it should as far as possible be bound hand and foot’ (Cossa, Introduction to Political Economy, translation, p. 235).

These ideas, neither new nor original even in his time, were maintained by Genovesi in many of his works, and brought together, but without any systematic order, in his Lezioni di Commercio ossia di Economia Civile (Napoli, 1765, e. ii. ediz. 1768–70, 2 vols). Though the Lezioni do not form a regular treatise, they contain the author's opinions on the mercantilist system and the most important principles of economics, which he terms Civile ‘la scienza che abbraccia le regole per rendere la sotto-posta nazione popolata, potente, saggia, polita’ (the science which embraces the laws which make a nation populous, powerful, wise, and cultured), limiting thus the science to the increase of population and the production of wealth.

As to population, Genovesi follows the mistaken principle of his times, exaggerating the advantage of a large population, proposing that government should encourage marriages by granting privileges and honours. He says that the population ought not only to be numerous but supplied with comforts, and he
sees the relation between population and means of subsistence or production of wealth. As a writer he is a mercantilist, though he does not regard money as the only form of riches; he says that the wealth of a nation is quite apart from the quantity of money treasured up. He derives the idea of value from demand, distinguishing different degrees of demand according to their abstract importance in several categories, maintaining that a thing which satisfies a want repeatedly has a higher value than what satisfies only a few wants or the same only sometimes (puo soddisfare ad un bisogno più volte, ha maggior prezzo che non quella, la quale o non puo soddisfare che pochi bisogni o al medesimo qualche volta). What is able to satisfy a great want is of more value than what satisfies a small want (una cosa fatta a soddisfare il maggior bisogno si apprezza più che quella la quale non é fatta che a soddisfare ad un minore); and further he asserts that the quality of things influences the value. Graziani (Storia della teoria del valore in Italia, Milano, 1889, p. 108) justly remarks that in this Genovesi approaches the important question which Galiani answered: namely, why do luxuries generally cost more than necessaries? In this he is obliged to have recourse to the element of scarcity, a line of argument which he does not know how to reconcile with those previously mentioned. Genovesi's want of originality is obvious, as F. Ferrara has shown (Bibl. dell’ Econo.,1a. S. vol. iii. Introduz.) in contradistinction to the exaggerated opinion which Bianchini held respecting him (La scienza del ben vivere sociale), since the Socialists of the Chair persist, erroneously, in considering him as a precursor of their opinions. This tendency is also attributed to Genovesi, as well as to Beccaria, Verri, and Romagnosi by the French socialist B. Malon; which is a further example of the errors of the socialists in their historical criticism of political economy.

Article

Henry George was by turns sailor, prospector, printer, reporter, San Francisco newspaper editor and publisher, orator and political activist beforecloseting himself to write on political economy. His Progress and Poverty (1879) electrified reformers, catapulted him to fame and began a worldwide movement for land reform and taxation, opening to George an extraordinary career in radical politics. Returning from Ireland as reporter for The Irish World of New York he was lionized by Irish-New Yorkers for his stand on the Irish land question. With ethnic, union and socialist backing he formed the United Labour Party and ran for mayor of New York in 1886, nearly winning. He toured Britain and won over the Radical-Liberals, and then toured Australia as a folk hero. At home he was courted by Democrat and later by Populist leaders. He died in 1897 while running again for New York mayor, but his followers rose in and helped shape the Progressive movement which dominated the next 20 years. His name has become a byword for ideas and policies he espoused.

George is best known today for Progress and Poverty (1879). Eloquent, timely and challenging, it soon became and remains the all-time best-seller on economic theory and policy.

George defines ‘The Problem’ as increase of want with increase of wealth. Dismissing Malthusian fatalism as merely a device to rationalize privilege, George attributes low wages and unemployment rather to artificial scarcity of land and barriers to free exchange. Artificial scarcity results from unequal dispensation of public lands, concentration and ‘speculation’. George's speculation is pervasive market failure endemic to land, which failure he attributes to holding for the unearned increment.

George proposed to raise the ad valorem property tax rate on bare land (broadly defined as all natural
opportunities), thus socializing rent without excess burden. He would remove other taxes, calling them
to commerce, employment and capital formation. The cash drain of the _ad valorem_ tax, while neutral
at the margin, would move and lubricate the land market as a whole, forcing land into full use.
Observation persuaded him that otherwise speculation overrode the incentives to use land fully.
Release of hoarded lands would open wider opportunities for both labour and man-made capital. His
overriding concern was for labour, but he saw capital mainly as a form of labour, produced by labour,
complementing labour. So in an era before payroll taxes it was actually capital and commerce he sought
to untax for the benefit of labour – a preview of ‘business Keynesianism’ in W. Heller’s production of
Camelot.
George did not see investment employing labour, but labour producing capital, a difference that to him
was more than a nuance. While admiring Quesnay he never absorbed the Physiocratic idea of ‘_avances_’. Instead he attacked its English derivative, the wages-fund theory with its advances of subsistence, a
concept he rejected as condescending to labour. He developed no concept of economic circulation, of
either capital or spending. He lacked a good capital theory, belittling Austrian interest theory and
botching his own. These faults narrowed the effective scope of his otherwise seminal work and
ultimately limited its influence, which is still wide and sustained but mainly outside the macroeconomic
field it addressed.
His programme would level barriers to exchange and specialization and production and synergy. These
include spatial barriers forced by land speculation (for example, scattered settlement and urban sprawl);
fiscal barriers like excise and wage taxes; and social barriers from unequal wealth and contempt for
workmanship, which he (like Veblen) traced to the influence of privilege and unearned wealth. This
‘true free trade’ would unleash technological, scientific, cultural and spiritual development in a more
egalitarian and moral society organized around a perfected market mechanism.
George drew on earlier thinkers: Quesnay, Smith, Ricardo, Spencer, and Mill. And he contributed much
to later thinking.
George was system-minded and sought to unify the laws of production and distribution in a coordinated
harmonious system. His theoretical framework is an early adumbration of the marginal productivity
theory of wages, which he integrates with Ricardo’s rent law. J.B. Clark was a nemesis, and P.
Wicksteed a friend, but both were formalizing insights from George.
Although best known as a deductive thinker, the journalist was also an observer with statistical intuition.
In debate with Francis Walker on ‘The March of Concentration’ in farming, George anticipated Lorenz’s
method of analysing size distributions and goaded the US Census into publishing farm size data in that
form.
George wanted radical redistribution but without revolution. He pioneered the idea that taxation,
properly crafted, can redistribute wealth without damage to the market. His influence on Fabianism was
early and wide; also on American reformers like Tom L. Johnson, Upton Sinclair, John R. Commons
and Norman Thomas. The modern ‘mixed economy’ is in the Georgist spirit of reform within traditional
forms.
Continued heavy reliance on real estate taxation in Canada and the United States, with separate
assessment of land value, reflects George’s influence, as do the inclusion of land rents and gains in the
income tax base, and the efforts of Lloyd George, Asquith and Snowden to introduce national land taxes
in Britain.
Free provision of public goods, social dividends, and marginal-cost pricing for urban mass transit and
utilities are vintage Henry George. H. Hotelling and W. Vickrey have acknowledged their debt. The optimistic ‘economics of abundance’ idea owes much to George. The prevailing ‘dismal’ economics was a science of choice where all the choices were bad and leaders could only call for more sacrifices. George promised full employment at higher wages by unlocking natural opportunities now held in speculation. Needed capital would be formed in the very process of making jobs, an idea pervading Keynes. Social synergy would produce a surplus that spills over into higher land rents, a ‘free lunch’ that government may tap in lieu of taxes that penalize and abort useful activity.

George lives too in urban economics and city planning. George's emphasis on the synergistic gains from urban linkages, and the wastes of sprawl caused by failure of the land market anticipates much of planning doctrine. Ebenezer Howard is an obvious link: his ‘Garden City’ presupposed Georgist taxation to move the land market.

The idea that environment is a common heritage for future generations in pure Georgism. ‘Spaceship Earth’, common property, and rights of the unborn are his very phrases. As to economic development, the economists are legion who have recommended a ‘dose of Henry George’ to help LDCs take off, and some, like Taiwan, belatedly following the counsel of the Georgist Dr Sun Yat-sen, have taken the dose with good results.

On the conservative side, George was a pioneer of tax limitation, insisting that land rent set an upper limit on government spending. The resurgence of libertarianism and supply-side economics may set a new stage for George, whose programme was mainly oriented to increasing production in the private sector. Religion in politics should not threaten George, who unabashedly presented economic policy as an implementation of religious ideals.

George's blend of radicalism and conservatism can puzzle one until it is seen as a reconciliation of the two. The system is internally consistent but defies conventional stereotypes.

Georgescu-Roegen, N.; integrability; transitivity; non-substitution theorem; input–output analysis; separating hyperplane theorem; regime switching; bioeconomics; entropy law.

Article

Born in Constanza, Rumania, on 4 February 1906, Georgescu-Roegen obtained his first degree in mathematics in 1926 from the University of Bucharest. He then went to Paris where, under the supervision of E. Borel and G. Darmois, he received in 1930 the doctorate in mathematical statistics. In October of the same year he moved to London to pursue further research with K. Pearson. By 1932 Georgescu was Professor of Statistics at the University of Bucharest. His life was inextricably bound up with the social and political events of his country, which explains the emergence of his interest in economics and his consequent decision to spend a two-year ‘apprenticeship’ (1934–6) at Harvard where he was able to work closely with Schumpeter. In 1937 he returned to Rumania, where he combined an active academic career with increasing responsibilities in public institutions. In February 1948 he fled from his country and, after a short stay at Harvard, was appointed professor at Vanderbilt University, where he remained until his retirement in 1976.

Georgescu-Roegen's scientific work is notable for an early phase centred around consumer theory, input–output analysis and production theory at large, and a later phase mainly devoted to growth modelling, methodological issues and the ambitious attempt to develop a ‘bioeconomic’ approach to economic thinking. The early phase is well represented by his 1936 classic article on consumer theory and his 1954 famous paper on ‘Choice, Expectations and Measurability’. In the former article, which deals with the ‘mysterious’ problem of integrability in the theory of demand, one finds two major results: the demonstration that the integral varieties do not necessarily coincide with the indifference varieties – whence the distinction between mathematical integrability and economic integrability – and the demonstration that the two kinds of varieties come to the same thing in the presence of the postulate of transitivity of preferences. The latter essay, focusing on the non-existence of the indifference map of the consumer as a consequence of the pervasiveness of lexicographic ordering of preferences, allowed him
to prove what he called the ‘ordinalist fallacy’ and to inquire about the origin and implications of probabilistic preferences, a subject that is at the very frontiers of economics even today.

On the other front, three contributions are particularly noteworthy. In Georgescu (1951a) we find the first and the most general statement of the celebrated non-substitution theorem: justifying the separation of scale and composition in linear multisectoral models, the theorem provides a theoretical underpinning and analytic rationale for the consistency of input–output analysis. The (1951b) paper offers the first ‘geometric’ proof of the existence of a von Neumann’s equilibrium by using the separating hyperplane theorem – a theorem that was to enter the toolbox of the economist. In his (1951c) essay, Georgescu challenged the two most intractable problems in macrodynamics – nonlinearities and discontinuities – providing, on the basis of an innovative application of the theory of relaxation oscillations, a fundamental result for investigations of regime switching.

The later phase begins with the 1966 famous methodological essay containing Georgescu-Roegen's critique of standard economics for having reduced the economic process to a mechanical analogue and a proposal of a new alliance between economic activity and the natural environment – what later would become his ‘bioeconomic programme’. The key to such a project is found in the entropy law (‘the most economical of physical laws’), which brought Georgescu to inquiry on the fundamental relation between mankind's existence and its environmental dowry. This problem prompted him to step over the fence of economics into thermodynamics, where he formulated a new law (the ‘fourth law’): the impossibility of the perpetual motion of the third kind defined as a closed system that could perform work at a constant rate indefinitely. The implications for economics of this line of thinking and in particular of his strong rebuttal of the ‘energetic dogma’ (‘only energy matters’) are nicely developed in his 1971 and 1976 books. In this last book, Georgescu lays the foundations of a new approach to production theory: the ‘flow-fund’ model as a radical alternative to both the production function model and the activity analysis model, models whose main drawback lies in their inability to tackle properly the time element in the productive process.

The long introductory essay (145 pages) that Georgescu wrote in 1983 for the English edition of Gossen's *The Law of Human Relations* is not simply a splendidly written intellectual biography, showing the depth and breadth of his economic culture, but it contains also a restatement in modern analytical terms and an expansion of Gossen's theory of economic behaviour. Georgescu-Roegen was one of those rare scientists able to couple a remarkable expertise in their specific field with a philosophical bent of mind. In this sense he was a true Renaissance man, which perhaps helps to explain the generalized *fin de non recevoir* of the profession with respect to his critical message, the message of a scholar who cannot be identified with any single school of economic thought and whose intellectual endeavour is best seen as a major contribution to the shifting of the frontiers of economic theory and methodology.

Article

Born on 30 June 1944 at Auxerre, Gérard-Varet studied economics and sociology at the University of Dijon, and prepared his doctorate partly at CORE (Louvain). He taught, as full professor, in Strasbourg, Toulouse and, for most of his academic career, Marseille, where he died on 31 January 2001. He played a quite important role, not only through his teaching and his scientific production, but also as an organizer, in particular as long-term director of his research centre (GRECAM, Marseille) and president of national and international economic associations.

The first set of the theoretical contributions of Gérard-Varet concerns mechanism design, a field in which he began to collaborate in 1973 with Claude d'Aspremont, in the context of a project on cross-border pollution. Starting from the Vickrey–Clarke–Groves mechanism, which ensures that truth revelation by each agent is a dominant-strategy equilibrium, but not that the budget is balanced, they introduced the expected externality (or AGV) mechanism, which is both truthfully implementable as a Bayesian equilibrium and budget-balanced. The mechanism was explicit, while requiring independence of agents' beliefs. This condition was considerably generalized by switching from a constructive to an existence proof, based on the Farkas lemma (1979; 1990a). Restrictions on beliefs under adverse selection were also shown to be transposable to stochastic outcome functions in team moral hazard, and to be applicable to two kinds of enforcement mechanisms: enforcement through transfer schemes and enforcement through repetition (1998). More generally, the work of the mid-1970s opened the way to a lifelong research programme.

The second set of the theoretical contributions of Gérard-Varet concerns oligopolistic competition (in...
partial, general and macroeconomic equilibrium). In 1980, he engaged in the analysis of the macroeconomic effects of significant output market power. He first showed the possibility of so-called involuntary unemployment (in Keynes's sense of persistent unemployment at an arbitrarily low money wage). This results either from the non-existence of a full employment equilibrium (because marginal revenue eventually becomes negative as wages decrease) or, when equilibria are multiple, from a failure to coordinate on that equilibrium (1990b). The early static results were extended to overlapping generation economies and linked to the emerging literature on markup variability as a source of endogenous fluctuations (1995a). The need for a unified treatment of different standard varieties of imperfect competition motivated the formulation of the \textit{P-equilibrium} concept, first applied to an industry or a group of industries (1991), then to the whole economy, in a general equilibrium approach (1997). Strategic agents simultaneously choose price signals in order to manipulate market prices through some \textit{pricing scheme} \textit{P}, and quantities, required to satisfy market realization constraints. A distinct but related concept of oligopolistic equilibrium was designed later (2007), where producers of elements of a composite good choose price–quantity pairs under two constraints, on market share and on market size. The associated Lagrange multipliers are used to build an index of \textit{competitive toughness}, parameterizing the set of equilibria and appearing as a foundation to the ‘conjectural variations’ parameter of the empirical industrial organization studies.

The preceding themes by no means exhaust the list of subjects on which Gérard-Varet has made theoretical and applied contributions, often combining features of public economics and industrial organization, of which the economics of visual arts is a good example (1995b).

German economics in the early 19th century

K. Tribe
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

During the 18th century ‘cameralism’ became a recognized part of the introductory curriculum of (mainly northern, Protestant) German universities. The French Revolution, the Napoleonic occupation, and Kant's new Critical Philosophy together swept established doctrine aside during the final decade of the century, allowing a reoccupation of the university curriculum by ‘modern economics’. Jean-Baptiste Say had more direct influence on this than Adam Smith's Wealth of Nations. When combined with a post-Critical emphasis on human needs, this directed German writings away from the English emphasis on value and distribution and laid the foundation for a new ‘marginalist’ economics in the 1870s.

Keywords

Article

Nationalökonomie emerged in early 19th century Germany as a new doctrine which took human needs and their satisfaction to be the first principle of economic analysis. Cameralism had become in mid-18th century Germany a regular part of the university curriculum in German universities, taught in faculties of philosophy to future state officials. By the 1820s this function had been modified, with lectures on economics becoming a compulsory part of the law curriculum, as elsewhere in Continental Europe. This institutional development coincided with the emergence of a new economics which displaced the older Cameralwissenschaften, together with their focus on state finance and national wealth. The older teaching was pushed to one side, and its place in the lecture room taken by the new principles and doctrine of Nationalökonomie. This joint development was not a direct outcome of the Revolutionary and Napoleonic Wars (although these certainly caused a great deal of
German economics in the early 19th century: The New Palgrave Dictionary of Economics

physical disruption to universities), nor a consequence of the new republican ideas fostered by these wars and by the French Revolution itself (although these certainly played some role). Nor did it follow directly from the diffusion of Adam Smith’s teaching, although Smith did in the early 1800s become a major point of reference in discussion of economic principles. This internal transformation in the teaching of economics in German universities resulted instead from an assault upon the older, eudaemonistic natural law tradition by converts to Critical (Kantian) Philosophy. This process was just gaining momentum around 1795; by 1805 the transformation was all but complete. Although textbooks in the cameralistic tradition still appeared, and, it can be assumed, professors continued as always to read out their old lectures, the teachings of Smith and Say now found a definite place within the university, as part of a new Fach, Nationalökonomie.

This new science drew on a range of sources, but remained quite distinct from the political economy being developed at the time in Britain by James Mill, Robert Malthus and David Ricardo. It shared neither their emphasis upon distribution between agents defined by the process of production, nor the peculiarly English preoccupation with value and its measurement. As we shall see, German writers were, directly or indirectly, influenced by the work of Jean-Baptiste Say rather than by any English political economist. Especially important was Say's tripartite schema of production, distribution and consumption, and his argument that production produced neither ‘things’ nor value, but utilities.

A direct line can therefore be traced from this early Nationalökonomie to the work of the early Austrian economists. When in 1871 Carl Menger published his Grundsätze der Volkswirtschaftslehre, he defined as ‘goods’ ‘utilities …related to the satisfaction of human needs’ (1871, p. 2). A long footnote was appended to this statement, beginning with Aristotle's conception of goods, proceeding on through Forbonnais, Le Trosne and Say; and listing as the first relevant German authors Soden, Jakob and Hufeland. These three writers were the principal architects of the new Nationalökonomie. Among them, Jakob's definition of a good is the most pithy: ‘Everything that serves the satisfaction of human needs’ (1805, §. 23). Jakob was also Say's German translator (1807), his own textbook of 1805 clearly following the organization and argument of Say's Traité d'économie politique. And, like Schlözer (1805, §. 12), Jakob made a clear distinction between state and economy, or politics and economics.

The definition of Nationalökonomie

‘German economics’ has always been primarily an academic rather than a public or popular discourse, but during the 18th century it had been not uncommon for teachers of cameralism to be shared with the practical world of state administration. Soden was one of the last representatives of this tradition – he was never a university teacher, but spent his working life in state administration before retiring in 1796 to his estate so that he might devote himself to literary pursuits. Prompted by what he saw as the lack of system in Adam Smith's Wealth of Nations, a new translation of which had just appeared (1794–6), Soden set out to provide a more systematic basis for the new science, defining it as:

…the Natural Law of sociable mankind with respect to the maintenance and promotion of its physical welfare, and in the same way that the Law of Nations outlines the laws according to which nations, in the reciprocal condition of co-existence, must adhere in every respect; so Nazional-Oekonomie provides the principles which … must be adhered
to, such that every member of every nation achieves the highest possible degree of physical welfare, and maintains this position. (1805, pp. v, vi)

The leading principle of Nationalökonomie was then described as ‘… the highest perfection of the physical condition of sociable mankind’ (1805, p. 14), underscoring the impact of the contemporary intellectual fashion for Critical Philosophy beyond the confines of philosophy and ethics. Gottlieb Hufeland, the third writer named by Menger, was, like Jakob, a professor of law who had become a ‘Kantian’ – and both, like Soden, found their way to Adam Smith via Kant's new philosophy. Hufeland's *Neue Grundlegung der Staatswirtschaftskunst* began with a review of the relative merits of James Steuart and Adam Smith as systematic theorists of economic life. Smith's *Wealth of Nations* had quickly been translated into German, but found at first little resonance among university professors, although, like the Physiocrats, Smith was more widely read by lay members of local literary and economic societies than by university scholars. The German ‘Smith reception’ proper began with the publication of the second translation in the mid-1790s, coinciding with the developing wave of enthusiasm for Critical Philosophy. And as Hufeland noted in his introductory remarks, it was only towards the end of the 1790s that there were clear signs that Smith had been read and understood (1807, n.p.).

Soden and Jakob, observed Hufeland, had dubbed their new field of study Nationalökonomie, and, while he did not find this very objectionable, he suggested that it would be ‘better and clearer’ to use a German expression, Volkswirtschaft – which is indeed the root term that became generally accepted about a century later. This latter expression was more suitable, he thought, because it expressed a clear distinction with respect to Staatswirtschaft, the generic term that cameralists had used to describe the domain of economic life in an intellectual system where no distinction was made between ‘state’ and ‘society’. The problem with the German word Wirtschaft, he noted, was that it implied a governing person – invoking the Aristotelian head of household on the one hand, and the more down-to-earth figure of the farmer or inn-keeper on the other (Landwirt, or simply Wirt). Such a figure was absent from the Volkswirtschaft ‘where many thousands pursue their economic life’ (wirtschaften) (1807, p. 14). This he later clarified as a ‘sphere of goods’, goods being defined as any medium for the realization of human purposes; hence, the ‘sphere of goods’ was a domain of autonomous human economic activity independent of state action (1807, pp.17–18, 116).

**Jakob and the architecture of Nationalökonomie**

Of the writers introduced so far, Ludwig Heinrich Jakob was the most influential in recasting German economics around the conception of human need. He began teaching a course on ‘Political Economy and State Economy according to Sartorius’ in 1801. Up to this time he had been preoccupied with the creation of a new natural law based on critical principles, exemplified by his *Philosophische Rechtslehre oder Naturrecht* of 1795. We can better see how this new natural law contributed to the reshaping of cameralism if we consider the structure of the book that Jakob first used as a textbook, Sartorius's *Handbuch der Staatswirtschaft zu Gebrauche bey akademischen Vorlesungen* (1796). It was a standard requirement that professors select a textbook to which their lectures were directed, and quite normal for a new course of lectures to be developed as a commentary on this text. It had also become established
practice that each lecturer found the existing texts in some way unsuited to his purposes, and so from this commentary there would develop a new text which became in turn the assigned text. If simple enthusiasm for the writings of Adam Smith had been sufficient to bring about the demise of cameralism and its replacement by Nationalökonomie, then we might reasonably expect Sartorius to have played a key role in this, for he was one of the first and most articulate Smithians. But while many late cameralistic writers recognized that Smith's *Wealth of Nations* was an important work, none of them contributed significantly to the new conception of human need, economic activity and welfare that was to survive as the core of German economics for more than a century.

Sartorius's textbook carries the subtitle *Nach Adam Smiths Grundsätzen ausgearbeitet*, for it is principally a condensed version of *Wealth of Nations*, about 40,000 words long, based on lectures that Sartorius had delivered in Göttingen since 1791 as a Privatdozent in the philosophy faculty. This, therefore, gives us an idea of what Sartorius taught, and also what argumentative opportunities this text presented to Jakob in his own initial lectures. Sartorius's presentation is brisk: Smith's 'Introduction and Plan of the Work' is dealt with in 16 lines, and by the fifth page we have already arrived at Book I, Ch. V. Books I and II of *Wealth of Nations* are dispatched in 90 pages of summary, each paragraph corresponding to a chapter or a part of a chapter in the original. Discursive sections of *Wealth of Nations* are reduced to bare propositions; importantly, the argument concerning the human propensity to exchange is suppressed entirely. Once the summary reaches the end of Smith's Book II, Sartorius inserts his own section which summarizes the principles of Books III–V as if they were part of a cameralistic treatise on *Staatswirtschaft*: the title runs ‘Of State Economy, or the Rules which the Government of a State must Pursue, so that Individual Citizens might be placed in the Position of being able to Create for Themselves a Sufficient Income, as well as Providing the Same for Public State Expenditures’. Here, although freedom is the means, a eudaemonistic conception of welfare is the objective. This shift towards an older German conception of the state, its tasks and objectives is continued into the treatment of public finances.

For all his admiration of Smith during the 1790s, Sartorius presented a brisk précis of *Wealth of Nations* rather than a summary of, or commentary upon, its leading principles. The characteristic emphasis that we have seen in Jakob, Hufeland, Schlözer and Soden upon human needs, upon goods as means for the satisfaction of such needs, and upon the economy as the domain within which human individuals sought to maximize their satisfaction of need finds no place here. Two years later Say's *Traité* was published, and this would prove a far more promising avenue through which these concerns, springing from Critical Philosophy, could be brought to bear upon economizing activity. Jakob notes in the Preface to his *Grundsätze* that he had used Sartorius's *Handbuch* for some years, but that he had come to the view that some of Smith's ideas were obscured by the form of presentation adopted. He proceeds to redefine the state and its affairs in a manner that denies it a decisive role in the formation and distribution of wealth, analogously to the manner in which Say had clearly separated politics from political economy. The expression 'State', Jakob argues, can be used to refer only to public affairs; state property is therefore merely a part of national property (*Volksvermögen*), separate from it and for use in pursuit of public and common ends.

*Staatswirtschaftslehre* can be in fact nothing other than financial science or Policey, insofar as care for public order is part of good public economy. (1805, p. vi)
How does this intent translate into the principles of Nationalökonomie, and what relationship is established to political economy on the one hand and the cameralistic sciences on the other?

The most striking initial feature of Jakob's book is its plan of organization. At the end of the 'Introduction', he states that Nationalökonomie deals with three principal issues:

1. The formation and increase of national wealth.
2. The principles of the most advantageous distribution of national wealth among the members of society.
3. The consumption of national property and the various effects of the same. (1805, p. 12 §. 20)

Or, in other words, the trinity of production, distribution and consumption introduced by Say in the second edition of his Traité (1814). Say had already stated in his first edition that Smith distinguished politics as the science of legislation from a political economy dealing with the formation, distribution and consumption of wealth (1803, vol. 1, pp. i–ii); but this first edition was divided into five books, dealing in turn with production, money, value, revenue and consumption. Jakob, by contrast, not only stated that Nationalökonomie dealt with the production, distribution and consumption of wealth; his book is divided up in this way too. Viewed from this perspective, the sequence of chapters in Jakob's 1805 textbook resembles more closely the order in which material is treated in Say than it is in Smith.

Karl Heinrich Rau and the systematization of Nationalökonomie

Jakob, Soden, Hufeland and Schlözer, more or less simultaneously and independently, created a new conception of economic life separate from the work of state administration, which had hitherto been thought to provide a necessary framework for the orderly conduct of production and consumption. This did, however, remain very general in outline, and in many cases it was simply taught alongside the traditional practical areas of economic administration, such as agriculture and forestry, finance, and botany. In 1826 Karl Heinrich Rau, since 1822 a professor at Heidelberg, published the first volume of a textbook that was to end this equivocal state of affairs. Three volumes of his new Lehrbuch der politischen Oekonomie – Rau chose to revert to a name for the subject generally accepted outside Germany and more recognizable to French or English readers – were published between 1822 and 1837. The work ran into many editions, the last revised edition appearing in 1876. Here again there is a clear line of connection to Austrian economics, for Menger drafted the first outline of his Grundsätze in the margins of his 1863 edition of Rau (Menger, 1963).

The first volume of the Lehrbuch deals with 'Die Volkswirtschaftslehre' – 'those characteristic laws which can be perceived in the economic activities of peoples regardless of the intervention of government' (1826, p. x). It begins by making a clear distinction between private and public economics. 'Private economics' is composed of the rules governing the optimum satisfaction of needs through the acquisition, maintenance, and use of material goods. 'Public economics' by contrast deals with the satisfaction of needs by the allocation of material goods on the part of the state – it has a strictly redistributive character, recirculating goods produced in the 'private economy' using revenues derived from taxation. Whereas the Volkswirtschaft is conceptualized by the individual pursuit of self-interest, there are general aims of the state that the individual cannot attain unaided, and so the role of
government in the economy is to intervene to ensure that these general aims are secured. Rau's account does not have the kind of internal theoretical structure that readers of English political economy might anticipate. Although he announces his intention to develop a theory of economic forces based upon natural laws, the volume merely enumerates economic objects without regard to their mutual relationship in production, distribution and consumption. The second volume, first published in 1828, is devoted to economic welfare. Although this has affinities with the older cameralistic teaching, Rau here consistently distinguishes between the wealth of an individual and the wealth of a people, only the latter being the proper object of economic analysis. The function of the state is strictly limited to the facilitation of individuals' desire to better their conditions, through educational provision and the promotion of commercial enterprise. Again, however, once past the initial principles the work becomes a review of specific measures fostering enterprise or removing hindrances to individual enterprise. Thus, we read under the heading 'Promotion of Exchange or Encouragement of Trade' about newspapers, fairs, weights and measures, money, roads, railways, canals, and bridges. Later we can read that savings and insurance are to be promoted, and gambling restricted. The proper employment of state expenditure and the relation of taxation to such employments are dealt with in the third volume, devoted to ‘financial science’. The first edition appeared in 1832, and Rau was revising the text for a sixth edition at the time of his death in 1870. Shortly beforehand he had suggested to his family that the work be taken over by Adolph Wagner, who published in 1872 his own revised version of Rau's treatment of financial science, which in successive editions became the standard textbook on finance up to and beyond the turn of the century.

Schumpeter's History of Economic Analysis (1954, p. 503 n. 2) devotes no more than a dozen lines to Karl Heinrich Rau, dismissing his textbook as adequate for teaching but of little further interest. But, as noted above, it was with this textbook that Menger started to draft his Grundsätze, while the link to Wagner reaches on to Richard Musgrave's work on public finance (he completed his Diplom Volkswirt in Heidelberg in 1933) and thence to Buchanan's conception of public goods. And Rau is also linked to the final writer considered here, Friedrich Benedict Hermann, who graduated from the University in Erlangen in 1823 only one year after Rau left for the chair in Heidelberg.

Towards post-classicism

Hermann's Staatswirthschaftliche Untersuchungen of 1832 sketched a clear relation between the supply of and demand for economic goods as formative of market prices. His introductory discussion identifies the level of profit and the relation of profit to wages as the most difficult area of economic analysis, given a rigorous treatment by Ricardo but still in need of much refinement. This immediately establishes an approach far more theoretical in character than was at the time usual for German writers on economics. But, while it is true that Hermann's work looks forward to the kind of discussion of price formation that we later find elaborated in Mangoldt (1863), it is clear that Hermann shares the preconceptions of all the writers outlined above. His account of basic principles begins with the definition of a good as anything satisfying human need, an 'economic good' being acquired through sacrifice of labour or money; and the book ends with the statement that consumption is destruction of use value, a conception drawn from Jean-Baptiste Say.

The initial discussion of need and its satisfaction reviews their treatment in James Steuart's 1767...
Principles and Say's 1828 Cours, arguing that use value is the main feature of a good because of its capacity to satisfy needs. This does not, however, prevent Hermann from developing an analysis of price formation in which the price level for a particular good is made dependent upon the relation of demand and supply or, what is much the same thing, the relation between the number of sellers and the number of buyers, which echoes Jakob's account of prices and effective demand, with the addition of the term ‘equilibrium’ to describe the point where ‘…goods are demanded and supplied in the same quantities’ (1832, p. 67). Given a basic cost which includes the usual rate of interest and entrepreneurial profit, he suggests that if the price falls below cost then capital and talent will move elsewhere; conversely, where the price prevails above cost then new entrepreneurs will be attracted, in turn leading to a steady reduction in the price until once more prices and costs are equalized (1832, pp. 4–5, 67–81). But even elementary arguments with this degree of clarity are rare in the literature of the period.

Conclusion

This account of German economics in the early 19th century has emphasized the way in which economic discourse had long been a part of university teaching. Left out of the above account are those lacking a university background and whose work thus falls outside this tradition, but who have since become noted as important parts of the early 19th century German context. First among these is Adam Müller, whose Dresden lectures of 1808–9 countered the new idea of society as a self-organizing system with a romantic, organic conception of man and the state (1922). This found no general resonance in contemporary economic writing, and was rediscovered later by early 20th century cultural critics of capitalism. The principal contemporary influence attributed to Müller connects him to Friedrich List, but there is little evidence for this supposition. List for his part did briefly teach at Tübingen during 1818 and 1819, but in ‘administrative practice’, not ‘economics’ in even the widest contemporary sense. The arguments that he developed during the 1830s and early 1840s, and for which he has been remembered, developed economic ideas he had discovered in American writing during the 1820s, and have no direct relation to German economics in this period. The reputation of Karl Marx, who as a law student during the late 1830s in Berlin would presumably have been exposed to some lectures in economics, likewise owes nothing to contemporary German economic writings, since his own interest in political economy was first stimulated by Friedrich Engels's enthusiasm for (English) Owenite ideas, was later developed as a critique of the classical economics of Mill and Ricardo, and betrays little knowledge of contemporary German writing in politics and economics.

German hyperinflation

Theo Balderston
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The erratic development of inflation in Germany during the First World War into the hyperinflation of 1922–3 has served as a major test-bed of monetary theory ever since. This article charts contemporary and modern explanations of its genesis, stabilization and effects. Modern analysis focuses on the interaction between fiscal and accommodating monetary policy and the expectations of financial asset holders; it disagrees, as did contemporaries, over the degree of agency of the government in determining its own deficit. After an optimistic ‘Keynesian’ assessment of its effects in growth, more recent scholarship has relapsed into pessimism as to its effects on investment.

Keywords

bubble; German hyperinflation; Germany, economics in the 20th century; gold standard; hyperinflation; inflation expectations; labour hoarding; money supply; public debt; quantity theory of money; rational expectations; seigniorage; velocity of circulation

Article

German hyperinflation after the First World War originated in the decision of July/August 1914 to suspend the gold convertibility of the mark and associated gold-reserve requirements. As with other hyperinflations, this one was irregular. German wholesale prices slightly more than doubled during the First World War. By February 1920 the ratio to 1913 prices was about 17, but then fell, irregularly, to a ratio of 13 in May 1921. After May 1921 inflation resumed and between then and June 1922 average monthly inflation was 13.5 per cent; in the following 12 months it reached 60 per cent (including a short cessation in early 1923 as the Reichsbank temporarily pegged the exchange rate), and 32,700 per cent or about 20 per cent per day between June and November 1923. The mark was stabilized in later November 1923 at one million millionth of its 1913 dollar exchange rate. Although only the period from June 1922 was ‘hyperinflationary’ (above 50 per cent per month), this period cannot be studied independently of...
the preceding inflationary history (Holtfrerich, 1986).
Contemporary explanation was highly politicized (Kindleberger, 1984a). The ‘quantity theory’ was adopted, especially by the French, to prove the agency of the German authorities in causing the inflation, allegedly in order to undermine the reparations regime. The official German counter-explanation was a variant of the ‘quantity theory’ known as the ‘balance of payments’ theory, whereby a budget deficit and its monetization followed inexorably from the exchange-rate collapse, which they blamed on the Treaty of Versailles and its reparations demands (see Williams, 1922). The quantity theory presumed a constant velocity of circulation, which was at variance with the facts (Graham, 1930; Bresciani-Turroni, 1931); an intellectually satisfying resolution of this puzzle awaited Cagan's (1956) embodiment of ‘expected inflation’ as an argument in the demand-for-money function. The rational expectations' revolution, however, argued that Cagan's formulation of price expectations as a weighted average of past inflation was rational only if the money supply were endogenously determined (Sargent and Wallace, 1973).

The question whether German hyperinflation was a ‘bubble’ divorced from monetary ‘fundamentals’ continues to be discussed, but the evidence remains inconclusive (for example, Chan, Lee and Woo, 2003). The centrality of fiscal policy and seigniorage to the generation of the German hyperinflation is generally agreed. It is the starting point of Webb's (1989) analysis. The Reichsbank, considering Germany still effectively in a state of war, subordinated its monetary policy to the financing of the Reich's expenditure. Though scarcely stable, a real deficit persisted throughout the inflation, albeit with some tendency to decline as inflation accelerated. The private sector's real investment in debt diminished as its belief weakened in the sufficiency of future budget surpluses to meet the state's contractual debt-serving obligations (including reparations). The private sector inferred from this insufficiency that prices would rise to reduce the real value of this debt-serving, and converted its non-monetary debt into money and money into goods. This forced greater monetization of the budget deficit; and the conjuncture of the declining real demand for money with rising nominal supply made the public expectation of inflation self-realizing. ‘Unpleasant monetarist arithmetic’ would probably have produced an analogous result even with Reichsbank independence (Holtferich, 1986, pp. 172 ff.).

Frenkel (1977) sought direct evidence of inflationary expectations from the forward discount on the mark in the London foreign exchange market; but, awkwardly from an analytical point of view, until July 1922 the mark sold at a forward premium. Webb argued that this reflected the animal spirits of – mainly foreign – speculators with their diversified portfolios, rather than inflationary expectations; these he inferred from the rate of shrinkage of the real value of government debt. On this basis he could link the major shifts in the rate of inflation with announcements of fiscal ‘news’ that prompted state debt-holders into revising their previous estimates of future real budget surpluses. Plausible connexions of this sort can be made for November 1918 (the Armistice), May 1919 (publication of the Treaty of Versailles), May 1921 (announcement of the Allies' London Reparations Plan) and June 1922 (refusal of a bankers' committee headed by J.P. Morgan Jr. to recommend a loan to Germany except on the – at that point unlikely – condition of a reduction in Allied reparations claims).

Webb explained the sudden cessation of inflation in March 1920 by a conjectural calculation that the expected revenues from the new federal direct taxation introduced by Finance Minister M. Erzberger in 1919 now harmonized with debt obligations (though the reparations obligation was still undefined). He explained the stabilization in November 1923 with reference to the cessation, in late September, of state-subsidized ‘passive resistance’ against the Franco-Belgian occupation of the Ruhr; to the imposition of
indexed tax liabilities from October (see Franco, 1990); to the appointment of the Dawes Committee to propose a temporary rescheduling of reparations; possibly to awareness that the Reichsbank was at last threatening to use the independence granted it in May 1922 to cease monetizing the deficit from the end of 1923; and to the successful pegging of the exchange rate against the dollar in mid-November. These developments have to be assumed to have influenced the minds of state debt-holders more than the evidence of the disintegration of the Reich, the collapse of the majority coalition on 3 November, and the lack of clarity, in the hour of France's triumph, over what level of reparations' revision would actually be agreed. Perhaps, after the trauma of hyperinflation, the ‘credibility bar’ over which stabilization policy had to jump was much lowered (Horsman, 1988, p. 33).

The ‘Structural School’ (Kindleberger, 1984b; see Alesina and Drazen, 1991) argues that domestic social conflict, especially on the labour market and partly operating through non-budgetary channels, was central to the hyperinflation. Burdekin and Burkitt (1996) focus on the hugely increased discounting of private-sector bills at the Reichsbank from mid-1922, in order (in their view) to pre-finance inflationary wage settlements. Prior to this, foreign speculation in the mark had financed bank lending to business at negative real rates of interest, so that domestic distributional conflicts could be assuaged out of the wealth of foreigners (Holtfrerich, 1986, pp. 279 ff.). However, once the forward exchange rate flipped over to discount in July 1922, in the absence of Reichsbank accommodation business would have had to pay positive real interest rates, with a correspondingly deflationary effect.

Webb (1989, p. 42) denied that inflation was deliberate government policy. The only reason that the stabilization after March 1920 did not ‘stick’ was that the Allies' ‘London Plan’ of May 1921 derailed it; without this element, the Erzberger fiscal reforms were propelling the budget towards surplus. It was irrational to operate in a hyperinflationary zone when, according to the theoretical consensus, real seigniorage revenues would have been greater at a lower rate of inflation. Webb also accepted the ‘structural’ case that parliamentary conditions and civil-service wage pressure prevented further fiscal reform before autumn 1923 (see Kunz, 1986). Cukierman (1988), however, argued for government agency in the inflationary process on the grounds that, due to increasing lags of inflationary expectations behind actual inflation, it could temporarily increase its seigniorage by increasing inflation, even if at the expense of lower seigniorage in the longer run. The foreshortened time preference of the Reich during its acute diplomatic crisis with the Allies made this rational. Only when expected inflation entered the zone where seigniorage revenues declined – partly due to substitution of other currencies (Bernholz, 1995) – did the government stabilize. Cukierman combines this with an argument that the government and the electorate in any case preferred lower long-run seigniorage revenues as these curbed the reparations capacity of the Allies.

Holtfrerich (1986, pp. 203–05) argued that the inflation counterfactually raised output by neutralizing the effects of the global post-war slump, and equalized income and wealth (but see Kindleberger, 1994). However, the ultra-low unemployment of the period was also partly due to vast labour hoarding by public enterprises, dating from the demobilization, and to a trough in participation rates. Bresciani-Turroni (1931, pp. 197–203, 403) argued that the inflation caused misallocation of investment; but Holtfrerich argued (1986, pp. 205–06) that not this misallocation but the deflationary gold-standard regime from 1924 caused the low-capacity utilization of the later 1920s. However, Lindenlaub's (1985) archival investigation concluded that, except for industries receiving government compensation for
treaty losses, real fixed investment was minimal (see Fischer, Sahay and Végh, 2002). Sargent (1986, pp. 40 ff.) argued that the credibility of the German stabilization made it virtually costless. But Dornbusch (1987) regarded the willingness to make monetary policy hurt from November 1923 to June 1924 as necessary to establishing credibility. The ‘stabilization boom’ of the second half of 1924 and the delayed but sharp year-long recession from June 1925 may roughly replicate recent high-inflationary experience (Fischer, Sahay and Végh, 2002).

Abstract

German reunification in 1990 posed the challenge of introducing markets to an economy with none. For citizens of the formerly Communist East Germany, the transition brought an immediate increase in political freedom and living standards, yet also a deep trough in output and persistent unemployment. I examine the reasons for the output trough and the subsequent labour market difficulties, analyse the impact of reunification on West Germany and Europe, and draw lessons for transition and economics generally.

Article

On 3 October 1990 the formerly Communist German Democratic Republic joined the Federal Republic of Germany, thereby reunifying Germany and posing the challenge of introducing markets to an economy with none. German reunification was part of the dramatic demise of Communism in Europe, an event as significant for economic as for political reasons. For citizens of the former German Democratic Republic (henceforth East Germany), the transition brought an immediate increase in both political freedom and living standards, yet also a large rise in economic uncertainty, manifested not least through the sudden emergence of high unemployment. Although markets and institutions were successfully introduced, they have not led to the rapid economic convergence of the two parts of Germany for which some had hoped, and unemployment has remained high. The enormous costs of reunification have proved a burden for West Germany, which prior to unification had been the economic engine of Europe. The shock of unification and the subsequent slow growth in West Germany have in turn affected the rest of Europe. Historical and contemporary factors ought to have ensured the best outcomes of any transition economy. Before the Second World War, East German GDP per capita was slightly above the German average (Sinn and Sinn, 1992), and both at that time and under Communism East Germany was richer than (other) eastern European countries. East Germany’s relatively small population – 20 per cent of unified Germany – made feasible the large financial transfers from its rich cousin, West Germany. East Germany has benefited from West German institutions, know-how and investment. Yet the Czech Republic had a GDP per capita only 13 per cent lower than that of East Germany in 2004 (OECD, 2005), and, if post-1999 trends continue, the Czech Republic will converge with West Germany before East Germany does.

In this article, I note the successful introduction to East Germany of markets, institutions, democracy and rule of law, and assess why the short-term cost in terms of output and employment was so high. I examine the reasons for the subsequent labour market difficulties, analyse the impact of reunification on West Germany and Europe, and draw lessons for transition and economics generally.

Chronology of unification

http://www.dictionaryofeconomics.com.proxy.library.csic.uned.edu/article?id=pde2008_E000266&goto=1&result_number=644
The process culminating in the unification of Germany was set in motion when the Hungarian government began allowing East German citizens to leave Hungary via Austria in May 1989. This occurred against the backdrop of reforms in the Soviet Union by President Michael Gorbachev. By August, large numbers of East Germans were reaching West Germany via Hungary, Czechoslovakia and Poland, and in September anti-government demonstrations began in East German cities. On the night of 9 November 1989, a combination of government weakness and confusion led to a crowd being permitted to breach the wall dividing Berlin. The ensuing mass migration to the West removed the power of the East German government to threaten its citizens; five per cent of the eastern population emigrated in 1989–1990.

The East German government organized free elections for March 1990. The victory of the counterpart of the western Christian Democrat Party was seen as a mandate for rapid reunification. Monetary, economic and social union occurred on 1 July 1990. Political union followed on 3 October 1990. As East Germany was formally joining the Federal Republic of Germany, all western institutions were transferred, and only a small number were subject to a transition period. The western systems of justice, regulation, industrial relations, banking, education and social security and welfare were all transplanted, to a large degree by experts from the west.

Faced with the task of integrating a region with decrepit infrastructure, outdated technology and no capitalist experience, the West German government confronted a number of important decisions in 1990. These included: the exchange rate at which to effect monetary union; how to privatize eastern firms; how to spend money in the east, especially how to spend on consumption versus investment (and infrastructure) and on capital versus labour, and the amounts and details of these expenditures; and whether to raise the money through taxes or debt. Important early decisions by other actors included the decision of labour unions to follow a high-wage strategy.

The financial implications of the government's decisions were colossal. From 1991 to 2003 the west spent four to five per cent of its GDP yearly on the east, including transfers within the social welfare system (Ragnitz, 2000, and updated numbers provided by Ragnitz to the author). This spending represented more than 50 per cent of eastern GDP in 1991, and stabilized at about 33 per cent in 1995.

Economic progress of East Germany

Table 1 documents the evolution of various indicators in east and west. Reunification precipitated a disastrous collapse in real eastern GDP, with falls of 15.6 per cent in 1990 and 22.7 per cent in 1991, cumulating to a one-third decline. Meanwhile, West Germany experienced two boom years with growth rates of over five per cent. From 1992, East Germany experienced four years of recovery followed by stagnation. Growth in the west has also been lacklustre since 1992.

German reunification, economics of: The New Palgrave Dictionary of Economics

Notes: Berlin is included in the eastern statistics, except for the figures in boldface, where east and west Berlin are included in eastern and western statistics respectively. West Berlin is about 13% of the population of the ‘greater east’. Productivity is measured as GDP per worker. The change in the eastern population in 1989 was –2.5%.

Labour productivity growth in the east was very rapid through 1994, but has since been modest, although higher than in the west. The eastern capital stock, on the other hand, grew at almost six per cent per year or more through 1998, and has continued to grow faster than the western stock since then. Emigration and a plunge in fertility (a 54 per cent fall between 1988 and the 1994 trough) have caused the eastern population to decline each year since unification. Meanwhile, the western population grew quickly in 1990–2 with the arrival of East Germans and immigrants from ex-Communist countries other than East Germany.

Table 2 represents key indicators as the ratio of east to west. Eastern GDP per capita improved from 49 per cent of the western level in 1991 to 66 per cent in 1995, since when convergence has stalled. Because many of the transfers from the west have been to consumption, disposable income per capita has reached a considerably higher plateau, at 81–3 per cent. Capital per worker has continued to converge gradually where other measures have stalled, reaching 84 per cent of the western level in 2002. Compensation per worker rose rapidly from 34 per cent in 1990 to 56 per cent in 1991 and 68 per cent in 1992, and then stabilized at 79 per cent in 1995.

Notes: East as a percent of west. Berlin is included in the eastern statistics, except for the figures in boldface, where east and west Berlin are included in eastern and western statistics respectively. 1990 figures are for the first quarter, seasonally adjusted. Productivity is measured as GDP per worker or GDP per hour worked.

Sources: Statistische Ämter des Bundes und der Länder; author’s calculations. For 1990, German Institute for Economic Research, Berlin; data on GDP, employment and compensation in East Germany (without West Berlin) from 1989 to 1998 no longer available on the Institute’s website.

Reunification might be considered a success in terms of standard of living were it not for problems in the labour market. The left panel of Figure 1 shows the share of the labour force registered as unemployed soared to 20 per cent (from officially zero at the start of 1990), while the western rate has also ratcheted up to a higher level than in 1990. The lack of a search requirement for registering as unemployed means these rates are overstated by several percentage points. The eastern rate is nevertheless very high, especially as some of the many active labour market programme participants would have been unemployed had they not been in the programme. The German Socio-Economic Panel data for the mid-1990s indicate that 15 per cent of the eastern female population and ten per cent of the male population were unemployed (searching and available). The right panel of Figure 1 shows the plunge in the eastern employment rate.

Figure 1
Splitting the east into its constituent states changes the picture little. The unemployment rates differ little across the six federal states of East Germany. Furthermore, with the exception of unified Berlin, the differences in GDP per capita across the six eastern states are small compared with the east–west gap. This may be seen in Figure 2, which plots real GDP per capita for Lower Saxony (Niedersachsen), the poorest western state in 2004, Saxony (Sachsen), the richest eastern state in 2004, and Mecklenburg–Vorpommern, the poorest eastern state in 2004.

Figure 2
Real GDP per capita for selected states
Even the fastest-growing states of Sachsen and Sachsen–Anhalt are growing considerably more slowly than the Czech Republic, as may be seen with the aid of Figure 3. While East German employment languishes at 60 per cent of its 1989 level, and real GDP has barely risen above its 1989 level, Czech GDP is 20 per cent above its 1990 level, and, while Czech employment has not recovered from liberalization, it fell much less than East German employment.

Figure 3
Czech and East German comparisons
All former Communist countries except China experienced output declines following price liberalization, and many countries of the former Soviet Union had larger and longer output falls than East Germany. Roland (2000) examines why price liberalization depressed output, emphasizing theories of disruption of supply chains and the need to identify new business partners before investing. The main other potential culprits for the GDP and employment declines in East Germany are a reduction in labour supply, substitution to western products, the exchange rate chosen for monetary union, the increase in wages, and the privatization process.

Reduction in labour supply

Some of the output decline could have been caused by the employment decline rather than the reverse. Employment declined by 3.3 million people from 1989 to 1992. The government paid one million people to stop working by offering early retirement onto the western pension benefits implied by easterners’ years of work experience. A further one million people emigrated to the west in 1989–91 (Hunt, 2006, draws lessons from eastern emigration).

Among the prime-aged remaining in the east, women experienced a particularly large employment decline, a fact often explained by the dismantling of the Communist day-care centres.
system. However, Hunt (2002) shows that the employment rate of women with small children fell by no more than that of other women.

**Substitution to western goods**

Immediately upon monetary union, eastern shops filled with western goods. Easterners wanted to consume western products, and at this time ‘one couldn't sell an East German egg’ (personal communication from eastern state politician; see also Sinn and Sinn, 1992). Economists agree that this caused a sudden fall in demand for eastern goods, and hence a fall in output.

**Monetary union exchange rate**

For political reasons, the (western) government decided to choose a one-to-one exchange rate between the eastern Ostmarks and the western Deutschmarks. Early studies, in particular, argued that an overvalued exchange rate had made the eastern products uncompetitive with western products, leading to an output decline. With hindsight, it seems unlikely that the exchange rate was an important contributor to the output decline, as eastern prices and wages subsequently rose, rather than falling to correct the real exchange rate.

**Unions and the wage increase**

Although it is possible that the rapid rise in wages was the result of factor price equalization across regions, there is a consensus that labour unions were the driving force behind the rise. Unions acquired great power at a time when employers had little, and were not acting only in the interests of eastern workers. Western unions established themselves in the east in 1990, and were very successful in recruiting new members. The new eastern unions were led by westerners, who were concerned with east–west equity and eastern welfare but also with western wages and the perceived threat to them of mass east–west migration. The unions pushed for rapid wage convergence with the west, believing this was just, would prevent mass migration, and would enable eastern workers who were laid off to receive higher unemployment benefits (these being tied to the pre-layoff wage). At this time, most firms had no owners, and the unions were bargaining either with managers, who had no incentive to resist wage increases, or even with members of the western employers’ federations, whose incentive was to prevent undercutting of western prices by eastern firms.

Most economists believe this rapid rise in wages represented a classic textbook wage floor that reduced employment, led to high unemployment, and made East German firms unviable, thereby leading to the output collapse (for example, Akerlof et al., 1991; Sinn and Sinn, 1992; Sachverständigenrat, 2004).

**Privatization**

Small, mostly service firms were privatized separately from large industrial firms. As in eastern European countries, this privatization was rapid and successful, and was completed by March 1992 (Sinn and Sinn, 1992). Large industrial firms were privatized by a politically independent body known as the Treuhandanstalt (THA). Its initial portfolio was 8,500 previously state-owned enterprises containing 44,000 plants and 45 per cent of the workforce (Carlin, 1994).

The THA closed the unviable firms and plants, reduced employment at the viable plants, and sought buyers for the remaining core businesses. The THA’s aim, at which it was successful, was to match firms with western management expertise in the same industry (Dyck, 1997). Weighted by employment, 74 per cent of sales were to West German firms or families, six per cent were to non-German firms, and only 20 per cent were to eastern buyers. Privatization thus created subsidiaries of western companies (Carlin, 1994). By 31 December 1994, the THA had finished its privatization with net losses of DM 193 billion (about 95 billion euros or 120 billion US dollars; Brada, 1996).

The THA destroyed many jobs in the short run, with the aim of curtailing inefficient production and promoting faster medium-run employment and output growth than would otherwise have occurred. Most economists studying privatization believe that the THA carried out its mandate well, leaving a legacy of viable and well-run companies. However, Roland (2000) believes that the employment reduction necessitated by the mandate caused a depression in the short run and retarded transition in the medium run.

**Explaining the persistent labour market problems**

Even observers who did not expect faster GDP convergence than has occurred are dismayed at the state of the labour market. Most explanations for the initial employment collapse apply to the short run only. Even labour union power has been severely weakened: while unions controlled wages from 1990 to 1993, a subsequent employer revolt allowed wages to be determined more freely. The share of workers whose employer belonged to an employer federation, which determines whether workers are paid the union wage, declined from 76 per cent in 1993 to 45 per cent in 1998 and 29 per cent in 2003 (Brenke, 2004).
Either the causes of the initial collapse have had lasting effects – for example, perhaps it is hard to reduce real wages in a low-inflation environment – or there must be other explanations. The leading one is the introduction of the western social welfare system. Others are investment subsidies, the wholesale transfer of western regulations, ineffectual active labour market programmes and impediments to the optimal allocation of resources across sectors.

Social welfare and wage floors

Many economists (for example, von Hagen and Strauch, 1999) stress the disincentives of the social welfare system as a cause of low employment in East Germany. After a very brief transition period, benefits were set at western levels, which in some cases made them higher relative to wages than in the west. This was the case in particular with Sozialhilfe, or social assistance (welfare), and with pensions. Unemployment insurance benefits are a fraction of the previous wage, so, to the extent that unemployment insurance is a greater problem than in the west, it is related to wages being too high. A generous social safety net sets a floor under wages, similar to a union wage, though affecting labour supply rather than labour demand.

The wage floor theory implies that wages at the bottom of the distribution should have risen the most, while employment of the least skilled should have fallen the most. Employment rates indeed fell more for the less skilled than the skilled. However, wage growth for the skilled was equal to or greater than that of the unskilled (Burda and Hunt, 2001). Furthermore, by 1999 wage inequality and the wage structure more generally were very similar to those in the west. Patterns of unemployment duration were also similar (Hunt, 2004). These results are inconsistent with the effect of a wage floor for the less skilled, which appears to rule out the social welfare theory. However, it is possible that a wage floor was too simple a model for the effects of the unions, who indeed appeared to aim to raise the wages of all members.

Investment subsidies

At least with hindsight, subsidizing capital (investment) in the face of grave labour market difficulties seems not obviously a good idea. Indeed, the capital–labour ratio in manufacturing is now higher in the east than the west (Sachverständigenrat, 2004). Furthermore, many have criticized the subsidies as being skewed towards structures at the expense of equipment (for example, Burda and Hunt, 2001). Finally, the subsidies were designed as tax breaks, and were hence attractive only to profitable, that is, established western, companies. The funds for investment subsidies appear not to have been spent optimally.

Active labour market programmes

Easterners are well educated, and the return to eastern schooling was not reduced by transition (Krueger and Pischke, 1995). The post-unification fall in the return to experience indicated that the human capital lacking was experience working in capitalist firms. Off-the-job training and make-work jobs were therefore unlikely to be very helpful, despite the large number of participants: in 1994 there were 259,000 participants in public training programmes and 280,000 participants in jobs whose wage was paid by the government, compared with 1,142,000 registered unemployed.

The best-documented effect of training programmes has been that of keeping participants out of the labour force for the duration of the sometimes long programmes (Lechner, Miquel and Wunsch, 2007). Meanwhile, participants in public jobs had no incentive to look for another job, as they received 100 per cent of the union wage (90 per cent from 1994 on). While some groups have benefited from some public programmes, the gains are unlikely to have justified the large expenditures (Eichler and Lechner, 2002; Lechner, Miquel and Wunsch, 2007).

Sectoral allocation

Various factors may have intervened to prevent an optimal allocation of resources across sectors. Brada (1996) observes that the THA requirement that buyers continue operating the firm in the same industry as before may have delayed sectoral restructuring. Unions, bargaining at the industry level, may have chosen the wrong wage structure across sectors, reducing incentives for restructuring (Burda and Hunt, 2001; Hunt, 2001). A further complicating factor has been the boom and subsequent bust of the construction industry. Many observers believe the manufacturing sector is too small, at 15 per cent of employment in 2004 compared with 22 per cent in West Germany and 30 per cent in the Czech Republic. Yet manufacturing in the United States employed a smaller share of the workforce than in East Germany in 2004, so East Germany may simply have leapfrogged West Germany in this regard.
In the short term, reunification was a positive aggregate demand shock for the west, leading to the boom seen in Table 1. The leap in the demand for capital for investment in the east, combined with the reduction in the money supply to contain inflation, raised the interest rate. As the cost of reunification became clear, the government was forced to raise taxes, but debt rose from 41.8 per cent of GDP in 1989 to 64.2 per cent in 2003. The budget went from surplus in 1989 to a 3.1 per cent deficit in 1991, and has been close to or above three per cent since then.

It is unclear to what degree the western stagnation that has followed the 1993 end of the boom can be attributed to reunification. While exports have recovered, domestic demand has remained weak (Sachverständigenrat, 2005). This could possibly be the result of government debt leading consumers to revise their wealth downwards, depressing consumption and growth (Carlin and Soskice, 2006). The increase in western unemployment, seen in Figure 1, could be caused in part by increases in payroll taxes to finance reunification. On the other hand, Siebert (2005) emphasizes that before reunification West Germany had already had problems with sluggish growth, rising unemployment, and funding social security.

Posen (2005) considers that approximately 1.4 per cent of German GDP per year is paid in transfers to the east that are for neither investment nor infrastructure, nor part of the unified social welfare system. He calculates the opportunity cost of this money (that could have been invested and received a return), the increase in interest payments on other debt (owing to a higher interest rate caused by higher debt), and the deadweight loss from increased taxes. He concludes that the burden of these transfers is (at most) 0.7 per cent of German GDP per year, a large sum.

Reunification has affected the West German labour market through the weakening of labour unions caused by the collapse of eastern unions. The impact of eastern immigrants and commuters is not known. The impact, if any, would have been in addition to that of the concomitant and similarly sized immigration of ethnic Germans from other formerly Communist countries.

**Effect of reunification on Europe**

The rise in the German interest rate had important consequences for Europe, as it led to a crisis in the European Exchange Rate Mechanism (ERM) that preceded European Monetary Union. The higher German interest rate meant that the Deutschmark required a revaluation within the ERM, or, equivalently, the devaluation of other ERM currencies. France and other countries attempted to maintain the existing exchange rates, fearful of a loss of deflationary credibility. But in 1992 speculative attacks forced several countries to devalue, while the United Kingdom and Italy left the ERM.

The crisis was not all bad in the long run: for the United Kingdom, which had joined the ERM at an unsuitable exchange rate, leaving the ERM proved to be an economic boon (Carlin and Soskice, 2006). However, Germany may have entered monetary union at a rate that would prove overvalued once the reunification shock to interest rates had passed (Sinn, 1999), thus requiring a later depreciation. The difficulty of price and wage adjustments within monetary union may currently be preventing such a depreciation from occurring, slowing German, and therefore European, growth (Carlin and Soskice, 2006).

**Lessons learned**

Because East Germany joined the well-functioning and larger Federal Republic of Germany, it could feasibly and credibly have an institutional ‘big bang’, immediately importing a coherent set of institutions generally suitable for the region. This provided confidence and familiarity to western investors. The institution that obviously made a poor transition was the industrial relations system: because labour unions were established before employer federations, labour unions were initially unnaturally strong, possibly with lasting consequences.

Some economists believe the social welfare system made an equally poor transition; yet the nature of reunification meant that there was politically no alternative to transferring the system fairly rapidly. Siebert (2005) bemoans the transfer of product regulation and taxation. Yet firms may have complied with western constraints even had they not been imposed on the east, either in the expectation of their being imposed later or for fear of disgruntlement in their western works council. For example, Volkswagen applied the western prohibition on female night work to its eastern plant although the east was exempt (Turner, 1998).

The feasibility of an institutional big bang made feasible an economic big bang. Price liberalization and macro stabilization were flawless. The privatization process was speedy and had many merits, although it may have led to an excessive employment decline, and was too expensive for most countries to countenance. However, Koreans should note that even an unusual transition that satisfies both the ‘Washington consensus’ economists, who emphasize speed of economic reform, and the ‘evolution-institutionalist’ economists, who stress the necessity of establishing institutions before economic reform, can leave in its wake a difficult regional convergence problem.

For economists interested in unemployment, East Germany is both a validation of textbook models and a puzzle. Surely the collapse in employment and output in 1990–2 must have been strongly influenced by high union wages. Yet, now that labour unions have much less influence and the wage structure is similar to that of the west, why has unemployment...
remained so high? Good education and high emigration are not enough to control unemployment.

Germany, economics in (20th century)

Harald Hagemann
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The development of German economics in the 20th century is characterized by an interaction between internal scientific factors and external political factors. The dominance of the Historical School ended with the death of Schmoller and the First World War. The pressing economic problems of the young Weimar Republic stimulated macroeconomic research and national income accounting, whereas the Nazis’ rise to power caused an important intellectual emigration from which German economics recovered only slowly after 1945. After an early period of ordoliberalism, as in other countries the development of economics has increasingly reflected a process of internationalization dominated by American economics.

Article

1900–1918: dominance of the Historical School

Until the beginning of the 20th century there were relatively few economics students in Germany and their training heavily depended on other disciplines. Not until the 1880s was a special Ph.D. option opened for economists, and it was not until 1923 that a special curriculum was set up that led to a diploma degree. Nevertheless, in the second half of the 19th century a growing professionalization process took place, with the emergence of scholarly journals and the foundation of economic societies, the most important of which was the Verein für Sozialpolitik in 1872 (Hagemann, 2001). The driving force behind, and chairman of, the Verein from 1890 until his death was Gustav Schmoller (1838–1917), the undisputed leader of the ‘Younger’ German Historical School and the most influential economist in imperial Germany, particularly in Prussia, at the beginning of the 20th century. Schmoller favoured a historical and ethical approach to economics and the inductive method of collecting large amounts of statistical material, rather than the abstract axiomatic–deductive method of the classical economists and his neoclassical contemporaries. From 1883 he was involved in a famous dispute on method with Carl Menger; however, although a major issue in German literature, this Methodenstreit did not play a significant role at the meetings of the Verein. In remarkable contrast, the question of whether economists or other social scientists should make normative judgements had been a heated issue since the 1880s. This Werturteilsstreit, in which Max Weber, with his strong plea for a clear separation of social science from social policy, was a key figure, escalated at the 1909 Vienna meeting. ‘The controversy about norms and values’ raged until the outbreak of the First World War, at which time it was still unsettled.

1918–33: the Weimar Republic and the new complexity

After the end of the First World War, and with the death of Schmoller in 1917, the Historical School lost the dominant position it had acquired in the German Empire from 1871, although it remained influential among many economists. In the early years of the Weimar Republic urgent policy problems, such as the socialization of production, reparation payments and particularly hyperinflation, dominated. From the mid-1920s onwards, theoretical and empirical research on business cycles became the most important issue, and a new generation of more theoretically oriented young economists came to the fore. This is best reflected in the 1928 Zurich meeting of the Verein für Sozialpolitik which focused on the explanation of business cycles. Major contributions were delivered by brilliant young economists including Adolph Lowe (born 1893), Friedrich August Hayek (born 1899), Wilhelm Röpke (born 1899) and Oskar Morgenstern (born 1902).

The long-run development of the capitalist economy and the study of the crises and economic fluctuations surrounding it had been a major issue since the mid-19th century. This holds for representatives of the ‘Older’ Historical School such as Wilhelm Roscher as well as for Karl Marx. At the beginning of the 20th century leading economists like Arthur Spiethoff and Werner Sombart became widely known with their studies on business cycles, with Joseph A. Schumpeter as the towering figure. In his Theory of Economic Development (Schumpeter, 1911/12) the idea of creative destruction by innovation and the notion that bank credit is the prerequisite of innovation and of the foundation of new
enterprises are of central importance. According to Schumpeter, capitalist development can proceed only in a wavelike form, and pioneering entrepreneurs are the key agents for this development. More systematic empirical research on business cycles became established with the foundation of the German Institute for Business Cycle Research in Berlin in 1925, with Ernst Wagemann as director (he was also President of the Statistisches Reichsamt, the German Statistical Office). Two years later the Austrian Institute for Research on Business Cycles was founded in Vienna on the initiative of Ludwig von Mises. Hayek, the first director, was succeeded by Morgenstern in 1931 after Hayek moved to the London School of Economics. Furthermore, in 1926 the Kiel Institute of World Economics engaged Adolph Lowe to build up a new department for statistical world economics and international trade cycles, which soon developed a most promising research programme. Lowe managed to recruit a group of highly talented young economists including Gerhard Colm, a leading expert on public finance and financial statistics (which was especially important for the payment of reparations), who later became the chief architect of West Germany’s successful currency reform of 20 June 1948; the monetary theorist Hans Neisser; Fritz (later Frank) Burchardt, who after the Second World War became director of the Oxford Institute of Statistics; Wassily Leontief (1927–28, 1930–31) who, while at Kiel, wrote his Berlin Ph.D. thesis on the economy as a circular flow but mainly worked on the statistical analysis of supply and demand curves; and Jacob Marschak (1928–30). Lowe's Kiel habilitation thesis, ‘How is business cycle theory possible at all?’ (Lowe, 1926), which raised the fundamental methodological problem of the (in)compatibility of business cycle theory with the theory of general economic equilibrium, also exerted a major influence on Hayek, as can be seen from the latter's 1928 Vienna habilitation thesis, published in English as *Monetary Theory and the Trade Cycle* (1933, ch. 1).

The pressing economic problems of the early Weimar Republic and the mass unemployment and deflation of the Great Depression in the closing years of the republic, which required practical solutions, can also explain why German economics in the interwar period was not completely dominated by academic economists. Practitioners at public and private research institutions as well as leading bureaucrats played a key role. This is reflected, for example, in the core members of the Kiel group, Lowe, Colm and Neisser, who all had worked for the Weimar government and/or the Statistisches Reichsamt, or in the personage of Wilhelm Lautenbach, a leading member of the Ministry of Economics whose practical proposals during the Great Depression earned him the nickname ‘the German Keynes’. Due to governmental needs the Weimar Republic invested heavily in macroeconomic research, which brought it to the forefront of statistical innovation and the development of national income accounting. Wagemann, as the key figure, provided the subsequent Nazi government with the statistical tools for economic planning (Tooze, 2001).

1933 and after: dismissal, expulsion, and emigration of German-speaking economists

The political events of 1933 marked an important turning point for the economics profession in Germany. Shortly after its rise to power the new Nazi government passed the Restoration of Civil Service Act, which formed the basis for the dismissal of ‘disagreeable’ persons from public services either for racist or for political reasons. By the winter of 1934/35 about 14 per cent of the faculty at German universities had been dismissed, but in economics the figure was 24 per cent. However, the dispersion was significant. Whereas some years later in Austria the great majority of dismissals and expulsions were concentrated on the University of Vienna, in Nazi Germany the three universities of
Berlin, Breslau (today's Wroclaw in Poland) and Frankfurt had to cope with the greatest losses. Breslau in Silesia had a large and recognized Jewish community – it was home, for example, to Fritz Haber, the Nobel Prize-winner in chemistry, and the historian Fritz Stern (1999). Neisser, the development economist Heinz Wolfgang Arndt, the trade theorist Warner Max Corden and the later architect of the Swedish workers' investment funds Rudolf Meidner, all came from Breslau.

In economics, the highest losses were suffered by the faculties of Heidelberg (which lost seven of 11 members), Kiel (five of ten) and Frankfurt (13 of 33). Heidelberg had been a blossoming centre of liberal intellectual discourse in the Weimar Republic and characterized by multidisciplinarity, as expressed in Emil Lederer's analysis of the 'new middle classes'. A key role there was played by the Institute for Social and State Sciences, founded in 1924, with Max Weber's younger brother Alfred as the director until 1933 when he ordered students to remove the swastika flag from the main campus building. (Alfred Weber can be regarded as one of the very few scholars for whom the notion of 'internal emigration' really fits.) The new Goethe University in Frankfurt had developed into a leading centre of the social sciences within the short period of the Weimar Republic, as can be seen by looking at the long list of outstanding scholars dismissed in 1933, including Franz Oppenheimer, Karl Pribram, Lowe, Fritz Neumark, Karl Mannheim and his research associate Norbert Elias, the theologian Paul Tillich, among others. When Gunnar and Alva Myrdal visited the Institute of World Economics in Kiel in the summer of 1933 on behalf of the Rockefeller Foundation they diagnosed a deteriorated scientific reputation because by then almost all the best scholars had emigrated.

The long-term loss of quality and of international reputation of German economics caused by the political events of 1933 and thereafter is also reflected in the evolution of scholarly journals. German-language journals not only lost most of the émigré economists as contributors, but also most foreign economists stopped writing in the German language or publishing in German (and from 1938 onwards also in Austrian) journals. The obverse of this was the increased number of articles written by émigré economists in the leading Anglo-Saxon journals. With the exception of Spiethoff, who stayed in office as the editor of Schmollers Jahrbuch, journal editors were replaced after the Nazis' rise to power (Hagemann, 1991). From 1904 the Archiv für Sozialwissenschaft und Sozialpolitik had been the leading journal in economics and the social sciences, with a run of fine editors, Max Weber, Werner Sombart and Edgar Jaffé, followed in 1922 by Emil Lederer and his two associates, Joseph Schumpeter and Alfred Weber. But this journal too had to cease publication under Nazi rule. For a short period in the 1930s the Vienna-based Zeitschrift für Nationalökonomie became the outstanding scholarly journal in economics in the German language, under the experienced editorship of Oskar Morgenstern. It published important articles particularly on capital theory, the role of time in economics or general equilibrium analysis, but after Hitler's invasion of Austria the quality of the journal collapsed. In the wake of the Anschluss the Vienna Institute for Research on Business Cycles became a branch office of the Berlin Institute.

The group of dislocated German and Austrian economists who had acquired academic degrees comprises 253 scholars, of whom 148 were dismissed from universities, 57 from private research institutes, and 28 from other public employment, and 20 were young economists who just had completed their studies, students like Richard Musgrave who had gained his diploma degree at the University of Heidelberg in May 1933 (Hagemann and Krohn, 1999). Some 221 (87 per cent) emigrated. Of the remaining 32 several were killed in the Holocaust, concentration camps, or Gestapo prisons, these including Rudolf Hilferding, Robert Liefmann and Cläre Tisch. The intellectual loss included 75
members of the so-called ‘second generation’, young students or pupils who emigrated with their parents and later made a career as economists, such as, for example, Robert Aumann, Michael Bruno, Otto Eckstein, Walter Eltis and Frank Hahn.

1933-45: German economics in the Nazi period

German economics in the Nazi period moved far away from economic liberalism, and state interventions and regulations such as price controls and wage freezes played a major role (Janssen, 2000). The 1932 Dresden meeting of the Verein für Sozialpolitik, organized by Mises, focused on problems of value theory and was dominated by the representatives of the Marginal Utility School, but was also clearly marked by heated debates on protection and the question of autarky. This meeting turned out to be the last before the outbreak of the Second World War because in December 1936 the majority of the members decided to dissolve the Verein in order to escape Gleichschaltung by the Nazis.

This decision shows that the group of dedicated National Socialists, which included Feder and Wiskemann, was remarkably small. More important in numbers and influence were the two groups of fellow travellers including Gottl-Ottlilienfeld, Predöhl, Wagemann and national and conservative opportunists including Sombart and Spann respectively (Rieter and Schmolz, 1993, p. 95), who largely followed the historical–holistic approach and also introduced ideas from contemporary German philosophy into economics. A fourth group consisted of ‘renegades’, former Nazis who later changed their views. Prominent members of this latter group include Jens Jessen – who in 1933 succeeded Harms as the director of the Kiel Institute and, as a result of his involvement in the failed attempt to assassinate Hitler in July 1944, was executed some months later – and Heinrich von Stackelberg, who probably only escaped the same fate because of his move to Spain in 1943. A fifth group consisted of opponents of the Nazi regime who either passively distanced themselves from the regime, thereby ending their professional careers, or actively fought against it, like the members of the Freiburg School.

The first subgroup of opponents included Hans Peter, a very able mathematical economist and theorist of the circular flow, who together with Erich Schneider and Stackelberg from 1935 to 1942 edited the new journal Archiv für mathematische Wirtschafts- und Sozialforschung. Due to his defence of his liberal socialist convictions in the Nazi period Peter obtained a full professorship at the University of Tübingen only in 1947. August Lösch, a brilliant economist of great personal integrity, received his habilitation from the University of Bonn in 1939 with his The Economics of Location, in which he applied general equilibrium theory to the space dimension. (Since the days of Thünen, then via Launhardt, Alfred Weber and Christaller to Lösch, spatial economics has been an area of economics where German economists have made important contributions.) Lösch himself, however, did not have a successful professorial career: because of his outspoken anti-Nazi views he survived fascism only by becoming a researcher at the Kiel Institute. He died tragically from scarlet fever a few weeks after the end of the war.

Although in international terms German economics fell behind in the Nazi period, there were nevertheless some significant contributions. Stackelberg was one of the most gifted theoretical economists. His Marktform und Gleichgewicht (1934), with its creation of the Stackelberg asymmetric duopoly, went beyond the work of Chamberlin and Joan Robinson in the depth of its theoretical analysis and in its mathematical rigour. However, although he was one of the very few German economists whose analysis was deeply embedded in the Anglo-Saxon approach to price and cost theory, and
although the book was immediately reviewed by top theorists such as Hicks, Kaldor, Lange, Leontief and Zeuthen, it failed to make an impact. Because its author was a well-known supporter of the Nazis and the book ended with a short paean to the corporate state, the book’s theoretical achievements were overlooked and even today it has not been translated into English.

Keynes was a central figure of reference in theoretical and policy debates in interwar Germany ever since his opposition to the reparation stipulations of the Versailles Treaty; not surprisingly, the first translation of his *General Theory* was into German (with a special Preface published in the same year 1936) and was extensively reviewed and debated. Leaving aside the complex question of German anticipations of the *General Theory* (Bombach et al., 1981), Carl Föhls *Geldschöpfung und Wirtschaftskreislauf*, published in 1937 but already completed in December 1935, exhibits striking parallels with Keynes’s theories (despite its using a different conceptual apparatus), and was the outstanding achievement in contemporary German literature on macroeconomics.

**The post-1945 development of economics in Germany: ordoliberalism and the social market economy**

As is well known, after the Second World War, economic order and economic policy in the new Federal Republic of Germany were decisively influenced by the ordoliberal thinking of Walter Eucken and the Freiburg School and the principles of the social market economy (Watrin, 1979). However, the roots of ordoliberalism go back to the years 1938–45, with opposition to National Socialism based on Christian convictions (Rieter and Schmolz, 1993). Eucken’s main work, *Foundations of Economics*, was published in 1940. Although he was a well-known critic of the Historical School, his taxonomic approach, which focuses on reconciling economic with legal, institutional and social factors, is clearly embedded in the German tradition of state sciences. Thus in the competitive order he perceived that the state plays a substantially stronger role than his Anglo-American colleagues would allow, not to speak of Austrian contemporaries such as Mises and Hayek. This is particularly visible in Eucken’s ‘regulating principles’ – that is, monopoly control, social policy, external effects – that supplement the ‘constituting principles’ of the market economy, that is, private ownership, competition in open markets, freedom of contract, a functioning price mechanism, monetary stability and consistency in economic policy.

German economics, which went through a laborious catching-up process after 1945 without being able to compensate fully in the following decades for the loss of qualified personnel in the Nazi period, suffered a further blow by the untimely deaths of Lösch (1945), Stackelberg (1946) and Eucken (1950). The economists who were driven out of Nazi Germany had meanwhile contributed significantly to innovative research in their host countries. This holds particularly for the United States, which was the final destination for about 60 per cent of the émigré economists, but also for the UK where the new field of development economics had been shaped by Paul Rosenstein-Rodan, Kurt Mandelbaum (Martin), Arndt, Hans Singer, Paul Streeten and others, all émigrés from German-speaking countries. In the United States economists at the New School for Social Research, where the graduate faculty had been founded as the ‘University in Exile’ in autumn 1933, gained a certain influence in the period of the Roosevelt and Truman presidencies (Krohn, 1993), but in the long run those who kept their distinctly German scholarly identity were less influential.

Among the important new developments in economics which were transferred to Germany after 1945, if with some delay, were game theory and econometrics, developed at the Cowles...
Commission in Chicago after Marschak became the Research Director there in 1943. This work was later mirrored in Wilhelm Krelle's research centre in econometrics at the University of Bonn in the 1960s and 1970s. The foundations of modern game theory were laid by John von Neumann and Oskar Morgenstern's *Theory of Games and Economic Behavior* (1944), which was the fruit of their cooperation at the Institute for Advanced Study in Princeton in the years 1939–43. Their work together came about as a result of exile, although the Budapest-born mathematician von Neumann had made his habilitation at the University of Berlin in 1927 and presented his famous paper on the general economic equilibrium of an expanding economy at Karl Menger's mathematical colloquium at the University of Vienna in 1936. The award of the Nobel Prize in economics in 1994 to John F. Nash, the Hungarian-born John C. Harsanyi, and Reinhard Selten as the first German economist, as well as in 2005 to Robert Aumann and Thomas Schelling, also reflects the great role of German, Austrian and Hungarian scholars in the development of game theory.

The development of modern public finance by Musgrave reflects the cross-fertilization of the more theoretically oriented and rigorous Anglo-Saxon tradition of public finance with the German tradition of *Finanzwissenschaft*, including its institutional, historical and legal aspects. With his division of the public sector into three branches, which besides allocation also include stabilization and distribution as a fiscal concern, Musgrave indicates some German influences in the émigré's baggage (Musgrave, 1996). The German translation of Musgrave's *Theory of Public Finance* (1959) was used at most universities for more than two decades as the standard textbook. Distributional theory and wealth formation among workers were also key issues for some leading German economists – Erich Preiser, Gottfried Bombach and Krelle – in the 1960s.

**1967–74: the high years of Keynesianism**

At German universities the Keynesianism of the Hicks–Samuelson neoclassical synthesis had become the dominant position since the late 1950s. This can largely be attributed to Erich Schneider, whose three-volume *Introduction into Economic Theory*, originally published in 1946–52, became the dominant textbook in the 1950s and 1960s, going through many editions. Schneider, who had made his habilitation with Schumpeter in Bonn in 1932 and became Professor in Aarhus in 1936, came back from Denmark in 1946 to become professor in Kiel, where he also directed the Institute of World Economics from 1961–9 (when he was succeeded by Herbert Giersch). From 1963 to 1966 Schneider was chairman of the Verein für Socialpolitik, which had been re-founded in 1948. When the influential Theoretical Committee was re-established shortly afterwards, Schneider exercised his power as chairman in the direction of a more mathematically oriented approach, which at the beginning had to overcome strong resistance (Schefold, 2004).

Until the recession of 1966–7, however, economic policy was still dominated by ordoliberal ideas. As a consequence, Ludwig Erhard, who had been a successful Minister of Economics from 1949 to 1963, lost his job as Chancellor in December 1966, when the first ‘Grand Coalition’ of Christian and Social Democrats was formed. With the Social Democrats' entry into government and the ratification of the Stability and Growth Act in June 1967, Keynesianism gained a relatively late admission into Germany. According to Article 1 of the Act, the federal and state governments
have to respect the requirement of macroeconomic equilibrium in their economic and financial policy measures which have to be taken in a way that they contribute, within the scope of a market economy, to simultaneously achieve stability of the price level, a high level of employment, and external equilibrium together with steady and appropriate growth.

These four macroeconomic goals appeared in the statutes of the German Council of Economic Advisers (CEA), which was founded in August 1963 and from autumn 1964 presented its annual report. The German council differs from the American in being an external and independent committee for policy consultation rather than part of the government.

In the public eye Karl Schiller's term of office as economics minister from the end of 1966 to the summer 1972 is remembered as the heyday of Keynesian economic policy in Germany. This is due to Schiller's remarkable ability to coin phrases such as ‘Globalsteuerung’ ('macroeconomic demand management’), and his charismatic interpretation of economic policy which contributed to a widespread belief in the government's management power of macro variables, before the first oil price shock and the new phenomenon of stagflation shook that confidence. However, it should not be overlooked that Schiller had always followed a synthesis of Keynesianism and ordoliberal ideas. This is expressed most clearly in his influential article on economic policy in the *Handwörterbuch der Sozialwissenschaften* (Handbook of Social Sciences) (Schiller, 1962), in which he formulated his famous credo: ‘competition to the extent possible, planning to the extent necessary’, with ‘planning’ understood in the sense of Keynesian demand management. Through his homage to Eucken, that is, in supplementing process policy with *Ordnungspolitik*, Keynesian policies took on a distinctly German tinge. This came against the background of discrediting the interventionist policies of the Nazi period, policies that were being pursued in Stalinist East Germany, and the need to safeguard the market economy against Marxist policies that were finally given up by the Social Democratic Party (SPD) only in its Godesberg programme adopted in 1959. In line with Giersch and the majority of the CEA, Schiller also advocated flexible exchange rates in the final years of the Bretton Woods system and in debates in the German 1969 election campaign when currency flexibility was heavily opposed by the Christian Democrats and the German export industry. The strong revaluation of the Deutschmark thereafter contributed to a dampening of inflation in Germany.

From 1974 to the present: is there a German economics?

Even in the short period when Keynesian influence on policy was at its peak, the Bundesbank was a powerful institution that followed its own policy of securing price stability, thereby constraining the implementation of Keynesian full employment policies. After the second oil price shock, when the German economy ran into a current account deficit in 1979–81 and there was unusual pressure to devalue the Deutschmark, the Bundesbank reacted by raising interest rates, a restrictive monetary policy that led to a major controversy with Chancellor Schmidt. After December 1974, when for the first time it had announced a target for the growth of the money supply, the Bundesbank followed an explicit monetarist policy, in line with many of the major central banks in the Western world. The Constance seminar on monetary theory and policy, initiated by Karl Brunner, which from 1970 had brought together American and German economists as well as practitioners from the Bundesbank and
commercial banks, was the main vehicle for the breakthrough of monetarist ideas in theory and practice. Since 1976 the CEA, the majority of whose members had favoured moderate wage policies – which repeatedly led them into controversy with the trade unions – explicitly propagated supply side policies. With German unification in 1990 another German Sonderweg ended. University economics faculties in East Germany, where from 1945 to 1989 economics had been mainly reduced to Marxism-Leninism and a narrowly defined socialist business administration, were now completely restructured, as also happened in law and the social sciences. The government tried to restore the pre-1933 prestige of the Humboldt University in Berlin, formerly Germany’s leading academic institution, which produced many Nobel Prize-winners in physics, chemistry and medicine. Its economics faculty entered the club of the leading faculties, which included Bonn, Mannheim and Munich.

The post-1945 development of economics is characterized by a growing process of internationalization combined with an increasing dominance of American economics (Coats, 1997; 2000). The triumphant ascent of American economics after the Second World War is the consequence of the economic and political leadership of the United States, the benefits of the importation of scholars from Hitlerian and Stalinist Europe – Scherer (2000, p. 622) calculates the citations received by the German-speaking émigré economists in the Social Science Citation Index (SSCI) for the period 1960–4 as ‘roughly equivalent to the adjusted citation output of the first-ranked Harvard and second-ranked MIT plus the 19th-ranked University of Illinois economics departments’ – and a national style of economic research characterized by the early introduction of graduate studies at the leading universities, with pressure to acquire the necessary mathematical and econometric tools for a specialized theoretical and applied work. The consequential international convergence process and the ‘professional Gleichschaltung’ (Peacock in Frey and Frey, 1995, pp. 267–71) associated with it led to increasing debates of the type ‘Is there a European economics?’ (Frey and Frey, 1995). In that sense, at the end of the 20th century there is no recognizable ‘German’ economics, as there was at the beginning of the century. German economists participate in international networks as do economists from other European countries or other parts of the globe, with English as the lingua franca. This is also reflected in the fact that since 2000 the Verein für Socialpolitik has published the international German Economic Review instead of the Zeitschrift für Wirtschafts- und Sozialwissenschaften, formerly Schmollers Jahrbuch, which had been revived under its old name but is no longer linked to the Verein, which in 2000 had 2,928 individual members from more than 20 countries.

Gerschenkron, Alexander (1904–1978)

Albert Fishlow
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
backwardness; capital accumulation; economic history; Gerschenkron, A.; Industrial Revolution; industrialization; Laspeyres index; latecomer development; Modernity; Paasche index; stages of growth; structural change

Article
Gerschenkron was born in Odessa in 1904 and died in Cambridge, Massachusetts, in 1978. He left Russia in 1920 and settled in Austria. In 1938, a decade after receiving the degree of doctor rerum politicarum from the University of Vienna, he emigrated to the United States and spent the next six years at Berkeley. After a short period at the Federal Reserve Board, he went to Harvard in 1948 to teach both economic history and Soviet studies. His passion for the former dominated, and he flourished there as the doyen of economic history in the United States. He influenced a generation of Harvard economists through his required graduate course in economic history and attracted several to his seminar and the field. His erudition and breadth were legendary, and defined an indelible, if unattainable, standard of scholarship for his colleagues and students.

Gerschenkron's principal contribution to economics was the elaboration of a model of latecomer economic development. Its central hypothesis is the positive role of relative economic backwardness in inducing systematic substitution for supposed prerequisites for industrial growth. State intervention could, and did, compensate for the inadequate supplies of capital, skilled labour, entrepreneurship and technological capacity found in follower countries. Thus the German institutional innovation of the ‘great banks’ provided access to needed capital for industrialization, even while greater Russian backwardness required a larger and more direct state role.

Gerschenkron's analysis is consciously anti-Marxian: it rejected the English Industrial Revolution as the normal pattern of economic development, and deprived the original accumulation of capital of much of its conceptual force. Elements of modernity and backwardness could survive side by side, and did in a systematic way. Apparent disadvantageous initial conditions of access to capital could be overcome. Success was rewarded with proportionately more rapid growth, signalled by a decisive spurt in industrial
expansion. This model, first presented in 1952 in an essay entitled *Economic Backwardness in Historical Perspective* (reprinted in 1962), underlay Gerschenkron's extensive research into the specific developmental experiences of Russia, Germany, France, Italy, Austria and Bulgaria. Out of those historical studies emerged a comparative, all-encompassing European picture. ‘In this fashion, the industrial history of Europe is conceived as a unified and yet graduated pattern’ (Gerschenkron, 1962, p. 1). In turn, his hypotheses became progressively more precise. They may be summarized as follows:

1. Relative backwardness creates a tension between the promise of economic development, as achieved elsewhere, and the reality of stagnancy. Such a tension motivates institutional innovation and promotes locally appropriate substitution for the absent preconditions of growth.
2. The greater the degree of backwardness, the more interventionist was the successful channelling of capital and entrepreneurial guidance to nascent industries. Also, the more coercive and comprehensive were the measures to reduce domestic consumption.
3. The more backward the economy, the more likely were: an emphasis upon producers' goods rather than consumers' goods; use of capital-intensive rather than labour-intensive methods of production; emergence of larger rather than smaller units of both plant and enterprise; dependence upon borrowed, advanced technology rather than indigenous techniques.
4. The more backward the country, the less likely was the agricultural sector to provide a growing market to industry through rising productivity, and the more unbalanced the resulting productive structure of the economy.

The considerable and continuing appeal of the Gerschenkron model derives from its logical and consistent ordering of the process of European development, the conditional nature of its predictions and its generalizability to the experience of the late latecomers of the present Third World. His formulation rises above other theories which emphasize stages of growth both because of its attention to historical detail and its insistence upon the special attributes of latecomer development that cause differential evolution. In Gerschenkron's own hands, his propositions afforded an opportunity to blend ideology, institutions and the historical experience of industrialization, especially that of Russia, in a dazzling fashion. For others, his approach has proved a useful starting point for the discussion of non-European latecomers, including Japan and the newly industrializing countries.

The model is, of course, not without its limitations. History, even of Europe alone, does not in every detail bear easily the weight of such a grand design. In other parts of the world, as might be expected from a concept rooted in the special features of the historical European experience, larger amendments are frequently required. And somewhat surprisingly, in view of Gerschenkron's own path-breaking essay in political economy, *Bread and Democracy in Germany* (1943), there is too little attention to the domestic classes and groups whose interests the interventionist state must adequately incorporate if it is to play the central role required. Backwardness too easily becomes an alternative, technologically rooted explanation, distracting attention from the state rather than focusing upon its opportunities and constraints.

Still, the concept of relative backwardness, and Gerschenkron's always insightful and rich elaborations in so many national contexts, represent a brilliant and original contribution to economic history for which he is justly celebrated. It is not the only one. The ‘Gerschenkron effect’, arising from the
difference between calculated Paasche and Laspeyres indexes of Soviet machinery output (1951), also commemorates him. Current price weights will tend to underestimate the extent of growth because prices and quantities are negatively correlated, just as base year weights exaggerate it. The larger is the difference between the alternatively constructed quantity indexes, the greater is the degree of structural change. Again, divergence rather than uniformity is the source of useful information about historical processes.

Alexander Gerschenkron has few peers, past or present, in his command of comparative economic history. Scholarly interest in contemporary economic development has brought him an increasing following. His insights thus continue to influence a new generation of scholars and guarantee him a central place in any assessment of the evolution of the discipline of economic history.

Gervaise, Isaac (fl. 1680–1720)

Peter Groenewegen
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
free trade; Gervaise, I.; Law, J.; specie-flow mechanism

Article

Merchant and economist of French Huguenot extraction. Gervaise was born in the second half of the 17th century, probably in Paris, and migrated with his family to London in 1681. With his father he was associated with the Royal Lustring Company (1688–1720) engaged in the manufacture of a fine, light, black, glossy silk under patent granted by parliament. Ironically, the year the company lost its charter saw the publication of Gervaise's 34-page pamphlet, *The System or Theory of the Trade of the World* with its attack on exclusive companies. Foxwell (1940, p. 167) described it as 'one of the earliest formal systems of political economy … stating one of the most forcible practical arguments for free trade'. Quite unlike much contemporary writing on trade, Gervaise's pamphlet is tersely written and especially noted for its peculiar terminology and highly abstract argument. Gervaise is presumed to have died in London by 1739.

The real discoverer of Gervaise's work, Viner (1937, pp. 79–80), has described it as 'an elaborate and close reasoned exposition of the nature of international equilibrium and of the self-regulating mechanism whereby specie obtained its “natural” or proper international distribution'. The novelty of Gervaise's treatment of the specie mechanism is his emphasis on the role of income rather than prices, in strong contrast with subsequent treatments by Cantillon, Vanderlint and Hume. The starting point for the analysis is the proposition that the equilibrium bullion stock of any nation is proportioned to its output in terms of labour and that such a stock also maintains the balance between consumption and production, exports and imports. Excess bullion breaks these balances by raising consumption and reducing production, thereby lowering exports and raising imports, hence bullion will be exported and the balances will be resorted. An inadequate bullion stock leads to specie inflow by raising production relative to consumption, and exports to imports. Gervaise treats credit as if it were bullion; oversupply or deficiency is self-correcting via the balance of trade, though the adjustment process with credit is more rapid through its additional income effects of interest payment to suppliers of credit, whom he sees as
consumers rather than producers. Hence ‘credit is of pernicious consequences to that Nation that uses or encourages it beyond nature’ (Gervaise, 1720, p. 14) – a comment perhaps not unrelated to contemporary developments with Law's system in France. War, capital consumption or export, and restrictions on trade may prevent or postpone attainment of monetary equilibrium. For this reason, and for the resource misallocation potential flowing from encouragement of specific manufactures through companies, laws or taxes on imports, Gervaise (1720, pp. 17–18) concluded that ‘Trade is never in a better condition, than when it's natural and free’. Gervaise also pointed out that the ‘natural proportion’ of bullion for specific countries was influenced by their situation, particularly as regards proximity to water transport, and that implementing policies of debasing the currency had similar effects on trade and the balance of consumption and production as credit oversupply. Although less elegantly written than Hume's later account of the specie mechanism, the emphasis on adjustment through income rather than price effects, though not always clearly explained, makes Gervaise's short and penetrating contribution to the subject more modern than most of its successors in the century and a half which followed.

Gesell, Silvio (1862–1930)

Victoria Chick

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

depressions; Gesell, S.; hoarding; land nationalization; stamped money principle

Article

Gesell was born in Germany but emigrated to the Argentine in 1886, where he was so successful as an importer that he retired to Switzerland in 1900 to farm and to continue to write. The ‘retirement’ included a return to the Argentine to manage his late brother's business and an involvement in Bavarian politics at their most chaotic. As a deposed minister of finance he was tried for high treason, and acquitted.

His prolific writing began in Argentina, provoked by the economic chaos of the late 1880s there. But his fame rests on The Natural Economic Order, originally published in two parts in 1906 and 1911. It was translated into English in 1929. Rent-free land and interest-free money characterize that Order. Land would be nationalized, its owners compensated by the issue of state bonds. Through the device of stamped money, which would remain current only if a stamp, obtained at a cost set by government, was regularly affixed, the rate of interest on these bonds and other lending instruments would eventually be driven to zero. With no income diverted to rent or interest the worker would receive the full value of his output. Mothers were to receive income from annuities based on the nationalized land, since their ‘output’, the population, was the source of demand for land and hence rent.

Gesell attributed depressions to inadequate investment and the latter to the fall in the expected rate of return as investment continued, coupled with a money rate of interest which was prevented from falling by the alternative opportunity of hoarding. This analysis substantially anticipates Keynes's (1936), as Keynes amply acknowledges (pp. 353–8). Gesell suggested adjusting the stamp duty on money to force down the rate of interest.

The stamped money principle was three times applied on a local scale in the 1930s: in Bavaria, in the Austrian Tyrol and in Alberta, Canada. In each case the scheme successfully raised demand and employment, but the money was soon banned by the authorities.

Though theoretical inadequacies and practical difficulties are claimed against Gesell's theory, its aim is
probably more responsible for its eclipse. But it lives on furtively, below the surface, in the underworlds of Keynes's *General Theory* and Fisher's *Booms and Depressions*.

A ghetto is an area of a city in which a minority group is highly segregated and kept there by social, legal, or political forces. This article describes the history of Jewish ghettos of medieval Europe through the Nazi period. The African-American experience is also described, along with the effects of segregation on racial differences in economic outcomes. Examples of ghettos in Japan (the Burakumin), Australia (aborigines), and South Africa (apartheid) are mentioned, along with the related concept of an ethnic enclave.

Keywords
apartheid; Burakumin; ghettos; housing markets; human capital; immigration; internal migration; neighbours and neighbourhoods; racial discrimination; racial segregation; restrictive covenant; urban segregation

A ghetto is a specific area of a city in which a racial, ethnic, or other minority group constitutes the overwhelming majority of residents, and which is maintained as such by social, political, or legal pressures.

In early medieval Europe local authorities granted Jews living quarters in exchange for services as traders, moneylenders, or tax collectors. With the Crusades, these voluntary arrangements turned compulsory, first in Spain and Portugal and later in Germany. The Jews of early 15th Venice were forced to live in the ghetto Nuevo, an abandoned foundry located on an island isolated from the general population (Curiel, Cooperman and Arici, 1990). Walls were erected and guards stood watch by the foundry gates. By day Jews could continue to conduct business but they were required to wear special clothing and were subject to punishment if they were found outside the ghetto at night. Within the walls of the typical Jewish ghetto an entirely separate world of institutions – courts, educational and cultural
institutions, retail establishments, and recreational facilities – emerged. Overcrowding, however, was the norm because geographic expansion at the periphery of the ghetto was severely limited, if it existed at all. By the 19th century the extant Jewish ghettos were seen as outmoded relics of an earlier age. In continental Europe the last ghetto to be abolished was the Roman ghetto in the late 19th century. The so-called Pale of Settlement in the far West of Russia survived until the October Revolution of 1917. A few decades later, Jewish ghettos were revived in German-occupied Europe with a vengeance by the Nazis, who used them primarily as holding pens prior to extermination (Browning, 1986).

In the early 20th century social scientists began to refer loosely to any area of a city in which a particular racial, ethnic, or religious group was very highly segregated as a ‘ghetto’ (Wirth, 1928). Later in the century the usage spread to other types of segregation (such as in the phrase ‘pink ghettos’, referring to the concentration of women in certain occupations). Numerical indices were devised, primarily by sociologists, to measure the extent of segregation (Massey and Denton, 1993; Echenique and Fryer, 2004).

Wacquant (2004) argues that the following are necessary, if not always sufficient, characteristics of a ghetto in the looser sense. First, the minority group must be readily identifiable. Second, the group must be kept physically isolated by the majority, which has the power to enforce the isolation. Third, institutions emerge within the ghetto to provide services that ghetto residents cannot otherwise obtain from the outside world. A distinct ghetto culture may also emerge, elements of which might persist long after the specific mechanisms that kept the affected group ‘in its place’ are abolished.

The word ‘ghetto’ has often been used to describe the experience of African Americans in urban areas in the 20th century (Drake and Clayton, 1945; Clark, 1965; Osofsky, 1971; Hirsch, 1983; Massey and Denton, 1993; Cutler, Glaeser, and Vigdor, 1999). In the late 19th century African Americans were concentrated in the rural southern United States, where they faced very high levels of racial discrimination. In the northern United States the African-American population was a small share of the total and of the urban population; and only in one city (Norfolk, Virginia) was the extent of racial segregation great enough to plausibly justify claims that a ghetto existed (Cutler, Glaeser and Vigdor, 1999).

Although a steady trickle of African Americans to urban areas had occurred since the end of the civil war, the trickle became a flood during the First World War. European immigration from Europe was largely cut off and, buoyed by wartime demand, urban manufacturers turned to southern blacks as a new labour supply. By 1940, virtually all major cities in the North had black ghettos, some known by specific names – ‘Harlem’ in New York, ‘Bronzeville’ in Chicago. Unlike the Jewish ghettos of the medieval Europe, the boundaries of the black ghettos were not set in stone, and whites living nearby adopted a variety of tactics, legal and otherwise, to limit the ghetto’s geographic expansion. One example was the restrictive covenant, a clause contained in a deed of sale that enjoined a white owner from selling to a black family. Such covenants were in widespread use until rendered unenforceable by the United States Supreme Court in 1948. the Second World War had a much greater effect on black migration from the rural South than the First World War had, and segregation levels continued to increase, reaching ‘staggering levels’ by 1970 (Cutler, Glaeser, and Vigdor, 1999, p. 470). Since 1970 racial segregation in American cities has declined, although levels remain relatively high compared with the late 19th century. Economists have considered how ghettos affect economic and social outcomes of African Americans. In the model developed by Cutler and Glaeser (1997), there are three groups: skilled whites, skilled blacks,
and unskilled blacks. The groups occupy a city which is divided into three neighbourhoods fixed in
geographic size. Economic decisions are made by parents, and parental utility is a positive function of
their children's human capital, which itself depends on the human capital of the parent and the average
level of human capital in the community where the household resides. Utility is a negative function of
housing costs and, in addition, blacks (whites) must pay a fixed entry cost to live in a white (black)
neighbourhood.
Cutler and Glaeser consider an initial equilibrium in which whites live in one neighbourhood while
skilled and unskilled blacks are distributed across the remaining two neighbourhoods. An increase in the
cost to blacks of entering the white neighbourhood reduces the number of skilled blacks living in the
white neighbourhood. White utility increases because housing costs fall and average skill levels are
unaffected. As more skilled blacks choose to live in one of the black neighbourhoods, housing costs in
the neighbourhood rise, which hurts unskilled blacks living there. However, average human capital in
the neighbourhood increases, which benefits the human capital production of the children of unskilled
blacks. The net effect on the location decisions of unskilled blacks is indeterminate but, depending on
the overall effect, it is possible for welfare of unskilled blacks to decrease.
Cutler and Glaeser conduct an empirical analysis of the relationship between segregation and economic
outcomes for African Americans, using census data for 1990. They show that an increase in residential
segregation reduces educational attainment and income and increases the incidence of motherhood at
younger ages. Collins and Margo (2000) replicate the empirical analysis for earlier census years, finding
that black ghettoes turned increasingly bad on all fronts after 1970. Collins and Margo (2003) study the
evolution of racial differences in the values of owner-occupied housing since 1940. They demonstrate
that, in the country as a whole, the racial gap in housing values was narrowing prior to 1970. However,
in central cities the racial gap widened in the 1970s, and the extent of widening was greater in cities that
were initially heavily segregated in 1970.
If high levels of racial segregation turned increasingly bad for African Americans in central cities after
1970, there was no shortage of possible causes. Massey and Denton (1993) emphasize
dehindustrialization, whereas Wilson (1987) hypothesizes that decreases in housing market discrimination
enabled middle- and upper-class Americans to leave central cities ghettoes, thereby removing effective
role models from the ghetto. Although the United States has a long (and terrible) history of race-related
civil disturbances, the number and geographic extent of those occurring in the 1960s were
unprecedented. Collins and Margo (2004a; 2004b) demonstrate that the occurrence of a severe riot
between 1960 and 1970 was associated with deteriorating employment, earnings, and housing values for
urban blacks, an association that persisted at least through the 1970s.
European Jews and African Americans are far from the only groups whose histories include ghettos or
ghetto-like conditions. One such group is the Burakumin of Japan. The Burakumin were descendants of
the lowest of four castes that existed during the feudal era of Japanese history. Viewed as ‘untouchable’
by the religious majority (Buddhists and Shinto), the Burakumin were faced with similar constraints to
those imposed on Jews, such as restrictions on intermarriage and geographic mobility. Like Jews, the
Burakumin had to wear special clothing and behave in a deferential manner towards the majority.
Although ‘emancipated’ by edict in 1871, a combination of formal and informal institutions nevertheless
resulted in the formation of numerous impoverished and crime-ridden ghettoes of Burakumin throughout
Japanese cities that have persisted (DeVos and Wagatsuma, 1966; Hane, 1982). Brock (1993) describes
the emergence, persistence, and functioning of three ‘outback’ ghettos (Poonindle, Koonidule, and Nepabunna) of Aboriginal people in Australia. Residential segregation was a key aspect of apartheid in South Africa as well as other colonial regimes (Abu-Lughod, 1980; Western, 1981). Large-scale international migrations have frequently resulted in ghetto-like conditions in the receiving countries (see Wirth, 1928, for a classic discussion). Such ‘ethnic enclaves’ may acquire names – ‘Chinatown’ (see Zhou, 1992) or ‘Little Italy’ – but are fundamentally different because the newcomers eventually assimilate into the broader society. The techniques developed for measuring racial segregation in the United States are now being routinely applied to other countries; see, for example, Peach (1996), and also Johnston, Forest, and Poulsen (2002), who shows that overall levels of ethnic segregation in British cities around 1990 were considerably lower than levels of racial segregation in American cities.

Gibrat was born on 23 March 1904 in Lorient, France, and died on 13 May 1980 in Paris. He studied at Saint Louis de Paris, as well as in Rennes, Lorient and Brest, and in 1922 he entered the Ecole Polytechnique to become a mining engineer. He received a bachelor's degree in science and a doctorate in law from the University of Paris. He was a technical consultant in private firms before being named director of electricity in the Ministry of Public Works, 1940–42. He became Secretary of State for Communications under the Laval government but resigned after the Allied invasion of North Africa. After the Liberation he was chief engineer of mines. He was consulting engineer for French Electric on tidal energy (1945–68) and served as Director General for atomic energy (Indatom, 1955–74), president of the scientific and technical committee of Euratom (1962), and as a consulting engineer for Central Thermique, 1942–80. He taught at Ecole des Mines from 1936 to 1968. He served as President of the French Society of Electricians, Vice President and President of the Civil Engineers of France, President of the Statistical Society of Paris (1966), President of the French Statistical Society, President and Honorary President of the Technical Committee for the Hydrotechnical Society of France, President of the French Meteorological Society (1969), Honorary President of the World Federation of Organizations of Engineers, and President of the French Section of the American Nuclear Society. Gibrat was the author of reports to the Academy of Sciences, some 100 professional articles and two books (on economics and tidal energy), and a Knight of the Legion of Honour.

His major contribution to economics is known as Gibrat's Law. This states that the expected growth rate for a firm is independent of its size. Gibrat's Law has been successfully tested by French and American investigators, among others. His famous economics work, *Les inégalités économiques*, was published in 1931. For his contributions to economics and mathematical economics he was elected a Fellow of the Econometric Society in 1948.

Gibrat's Law

José Mata
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Gibrat's law states that a great deal of the evolution of firm size distribution over time is due to the action of chance. While chance is still seen as an important driver of the size of firms, recent studies call for chance to be supplemented by some more structured models in order to explain the observed patterns of firm size evolution.

Keywords

concentration; firm growth; firm size; firm size distribution; Gibrat's law; heteroskedasticity

Article

In one of the first studies on firm size distribution (FSD) Gibrat (1931) observed that the size of firms followed the lognormal distribution very closely, from which he concluded that firms' rate of growth ought to be a random process. In particular, he reasoned that growth should not depend on the initial size of firms, as such a process would inevitably produce a lognormal distribution. This assertion became known as Gibrat's law.

If we denote the size of the firm at time $t$ by $S_t$ and the proportional growth between $t$ and $t-1$ by $\varepsilon_t$

$$\frac{(S_t - S_{t-1})}{S_{t-1}} = \varepsilon_t$$

$$S_t = S_{t-1}(1 + \varepsilon_t) = S_0(1 + \varepsilon_1)(1 + \varepsilon_2)...(1 + \varepsilon_t),$$
taking logs and using the approximation $\log(1+\varepsilon_t) \approx \varepsilon_t$ leads to

$$\log S_t = \log S_0 + \varepsilon_1 + \varepsilon_2 + \ldots + \varepsilon_t.$$

As $t \to \infty$, $\log S_0$ becomes less important relative to $\log S_t$ and, if $\varepsilon_t$ is drawn from a normal distribution with mean $\mu$ and variance $\sigma^2$, $\log S_t$ can be approximated by a normal distribution with mean $\mu t$ and variance $\sigma^2 t$. The result that the variance of the FSD is bound to increase over time due to the sole action of chance is probably responsible for the popularity of Gibrat's law in industrial organization, as it provides a nice explanation for the observed empirical regularity that industrial concentration increased over time. Other fields in which the application of Gibrat's law has been discussed include those of distributions of income (Sahota, 1978) and the size of cities (Eeckhout, 2004).

It is not surprising that soon after the publication of Gibrat's book, different studies tried to test the law empirically (see Sutton, 1997, for a survey). Some proceeded to compare the observed firm size distribution with the lognormal distribution, others analysed the relationship between firm size and firm growth. By and large, the results coincided. The firm size distribution seemed to conform well to the lognormal distribution, and firm growth seemed to be largely independent of firm size.

The studies in this first wave typically used data that were readily available in public sources, that is, data on the largest firms in the economy. In an influential study published in the early 1960s, however, Mansfield (1962) collected data on ‘practically all firms’ in three American industries in different time periods and analysed the relationship between the size and the growth of firms. He suggested that different interpretations regarding the extent to which Gibrat's law was applicable were possible, and tested the validity of the law according to these different interpretations. According to the first interpretation Gibrat's law would hold for all firms including those that exit; with this interpretation, a negative relationship between initial size and growth was discovered in the majority of the samples that were considered. The second interpretation posited that the law would hold only for those firms that had not exited; a significant relationship showed up only in a minority of samples. The third interpretation stated that the law would hold only for those firms whose size exceeded a given threshold. Setting this threshold as the minimum efficient scale in the industry, Mansfield found no significant relationship in any of the samples. Yet, even with this restricted interpretation, Mansfield's samples failed to pass a second test of Gibrat's law, that the variance of growth would be independent of size.

The topic did not attract much attention during the rest of 1960s and the 1970s. When it again came under scrutiny in the mid- to late 1980s, new data sources had became available. These new data sources covered many more firms than before, providing a much better coverage of the smallest firms in the economy. Furthermore, their longitudinal dimension, which allowed researchers to follow firms over time, led to the discovery that the entry, exit and growth movements that were taking place in most industries of developed countries were of a previously unsuspected large magnitude (see Caves, 1998,
Concerning Gibrat's law, the major consequence was that attention was this time mostly drawn to the relationship between firm growth and size, and problems of sample selection became routinely addressed using econometric techniques that had meanwhile become available. Whether or not sample selection was taken into account, however, the results of the studies using these recently developed databases suggested that firm growth was not independent of firm size, smaller firms growing faster than their larger counterparts (for example, Evans, 1987). Another systematic concern of this literature was heteroskedasticity: most studies found that large firms display a less variable pattern of growth than do smaller units. Although consistent with the idea that the diversification associated with size reduces risk, this is a pattern that does not conform well to Gibrat's postulate.

A negative relationship between size and growth does not imply that concentration does not increase. This point can be clearly seen by imagining that there are firms of only two sizes, small and large, present in equal numbers in an economy. If those firms that are small in one period become large in the next period and vice versa, the overall distribution remains constant despite the obvious relationship between growth and size. There have been few studies in this new wave that have specifically examined the FSD. McCloughan (1995) simulated the effect of different violations of Gibrat's postulates upon the development of market structure and concluded that the nature of the size–growth relationship (in contrast to the effect considering entry and exit) was the most important determinant of the evolution of concentration.

In one of the few studies that have used these new comprehensive data-sets to analyse the actual development of the FSD, Cabral and Mata (2003) found that the FSD is considerably more skewed than the lognormal in the earliest years, but gradually approaches it as firms get older. Convergence to the lognormal is what would be expected from a Gibrat process, and the fact that the lognormal is approached from a more skewed distribution may seem to be unimportant from the strict standpoint of Gibrat's law, as the law posits that the starting point does not matter in the long run. The finding, however, creates an additional challenge: if we are to rely on random forces to explain the evolution of the FSD, what can possibly explain its starting position? How can this be part of a theory of the evolution of firm size, and how can it coexist with models such as Jovanovic's (1982), in which skewedness emerges gradually as firms learn about their abilities? One possibility is that the size of firms at start-up is the minimum of two sizes: a size to be achieved in the long run – determined by the ability of the entrepreneur in the spirit of Lucas (1978) – and a short-run size, given by some constraint. Cabral and Mata suggested that this constraint could to be a financial one, but other constraints might do the job as well.

An unaddressed question is the extent to which the FSD converges to a position that depends on a pre-existing distribution of abilities and to what extent abilities are a product of explicit decisions made by firms as to the learning process (Ericson and Pakes, 1995). Another question pertains to the appropriate level of analysis. Machado and Mata (2000) report that failure to control for industry-specific conditions leads to a significantly greater departure from the lognormal than when these conditions are controlled for. It is also not obvious that the FSD should be governed by the same forces and evolve along the same lines irrespectively of the specific competitive conditions in the industry (Sutton, 1997), but little work has been done on how these conditions affect the FSD. Perhaps the streams of the literature that has given more attention to the evolution of industries is that following the work by Klepper and Graddy.
Gibrat's Law: The New Palgrave Dictionary of Economics (1990), which shows that, over their life cycle, industries exhibit significant variation, namely, with respect to the changes in the number of firms and their patterns of growth. The implications of these changes to the evolution of the FSD of industries are still under-explored.

Giffen, Robert (1837– 1910)

Murray Milgate
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Giffen, R.; measurement; Royal Economic Society; Royal Statistical Society; statistical comparisons

Article

Robert Giffen's name seems likely to be known by students of economics for generations to come in relation to the famous result in the theory of consumer demand which bears his name but about which, so far as can be determined, he had nothing to say. Marshall originated the tradition when he associated the result with Giffen's name in the third edition of his *Principles* in 1895 (p. 208).

Giffen was born in Lanarkshire. At the age of 13 he was apprenticed to a solicitor in Strathaven, and continued in the same vocation until 1860 (though during the last seven years of this period he resided and worked in Glasgow). Still only 23 years old, Giffen struck out on a career in journalism – in which he was to be successful in establishing his reputation in economic circles of the day. He begun as a sub-editor for the *Stirling Journal*, moved to London in 1862 to work at the *Globe*, transferred to the *Fortnightly Review* in 1866, and in 1868 became assistant editor at *The Economist* – a post at which he remained until his next change of vocation in 1876. He was also city editor at the *Daily News* between 1873 and 1876. Giffen's third and final career was as a professional civil servant, first as chief of the statistical department at the Board of Trade, and then in 1882 as its Assistant Secretary. He retired from the civil service at the age of 60. Giffen served on numerous royal commissions (including the Gold and Silver Commission of 1886–8); he was editor of the *Journal of the Royal Statistical Society* (1876–91), President of that society (1882–4), twice presided over the economics section of the British Association (1887 and 1901), and was one of the founders of the Royal Economic Society. In short, he was one of those figures encountered frequently in British economics whose not inconsiderable power and prestige appears to be disproportionate to their actual contribution to economic science.

In so far as he was primarily a statistician, Giffen's work did attempt to alert economists to the dangers of theory without measurement. His presidential address to the Royal Statistical Society in 1882 was devoted to the subject, and in 1901 as president of Section F of the British Association (his second term in that office) he returned to the same theme (see 1904, vol. 2, chs 13 and 28). Indeed, according to
Higgs in his edition of this *Dictionary* (1925), Giffen's statistical prowess was one of the factors which helped to secure the respect of theorists. His article on international statistical comparisons in the *Economic Journal* (1892b), for example, can be singled out for special mention since it treats for the first time a problem which has still not been adequately resolved. Of course, it was not always the case that Giffen's careful mustering of the statistical evidence allowed him, any more than the theorists, to avoid the pitfalls of making predictions which subsequent experience has proven to be silly – witness his claim that the whole protectionist school would die out within a decade (1898, p. 16). However, in the final analysis it is in Giffen's attempts to provide reasonably accurate measurements of indicators like wage rates, economic growth (see 1884), and national product (1889) that one should isolate his main contribution. While it is true that subsequent work in this field has advanced well beyond Giffen's early efforts, he remains one of the pioneers of applied economics in its modern sense. It seems that Giffen was also a strong supporter of a Channel tunnel: not for one between England and France, but between Ireland and England. He died on 12 April 1910 and is buried in Strathaven.

Giffen's paradox

John Nachbar
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
comparative statics; general equilibrium; Giffen good; Giffen preferences; Giffen, R.; Giffen's paradox; income effect; law of demand; preference externalities; revealed preference; Slutsky equation; substitution effect

Article

Giffen's paradox refers to the possibility that standard competitive demand, with nominal wealth held constant, can be upward sloping, violating the law of demand. From the Slutsky equation, Giffen's paradox arises if and only if a good is inferior and the income effect is larger than the absolute value of the substitution effect. A Giffen good is a good for which Giffen's paradox can arise. Giffen preferences are preferences that can exhibit Giffen's paradox. For explicit examples of Giffen preferences, see Moffatt (2002) and Sorensen (2005).

The term ‘Giffen's paradox’ originates in a passage in Marshall (1920), which credits the statistician Robert Giffen (1837–1910) with observing a failure of the law of demand in the market for bread. The widespread association of Giffen's paradox with potatoes during the Irish potato famine of the 1840s may have originated in Samuelson (1964). A number of authors have since argued that potatoes were not, in fact, a Giffen good for Irish potato farmers (for example, Dwyer and Lindsay, 1984; Rosen, 1999). For more on the tortured intellectual history of Giffen's paradox, see Walker (1987). For empirical evidence that Giffen goods may exist, see Baruch and Kannai (2001) and Jensen and Miller (2002).

In thinking about Giffen's paradox, bear in mind four points. First, the budget constraint forces a crude form of compliance with the law of demand: as the price of a good goes to infinity, consumption of that good must go to zero. Conversely, under standard assumptions on preferences (such as monotonicity), as the price of a good goes to zero, demand for the good becomes large. Thus, under standard assumptions, the graph of demand for a Giffen good, with price on the vertical axis, is roughly Z-shaped.

Second, whether Giffen's paradox arises for aggregate demand, summed across consumers, depends on...
the wealth distribution as well as on individual preferences. This point is a variation on the preceding one. For any given consumer, if prices are held fixed, consumption of any good must fall for large enough drops in nominal wealth, which implies that no good is inferior for all wealth levels. Therefore, even if consumers have the same Giffen preferences, if consumers have different wealth levels, then, over any given price interval, the law of demand may hold for some consumers even if it is violated for others. As a consequence, even if all consumers have the same Giffen preferences, aggregate demand may obey the law of demand. A striking example is due to Hildenbrand (1983): if there is a continuum of consumers all of whom have the same preferences and if nominal wealth is uniformly distributed on an interval containing zero, then aggregate demand cannot exhibit Giffen's paradox.

Third, in a general equilibrium (GE) model, with endogenous wealth, the comparative statics of Giffen goods can run counter to standard textbook intuition. Consider an exchange economy (no production) with two goods and only one consumer. In the equilibrium of this trivial economy, the consumer eats her own endowment. Equilibrium relative prices (which are well defined even though there is no trade) are given by the slope of the consumer's indifference curve through her consumption/endowment point. Naive textbook supply and demand analysis predicts that, if demand for good 1 is upward sloping, then an increase in the endowment of good 1 results in a higher equilibrium price (if we assume that the price of good 2 is constant). One can easily show, however, that in this economy an increase in the endowment of good 1 can increase its equilibrium price only if the good is normal, hence not Giffen. In fact, if the good is Giffen then the endowment increase causes the price to fall by so much that nominal wealth falls (causing the demand curve to shift out, since the good is inferior), even though the endowment increase makes the consumer better off.

The critical feature of this example is that individual demand automatically obeys the weak axiom of revealed preference, and in exchange economies the weak axiom implies the law of demand for endogenous wealth demand near equilibrium. Thus, if preferences are Giffen, endogenous wealth demand slopes down at equilibrium even though fixed wealth demand slopes up, and it is endogenous wealth demand that drives GE comparative statics. This analysis generalizes to multi-consumer economies, with active trade, provided aggregate, endogenous wealth demand satisfies the weak axiom (see Nachbar, 2002); the basic intuition goes back to Hicks (1939). Note, however, that in multi-consumer economies aggregate demand does not automatically satisfy the weak axiom.

For other work that investigates the behavior of Giffen goods in environments richer than those usually considered in textbook treatments, see Barzel and Suen (1992) and Rosen (1999).

Finally, in standard economics usage, Giffen's paradox refers both to a phenomenon – failure of the law of demand for standard competitive demand – and to a particular mechanism underpinning that phenomenon – income effects. Giffen's paradox is, however, sometimes conflated with similar phenomena arising from quite different mechanisms, often based on preference externalities of some form. A classic citation is Leibenstein (1950). For an interesting application, see Pesendorfer (1995).

Gilman was born on 3 July 1860 in Hartford, Connecticut, and died on 17 August 1935 in Pasadena, California. Known worldwide as a feminist theorist and a generally iconoclastic social critic, Gilman was a major intellectual force in America at the turn of the 20th century. Largely self-educated, problems with her first marriage led her to separate from her first husband and begin an unconventional freelance life based in California, earning her living from her lecturing and writing. *Women and Economics* (1898) was her first book-length exposition of her theory of the evolution of gender relations. Influenced by the ideas of Edward Bellamy, Lester Frank Ward, Darwin, the Webbs and G. Bernard Shaw, she explained that human institutions (like the species itself) has evolved over time, favouring the survival of the best adapted. A major exception, however, was the definition of ‘women's place’. Here social development had been frozen by Tradition. Women were confined to households which were no longer the locus of any socially productive activity, since now the factory produced the needed consumption goods, and children were better raised in schools, by professionals. The role of full-time housewife and mother had become anachronistic, reducing women to the state of social parasites. As she also argued in her 1903 classic *The Home* that, for their own progress and for the progress of human civilization overall, women would have to leave these domestic prisons and take up socially useful work in the larger world of production. In the articles and didactic fiction that she wrote for her monthly magazine the *Forerunner*, she developed a wide range of startlingly rational ideas for social reorganization.

Gini ratio

Camilo Dagum
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

In a national economy, the price system determines both resource allocation and the income distribution. The imputation to the factors of production of the mass of income associated with an economy's output determines its distribution by factor shares, or functional income distribution. This mainstream of research follows Ricardo's (1817) contribution. Another mainstream of research was initiated by Pareto (1895, 1897), and deals with the distribution of a mass of income among the members of a set of economic units (family, household, individual), considering either the total income of each economic unit or its disaggregation by source of income, such as wages and salaries, property income, self-employment income, transfers, etc. This type of inquiry deals with distribution by size of income, or personal income distribution, and the quantitative assessment of the relative degree of income inequality among the members of a given set of economic units. Such inquiries provide basic quantitative information in support of a comprehensive research strategy on income distributions, including causal explanations for social welfare and policy.

It is of interest to remark that Pareto's research on income distribution was motivated by the polemic he engaged in with French and Italian socialists concerning the ways and means of achieving a less unequal distribution. Thus, the actual measurement of inequality was brought to the fore, with its main purposes the assessment of (i) the evolution of inequality in a given country or region, and (ii) the relative degree of inequality between countries or regions.

In a series of methodological and applied contributions Corrado Gini (1955) enriched this field of research. In 1910 he corrected the interpretation of Pareto's inequality parameter and, in 1912, proposed a new measure of income inequality, the Gini ratio.

Pareto (1896, 1897) specified three versions of this model of income distribution. The most widely used model is Pareto Type I

\[ S(x) = 1 - F(x) = \left(\frac{x}{x_0}\right)^{-\alpha}, \quad 0 < x_0 < x, \alpha > 1, \]

where \( S(x) = P(X > x) \) is the survival distribution function (SDF) of the income variable \( X \), \( F(x) \) is the cumulative distribution function (CDF), \( x_0 \) is the minimum value of \( X \), \( \alpha \) is a scale-free inequality parameter, and the mathematical expectation of income is

\[ \mu = E(X) = \alpha x_0^\alpha \int_{x_0}^\infty x^{-\alpha}dx = \alpha x_0 / (\alpha - 1). \]

Pareto seems to have assumed that income growth implies less income inequality. This assumption, together with eqn (2), led him to the conclusion that income inequality is an
Gini ratio: The New Palgrave Dictionary of Economics

increasing function of \( \alpha \). Gini (1910) reversed this interpretation, proving that, given model (1), income inequality is a decreasing function of \( \alpha \). Gini’s rationale was as follows:

given \( n \) units with incomes \( x_1 \leq x_2 \leq x_3, \ldots \leq x_n \), the average of the last \( m (m \leq n) \) income units \( \sum_{i=0}^{m-1} x_{n-i} / m \) is greater than or equal to the average income \( \mu = \frac{\sum_{i=0}^{n} x_i}{n} \) of the population, hence, there exists a \( \delta \geq 1 \) such that

\[
\left( \frac{m-1}{\sum_{i=0}^{m-1} x_{n-i} / \sum_{i=1}^{n} x_i} \right) \delta = m / n, \delta \geq 1,
\]

Equation (3) is known as the Gini model. Gini (1910) interpreted the scale-free parameter \( \delta \) as a measure of income inequality and called it a concentration ratio because it is an increasing function of the concentration of income in the upper income groups. For this reason, Gini called eqn (3) a concentration curve, where the abscissa represents the CDF \( F(x_m) = m/n \) and the ordinate the income share \( \sum_{i=1}^{m} x_i / \sum_{i=1}^{n} x_i, m = 1, 2, \ldots, n \), \( \delta \) being an unknown parameter that has to be estimated.

Using the CDF \( F(x) \) and the Lorenz curve \( L(x) \) (also called the Lorenz-Gini curve since it was independently introduced by both authors), eqn (3) takes the form

\[
1 - F(x) = \left[ 1 - L(x) \right] \delta, \delta \geq 1,
\]

where

\[
L(y) = \left( \frac{1}{\mu} \right) \int_{0}^{y} x \delta F(x).
\]

Replacing \( F(x) \) from model (1) into eqns (4) and (5), Gini (1910) proved that \( \delta = \alpha / (\alpha - 1) \) and thus reversed Pareto’s interpretation of \( \alpha \). In fact, when \( \alpha \to \infty \), \( \delta \to 1 \) and \( F(x) = L(x) \), and the mass of income is equally distributed.

Gini (1912) specified the Gini mean difference with and without replacement. The latter is by definition

\[
\Delta = \sum_{j=1}^{n} \sum_{i=1}^{n} |x_j - x_i| / n(n-1), 0 \leq \Delta \leq 2\mu,
\]

and using the Riemann–Stieltjes integral, which covers, as particular cases, both discrete and continuous distributions, we have
where $X$ and $Y$ are identically and independently distributed variables. When $x_1=x_2=\ldots=x_n$, $\Delta = 0$, and when $x_1=x_2=\ldots=x_{x-1}=0$ and $x_n=n\mu$ (the total income), $\Delta = 2\mu$. Since $\Delta$ is a monotonic increasing function of the degree of income inequality, Gini (1912) specified

$$G = \frac{\Delta}{2\mu}, \quad 0 \leq G \leq 1$$

(8)

as an income inequality measure. Equation (8) is known as the Gini ratio or Gini index and it is widely used in theoretical and applied research on income and wealth distributions. Gini (1914) proved the important theorem that $G=\Delta / 2\mu$ is equal to twice the area between the equidistribution line $F(x)=L(x)$ and the Lorenz curve $L(x)$ (see Figure 1). Moreover,

$$G = \Delta / 2\mu = 2 \int_0^\infty (F - L) \, dF = \frac{1}{2\mu} \int_0^\infty x \left[ F(x) - \frac{1}{2} \right] \, dF(x) = \frac{1}{2\mu} \int_0^\infty \left[ \frac{1}{2} - S(x) \right] \, dF(x).$$

(9)

Figure 1
Lorenz curve $L(x)$ and Gini ratio $G$. 

![Lorenz curve and Gini ratio](http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_G000047&goto=B&result_number=658)
For the discrete case, it follows from eqns (6) and (8), that

\[ F(x) = \frac{1}{\mu} \int_0^x \gamma dF(y) G = 2B = 1 - A = 1 - \int_0^1 LdF \]
showing that the welfare function underlying the Gini ratio is a rank-order-weighted sum of the economic units' income shares.

The properties that an income inequality measure must fulfil were first discussed by Dalton (1920). It can be shown (Dagum, 1983, pp. 34–5) that $G$ fulfils the properties of (i) transfer, (ii) proportional addition to incomes, (iii) equal addition to incomes, (iv) proportional addition to persons, (v) symmetry, (vi) normalization, and (vii) operationality.

The properties of an income inequality measure must fulfils first discussed by Dalton (1920). It can be shown (Dagum, 1983, pp. 34–5) that $G$ fulfils the properties of (i) transfer, (ii) proportional addition to incomes, (iii) equal addition to incomes, (iv) proportional addition to persons, (v) symmetry, (vi) normalization, and (vii) operationality.

The Gini ratio is sensitive to transfers to all income levels. In fact, it follows from eqn (10), that a transfer of $h$ dollars from the richer $j$ to the poorer $i$ theorem, without modifying their income ranks, is

$$
\Delta G(j, i; h) = -2 (j - i) h / n(n - 1) \mu > 0, \quad j > i,
$$

therefore $-\Delta G$ is an increasing function of $j-i=F(x_j)-F(x_i)$ and a decreasing function of both $n$ and $\mu$. The maximum reduction of $G$ is achieved when $h=(x_j-x_i)/2$, and is not necessarily given by eqn (11) unless the transfer fulfils certain conditions with respect to the original income ranking of the population.

Often, the Gini ratio is misinterpreted when it is incorrectly claimed that it attaches more weight to transfers to income near the mode of the distribution than at the tails. In particular, the misinterpretation arises when eqn (11) instead of eqn (9) is applied to unimodal distributions when assessing the relative sensitivity of $G$ to income transfers. Consequently, the assumptions supporting the mathematical structure of eqn (11) are ignored.

It follows from eqn (10) that the Gini ratio fulfils the duality principle between the representation of an inequality measure ($I$) satisfying the principle of transfer, i.e. $I=E[V(x)]$, and that of a social welfare (SW) function, i.e. $SW=E[-V(x)]$, where $-V(x)$ is concave, or more generally, S-concave (Berge, 1966). It follows from eqn (9), that two equivalent forms of $V(x)$ in $G=E[V(x)]$ are

$$
V(x) = 2 x F(x) / \mu - 1, \quad \text{and} \quad V(x) = x [2 F(x) - 1] / \mu.
$$

Sen (1974) introduced an axiomatic system for the SW interpretation of the Gini ratio based on the individual income ranking of the population suggested by the structure of eqn (10). Following Sen’s ideas, Kakwani (1980, pp. 77–9) presented a SW interpretation of the Gini ratio as a function of income. Both approaches can be presented in a compact form by making use of the SDF $S(x)=1-F(x)$ and the first moment survival distribution function $S_1(x)=1-L(x)$. In fact, specifying the SW function

$$
SW(X) = E[X \nu(x)]
$$
where \( v(X) \) is a decreasing and differentiable function of \( X \), and making \( v(X) = 2S(X) = 2(1-F(X)) \), i.e., twice the frequency of economic units with income greater than \( X \), we deduce

\[
SW(X) = 2 \int_0^\infty xS(x) \, dF(x) = \mu (1 - G),
\]

which proves Sen’s (1974, p. 410) theorem that the SW function \( 14 \) ranks a set of distributions of a constant total income and population in precisely the same way as the negative of the Gini ratio of the respective distributions, i.e. in reverse order from that by the cardinal value of the Gini ratio. On the other hand, making \( v(X) = bS_1(X) = b[1-L(X)] \), \( b > 0 \) and \( \int_0^\infty v(x) \, dF(x) = 1 \), where \( S_1(x) \) is the income share of the economic units with income greater than \( x \), we deduce

\[
b \int_0^\infty [1 - L(x)] \, dF(x) = b(1 + G) / 2 = 1, \quad \text{and} \quad SW(X) = [2 \int_0^\infty x[1-L(x)] \, dF(x) = \mu / (1 + G),
\]

which also states that the SW function \( 15 \) is a decreasing function of the Gini ratio. The result obtained in eqn \( 14 \) supports Sen’s (1976, p. 384) cogent statement that ‘one might wonder about the significance of the debate on the non-existence of any additive utility function which ranks income distributions in the same order as the Gini ratio’.

The Gini ratio stimulated important contributions such as:

1. (i) The construction of a confidence interval for \( G \). Given a random sample of size \( n \), eqn \( 10 \) is an unbiased estimator of \( G \). However, income distribution data are presented by class intervals, hence Gini (1914) proposed the formula \( G_L = 1 - 2A \), where \( A \) is the area under the Lorenz curve (Figure 1) estimated by application of the trapezoidal approximation to

\[
\int_0^1 l \, dF,
\]

thus underestimating \( G \) because the trapezoidal rule implies that within each interval, income is equally distributed. Gastwirth (1972) derived an upper bound \( G_u \) by maximizing the spread within each income interval, and proposed \( (G_L, G_u) \) as a confidence interval within which a parametric estimate of \( G \) should fall. Dagum (1980a) proved that his confidence interval is a necessary but not sufficient condition to assess a model goodness of fit.

2. (ii) The Gini ratio gives a welfare ranking (weak ordering) of a set of income distributions of a constant mass of income and over a constant population, and a strict partial ordering among the subset of income distributions with non-intersecting Lorenz curves. This conclusion is further supported by eqns \( 14 \) and \( 15 \).

3. (iii) The welfare ranking of income distributions with equal and different means can be obtained via a decision function \( R(G, D) \), where the ratio \( G \) states the preference for less inequality (inequality aversion) regardless of the mean income (so that the partial derivative \( R_G < 0 \)), and the relative economic affluence \( D \) (Dagum, 1980b, 1987) states the preference for more income (poverty aversion), so that the partial derivative \( R_D > 0 \).

4. (iv) Research on the economics of poverty led Sen (1976) to the specification of an axiomatic structure of a new poverty measure as a function of (a) the relative frequency of the poor members of the population, (b) a weighted average of the poverty gap, i.e. the aggregate shortfall from the poverty line of the poor population, and (c) the Gini ratio of
the income distribution of the subpopulation with incomes below the poverty line.

5. (v) Gini (1932) introduced a new coordinate system taking as the abscissa the egalitarian line $F=L$ and as the ordinate the distance between the Lorenz curve and the egalitarian line. Gini thoroughly analysed this new coordinate system and its relation to the $G$ ratio. Kakwani (1980, ch. 7) worked with a similar transformation.

6. (vi) Analysing consumer behaviour in India, Mahalanobis (1960) extended and generalized the Lorenz curve and Gini ratio with the introduction of the concentration curve and ratio, respectively. Other authors such as Kakwani (1980, chs 8–14) made further contributions and dealt with the relationships among the distribution of several economic variables such as expenditures and income after tax, and investigated the degree of tax and public expenditure progressivity or regressivity. If $y=g(x)$ is the function of income that is the object of inquiry, $g(x)$ must be non-negative. For the particular case of $g(x)=x$, the concentration curve and ratio are identical to the Lorenz curve and Gini ratio, respectively. Moreover, if $g(x)$ is an increasing and differentiable function of $x$, i.e. $g'(x)>0$, then the concentration ratio is equal to the Gini ratio for the function $g(x)$.

7. (vii) The decomposition approach disaggregates a population according to some relevant socio-economic attributes and analyses the equality within each subpopulation and between them, and assesses the contribution of each subpopulation to overall inequality. This approach also disaggregates the income variable by source of income such as wages and salaries, self-employment, pension and government transfers. Bhattacharya and Mahalanobis (1967) were the first to deal with the decomposition of the Gini ratio. Several authors made further contributions to this topic, among them Pyatt (1976) and Shorrocks (1983).

demography; distribution of income and wealth; Gini Coefficient; Gini identity; Gini mean difference; Gini, C.; human capital; index numbers; inequality (measurement); internal migration; international migration; statistics and economics

Article

Gini, perhaps best known to economists because of the Gini Coefficient, was born in Motta di Livenza, Italy and died in Rome. He studied at the University of Bologna; his doctoral thesis Il sesso dal punto di vista statistico (1908), defended in 1905, was awarded the Vittorio Emanuele prize for social sciences. Gini distinguished himself as a teacher and a researcher. In 1909 he was appointed an assistant professor of the University of Cagliari, becoming full professor a year later. Gini won a chair at the University of Padova in 1913, then joined the University of Rome in 1925, where in 1955 he was awarded the distinction of emeritus professor. Social scientist and statistician, Gini taught economics, statistics, sociology and demography, making path-breaking contributions to these highly related disciplines. Among them we mention the neo-organicist theory (Gini, 1909; 1924a) that presents a dynamic theory of society in which demographic factors (differential birth rates among social classes and social mobility) play a basic role. In this theory, Gini introduced and analysed self-conservation, self-regulative and self-re-equilibrating mechanisms, thus offering a well-structured anticipation of Wiener's cybernetics, von Bertalanffy's general system theory and modern disequilibrium economics. He provided new insights to the analysis of inter- and intra-national migrations (Gini, 1948) and demographic dynamics (Gini, 1908; 1909; 1912a; 1931). He developed a methodology to evaluate the income and wealth of nations (Gini, 1914a; 1959) including a discussion of human capital, already present in his research on the causes and consequences of international migrations. In this context he specified a model of income and wealth distributions and a measure of income and wealth inequalities (Gini, 1909; 1912b; 1914b; 1955). Gini's research interests motivated important contributions to statistics and economics, such as the Gini identity (1921; 1924b) on price index numbers, the Gini mean difference (1912b), the transvariation theory (Gini, 1916; 1960), the index of dissimilarity (Gini, 1914c) and the Gini...

Coefficient. Gini founded several scientific journals, such as *Metron* and *Genus*, and academic institutions, such as the Institute and Faculty of Statistics, Demography and Actuarial Sciences of the University of Rome; and was the organizer and first president (1926–32) of the Istituto Centrale di Statistica. An extraordinarily prolific writer and thinker, endowed with powerful new ideas that he developed in more than 70 books and 700 articles, Gini was in the 20th century a true Renaissance man.

GIS data in economics

Henry G. Overman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Geographical information systems (GIS) are used for inputting, storing, managing, analysing and mapping spatial data. This article considers the role each of these functions can play in economics. GIS can map economic data with a spatial component, generate additional spatial data as inputs to statistical analysis, calculate distances between features of interest and define neighbourhoods around objects. GIS also introduce economics to new data. For example, remote sensing provides large amounts of data on the earth's surface. These data are of inherent interest, but can also provide an exogenous source of variation and allow the construction of innovative instrumental variables.

Keywords

gerographical information systems (GIS) and economics; spatial data; hedonic analysis

Article

Geographical information systems (GIS) are used for inputting, storing, managing, analysing and mapping spatial data. In this article, we consider each of these functions to help assess the role that GIS can play in economic analysis. Of course, a wide range of software can provide similar functions for quantitative data, so it is the geographical, or spatial, element that separates GIS. That spatial dimension is the focus here. One important aspect of GIS that is not covered is the choice of software. Standard texts, such as Longley et al. (2005, ch. 7), consider the question of appropriate software in some depth. At the outset, note that, while GIS are widely used in business, government and a range of academic disciplines, their application in economics has to date been more limited. The most frequent application in economics is the use of GIS to visualize or map economic data with a spatial component. Most entry-level courses in econometrics begin with a plea to ‘plot the data’ at an early stage of the analysis to help identify trends, outliers and so forth. Much the same could be said of the role of mapping spatial data, and GIS provide a simple and efficient way to do this.

Less common, but arguably more interesting, is the use of GIS storage and management functions to
generate additional data as inputs into further statistical analysis. In the simplest case this will involve using GIS to manage spatial data from a variety of sources. Many of these sources – for example, sampling and census data – will be familiar to economists, others, such as aerial photography and remote sensing data, less so. The spatial nature, or format, of the data will depend on the geographical data model used. The two most common models are raster format (assigning a code to each cell on a regular grid) and vector format (assigning a code to, and providing coordinates for, irregular polygons). GIS provide tools for moving between these different geographical data models. While the methods used to do this are rather intuitive, the devil is in the detail. As with the implementation of pre-packed econometric routines, one should understand the underlying basis of these transformations before proceeding. These issues are covered at depth in most, if not all, of the standard references, and we do not consider them further here.

More generally, it is the ability of GIS to reconcile spatial data from different sources that allows the creation of new data-sets. In the simplest case, this may involve combining socio-economic data from different spatial units – for example, population data from US census tracts with employment data for US zip codes. Many economists will be used to using ready-made concordances (that is, mappings from one set of spatial units to another) for undertaking such data merges. GIS bring the flexibility of allowing users to define their own concordances between different geographical units of observation when faced with data from different sources.

The construction of more ambitious data-sets is possible if one is willing to draw on a range of analytical functions available in the more advanced GIS. GIS can be used to identify whether observations occur at particular locations and, if so, to identify the characteristics of observations at those locations. For example, one of the most frequent applications of GIS in economics to date has been to identify and characterize properties for use in hedonic analysis (see Bateman et al., 2002, for a review). At its most basic, this will simply involve the merging of different data-sets as described above. However, much more complex analysis is possible. Given that GIS data are spatial, a natural use is to measure the distance between observations or between observations and other features of interest. These distances could be physical distances or network distances (for example, along a transport network), or involve some more general concept of social distance.

Observation-to-observation distance calculations have been widely applied in the fields of biology and biomedical sciences through the statistical analysis of spatial point patterns (see Diggle, 2003). Knowing the distance between observations is useful if we think that there may be interactions between them and that the strength of these interactions is mitigated by distance. For example, in industrial organization models of spatial competition the intensity of competition may depend on the distance between firms. Observation-to-observation distances are also useful when the underlying entities are free to choose their location and we want to assess whether there are systematic patterns to those location decisions. For example, the study of localization asks whether firms in a particular industry tend to be spatially concentrated relative to overall economic activity. If they do, one would expect the observation-to-observation distances to be less for firms in that industry than for a randomly chosen set of firms from the economy at large. The increasing availability of geo-referenced economic data suggests that the application of appropriately adapted procedures will become more common in economics (see Duranton and Overman, 2005). Hedonic analysis again provides the most frequent application of GIS to calculate distances of observations from other features. For example, in their study valuing rail access Gibbons
and Machin (2005) use GIS to measure the proximity of properties to rivers, coasts, woodlands, roads, railway lines and airports.

In addition to the calculation of distances, GIS can be used to construct measures of area or to define neighbourhoods (or ‘buffers’) around objects. For example, Burchfield et al. (2006) in their study of urban sprawl use GIS to calculate the percentage of the urban fringe – defined as a 20-kilometer buffer around existing development – that lies above water-yielding aquifers.

These examples cover the main types of spatial analyses that are undertaken to construct spatial data in economic applications, but others are possible and should be covered in any of the standard texts. It should be noted that in advanced GIS these operations can be done both interactively and automatically using batch files (that is, where the user writes a sequence of commands in a file that the computer implements one by one). Both approaches, but particularly the latter, involve fairly large fixed costs in terms of both purchasing software and learning how to implement the relevant procedures. There are other methods for conducting many of these analyses that do not imply the use of GIS. For example, great circle distances can easily be calculated on the basis of latitude and longitude (see Overman and Ioannides, 2004). Whether the fixed cost investment is worthwhile will depend on individual circumstances. The benefits can be substantial. In many circumstances, GIS calculations should be more accurate than short cuts implemented with the use of non-spatial software, and some analysis such as the calculation of areas and buffers is much easier to implement in GIS.

GIS also introduce economics to new sources of data. In particular, remote sensing from either satellite or aerial photography, or digitized geological maps, can provide a huge amount of data on the earth's surface. Early applications using these kinds of data tended to focus on issues arising from natural resource management such as valuing timber yields from forested areas. However, data on land cover and land use (that is, the physical features that cover the land and what those features are used for), soil type, geological and landscape features, elevation and climate are opening up new avenues of research. These data sources allow the description of different features of the economic landscape that one might seek to explain. For example, Burchfield et al. (2006) use remote sensing data to track the evolution of land use on a grid of 8.7 billion 30×30 metre cells covering the conterminous United States and then seek to explain differences in land development patterns across cities. Another example is Rappaport's (2006) study of the role that weather plays in explaining population changes in US counties. The meteorological data that he uses comes from 6,000 meteorological stations and covers 20 winter, summer and precipitation variables. GIS analysis by the Spatial Climate Analysis Surface at Oregon State University applied to this meteorological data allows the construction of weather variables for a two-kilometre grid covering the continental United States.

GIS data also have the potential to contribute to a range of established areas of study, particularly because data on the earth's surface can provide an exogenous source of variation and thus allow researchers to construct instrumental variables using GIS. Some examples should help to make this idea concrete. Hoxby (2000) is interested in whether competition among public schools improves school outcomes. That is, do cities with more school districts have better public schools and less private schooling? The problem that the analysis needs to confront is that, for a city of a given size, better public schools and fewer private schools in a city should imply more school districts. That is, the number of districts is endogenous to public school quality. What is needed is an instrument that should determine the supply of school districts but that is independent of the local public school quality. Hoxby argues
that the number of streams in a metropolitan area provides such an instrument. Cities with a large number of streams end up with more school districts for reasons that are surely nothing to do with public school quality. Hoxby provides a well-known example of the strategy, although not of the use of GIS, as her work is based on the study of detailed paper maps.

Rosenthal and Strange (2005) provide an example of the use of GIS to implement such an instrumental variables strategy. They are interested in whether density of employment helps determine wages. The problem is that higher wages should attract more workers and lead to higher employment densities. That is, density may be caused by wages and not vice versa. Rosenthal and Strange argue that the density of employment will be partly determined by the height of buildings in a location. They point out that the height of buildings is, in turn, partly dependent on the underlying geology of the site. Given that geology should not determine wages directly (they are studying cities, not agricultural production), the underlying geology can be used as an instrument. Locations with a suitable underlying geology can have higher buildings and higher employment density, and should thus have higher wages. Rosenthal and Strange use GIS data on the type of underlying bedrock, seismic and landslip hazard as instruments for the density of employment in their regressions of wages on employment density. Such examples suggest a potentially important role in future work for GIS data as a component in novel instrumentation strategies.

This piece has only skimmed the surface of the potential applications of GIS in economics. As spatially referenced socio-economic data becomes more widely available, it is to be expected that the scope for applications can only increase.

Abstract

Global analysis in economics puts the main results of classical equilibrium theory into a global calculus context. The advantages of this approach are: (a) the proofs of existence of equilibrium are simpler (the main tool is the calculus of several variables); (b) comparative statics is integrated into the model in a natural way; (c) the calculus approach is closer to the older traditions of the subject; and (d) as far as possible the proofs of equilibrium are constructive.

Keywords

Arrow–Debreu theory; calculus of variations; comparative statics; existence of equilibrium; global analysis in economic theory; inverse function theorem; proofs of equilibrium; Sard's theorem; Walras's Law

Article

The goal here is to illustrate ‘global analysis in economics’ by putting the main results of classical equilibrium theory into a global calculus context. The advantages of this approach are fourfold:

1. 1. The proofs of existence of equilibrium are simpler. Kakutani's fixed point theorem is not used, the main tool being the calculus of several variables.
2. 2. Comparative statics is integrated into the model in a natural way, the first derivatives playing a fundamental role.
3. 3. The calculus approach is closer to the older traditions of the subject.
4. 4. In so far as possible the proofs of equilibrium are constructive. These proofs may be implemented by a speedy algorithm, which is Newton's method modified to give global convergence. On the other hand, the existence proofs are sufficiently powerful to yield the generality of the Arrow–Debreu theory.
Only two references are given at the end of this entry, each containing an extensive bibliography with historical notes. The two references themselves give detailed, expanded accounts of the subject of global analysis in economic theory.

Let us proceed to an account of this model. The basic equation of equilibrium theory is ‘supply equals demand’, or in symbols, \( S(p) = D(p) \). Since we are in a situation of several markets, there are several variables in this equation. Equilibrium prices are obtained by setting the excess demand \( z = D - S \) equal to zero and solving. Consider this function \( z \) on a more abstract level.

Suppose that, given an economy of \( l \) markets, or of \( l \) commodities with corresponding prices written as \( p_1, \ldots, p_l \), the excess demand for the \( i \)th commodity is a real valued function \( z_i = z_i(p_1, \ldots, p_l) \) \( p_j \geq 0 \) and we form the vector \( z = (z_1, \ldots, z_l) \). Thus the excess demand can be interpreted as a map, which we take to be sufficiently differentiable, from \( \mathbb{R}^l_+ \) to \( \mathbb{R}^l_+ \), where \( \mathbb{R}^l_+ = \{ p \in \mathbb{R}^l / p_j \geq 0 \} \). An economic equilibrium is a set of prices \( p = (p_1, \ldots, p_l) \), for which excess demand is zero, that is, \( z(p) = 0 \).

Economic theory imposes some conditions on the function \( z \) which go as follows.

First and foremost is Walras's Law, which is expressed simply by \( p \cdot z(p) = 0 \) (inner product). Written out, this is

\[
\sum_{i=1}^{l} p_i \cdot z_i(p_1, \ldots, p_l) = 0
\]

and states that the value of the excess demand is zero. This is a budget constraint which asserts that the excess demand is consistent with the total assets of the economy. It can be proved from a reasonable microeconomic foundation, as can be seen below.

Second is the homogeneity condition \( z(\lambda p) = z(p) \) for all \( \lambda > 0 \). Changing all prices by the same factor does not affect excess demand. This condition reflects the fact that the economy is self-contained; prices are not based on anything lying outside the model.

The final condition is the boundary condition that \( z_i(p) \geq 0 \) if \( p_i = 0 \). This may be interpreted as: if the good is free, then there will be a non-negative excess demand for it.

The following result and its generalizations and ramifications lie at the heart of economic theory.

**Existence**

Suppose that an excess demand \( z \) satisfies Walras's Law, homogeneity, and the boundary condition. Then there is a price equilibrium.

We will give the proof under the additional mild non-degeneracy condition that the derivative of \( z \) is non-singular somewhere on the boundary of \( \mathbb{R}^l_+ \). This proof is based on Sard's theorem and the inverse function theorem, two basic theorems of global analysis.
Consider a differentiable map \( f \) from a set \( U \) contained in \( \mathbb{R}^k \) to \( \mathbb{R}^n \). A vector \( \gamma \in \mathbb{R}^n \) is said to be a \textit{regular} value if at each point \( x \in U \) with \( f(x) = \gamma \), the derivative \( Df(x) : \mathbb{R}^k \to \mathbb{R}^n \) is surjective. A subset of \( \mathbb{R}^n \) is of \textit{full measure} if its complement has measure zero.

\textbf{Sard's theorem}

If a map \( f : U \to \mathbb{R}^n \) is of class (sufficient differentiability \( C^r \), \( r > k - n, 0 \)) then the set of regular values of \( f \) has full measure.

A subset \( V \) of \( \mathbb{R}^n \) is called a \textit{k}-dimensional \textit{submanifold} if for each point, there is a neighbourhood \( U \) in \( V \) and a change of coordinates of \( \mathbb{R}^n \) which throws \( U \) into a coordinate subspace of dimension \( k \).

\textbf{Inverse function theorem}

If \( \gamma \in \mathbb{R}^n \) is a regular value of a smooth map \( f : U \to \mathbb{R}^n \), \( U \subset \mathbb{R}^k \), then either \( f^{-1}(\gamma) \) is empty or it is a submanifold of dimension \( k-n \).

Let us sketch out the proof of the existence theorem. Define the space of normalized prices by

\[
\Delta_1 = \left\{ p \in \mathbb{R}_+^l / \Sigma p_i = 1 \right\}.
\]

A space auxiliary to the commodity space is defined by

\[
\Delta_0 = \left\{ z \in \mathbb{R}_+^l / \Sigma z_i = 0 \right\}.
\]

From the excess demand map \( z : \mathbb{R}_+^l \to \mathbb{R}_+^l \), define an associated map \( \varphi : \Delta_1 \to \Delta_0 \) by

\[
\varphi(p) = z(p) - \varphi^l(p) p.
\]

Note that \( \varphi(p) \) is well-defined (i.e. \( \varphi(p) \in \Delta_0 \)) and also smooth. Note moreover that if \( \varphi(p) = 0 \), then \( z(p) = 0 \), and that \( p \) is a price equilibrium. This follows from Walras's Law as follows. If \( \varphi(p) = 0 \), then \( z(p) = \Sigma z_i(p) p \) and so \( p \cdot z(p) = \Sigma z_i(p) p \cdot p = 0 \). Therefore \( \Sigma z_i(p) = 0 \), since \( p \cdot p \neq 0 \). By the previous equation \( z(p) \) must be zero.

The boundary condition on \( z \) implies that \( \varphi \) satisfies a similar boundary condition. That is, if \( p_i = 0 \) then \( \varphi_i(p) = z_i(p) \geq 0 \).

It is now sufficient to show that \( \varphi(p) = 0 \) for some \( p \in \Delta_1 \). The argument for this proceeds by defining yet another map \( \tilde{\varphi} \) by
\[ \hat{\varphi}(p) = \frac{\varphi(p)}{||\varphi(p)||} \]

where \( E = \varphi^{-1}(0) \) and \( S^{1-2} \) is the set of unit vectors in \( \Delta_0 \).

By definition the set \( E \) is the set of price equilibria, which is to be shown not empty.

Let \( p_0 \) be a price vector on the boundary of \( \Delta_1 \) where the derivative \( D\varphi(p_0) \) is non-degenerate (our special hypothesis implies the existence of this \( p_0 \)). One applies Sard's theorem to obtain a regular value \( y \) of \( \varphi \) in \( S^{1-2} \) near \( \varphi(p_0) \), where \( \varphi^{-1}(y) \) is non-empty.

From the inverse function theorem it follows that \( \varphi^{-1}(y) \) a smooth curve in \( \Delta_1 \), (a 1-dimensional submanifold). From the boundary condition and a short argument which we omit, it follows that this curve cannot leave \( \Delta_1 \).

Since the curve \( \varphi^{-1}(y) \) is a closed set in \( \Delta_1 - E \) and has no end points (the inverse function theorem implies that) it must tend to \( E \). In particular, \( E \) is not empty and therefore the existence theorem is proved.

The above proof is ‘geometrically” constructive in that a curve \( Y = \varphi^{-1}(y) \) is constructed which leads to a price equilibrium. This picture can be made analytic by showing that \( y \) is a solution of the ordinary differential equation ‘Global Newton’, \( d\varphi / dt = \lambda D\varphi(p)^{-1}\varphi(p) \), where \( \lambda \) is \( +1 \) or \( -1 \) determined by the sign of the determinant of \( D\varphi \) \( (p) \). As a consequence the Euler method of approximating the solution of an ordinary differential equation can be used to obtain a discrete algorithm for locating a price equilibrium. By an appropriate choice of steps, \( \pm 1 \), this discrete algorithm near that equilibrium is Newton's Method; thus the appellation ‘Global Newton' for the differential equation.

One would like to understand the process of convergence to equilibrium in terms of decentralized mechanics of price adjustment. Unfortunately the situation in this respect is unclear.

Next we give a brief picture of how global analysis relates to a pure exchange economy. This will allow a microeconomic derivation of the excess demand function discussed above, so that the existence theorem just proved will imply an existence theorem for a price equilibrium of a pure exchange economy. Continuing in this framework one can prove Debreu's theorem on generic finiteness of price equilibria, by putting the structure of a differentiable manifold on the big set of price equilibria. The equilibrium manifold is a natural setting for comparative statics.

A trader's preferences will be supposed to be represented by a smooth utility function \( u: P \rightarrow \mathbb{R} \), where \( P = \{ x \in \mathbb{R}^I, x_i > 0 \} \), is commodity space. The indifference surfaces are those \( u^{-1}(c) \subset P \). We make strong versions of classical hypotheses on this function.

**Monotonicity.** The gradient, \( \text{grad} u(x) \), has positive coordinates.

**Convexity.** The second derivative \( D^2u(x) \) is negative definite on the tangent space at \( x \) of the corresponding indifference surface.
Boundary condition. The indifference surfaces are closed sets in $\mathbb{R}^I$ (not just $P$).

From the utility function, one defines for the individual trader a demand function $f: \mathbb{R}_+^I \times \mathbb{R} \rightarrow P$ of prices $p \in \mathbb{R}_+^I$ and wealth $w > 0$. For this, consider the budget set $B_{p,w} = \{x \in P | p \cdot x = w\}$. Then $f(p, w)$ is the maximum of $f$ on $B_{p,w}$.

One can prove:

**Proposition**: The demand function $f$ satisfies

1. (a) $\text{grad } u(f(p, w)) = \lambda p$, for some $\lambda > 0$
2. (b) $p \cdot f(p, w) = w$
3. (c) $f(\lambda p, \lambda w) = f(p, w)$ any $\lambda > 0$
4. (d) $f$ is smooth.

A pure exchange economy will be a set of $m$ traders, each with preferences as discussed above, associated to utility functions $u_i, i = 1, \ldots, m$ defined on the same commodity space $P$. Also associated to the $i$th trader is an endowment vector $e_i \in P$. At prices $p$, this trader's wealth is the value of his endowment $p \cdot e_i = w_i$. A state is an allocation $(x_1, \ldots, x_m), x_i \in P$ and a price system $p \in \mathbb{R}_+$. Feasibility is the condition:

$$\sum x_i = \sum e_i$$

A kind of satisfaction condition of a state is

(S) For each $i$, $x_i$ maximizes $u_i$ on the budget set

$$B = \{y \in P | p \cdot y = p \cdot e_i\}$$

An economic equilibrium of a pure exchange economy $(e_1, \ldots, e_m, u_1, \ldots, u_m)$ is a state $[x_1, \ldots, x_m, p]$ satisfying $(F)$ and $(S)$.

**Theorem**: There exists a price equilibrium of every pure exchange economy.

The proof goes by applying the previous existence theorem above. Define the excess demand $Z = D - S$ as follows:

$$S(p) = \sum e_i, \quad D(p) = \sum f_i(p, p \cdot e_i)$$
where \( f_i \) is the above defined demand of the \( i \)th trader. One then shows Walras's Law:

\[
p \cdot Z(p) = p \cdot D(p) - p \cdot S(p) = \sum p_i f_i(p, p \cdot e_i) - p \cdot \sum e_i = 0
\]

using (b) of the proposition above.

Use (c) of the proposition to confirm the homogeneity of \( z \). The use of the boundary condition is more technical. But under the rather strong hypotheses, this gives a fairly complete existence proof for a price equilibrium of a pure exchange economy. This existence proof extends to prove the Arrow–Debreu theorem in the generality of the latter's *Theory of Value*.

Global games are a class of incomplete information games where small uncertainty about payoffs implies a significant failure of common knowledge. This allows strategic uncertainty to play a crucial and natural role in pinning down equilibrium play. Introduced in the context of two player, two action games by Carlsson and van Damme (1993), global games have inspired tractable modelling frameworks that have been used in a wide variety of applications. This article reviews the key ideas that have played a role in theoretical analysis and creating useful applied tools.

Article
Complete information games often have multiple Nash equilibria. Game theorists have long been interested in finding a way of removing or reducing that multiplicity. Carlsson and van Damme (1993) (CvD) introduced an original and attractive approach to doing so. A complete information model entails the implicit assumption that there is common knowledge among the players of the payoffs of the game. In practice, such common knowledge will often be lacking. CvD suggested a convenient and intuitive way of relaxing that common knowledge assumption: suppose that, instead of observing payoffs exactly, payoffs are observed with a small amount of continuous noise; and suppose that – before observing their signals of payoffs – there was an *ex ante* stage where any payoffs were possible. Based on the latter feature, CvD dubbed such games ‘global games’. It turns out that there is a unique equilibrium in the game with a small amount of noise. This uniqueness remains no matter how small the noise is and is independent of the distribution of the noise. Since complete information, or common knowledge of payoffs, is surely always an idealization anyway, the play selected in the global game with small noise can be seen as a prediction for play in the underlying complete information game.

The following example illustrates the main idea. There are two players each of whom must decide whether to invest or not invest. Action ‘not invest’ always gives a payoff of 0. Action ‘invest’ always gives a payoff of \( \theta \); but there are strategic complementarities, and if the other player does not invest, then the player loses 1. Thus the payoff matrix is:
Let us first examine the Nash equilibria of this game when $\theta$ is common knowledge. If $\theta < 0$, then ‘invest’ is a strictly dominated action for each player, and thus ‘not invest, not invest’ is the unique Nash (and dominant strategies) equilibrium. If $\theta > 1$, then ‘not invest’ is a strictly dominated action for each player, and ‘invest, invest’ is the unique Nash (and dominant strategies) equilibrium. The multiplicity case arises if $0 < \theta < 1$. In this case, there are two strict Nash equilibria (both not invest and both invest) and there is also a strictly mixed Nash equilibrium.

But suppose the players do not exactly observe $\theta$. Suppose for convenience that each player believes that $\theta$ is uniformly distributed on the real line (thus there is an ‘improper’ prior with infinite mass: this does not cause any technical or conceptually difficulties as players will always condition on signals that generate ‘proper’ posteriors). Suppose that each player observes a signal $x_i = \theta + \varepsilon_i$ where each $\varepsilon_i$ is independently normally distributed with mean 0 and standard deviation 1.

In this game of incomplete information, a pure strategy for player $i$ is a mapping $s_i : \mathbb{R} \rightarrow \{\text{Invest, Not invest}\}$. Suppose player 1 was sure that player 2 was going to follow a ‘threshold’ strategy where she invested only if her signal were above $k$, so

$$s_2(x_2) = \begin{cases} \text{Invest, if } x_2 > k \\ \text{Not invest, if } x_2 \leq k \end{cases}$$

What is player 1’s best response? First, observe that his expectation of $\theta$ is $x_1$. Second, note that (under the uniform prior assumption) his posterior on $\theta$ is normal with mean $x_1$ and variance $\sigma^2$, and thus his posterior on $x_2$ is normal with mean $x_1$ and variance $2\sigma^2$. Thus his expectation that player $j$ will not invest is

$$\Phi\left(\frac{x_2 - x_1}{\sqrt{2}\sigma}\right),$$

where $\Phi$ is cumulative distribution of the standard normal. Thus his expected payoff is

$$x_1 - \Phi\left(\frac{x_2 - x_1}{\sqrt{2}\sigma}\right).$$

and player 1 will invest if and only if (1) is positive. Now if we write $b(k)$ for the unique value of $x_1$ setting (1) equal to 0 (this is well defined since (1) is strictly increasing in $x_1$), the best response of player 1 is then to follow a cut-off strategy with threshold equal to $b(k)$. Observe that as $k \to -\infty$ (player 2 always invests), (1) tends to $x_1$, so $b(k) \to 0$. As $k \to \infty$ (player 2 never invests), (1) tends to $x_1 - 1$, so $b(k) \to 1$. Also observe that if $k = \frac{1}{2}$, then $b(k) = \frac{1}{2}$, since if player 1 observes signal $\frac{1}{2}$, his expectation of $\theta$ is $\frac{1}{2}$ but he assigns probability $\frac{1}{2}$ to player 2 not investing. Finally, observe that (by total differentiation)
so $b(k)$ is strictly increasing in $k$ and we can immediately conclude that there is a unique ‘threshold’ equilibrium where each player uses a threshold of $\frac{1}{2}$.

The strategy with threshold $\frac{1}{2}$ is in fact the unique strategy surviving iterated deletion of (interim) strictly dominated strategies. In fact, a strategy $s$ survives $n$ rounds of iterated deletion of strict dominated strategies if and only if

$$s(x) = \begin{cases} \text{Invest, if } x > b^n(1) \\ \text{Not invest, if } x < b^n(0) \end{cases}$$

where $b^n(k) = b(b(...b(k))))$.

The key intuition for this example is that the uniform prior assumption ensures that each player, whatever his signal, attaches probability $\frac{1}{2}$ to his opponent having a higher signal and probability $\frac{1}{2}$ to him having a lower signal. This property remains true no matter how small the noise is, but breaks discontinuously in the limit: when noise is zero, he attaches probability 1 to his opponent having the same signal.

In this article, I will first report how Carlsson and van Damme’s (1993) analysis can be used to give a complete general analysis of two player two action games. I will then report in turn theoretical extensions of their work and a literature that has used insights from global games in economic applications. This dichotomy is somewhat arbitrary (many ‘applied’ papers have significant theoretical contributions) but convenient.

1 Two-player, two-action games

Let the payoffs of a two-player, two-action game be given by the following matrix:

<table>
<thead>
<tr>
<th></th>
<th>A</th>
<th>B</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>$\theta_1, \theta_2$</td>
<td>$\theta_3, \theta_4$</td>
</tr>
<tr>
<td>B</td>
<td>$\theta_5, \theta_6$</td>
<td>$\theta_7, \theta_8$</td>
</tr>
</tbody>
</table>

Thus a vector $\theta \in \mathbb{R}^8$ describes the payoffs of the game and is drawn from some distribution. For a generic choice of $\theta$, there are three possible configurations of Nash equilibria.

1. There is a unique Nash equilibrium with both players using strictly mixed strategies.
2. There is a unique strict Nash equilibrium with both players using pure strategies.
3. There are two pure strategy strict Nash equilibria and one strictly mixed strategy Nash equilibrium.

In the last case, Harsanyi and Selten (1988) proposed the criterion of risk dominance to select among the multiple Nash equilibria. Suppose that \((A, A)\) and \((B, B)\) are strict Nash equilibria of the above game (that is, \(\theta_1 > \theta_5, \theta_7 > \theta_3, \theta_2 > \theta_4\) and \(\theta_8 > \theta_6\)). Then \((A, A)\) is a risk dominant equilibrium if

\[
(\theta_1 - \theta_5)(\theta_2 - \theta_4) > (\theta_7 - \theta_3)(\theta_8 - \theta_6).
\]

Generically, exactly one of the two pure Nash equilibria will be risk dominant.

Now consider the following incomplete information game \(G(\sigma)\). Each player \(i\) observes a signal \(x_i = \theta + \sigma \varepsilon_i\), where the \(\varepsilon_i\) are eight-dimensional noise terms. Thus we have an incomplete information game parameterized by \(\sigma \geq 0\). A strategy for a player is a function from possible signals \(\mathbf{R}^8\) to the action set \(\{A, B\}\). For any given strategy profile of players in the game \(G(\sigma)\) and any actual realization of the payoffs \(\theta\), we can ask what is the distribution over action profiles in the game (averaging across signal realizations).

**Theorem:** For any sequence of games \(G(\sigma^k)\) where \(\sigma^k \to 0\) and any sequence of equilibria of those games, average play converges at almost all payoff realizations to the unique Nash equilibrium (if there is one) and to the risk dominant Nash equilibrium (if there are multiple Nash equilibria).

This is shown by the main result of Carlsson and van Damme (1993) in cases (2) and (3) above. They generalize the argument from the example described above to show that, if an action is part of a risk dominant equilibrium or a unique strict Nash equilibrium of the complete information game \(\theta\), then – for sufficiently small \(\sigma\) – that action is the unique action surviving iterated deletion strictly dominated strategies. Kajii and Morris (1997) show that, if a game has a unique correlated equilibrium, then that equilibrium is ‘robust to incomplete information’, that is, will continue to be played in some equilibrium if we change payoffs with small probability. This argument can be extended to show the theorem for case (1) (the extension is discussed in Morris and Shin, 2003).

2 Theoretical extensions; many players and many actions

Carlsson and van Damme (1993) dubbed their perturbed games for the two player, two action case ‘global games’ because all possible payoff profiles were possible. They showed that there was a general way of adding noise to the payoff structure such that, as the noise went to zero, there was a unique action surviving iterated deletion of (interim) dominated strategies (a ‘limit uniqueness’ result). And they showed that the action that got played in the limit was independent of the distribution of noise added (a ‘noise independent selection’ result). Their result does not extend in general to many player many action games. In discussing known extensions, we must carefully distinguish which of their results extend.

Frankel, Morris and Pauzner (2003) consider games with strategic complementarities (that is, supermodular payoffs). Rather than allow for all possible payoff profiles, they restrict attention to a one-dimensional set of possible payoff functions, or states, which are ordered so that higher states lead to higher actions. The idea of ‘global’ games is captured by a ‘limit dominance’ property: for sufficiently low values of \(\theta\), each player has a dominant strategy to choose his lowest action, and that for sufficiently high values of \(\theta\), each player has a dominant strategy to choose his highest action. Under these restrictions, they are able to present a complete analysis of the case with many players, asymmetric payoffs and many actions. In particular, a limit uniqueness result holds: if each player observes the state with noise, and the size of noise goes to zero, then in the limit there is a unique strategy profile surviving iterated deletion strictly dominated strategies. Note that while Carlsson and van Damme required no strategic complementarity and other monotonicity properties, when there are multiple equilibria in a two-player, two-action game – the interesting case for Carlsson and van Damme’s analysis – there are automatically strategic complementarities.

Within this class of monotonic global games where limit uniqueness holds, Frankel, Morris and Pauzner (2003) also provide sufficient conditions for ‘noise independent selection’. That is, for some complete information games, which action gets played in the limit as noise goes to zero does not depend on the shape of the noise. Frankel, Morris and Pauzner (2003) show that a generalization of the potential maximizing action profile is sufficient for noise independent selection. This sufficient condition encompasses the risk dominant selection in two player binary action games; the selection of the ‘Laplacian’ action (a best response to a uniform distribution over others’ actions) in many player, binary action games (Morris and Shin, 2003). It also yields unique predictions in the continuum player currency crisis of Guimaeres and Morris (2004) and in two-player, three-action games with symmetric payoffs. Morris and Ui (2005) give further sufficient conditions for equilibria to be ‘robust to incomplete information’ in the sense of Kajii and Morris (1997), which will also ensure noise independent section.
However, Frankel, Morris and Pauzner (2003) also provide an example of a two-player, four-action, symmetric payoff game where noise independent selection fails. Thus there is a unique limit as the noise goes to zero, but the nature of the limit depends on the exact distribution of the noise. Carlsson (1989) gave a three-player, two-action example in which noise independent selection failed. Corsetti et al. (2004) describe a global games model of currency crises, where there is a continuum of small traders and a single large trader. This is thus a many-player, two-action game with asymmetric payoffs. The equilibrium selected as noise goes to zero depends on the relative informativeness of the large and small traders’ signals. This is thus an application where noise-independent selection fails.

More limited results are available on global games without supermodular payoffs. In many applications – such as bank runs – there are some strategic complementarities but payoffs are not supermodular everywhere: conditional on enough people running on the bank to cause collapse, I am better off if I run if few people run and share in the liquidation of the bank’s assets. An important paper of Goldstein and Pauzner (2005) has shown equilibrium uniqueness for ‘bank run payoffs’ – satisfying a single crossing property – with uniform prior and uniform noise. This analysis has been followed in a number of applications. They establish that there is a unique equilibrium in threshold strategies and there are no non-threshold equilibria. However, their analysis does not address the question of which strategies survive iterated deletion of strictly dominated strategies. Morris and Shin (2003) discuss how the existence of a unique threshold equilibrium can be established more generally under a signal crossing property on payoffs and a monotone likelihood ratio property on signals (not required for global games analysis with supermodular payoffs); however, these arguments do not rule out the existence of non-monotonic equilibria. Results of van Zandt and Vives (2007) can be used more generally to establish the existence of a unique monotone equilibrium under weaker conditions than supermodularity.

The original analysis of Carlsson and van Damme (2003) relaxed the assumption of common knowledge of payoffs in a particular way: they assumed that there was a common prior on payoffs and that each player observes a small conditionally independent signal of payoffs. This is an intuitively small perturbation of the game and this is the perturbation that has been the focus of study in the global games literature. However, when the noise is small one can show that types in the perturbed game are close to common knowledge types in the product topology on the universal type space: that is, for each type in the perturbed game, there is a common knowledge type such that type and almost agree in their beliefs about payoffs, they almost agree about their beliefs about the opponents’ beliefs, and so on up to any finite level. Thus the ‘discontinuity’ in equilibrium outcomes in global games when noise goes to zero is illustrating the same sensitivity to higher order beliefs of the famous example of Rubinstein (1989). Now we can ask: how general is the phenomenon that Rubinstein (1989) and Carlsson and van Damme (1993) identified? That is, for which games and actions is it the case that, under common knowledge, the action is part of an equilibrium (and thus survives iterated deletion of strictly dominated strategies) but for a type ‘close’ to common knowledge of that game, that action is the unique action surviving iterated deletion of strictly dominated strategies. Weinstein and Yildiz (2007) shows that this is true for every action surviving iterated deletion of strictly dominated strategies in the original game. This observation highlights the fact that the selections that arise in standard global games arise not just because one relaxes common knowledge, but because it is relaxed in a particular way: the common prior assumption is maintained and outcomes are analysed under that common prior, and the noisy signal technology ensures particular properties of higher-order beliefs, that is, that each player’s beliefs about how other players’ beliefs differ from his is not too dependent on the level of his beliefs.

3 Applications, public signals and dynamic games

Complete information models are often used in applied economic analysis for tractability: the complete information game payoffs capture the essence of the economic problem. Presumably there is not in fact common knowledge of payoffs, but if asymmetries of information are not the focus of the economic analysis, this assumption seems harmless. But complete information games often have multiple equilibria, and policy analysis – and comparative statics more generally – are hard to carry out in multiple equilibrium models. The global games analysis surveyed above has highlighted how natural relaxations of the common knowledge assumptions often lead to intuitive selections of a unique equilibrium. This suggests these ideas might be useful in applications. Fukao (1994) and Morris and Shin (1995) were two early papers that pursued this agenda. The latter paper – published as Morris and Shin (1998) – was an application to currency crises, where the existing literature builds on a dichotomy between ‘fundamentals-driven’ models and multiple equilibrium or ‘sunspot’ equilibria views of currency crises. This dichotomy does not make sense in a global games model of currency crises: currency attacks are ‘self-fulfilling’ – in the sense that speculators are attacking only because they expect others to do so – but their expectations of others’ behaviour may nonetheless be pinned down by higher order beliefs (see Heinemann, 2000, for an important correction of the equilibrium characterization in Morris and Shin, 1998). Morris and Shin (2000) laid out the methodological case for using global games as a framework for economic applications. Morris and Shin (2003) surveys many early applications to currency crises, bank runs, the design of international institutions and asset pricing, and there have been many more since. Rather than attempt to survey these applications, I will highlight two important methodological issues – public signals and dynamics – that have played an important role in the developing applied literature.

To do this, it is useful to consider an example that has become a workhorse of the applied literature, dubbed the ‘regime change’ game in a recent paper of Angeletos, Hellwig and Pavan (2007). The example comes from a 1999 working paper on ‘Coordination Risk and the Price of Debt’ presented as a plenary talk at the 1999 European meetings of the Econometric Society, eventually published as Morris and Shin (2004). A continuum of players must decide whether to invest or not invest. The cost of investing is C. The payoff to investing is one if the proportion investing is at least 1 - θ, 0 otherwise. If there is common knowledge of θ and θ ∈ (0, 1), there are multiple Nash equilibria of this continuum.
player complete information game: ‘all invest’ and ‘all not invest’. But now suppose that $\theta$ is normally distributed with mean $\gamma$ and standard deviation $\tau$. Each player in the continuum population observes the mean $\gamma$ (which is thus a public signal of $\theta$). But in addition, each player $i$ observes a private signal $x_i$, where the private signals are distributed in the continuum population with mean $\theta$ and standard deviation $\sigma$ (that is, as in the example at the beginning of this article). Morris and Shin (2004) show that the resulting game of incomplete information has a unique equilibrium if and only if

$$\sigma \leq \sqrt{2\pi\tau^2},$$

that is, if private signals are sufficiently accurate relative to the accuracy of public signals. This result is intuitive: we know that if there is common knowledge of $\theta$, there are multiple equilibria. A very small value of $\tau$ means that the public signal is very accurate and there is ‘almost’ common knowledge.

This result makes it possible to conduct comparative statics within a unique equilibrium not only in the uniform prior, no ‘public’ information, limit but also with non-trivial public information. A distinctive comparative static that arises is that the unique equilibrium is very sensitive to the public signal $y$, even conditioning on the true state $\theta$ (see Morris and Shin, 2003; 2004; Angeletos and Werning, 2006). This is because, for each player, the public signal $y$ becomes a more accurate prediction of others’ behaviour than his private signal, even if they are of equal precision.

But the sensitivity of the uniqueness result to public signals also raises a robustness qst. Public information is endogenously generated in economic settings, and thus a qst that arises in many dynamic applications of global games in general and the regime change game in particular is when endogenous information generates enough public information to get back multiplicity (Tarashev, 2003; Dasgupta, 2007; Angeletos, Hellwig and Pavan, 2006; 2007; Angeletos and Werning, 2006; Hellwig, Mukherji and Tsyvinski, 2006). This literature has highlighted the importance of endogenous information revelation and the variety of channels through which such revelation may lead to multiplicity or enhance uniqueness.

In addition, these and other dynamic applications of global games raise many other important methodological issues, such as the interaction between the global game uniqueness logic and ‘herding’ – informational externalities in dynamic settings without payoff complementarities – and ‘signalling’ – biasing choices from static best responses in order to influence opponents’ beliefs in the future.

globalization and labour

Richard B. Freeman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The entry of China, India, and the ex-Soviet countries into the world trading system in the 1990s has made globalization an increasingly important driver of labour outcomes across the world. Through trade, capital flows, the spread of technology and education, the world has begun to move towards a truly global labour market. Still, the dispersion of wages for similar work across countries remains high and immigration is the least developed part of globalization, leaving considerable scope for national labour markets, policies, and institutions to affect wages and worker well-being into the foreseeable future.

Article

Globalization – the export and import of goods and services, international capital mobility, labour mobility, and technical knowledge across national borders – connects economies and influences the economic well-being of workers worldwide. Imports reduce the demand for workers in a country by substituting foreign labour, whose work is embodied in the imports, for domestic labour. Exports increase the demand for workers by selling what workers produce to other countries. Since the wages paid for labour differ among countries, firms have sizable incentives to offshore some jobs to foreign countries, including many service sector jobs that have been historically non-tradable. Capital mobility
globalization and labour: The New Palgrave Dictionary of Economics

changes the capital stock with which workers operate, raising or lowering demand for labour. Immigration, business trips, international study and tourism affect the supply and demand for labour. And, most important of all, the flow of knowledge across borders allows countries to improve their technical and economic prowess and operate along the global production possibility frontier even when they lack the scientific base to expand the frontier. Although economic analyses generally treat trade in goods and services, capital flows, labour flows, and the transfer of knowledge separately, these four facets of globalization have feedbacks and connections that help determine their impact on the economy and on the work force.

At the end of the 20th century globalization became a more powerful driver of labour market outcomes than ever before. The collapse of Soviet Communism, China's shift to market capitalism and India's market reforms and entry into the global trading system produced a single economic world based on capitalism and markets. Before those changes, the global economy encompassed roughly half of the world's population – the advanced countries, Latin America, the Caribbean, Africa, and some parts of Asia – while the other half lived in separate economic spaces. Workers in the United States and other higher income countries and in market-oriented developing countries did not face competition from low-wage Chinese or Indian workers nor from workers in the Soviet empire. The entry of these economies into the world trading system in the 1990s increased the global labour pool from approximately 1.46 billion workers to 2.93 billion workers – 'the great doubling' (see Freeman, 2005a; 2005b).

As documented in Freeman (2006, pp. 150–1) and data given on the International Monetary Fund (IMF) website, all aspects of globalization grew at the turn of the 21st century. World trade increased relative to world GDP so that world exports rose to 27 per cent of world GDP in 2005 compared to just 12 per cent of world GDP in 1970. Foreign direct investment, which had been 2–3 per cent of global gross capital formation in the 1970s rose to 7–20 per cent of gross capital formation in the 1990s–2000s. The share of foreign equities in investors’ equity portfolios rose from negligible numbers to about 15 per cent in the early 2000s. Immigration from developing countries to advanced countries increased so that in 2000 8.7 per cent of the population in the high income countries had been born elsewhere. The single biggest recipient of immigrants was the United States, where the share of immigrants nearly tripled from 1970 to 2005 and where roughly one in five workers aged 25–39 was foreign-born. As for the transfer of knowledge, university enrolments grew rapidly worldwide and multinationals moved production to developing countries. China, in particular, made rapid gains in measures of technological prowess. According to the Georgia Technology Policy and Assessment Center, between 1993 and 2005, China more than tripled its rating in technological standing (Porter et al., 2006, Table 3).

A comparison of the different facets of globalization indicates that the ratio of immigrants to the world work force is lower than the ratio of trade to goods production and international capital flows to activity in capital markets, which suggests that immigration is the least developed part of globalization. To some extent, this may reflect the greater personal cost in moving from one country to another than to ship goods or capital across borders. But there is a political economy reason as well. Even countries committed to freer trade and capital mobility do not allow for free immigration.

Economists use two types of models to analyse the effects of globalization on economic performance and the well-being of workers. They use the basic Heckscher–Ohlin model of comparative advantage to analyse trade between advanced countries and developing countries. This model takes country factor endowments (labour skills, natural resources, capital) as given and examines how these differences affect trade, capital flows, and labour flows, and through them prices, wages, and returns to capital. In
this model trade and factor mobility are substitute ways to reduce the economic effects of differing factor endowments and thus to reduce price and wage differences across countries. Restrictions of trade induce capital or labour flows that substitute for the restricted trade, and conversely restrictions on factor mobility induce trade (Mundell, 1957).

To analyse trade among countries with similar levels of economic development, economists use Ricardian models of trade. These models treat differences in technology as the fundamental determinant of trade and factor flows and examine how investments in technology create comparative advantage. Factor mobility magnifies differences in factor endowments because labour and capital move to economies where the technological advantage creates greater demand for them. Trade and factor mobility are complements in the sense that a technologically advantaged sector which uses, say highly skilled labour, will attract highly skilled immigrants to help it expand. Because factor endowments and technology differ across countries and change over time, both sets of models are needed to make sense of globalization and labour.

When factor endowments differ

If one identifies skilled labour, unskilled labour, capital, and natural resources as the relevant factors of production, trade patterns between advanced and developing countries fit the Heckscher–Ohlin model to a first approximation (Debaere, 2003, gives a favourable reading of the empirical validity of this model, while Trefler, 1995, is more critical). Countries with abundant skilled labour, such as the United States, export goods produced by skilled workers, and import goods made by low-skill labour, while countries with natural resources export those resources and import goods and services made with other inputs. But Heckscher–Ohlin models are silent on the huge volumes of trade among advanced countries with similar factor endowments and on the huge volumes of trade within industries (see Ruffin, 1999).

In addition, the pattern of factor flows is not consistent with the Heckscher–Ohlin model. Unskilled labour migrates from developing countries, where it is relatively abundant, to advanced countries, where it is relatively scarce, as the model predicts, but skilled labour also migrates to advanced countries, while it should move in the other direction. The brain drain, which is a sizable part of immigration, magnifies differences in factor proportions across countries, and thus creates a problem for analyses that view factor flows as responses to factor endowments.

The model also has predictions about the impact of globalization on factor prices that do not fit reality. It predicts that trade and factor flows will lower the relative returns to scarce factors and reduce the returns to abundant factors. This implies that globalization should increase wage differentials and inequality in advanced countries and reduce wage differentials and inequality in less advanced countries.

Globalization is associated with rising inequality in advanced countries, which is consistent with the model, but it is also associated with rising inequality in many developing countries, which is inconsistent with the model. (For a review of studies showing rising wage differentials in developing countries associated with globalization, see Goldberg and Pavcnik, 2007.) One explanation for this is that the skilled workers in the developing countries are more comparable in their skills to the unskilled workers in the advanced countries, so that when the developing countries export products previously made by the unskilled workers in advanced countries, demand for skilled workers in developing countries is increased. But other factors may be at work as well (see Zhu and Trefler, 2005), so there is no clear
resolution to this surprising pattern.

**Wage and factor price equalization**

Goods and factor flows motivated by national differences in factor endowments should reduce the cross-country dispersion of prices, the cost of capital and the wages of comparable workers. The factor price equalization theorem predicts that under specified conditions, trade alone will equalize factor prices. While some trade theorists dismiss factor price equalization as a theoretical curiosum, the logic of globalization dictates market pressures towards equality of wages as well as other prices across country lines.

In fact, the prices of many goods and services differ only moderately across countries. For instance, in 2004 the price of McDonald's Big Mac sandwich showed a narrow distribution across countries. The 80th percentile of Big Mac prices among 65 countries was 2.65 dollars while the 20th percentile of Big Mac prices was 1.40 dollars – a 1.9:1 spread (Freeman, 2006, p. 151). Similarly, estimates of international differences in the cost of capital show a ratio of costs at the top 25th percentile of countries to costs at the bottom 25th percentile of 1.43. This averages estimates from five different sources from Hail and Leuz (2004, Table 1). By contrast, the variation of wages in the same occupation is much greater. The 1998–2002 occupational wages around the world data file shows that wages for the country at the top 20 per cent point of the earnings distribution of countries for a given narrowly defined occupation are about 12 times the wages in the country at the bottom 20 per cent point of earnings distribution, if one uses exchange rates to compare currencies, and four to five to one if one compares currencies with purchasing power parity price indices – that is, price indices of different currencies based on a given basket of good that differ from exchange rates in part due to the different prices of non-tradables across countries (Freeman and Oostendorp, 2001). While part of the cross-country variation in wages for workers in the same occupation reflects differences in the education and skill of workers in the same occupation in advanced and developing countries, this cannot explain the wide variation in the earnings of, say, barbers in low-income countries and in high-income countries. The offshoring of computer programming and of call-centre work to India in the 2000s highlighted the fact that in some occupations workers in low-income countries have similar skills to those in more advanced countries. What differs are the wages paid across countries.

That the cross-country dispersion of wages is greater than the cross-country dispersion of prices or of the cost of capital suggests that globalization has had a smaller impact on the price of labour than on the prices of other factors. One possible reason for this is that, as noted earlier, international migration is a quantitatively smaller facet of globalization than trade or the international flow of capital. This explanation requires that the direct effect of trade on the prices of goods and services and the direct effect of capital flows on the cost of capital is greater than their indirect effect on wages.

**The labour standards debate**

Globalization has made labour standards – workplace safety, freedom from discrimination, rights to unionize, hours and wage regulations – in developing countries a major issue for the international community. Human rights activists in advanced countries campaign to get multinational firms to
implement better labour conditions in their plants and in those of their subcontractors in developing countries. The activists contend that consumers are willing to pay for the higher standards through higher prices and will avoid products made under bad conditions. There is indeed evidence that consumers will pay a bit more for ‘fair trade’ products and will shun products made under poor conditions (see Elliot and Freeman, 2003; Hiscox and Smyth, 2005). In response to activist pressures, many multinationals have developed and implemented codes of conduct for their operations in developing countries. Although activists fear that low standards in developing countries will produce a global race to the bottom in standards, labour standards have risen in advanced countries during the period of rapidly increased trade with developing countries and in many developing countries as well. One indication of this is that advanced and developing countries have signed on to more International Labor Organization conventions during the period of globalization than ever before. Even the poorest countries have sought to reduce the use of child labour (see Elliot and Freeman, 2003).

Some advocates of free trade regard the activist pressure for improved labour standards in developing countries as disingenuous protectionism. ‘The talk of “exploitation”, failure to pay a “living wage”…is little more than cynical manipulation of our moral instincts and an obfuscation of the reality to pursue our economic interest’ (Bhagwati, 2000). ‘The demand for linkage between trading rights and the observance of standards with respect to the environment and labour would seem to arise largely from protectionist motivation’ (Srinivasan, 1994, p. 36). But the activists are not rival producers of imported products who aim to move production from developing countries to advanced countries. Rather, they are students, consumers, and members of non-governmental organizations who seek to organize retail markets so that consumers pay higher prices for items made under better conditions. Their motivation is intrinsic, not pecuniary interest.

What troubles free trade advocates is the danger that standards will impair the comparative advantage of developing countries. Motives aside, even policies intending to help workers in developing countries could harm them if those policies were so costly that they reduced the cost advantage of developing countries to expand in some low-wage labour-intensive sectors. However, the huge gap in labour costs between countries suggests that improved standards cannot threaten comparative advantage. In any case, part of the cost of standards falls on workers who prefer higher standards to lower standards; and part will be paid by consumers who want products made under good conditions. Some standards that raise costs to firms, moreover, benefit developing economies over the long run. Child labour laws, and school attendance laws, for instance, increase human capital formation; while occupational safety regulations reduce injuries and fatalities that may burden a country's medical or welfare system. As long as countries have flexible exchange rates, moreover, they can buy whatever labour standards they want without suffering economic disaster. If Brazil chooses to spend more on occupational health and safety than China, Brazilian firms will be at a competitive disadvantage at a given exchange rate. But the Brazilian currency will depreciate in relation to the Chinese currency, and all Brazilians will bear the cost of the health and safety standards through the higher cost of imports. Brazilian industries that spend a lot more to meet health and safety standards will contract as Brazil's comparative advantage shifts to industries that do not need to spend much more. Thus, globalization does not restrict national choices in labour standards or in other areas of social choice.
In a truly global labour market the same worker would earn roughly comparable real pay in different countries, as measured in the purchasing power parity price indices that give a more realistic comparison of living standards across countries than do comparisons of earnings based on exchange rates. The labour market at the outset of the 21st century was far from a single global market. Workers from a low-income country could make more than six times the earnings in their home country by immigrating to an advanced country (see Freeman, 2006). Why? Because the advanced country had higher capital–labour ratios, superior infrastructure, greater legal protections of property and persons, and more advanced technology, which raised productivity compared to productivity in the immigrant's native country. The differences in technology that affect earnings should be thought of in broad terms as including differences in organizational structure and business practices as well as differences in engineering or scientific technology. They include the economies of scale that give ‘first mover’ advantages to the firm or country that produces a good first. Countries with a comparative advantage in a sector – higher productivity in relation to other sectors compared to trading partners – will export output of that sector and import goods and services from sectors in which its trading partner has a comparative advantage. The sector with comparative advantage will expand, raising the wages of the factors that it uses the most and attracting those factors from the country and the rest of the world. If an advanced country has comparative advantage in, say, high tech that uses many computer scientists, persons with computer science degrees will immigrate to the country and strengthen its advantage in that sector. Trade and mobility magnify differences in factor endowments. Since countries will shift resources towards sectors in which they have comparative advantage, world output will rise, and so too will the wages of workers. The ‘North–South’ model provides a platform for analysing trade between advanced countries (North) and developing countries (South) when investment in technology creates comparative advantage. In this model the North's advantage is in innovative high-tech products because it has many scientists, engineers, and other high-skilled workers, while the South's advantage is in producing standard products that use less skilled labour. The wages of ordinary workers in the North exceed those of workers in the South because the North earns a monopoly rent on technological innovation. The wage advantage is higher the greater the rate of technological innovation in relation to the rate of knowledge transfers to the South. The result is an industry or product life cycle that begins with an innovation in the North and ends with production in the South. Krugman (1979) gives a clear exposition of this model.

When technology creates comparative advantage, the productivity advances in one country can affect the economy of a trading partner positively or negatively depending on whether the advance occurs in goods or services that the trading partner exports or goods/services that it imports. If a trading partner improves productivity in an import, this will reduce the cost of production and the price of the import, which benefits the country that imports the good as well as (in most cases) the exporter. But if a trading partner improves technology in an export, this can harm the exporting country, just as an improved technology in a competitor can harm a firm. The increased supply of an exported good will drive down its price and thus the income of the country that originally dominated the production.

As a result, when countries make their comparative advantage by investing in skills or technology rather than having comparative advantage set by factor endowments there can be situations of ‘conflicting national interests’ in trade, as stressed by Gomory and Baumol (2000). If a foreign competitor gains comparative advantage in industries that have desirable attributes – that employ large numbers of highly educated and skilled workers or offer great opportunities for rapid technological advance – the lead
economy will have to shift resources to less desirable sectors – and lose some of the advantages it had gained from trade. Applying these analyses to debates over offshoring and technological transfer in the United States, Paul Samuelson reminded trade economists that while the spread of technology around the world raises world output and productivity it need not be in the interest of the technological leader (Samuelson, 2004).

Globalization/labour debates: human resource leapfrogging

The rapid growth of higher education in populous developing countries, notably China and India, challenges the assumption that advanced countries inevitably have comparative advantage in high-tech sectors. The share of scientific papers from Asia has risen substantially, due largely to increased scientific activity in China, which is moving to the forefront of science and technology. Digitalization of work has led to offshoring computer-related work, particularly to India. To take advantage of low-priced scientists and engineers in these countries, multinational firms have established research centres there. While the South has far fewer scientists and engineers per capita than the North, it can compete in high tech because success at the technological frontier depends on the absolute number of scientists and engineers in an area, not simply on the number in relation to the total work force. A country like China or India can have proportionately fewer scientists, engineers, and entrepreneurs per capita than an advanced country but still have absolutely more of these workers available at lower wages than the advanced country. By producing numerous graduate scientists, engineers, and other university specialists and deploying them in the high-tech innovative sectors that the advanced countries had viewed as their birthright, the populous developing countries can move to the technological frontier through ‘human resource leapfrogging’.

This does not mean that advanced countries lose when developing countries raise their technological prowess and economic competitiveness. The increased supply of highly educated workers around the world should expand the world's production possibility frontier rapidly, which will benefit all countries. In addition, the lower prices of high-tech goods and services produced in developing countries, such as PCs from China and call centre technical advice from India, benefit all consumers. But increased competition from low-wage countries in sectors where advanced countries have had comparative advantage can reduce or eliminate their advantages in those sectors. Comparative advantage in high-tech or most other sectors is not the birthright of any country. Globalization of technological progress will raise world output and income. It is likely to benefit workers in developing countries more than those in advanced countries, reducing global income inequality. It could lower the living standards or rate of growth of the living standards of advanced country workers for whom workers in low-income countries are good substitutes.

Does globalization rule the roost? Will it dominate labour outcomes in the future?

In 1995 I posed the question ‘Are your wages set in Beijing?’ to direct attention towards the impact of globalization on wages in advanced countries (Freeman, 1995). My answer then, and now, is negative. The dispersion of wages for similar work around the world documented earlier shows that globalization does not rule labour markets. National labour markets, and the policies and institutions that unions,
firms, and countries use to regulate those markets, affect wages and worker well-being independent of what happens in other countries. But the pressures of globalization on wage setting around the world will rise as the highly populous economies of China and India increase their share of the global economy. Globalization makes what happens in Beijing and Calcutta and Rio and Warsaw and so on, important drivers of labour market developments worldwide. Still, the persistence of variation in labour market outcomes across the states in the United States, where there are no restrictions on goods, factor flows, or knowledge flow, suggests that, even though global economic forces are likely to increase their impact on wages and other outcomes, they will not ‘rule the roost’. There will remain space for variation in labour markets among countries just as there is for regional and local markets within countries.

Globalization and the welfare state are commonly considered to be related; more precisely, many people believe that globalization exerts a negative influence on the size and scope of the welfare state. This contention has been examined in an impressive number of scholarly investigations. Since globalization has far-reaching effects on income distribution, this issue has, however, attracted not only social scientists but also all kinds of political entrepreneurs: well-meaning public figures concerned with the globalization-induced social dynamic, political demagogues vying for political support, and even street rioters.

The worries of the well-meaning objectors to global economic integration originate in the conviction that globalization will bring about a loss of power of the nation states in general. They argue that liberalization of international transactions renders tax bases increasingly footloose, which induces a global tax race to the bottom and, as a consequence, jeopardizes the nation states' ability to finance welfare state activities. This downward pressure on the supply side of public welfare programmes, depending on the viewpoint of the observer, reduces the efficiency of benevolent governments and/or disciplines egoistic governments that transform discretionary power into political support. At any rate, the so-called efficiency or discipline effect of globalization tends to reduce the size and scope of government welfare programs.

The opponents of globalization ignore, however, the demand side of the political market, which derives from governments' political support maximization motives to redistribute the gains from globalization; that is, the losers from globalization, in particular workers who become exposed to higher labour market risks, will to some extent be compensated via an extension of social welfare programmes. Reviving Ruggie's (1982) notion of ‘embedded liberalism’, Rodrik (1998) interprets this kind of compensation as an exchange of social insurance in return for public support for openness. The so-called ‘compensation’ effect thus counteracts the ‘efficiency’ effect, implying that, from a theoretical point of view, the total effect of globalization on the welfare state remains ambiguous.

The interaction of the two effects is summarized in Figure 1. The marginal benefit (in terms of political support) of welfare state expenditures decreases, whereas the marginal cost increases. Political support is maximized at the level where the MB and the MC curves intersect. A deepening or widening of economic integration now increases the marginal cost of supplying social welfare programmes and also increases the marginal benefit via increased demand, thereby shifting the two curves upwards (MC0 to MC1 and MB0 to MB1).

Whether the resulting efficiency effect of globalization dominates the compensation effect or vice versa is a matter that can be resolved only by empirical research.

Welfare state expenditures
The first-generation literature on the globalization–welfare state nexus which appeared in the 1990s focused on this task of estimating globalization's net influence on government spending. Surveying this literature, Schulze and Ursprung (1999, pp. 345–7) arrive at the following conclusion:

The general picture drawn by the few econometric studies available thus far does not lend any support to any alarmist view. At an aggregate level, many of these studies find no negative relationship between globalization and the nation states' ability to conduct independent fiscal policies. No strong evidence points to a significant globalization-induced change of the level of public spending. But also accustomed expenditure patterns do not appear to have changed in the course of globalization. This may be due, however, to a lack of studies using strongly disaggregated public expenditure data.

In the meantime, many scholars have indeed taken up this implicit challenge and have used more disaggregated data; others have analysed specific groups of countries, have refined the empirical methods, or have investigated non-economic routes of influence. To foreshadow the main result of the second-generation literature, no unambiguous consensus has thus far emerged from these investigations. Instead, the new approaches have painted a multi-faceted picture that does not lend itself to a straightforward overall interpretation. Common to all empirical investigations is, however, the general research strategy which implies – usually in the framework of a panel data-set – the regression of some measure of welfare state activities on a set of explanatory variables which include globalization-related determinants, domestic economic and/or demographic determinants, and variables describing the domestic political–institutional setting.

As far as the dependent variable is concerned, one observes that measures of the size of the government sector (such as the ratio of total government expenditures to GDP) have been replaced by variables that better describe the size or scope of welfare policies; examples are expenditures on health, education, and social security (usually as a share of GDP) or net replacement rates of unemployment insurance. In addition, it has been argued that year-to-year policy adjustments and discontinuous policy shifts may be governed by different forces. Hicks and Zorn (2005), for example, identify welfare retrenchment events in OECD countries and find that they are not induced by direct globalization effects. They do, however, dampen subsequent globalization-induced increases of social spending. Factors that promote welfare policies may therefore (by doing so excessively and in ways that aggravate the policy's negative by-products) build up pressures for sudden policy reversals. Another novel way of looking at the welfare-state implications of globalization proposed by Hays, Ehrlich and Peinhardt (2005) bridges the micro–macro divide in the traditional literature by investigating the extent to which trade policy stances of voters depend on the welfare policies conducted in their respective home countries. It transpires that protectionist sentiments of workers in import-competing industries can indeed be reduced with welfare policies that provide some kind of insurance against the labour market risk that is supposed to be associated with international exposure.

The crucial independent variables capturing the influence of globalization have also become more precisely tailored over time. Traditional measures of globalization, such as total international trade (imports plus exports) as a share of GDP, financial deregulation indices, and foreign direct investment (FDI) as a share of GDP, are not sufficiently focused on the dark side of globalization which gives rise to compensatory demands. Better suited for this purpose are, for example, imports as a share of GDP, imports from low-wage countries as a share of total imports, and outward FDI flows as a share of GDP. A further refinement of these measures is based on the argument that flow shares are biased with respect to country size because small countries are by nature more open than larger ones. Bretschger and Hettich (2002) have therefore decided to work with a measure of trade openness which controls for country size. A more substantial refinement consists in taking non-economic dimensions of globalization into account. Dreher (2006) derives indices of three dimensions of globalization – namely, economic, political and social globalization – and arrives at the result that none of the three dimensions appears to have a significant impact on overall and social expenditures. Jahn (2006), in a similar attempt, introduces diffusion processes in order to capture globalization forces that transcend purely economic channels of influence.

Diffusion mechanisms allow for learning and emulation processes which, in a setting of deepening globalization, become increasingly important since political-economic integration allows all political agents to better compare domestic policy efficiency with policy efficiency pursued in other countries. The diffusion variable employed in Jahn's study measures – for each country – the weighted average of the dependent variable of the other countries, where the weights represent closeness in terms of the respective bilateral trade intensity. This diffusion variable has a statistically significant influence on the social expenditure behaviour in the 16 OECD countries analysed, which may be interpreted to imply that globalization, via political yardstick competition, facilitates the adoption of best-practice policies.

Even though most of the second-generation studies do not support the efficiency hypothesis, there are notable exceptions. Garrett and Mitchell (2001), in particular, have claimed that 'year to year' increases in total trade are associated with less total government spending, less government consumption and lower security benefits as a share of GDP. This result has been construed to imply a preponderance of the efficiency effect over the compensation effect even though most of the financial globalization indicators employed in this particular study actually do not point into this direction and the share of low-wage country imports even appears to have a positive, compensatory, effect. More momentous than the daring interpretation of the study's results is, however, the critique that has been levelled against the econometric modelling. A whole series of recent studies have taken this controversial study as a starting point for scrutinizing the appropriate specification of panel data regression models of welfare state development (Kittel and Winner, 2005; Plümper, Manow and Troeger, 2005; and Podesta, 2006). What has unambiguously emerged from this deliberation is that panel data inferences react in a very sensitive manner to the chosen model specification and that the controversial Garrett–Mitchell estimates are driven by misspecifications. Re-estimating the relationship using the original variables but statistically better...
behaved models reveals that changes in government spending are primarily driven by the state of the domestic economy. This finding is in line with the influential study by Iversen and Cusack (2000), who do not find any relationship between globalization and the level of labour-market risk, presumably because trade not only increases this risk via specialization, but at the same time also diversifies it across a larger market, implying that the net effect of increased trade exposure remains ambiguous. According to Iversen and Cusack, most of the uncertainties in modern societies originate from dislocations caused by technologically induced structural transformations, and it is this transformation towards deindustrialization that has spurred electoral demands for welfare state compensation and risk sharing. Demand for welfare state extensions thus appear to be largely home-made.

Most studies investigating the nexus between globalization and the welfare state focus on OECD countries, that is, countries that were blessed with democratic government in the period under review. Only recently have scholars begun to concern themselves with developing countries, which requires that one squarely address the crucial role of the political regime and the labour market institutions in accommodating the demand for welfare policies. After all, defending welfare benefits under the pressures of globalization is likely to be much easier in countries honouring civil and political rights than in countries in which the losers of globalization are politically powerless and poorly organized. Most studies indeed confirm that democracies are more responsive to compensation demands than autocratic regimes. Avelino, Brown and Hunter (2005), to name a prominent study on Latin America, arrive at a somewhat more differentiated conclusion: they confirm that democracies have a strong positive influence on social spending, but also point out that it is questionable whether this influence is reinforced by globalization-induced social insurance demands. Further analysis is needed to obtain a better understanding of how globalization and regime effects interact.

Even though the globalization–welfare state nexus has been the subject of intense empirical research since the early 1990s, the underlying relationship has remained rather elusive. To be sure, the second-generation studies corroborate the conclusions that have been drawn from the earlier studies, that is, the evidence certainly does not point towards an alarming globalization-induced ‘race to the bottom’. The available signs of compensatory welfare policy measures are, however, rather weak and inconclusive. What does this mean in the final analysis? Some scholars believe that globalization simply does not matter. Swank (2002, pp. 119–20), for example, squarely declares that ‘the conventionally hypothesized globalization dynamics are absent. Internationalization has no systematic impact on welfare policy change.’ On the other hand, one could argue that globalization gives rise to significant efficiency and compensation effects which, however, neutralize each other. In order to discriminate between these two views the macro-perspective that characterizes the bulk of the relevant literature does not seem to be helpful. Future research, therefore, will have to undergo a reorientation.

The leading scholars in the field no longer believe that globalization and the welfare state represent low-dimensional phenomena which are linked by a simple causal relationship. The ambiguous empirical results are often attributed to the fact that the nexus between globalization and the welfare state is more complex than the mechanism illustrated in Figure 1 suggests. This view implies that future research needs to focus even more on the interaction at the level of very specific globalization forces and on social policy responses which are just as narrowly specified. Nobody expects, however, that these micro-level interdependencies will add up to a sufficiently consistent macroeconomic response that would allow ostentatious claims of the sort that stimulated the early literature.

A second aspect that is likely to influence future research concerns econometric methods. To be sure, much progress has been made in perfecting empirical methods, but the struggle for better methods has certainly not yet come to an end. This is not meant to imply that the ambiguity of the results will disappear when proper empirical methods are applied across the board. On the other hand, it cannot be denied that methodological shortcomings may well be responsible for some of the observed discrepancies between studies that analyse closely related issues.

A final point concerns the fact that the empirical models employed almost invariably rest on ad hoc postulates. Even though political economy has become an integral part of mainstream economic thinking, theoretical arguments concerning the identity and the stakes of the involved political agents and a detailed investigation of how the strategic interaction of these interests shapes the ongoing political process have not found their way into the predominantly empirical literature on welfare state development. Investigations which are firmly based on political economy arguments would not only guide the empiricist in identifying worthwhile associations but also shift the focus of the discussion from addressing questions associated with political recriminations back to issues which are more securely rooted in the traditional scholarly discourse.

globalization

William Easterly
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The passion that surrounds the vague term ‘globalization’ is best seen as a proxy for the long-standing debate about free-market capitalism. The zero-sum mindset, the difference between Pareto superiority and common norms of fairness, and the belief that all outcomes are caused by an intentional agent often cause communication problems between non-economists and free-market economists, who themselves often exaggerate what ‘free-market reforms’ can accomplish and endorse overly ambitious programmes of change (‘shock therapy’), underestimating problems of transition and the second best. Economists could try to understand the protests against ‘globalization’ rather than dismissing them out of hand.

Article

‘Globalization’ is a word that gets both its proponents and opponents very agitated. But what exactly is it? What is the globalization debate really about? The answer is that the globalization debate is about a surprisingly large number of issues, including some that lie outside of economics. A non-exhaustive list of issues derived from a reading of the writings of both economists and non-economists (see a very partial list of references in the bibliography) follows:

1. Liberalization versus regulation of international trade, capital movements, and migration.
2. Market imperfections that arise with (either domestic or international) goods markets, capital markets, privatization, macroeconomic crises, intellectual property rights, and so on.
3. Evaluation of the performance of the International Monetary Fund (IMF) and the World Bank, including in particular their policy prescriptions (the ‘Washington Consensus’, ‘shock therapy’, or ‘structural adjustment’).
4. Effects of freer trade and capital movements on rich country workers (‘out-sourcing’) and on poor country workers (‘sweatshops’).
5. Extreme world inequality and poverty.
6. Capitalism (‘neoliberalism’) versus alternative systems.
7. Westernization/Americanization versus local culture.
8. Unequal distribution of political power between the West (both Western governments and corporations) and the Rest.
10. Western imperialism and military intervention in the rest of the world.
Arguably, the vagueness of a term that includes at least ten separate debates has done a disservice to economic and political debate, causing many ‘globalization’ debate participants to think they disagree with people with whom they really agree, or to think they agree with people with whom they really disagree. It also explains some of the difficulties in communication between economists and non-economists about globalization, because the two groups really have different debates in mind. Economists (including those identified as ‘globalization critics’) have focused largely on issues 1–5, while the non-economists – though not ignoring 1–5 – seem to have something else in mind like 6–10.

For example, Dani Rodrik (1997) and Joseph Stiglitz (2002), who have both acquired a reputation as globalization critics by focusing mainly on issues 1–3, are embraced eagerly by some ‘globalization protesters’ whose main issue is really 6: the critique of capitalism (sometimes called ‘neoliberalism’). This is not meant as a criticism of Rodrik and Stiglitz; rather, it highlights the confusion that exists when two prominent mainstream economists who are talking about tinkering with and fine-tuning capitalist markets are seen as allies by those who are opposed to free market capitalism.

This article can hardly do justice to the complexity of all of these debates, nor is there much hope of getting everyone to discontinue the almost criminally vague use of the term ‘globalization’ in debate. The article argues that most of the energy in the debate indeed comes from the clash of attitudes – enthusiastic and antipathetic – towards capitalism and free markets.

This article thus focuses on two key themes about the globalization debate. First, I give some intellectual history of the debate about capitalism (issue 6), which will place in perspective some of today’s globalization debate including that by the non-economists. This has the objective of dispelling some of the puzzelement that many economists feel about the sound and fury surrounding globalization, through realization that it is partly just another manifestation of a long intellectual debate about capitalist free markets, which economists have been engaged in for decades if not centuries. Second, the article tries to place the antipathy towards free markets in contemporary perspective by discussing whether overly simplistic models and unrealistic promises of quick and sizeable results from ‘globalization’ for poor countries have further fuelled this antipathy. I consider at the same time whether the zeal of the globalizers may have led them to endorse counterproductive and unrealistic attempts at wholesale social transformation, which generate an even more severe backlash.

Let’s start with the long-standing debate about capitalism. Intellectual history makes clear how the gains from trade (in goods, finance, and labour services) under capitalism amount to such a revolutionary idea that economists are often its lone proponents in the wilderness. There are three major habits of thinking that create difficulty in communication between economists and non-economists on gains from trade. One is the mindset that holds that economic interactions are zero-sum games (a partially understandable mindset when capitalists have such skeletons in the closet as military conquest, colonization, slavery, predatory behaviour by firms, and so on). The second is the difference between economists’ notion of Pareto-superior outcomes and common social norms of fairness. The third barrier to communication is the difficulty of accepting the economists’ notion of the invisible hand that creates spontaneous outcomes not designed by anyone, where the common habit of thinking is that a good or bad outcome must be the result of intentional action by a good or bad agent.

To start with the zero-sum mindset, one early father of Christianity, St. Jerome, thought any wealth was automatically ‘unjust riches’, since ‘no one can possess them except by the loss and ruin of others’. St. Augustine put it more tersely: ‘If one does not lose, the other does not gain’ (quoted by Muller, 2002, p. 6).

Centuries later, even after Adam Smith and the Industrial Revolution, both sides of the political spectrum still often thought in zero-sum terms. Friedrich Engels wrote that ‘the consequences of the factory system’ were ‘oppression and toil for the many, riches and wealth for the few’ (quoted by Muller, 2002, p. 180). Henry Adams saw capitalism as a system that divided humanity ‘into two classes, one which steals, the other which is stolen from’ (quoted by Herman, 1997, p. 160).

We are so used to thinking of conservatives as pro-market that it surprises us that some on the Right in the 19th century also attacked free market economics (see Levy, 2001, for a fine narrative). The Right’s attack on the laissez-faire Left (how things have changed!) was that the latter were hypocritical advocating both capitalism and the end of slavery, because capitalism made ‘free’ workers no better than slaves. For example, Thomas Carlyle (the man who disliked economists so much that he coined the phrase ‘dismal science’) told workers: ‘you are fallen captive to greedy sons of profit-and-loss; to bad and ever to worse … Algiers, Brazil or Dahomey hold nothing in them so authentically slave as you are’ (Carlyle, 1850). This is zero-sum thinking in the extreme!

Similarly, on the American 19th-century Right, John C. Calhoun defended American slavery in 1828 by claiming that industrial capitalism in the North was no better; it caused wages to ‘sink more rapidly than the prices of the necessaries of life, till the operatives … portion of the products of their labor … will be barely sufficient to preserve existence’ (quoted by Muller, 2002, p. 177). Ironically the great African-American intellectual W. E. B. Du Bois, reached similar conclusions to Calhoun’s about industrial capitalism, as he observed it in the South after the Civil War:

[The] men who have come to take charge of the industrial exploitation of the New South…thrifti and avaricious Yankees•…•. For the laborers as such, there is in these new captains of industry neither love nor hate, neither sympathy nor romance; it is a cold question of dollars and dividends. Under such a system all labor is bound to suffer•…•The results among them, even, are long hours of toil, low wages, child labor, and lack of protection against usury and cheating. (Du Bois, 1903)

Lenin famously linked zero-sum Western imperialism and non-zero-sum trade and capital flows. Profits for the companies that follow in the wake of the imperialists are high in the ‘backward countries’, where the capitalists relocate their capital because ‘the price of land is relatively low, wages are low, raw materials are cheap’ (Lenin, 1917). Lenin may have
been the first 20th-century critic of outsourcing.

Today, we see similar zero-sum thinking in globalization critics on the Left and the Right. Oxfam GB (2004, p. 12) identifies such products as Olympic sportswear as forcing labourers into ‘working ever-faster for ever-longer periods of time under arduous conditions for poverty-level wages, to produce more goods and more profit’ (Statements like this come from an organization that is actually much friendlier to free trade than most non-governmental organizations.)

Global Policy Forum, a popular globalization website elaborates: ‘trade is inherently unequal and poor countries seldom experience rising well-being but increasing unemployment, poverty, and income inequality.’ Former Tanzanian President Julius Nyerere summarized the zero-sum mindset back in a 1975 state visit to Britain: ‘I am poor because you are rich’ (quoted in Lindsey, 2001, p. 105).

On the Right, there is still today concern about free markets creating winners at the expense of losers. Patrick Buchanan claimed in a 1998 book that free trade causes ‘broken homes, uprooted families, vanished dreams, delinquency, vandalism, crime’ (quoted in Micklethwait and Wooldridge, 2000, p. 282). Edward Luttwak claimed that global capitalism requires ‘harsh laws, savage sentencing, and mass imprisonment’ to deal with ‘disaffected losers’ (1999, p. 236). Although of course the Right in general is today more sympathetic to free market capitalism than the Left, the persistence of this thinking shows how the zero-sum mindset is an independent force from political ideology.

Of course, capitalism/globalization does create losers as well as winners, unleashing gales of creative destruction. Since losers tend to be more vocal than winners, it is easy to understand the perception that the losers outnumber the winners, which then reinforces the already ingrained habit of thinking in zero-sum terms. To complicate matters further, some poorly conceived attempts at rapid transition from non-capitalism to capitalism (for example, ‘shock therapy,’ to be discussed below) can in fact create more losers than winners.

The second source of communication breakdown about globalization is the difference between economists’ general enthusiasm for Pareto improvements and common norms of fairness (see Aisbett, 2005, for a provocative discussion). Following Aisbett, let’s say for example that a multinational firm opens a factory in a low-income country. Suppose that the new investment enables the firm to double its profits and the newly employed workers in the factory to double their previous incomes. Suppose the workers were formerly part of the extreme poor (conventionally measured as an income of a dollar a day), so that now they have escaped extreme poverty. Who can argue with such a Pareto improvement?

From another perspective, however, what is happened is that a very poor person has gained a dollar (in a ‘sweatshop’) while a captain of industry previously making, say, $1,000 a day has gained another $1,000. It violates many norms of fairness (abundantly confirmed in the laboratory by experimental economics), when someone already far better off gains 1,000 times more than the less fortunate person from this transaction. To point this out doesn’t lead to any obvious conclusions – most economists will say the transaction is still worth doing to relieve absolute poverty, while critics will protest that a more fair division of the gains should be possible (but even if the worker gets a fivefold increase in income – an amazing escape velocity from poverty – while the capitalist just doubles his income, the capitalist’s gains are still 250 times larger).

The third barrier to constructive communication about globalization is the common assumption that an outcome must result from an intentional action by an identifiable agent. This couldn’t contrast more with the economists’ notion of the invisible hand. The intentionality mindset is that ‘globalization’ represents someone’s agenda, and it is to blame for the tragedies of world poverty. To give an illustrative example of this kind of anti-globalization rhetoric (not necessarily representative): the ‘transnational corporations … expand, invest and grow, concentrating ever more wealth in a limited number of hands. They work in coalition to influence local, national and international institutions’. ‘Corporate elites… forge common agendas outside the formal institutions of democracy.’ They use forums such as the Trilateral Commission, the International Chamber of Commerce, the World Economic Forum, trade associations, and the many national and international business and industrial roundtables’ (IFG, 2002, p. 140). The participants at such ‘posh gatherings… chart the course of corporate globalization in the name of private profits …’ (IFG, 2002, p. 4). Searching for whom to blame for the miseries of the poor, the rich multinational corporations make for natural villains (alternative villains are the IMF and World Bank). These are not only villains, but foreign villains! This mindset is further strengthened when corporations (who of course really are self-interested profit-seekers) get caught doing something like despoothing the environment in a poor country or doing shady deals with the local kleptocrats. The economists’ idea of a spontaneous system of myriads of uncoordinated agents, with nobody in charge, generating outcomes that are not intended (or even foreseeable) by anyone is a lot harder sell.

With such fundamental differences in thinking, perhaps we can understand why there is little prospect of a constructive conversation between advocates and opponents of globalization/free market capitalism/neoliberalism. The World Social Forum, the counterpoint annual meeting to that of the capitalist globalizers at the World Economic Forum in Davos, says in its charter that it is ‘an open meeting place for reflective thinking, democratic debate of ideas, free exchange of experiences’, except that the debate is limited to ‘groups and movements of civil society that are opposed to neoliberalism’. A similar spirit seems to inform the complaint that the case for capitalism arises from ‘rationalist constructions of knowledge’ featured in such reunions of the ‘global managerial class’ as ‘AEA conventions’ (Global Policy Forum, 2006). Of course, mainstream economists probably do not seem to their critics much more open to debate on ‘neoliberalism’!

Things are made even worse by the second major theme of this article, the overselling of globalization. Simplistic models and promises of quick and sizeable results create expectations, and when these expectations are disappointed (even when the results are gradually and increasingly positive), there is a backlash against globalization.

A classic example of the overselling of globalization is the World Bank (2002) report Globalization, Growth, and Poverty. The following graph (Figure 1), the first one shown in the report, is prominently displayed in the overview (2002, p. 5):

Figure 1
Divergent paths of developing countries in the 1990s
GDP per capita growth rate (percent)
Although never explicitly stated and some caveats are expressed, the impression left with many readers is that being more globalized makes the difference between five per cent per capita growth and minus one per cent per capita growth, which is an amazingly strong claim for the effects of globalization. World Bank researchers reinforce this kind of claim with statements promising that world poverty can be cut in half with policy reforms: ‘Poverty reduction – in the world or in a particular region or country – depends primarily on the quality of economic policy. Where we find in the developing world good environments for households and firms to save and invest, we generally observe poverty reduction’ (Collier and Dollar, 2001). (I have to admit with some embarrassment that this statement was based on one of my own unpublished growth regressions, which eventually showed up in published form in Easterly 2001 making the opposite point – that the growth response to policy reform was disappointing. Regressions can be dangerous!)

The IMF likewise has a standard set of policies that it advocates (together, the IMF's and the World Bank's notion of 'good policies' form what is often called the 'Washington Consensus'), many of which are oriented towards creating freer markets (more 'globalization'). The IMF also claimed that 'Where [good] policies have been sustained, they have raised growth and reduced poverty' (2000).

This is speculation, but some of the World Bank/IMF belief in policy reforms to explain good outcomes may ironically stem from the same intentionality impulse that makes critics blame the World Bank and IMF for bad outcomes. People find it more comfortable to attribute success to the action of a few heroic policy reformers or technocrats (or strong leaders implementing good policies, like Singapore's Lee Kuan Yew), rather than to some more mysterious bottom-up process of many spontaneous individual entrepreneurs. Unfortunately, there is little evidence for strong growth effects of policy changes that involve anything less than getting rid of self-destructive extremes (like moving from autarchy to...
allow some trade, or from hyperinflation to moderate inflation), and even then hardly six percentage points of permanent change in growth, as documented in Easterly (2005).

Contrary to the impression conveyed in the foregoing statements, the economics profession actually knows very little about how to raise economic growth over the short to medium run with policy changes in the range in which most countries are operating (see for example the survey in Kenny and Williams, 2001). (Besides this, the methodological problem is that countries that are more or less globalized are not defined in terms of policies that promote free trade, free capital movements, free migration, or some other policy measure that features in the debates on globalization. The ‘more globalized’ countries are defined in terms of outcomes: it is those that are in the top third of countries in terms of the increase in their trade-to-GDP ratios. Defining globalisation in terms of one endogenous measure of success that is likely related to other endogenous measures of success – like the GDP growth rates being explained – is rather unfortunate.) Growth in developing countries is extremely volatile (on average 75 per cent of a country’s deviation from the global mean per capita growth in a five- or ten-year period disappears in the following period, as pointed out in Easterly et al., 1993, since replicated with more recent data.) Overeager growth-watchers are too quick to proclaim ‘growth miracles’ and the lessons that allegedly follow from them. As Dixit (2006, p. 23) says,

At any time, some country is doing well, and academic as well as practical observers are tempted to generalize from its choices and recommend the same to all countries. After a decade or two, this country ceases to do so well, some other country using some other policies starts to do well, and becomes the new star that all countries are supposed to follow.

The success of China and the earlier successes of the East Asian miracles (all associated with great success in global markets) are often used by promoters of globalization to bolster their case. Unfortunately, the implicit promise that such unusually rapid growth (on the order of five per cent per capita) is available to all ‘globalizers’ rests on very shaky ground. First, such rapid growth is very rare – 1.7 per cent of countries registered five per cent per capita growth or more over 1950–2001, and only 0.7 per cent of all half-century period per capita growth episodes since 1820 surpassed five per cent (Maddison, 2003). Most rich countries today (usually agreed to have been globalized and capitalist for quite some time) got to be rich by registering something on the order of two per cent per capita growth for one or two centuries.

Things are made worse when casual empiricism is married to simplistic theory. In the simplest textbook model, freedom of trade and capital movements each promotes poverty alleviation, that is, rapid catching up of wages or incomes in capital-scarce, labour-abundant poor countries to wages or incomes in rich countries. According to the model, free trade allows unskilled wages in poor countries to rise rapidly through labour-intensive exports, while free capital movements allow high investment in poor countries to remedy the gap in capital per worker between rich and poor countries. A side effect would be that inequality within the poor country (driven mainly by the differences between labour and capital earnings) should decrease. Even aside from the fact that a vast trade literature does not support most predictions of the first story, the growth and development literature has pointed out that total factor productivity differences between countries are a much more plausible explanation of income differences between countries than differences in capital per worker (Hall and Jones, 1999; Klenow and Rodriguez-Clare, 1997; Easterly and Levine, 2001; Hsieh, 2002). Stylized facts on trade, inequality, and poverty do not support the predictions of the simple textbook model where income differences are due to differences in capital per worker. (See Easterly, 2006, for a more extensive discussion of these points.)

These false expectations of very rapid growth through globalization (or ‘free markets’ in general) have arguably done a lot of damage, creating fertile ground for an anti-capitalist backlash in places as diverse as Thailand, South Africa, Russia, Bolivia, Venezuela, Peru, Argentina, Ecuador and Mexico. The critics of globalization can all the more easily seize upon any growth setbacks (such as the Mexico crisis of 1994/95, the East Asian crisis of 1997/98, or the Argentine crisis of 2001, or disappointing growth in Latin America in general since market liberalization in the 1980s), whatever their cause (usually hard to explain anyway in the volatile pattern described earlier), to say ‘see, globalization/neoliberalism doesn’t work’.

The backlash has been made all the worse because of the overconfidence of IMF and World Bank policymakers (and freelance ‘reform consultants’) ‘globalizing’ whole societies that start out with many different barriers to efficient free markets. The economics profession can demonstrate fairly convincingly that some long-run market-friendly policies and institutions are most conducive to prosperity, but it knows very little about the sequencing and the transitional paths of reforms to get from initial conditions to that ideal state. (Lipsey and Lancaster’s, 1956–57, theory of the second best recognized this problem, but it seems that each new generation must discover it afresh.) It is obvious that different kinds of reforms are complementary to each other – for example, financial market liberalization works well only if there is sufficient transparency of banks to depositors, and a good regulatory and supervisory framework to ensure that banks don’t cheat (Barth, Caprio and Levine, 2006). Otherwise, financial liberalization often leads to bad loans, enrichment of insiders, and subsequent banking system crises, as abundant experience has already demonstrated.

Yet the usual answer to policy complementarity – ‘do everything at once’ ‘structural adjustment,’ or ‘shock therapy’ – doesn’t really escape the curse of the second-best. Policymakers neither know what ‘everything’ is nor have the ability to change ‘everything’ at once (or any time soon). The choice is really between large-scale partial reforms (which shock therapy mislabels ‘comprehensive reform’) and small-scale partial reforms. Any economy is a complex system of informal networks, social norms, relationships, trades, and formal institutions, many of which lie outside the control of the policymaker. As Dixit (2004) points out, an existing network under the current system of rules can at least enforce contracts in that it can threaten to expel any member who cheats another member. Drawing up a brand-new set of rules overnight (like moving abruptly from an interventionist economy to a free-market economy) can have perverse impacts in the short run. It can mean that people can choose to exit the old network (cheating their old partners) because they now have the

option of operating under the new system of rules and the new networks generated by the new rules. The net effect can be to disrupt the functioning of the old economy much more than it facilitates the creation of the new economy. This is theoretical speculation at this point, but it does illustrate the potential pitfalls of promising rapid results from rapid reforms. To think that economists could re-engineer the whole society and economy looks in retrospect like the worst kind of intellectual hubris (see McMillan, 2007, for a great discussion). Attempts at rapid ‘comprehensive’ reform of poor countries look a lot like what Karl Popper long ago decried as ‘utopian social engineering’ versus what has worked for most rich countries to attain prosperity: ‘piecemeal democratic reform’.

The most notorious case of this hubris was the attempt to reform the former Soviet Union with ‘shock therapy’. Murrell (1992; 1993) – a long-time scholar of centrally planned economies – argued against shock therapy as utopian social engineering. His objections are all the more compelling because they were *ex ante* rather than *ex post*. History vindicated his scathing description of shock therapy at the time:

> There is complete disdain for all that exists … History, society, and the economics of present institutions are all minor issues in choosing a reform program… Establishment of a market economy is seen as mostly involving destruction… shock therapists assume that technocratic solutions are fairly easy to implement… One must reject all existing arrangements••••(Murrell, 1993)

Murrell was quick to realize the relevance of Popper for what was later half-jokingly called a Leninist push for free markets in Russia. His quote from Popper in 1992 is a perfect prediction of how Russian reform would fail: ‘It is not reasonable to assume that a complete reconstruction of our social system would lead at once to a workable system’ (quoted in Murrell, 1992). After the former Soviet republics experienced some of the greatest depressions in economic history, the prescience of such viewpoints became apparent.

For its part, IMF- and World Bank-supported ‘structural adjustment’ was also uncomfortably like ‘utopian social engineering’, and produced a similar debacle in Africa and Latin America. The resulting anti-market/anti-globalization backlash (in the former Soviet Union as well as Africa and Latin America) was all the more severe because the reforms involved some IMF/World Bank coercion through conditional loans. One can hardly think of a better formula for an anti-capitalist backlash in poor countries than to introduce overambitious, oversold programmes of large-scale ‘globalization’ reforms imposed by foreigners!

In conclusion, economists are unlikely to find the term ‘globalization’ a precise enough concept to advance most research agendas. Instead, it mainly seems to point to the long-standing debate about economists’ traditional embrace of free-market capitalism. Perhaps some progress in these debates can be made by understanding some of the traditional mindsets that make a system of spontaneous gains from trade such a revolutionary concept. It also would help a great deal if policymakers and the economists advising them did not pursue overambitious attempts at rapid wholesale transformation of the economy and society, and did not exaggerate the likely size and speed of the gains for the economy from such programmes.

Articulate arguments of the case for capitalism/globalization continue to be made in books such as Lindsey (2001) and Wolf (2004). Mishkin (2006) has recently made a fascinating case for the kind of globalization that opponents find most frightening (and even many economists shy from), financial globalization. Despite such eloquent statements, the discomforts caused by the spectre of globalization are unlikely to abate any time soon. Economists can arguably contribute more to the debate by seeking to understand the discomfort rather than dismissing it out of hand.

Gold standard

Lawrence H. Officer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The world has had two experiences with gold standards: the classical gold standard and the interwar gold standard. The ‘rules of the game’, government policies to preserve the gold standard, were rarely followed. Rather, government responsible policy and credible commitment to the standard, private stabilizing arbitrage and speculation, and stable political and economic environment made the classical gold standard a success. The absence of these elements and the presence of the Great Depression combined to make the interwar gold standard a failure.

Article

The classical gold standard (which ended in 1914) and the interwar gold standard are examined within the same framework, but their experiences are vastly different.

Types of gold standard

All gold standards involve (a) a fixed gold content of the domestic monetary unit, and (b) the monetary authority both buying and selling gold at the mint price (the inverse of the gold content of the monetary unit), whereupon the mint price governs in the marketplace. A ‘coin’ standard has gold coin circulating
as money. Privately owned bullion (gold in form other than domestic coin) is convertible into gold coin, at (approximately) the mint price, at the government mint or central bank. Private parties may melt domestic coin into bullion – the effect is as if coin were sold to the monetary authority for bullion. The authority could sell gold bars directly for coin, saving the cost of coining.

Under a pure coin standard, gold is the only money. Under a mixed standard, there are also notes issued by the government, central bank, or commercial banks, and possibly demand deposits. Government or central-bank notes (and central-bank deposit liabilities) are directly convertible into gold coin at the fixed price on demand. Commercial-bank notes and demand deposits are convertible into gold or into gold-convertible government or central-bank currency. Gold coin is always exchangeable for paper currency or deposits at the mint price. Two-way transactions again fix the currency price of gold at the mint price.

The coin standard, naturally ‘domestic’, becomes ‘international’ with freedom of international gold flows and of foreign-exchange transactions. Then the fixed mint prices of countries on the gold standard imply a fixed exchange rate (mint parity) between their currencies.

A ‘bullion’ standard is purely international. Gold coin is not money; the monetary authority buys or sells gold bars for its notes. Similarly, a ‘gold-exchange’ standard involves the monetary authority buying and selling not gold but rather gold-convertible foreign exchange (the currency of a country on a gold coin or bullion standard).

For countries on an international gold standard, costs of importing and exporting gold give rise to ‘gold points’, and therefore a ‘gold-point spread’, around the mint parity. If the exchange rate, number of units of domestic per unit of foreign currency, is greater (less) than the gold export (import) point, arbitrageurs sell (purchase) foreign currency at the exchange rate and also obtain (relinquish) foreign currency by exporting (importing) gold. The domestic-currency cost of the transaction per unit of foreign currency is the gold export (import) point; so the ‘gold-point arbitrageurs’ receive a profit proportional to the exchange-rate/gold-point divergence. However, the arbitrageurs’ supply of (demand for) foreign currency returns the exchange rate to below (above) the gold export (import) point. Therefore perfect arbitrage would keep the exchange rate within the gold-point spread. What induces gold-point arbitrage is the profit motive and the credibility of the monetary-authorities’ commitment to (a) the fixed gold price and (b) freedom of gold and foreign-exchange transactions.

A country can be effectively on a gold standard even though its legal standard is bimetallism. This happens if the gold–silver mint-price ratio is greater than the world price ratio. In contrast, even though a country is legally on a gold standard, its government and banks could ‘suspend specie payments’, that is, refuse to convert their notes into gold; so that the country is in fact on a ‘paper standard’.

**Countries on the classical gold standard**

Britain, France, Germany and the United States were the ‘core countries’ of the gold standard. Britain was the ‘centre country’, indispensable to the spread and functioning of the standard. Legally bimetallic from the mid-13th century, Britain switched to an effective gold standard early in the 18th century. The gold standard was formally adopted in 1816, ironically during a paper-standard regime (Bank Restriction Period). The United States was legally bimetallic from 1786 and on an effective gold standard from 1834, with a legal gold standard established in 1873–4 – also during a paper standard (the greenback period). In 1879 the United States went back to gold, and by that year not only the core
countries but also some British dominions and non-core western European countries were on the gold standard. As time went on, a large number of other countries throughout the globe adopted gold; but they (along with the dominions) were in ‘the periphery’ – acted on rather than actors – and generally (except for the dominions) not as committed to the gold standard.

Almost all countries were on a mixed coin standard. Some periphery countries were on a gold-exchange standard, usually because they were colonies or territories of a country on a coin standard.

In 1913, the only countries not on gold were traditional silver-standard countries (Abyssinia, China, French Indochina, Hong Kong, Honduras, Morocco, Persia, Salvador), some Latin American paper-standard countries (Chile, Colombia, Guatemala, Haiti, Paraguay), and Portugal and Italy (which had left gold but ‘shadowed’ the gold standard, pursuing policies as if they were gold-standard countries, keeping the exchange rate relatively stable).

Elements of instability in classical gold standard

Three factors made for instability of the classical gold standard. First, the use of foreign exchange as official reserves increased as the gold standard progressed. While by 1913 only Germany among the core countries held any measurable amount of foreign exchange, the percentage for the rest of the world was double that for Germany. If there were a rush to cash in foreign exchange for gold, reduction of the gold of reserve-currency countries would place the gold standard in jeopardy.

Second, Britain was in a particularly sensitive situation. In 1913, almost half of world foreign-exchange reserves was in sterling, but the Bank of England had only three per cent of gold reserves. The Bank of England’s ‘reserve ratio’ (ratio of ‘official reserves’ to ‘liabilities to foreign monetary authorities held in London financial institutions’) was only 31 per cent, far lower than those of the monetary authorities of the other core countries. An official run on sterling could force Britain off the gold standard. Private foreigners also held considerable liquid assets in London, and could themselves initiate a run on sterling.

Third, the United States was a source of instability to the gold standard. Its Treasury held a high percentage of world gold reserves (in 1913, more than that of the three other core countries combined). With no central bank and a decentralized banking system, financial crises were more frequent and more severe than in the other core countries. Far from the United States assisting Britain, gold often flowed from the Bank of England to the United States, to satisfy increases in US demand for money. In many years the United States was a net importer rather than exporter of capital to the rest of the world – the opposite of the other core countries. The political power of silver interests and recurrent financial panics led to imperfect credibility in the US commitment to the gold standard. Indeed, runs on banks and on the Treasury gold reserve placed the US gold standard near collapse in the 1890s. The credibility of the Treasury’s commitment to the gold standard was shaken; twice the US gold standard was saved only by cooperative action of the Treasury and a bankers’ syndicate, which stemmed gold exports.

Automatic force for stability: price specie-flow mechanism

The money supply is the product of the money multiplier and the monetary base. The monetary authority alters the monetary base by changing its gold holdings and domestic assets (loans, discounts, and securities). However, the level of its domestic assets is dependent on its gold reserves, because the authority generates demand liabilities (notes and deposits) by increasing its assets, and convertibility of
these liabilities must be supported by a gold reserve. Therefore the gold standard provides a constraint on the level (or growth) of the money supply.

Further, balance-of-payments surpluses (deficits) are settled by gold imports (exports) at the gold import (export) point. The change in the money supply is the product of the money multiplier and the gold flow, providing the monetary authority does not change its domestic assets. For a country on a gold-exchange standard, holdings of foreign exchange (a reserve currency) take the place of gold.

A country experiencing a balance-of-payments deficit loses gold and its money supply decreases automatically. Money income contracts and the price level falls, thereby increasing exports and decreasing imports. Similarly, a surplus country gains gold, exports decrease, and imports increase. In each case, balance-of-payments equilibrium is restored via the current account, the ‘price specie-flow mechanism’. To the extent that wages and prices are inflexible, movements of real income in the same direction as money income occur; the deficit country suffers unemployment, while the payments imbalance is corrected.

The capital account also acts to restore balance, via interest-rate increases in the deficit country inducing a net inflow of capital. The interest-rate increases also reduce real investment and thence real income and imports. The opposite occurs in the surplus country.

Rules of the game

Central banks were supposed to reinforce (rather than ‘sterilize’) the effect of gold flows on the monetary base, thereby enhancing the price specie-flow mechanism. A gold outflow decreases the international assets of the central bank and the money supply. The central-bank's ‘proper’ response is: (1) decrease lending and sell securities, thereby decreasing domestic assets and the monetary base; (2) raise its ‘discount rate’, which induces commercial banks to adopt a higher reserves–deposit ratio, thereby reducing the money multiplier. On both counts, the money supply is further decreased. Should the central bank increase its domestic assets when it loses gold, it engages in sterilization of the gold flow, violating the ‘rules of the game’. The argument also holds for gold inflow, with sterilization involving the central bank decreasing its domestic assets when it gains gold.

Monetarist theory suggests the ‘rules’ were inconsequential. Under fixed exchange rates, gold flows adjust money supply to money demand; the money supply is not determined by policy. Also, prices, interest rates, and incomes are determined worldwide. Even core countries can influence these variables domestically only to the extent that they help determine them in the global marketplace. Therefore the price-specie flow and like mechanisms cannot occur. Historical data support this conclusion: gold flows were too small to be suggestive of these processes; and, at least among the core countries, prices, incomes, and interest rates moved closely in correspondence, contradicting the specie-flow mechanism and rules of the game.

Rather than rule (1), central-bank domestic and international assets moving in the same direction, the opposite behaviour – sterilization – was dominant, both in core and non-core European countries. The Bank of England followed the rule more than any other central bank, but even so violated it more often than not!

The Bank of England did, in effect, manage its discount rate (‘Bank Rate’) in accordance with rule (2). The Bank's primary objective was to maintain convertibility of its notes into gold, and its principal tool was Bank Rate. When the Bank's ‘liquidity ratio’ (ratio of gold reserves to outstanding note liabilities)
decreased, it usually increased Bank Rate. The increase in Bank Rate carried with it market short-term interest rates, inducing a short-term capital inflow and thereby moving the exchange rate away from the gold-export point. The converse also held, with a rise in the liquidity ratio generating a Bank Rate decrease. The Bank was constantly monitoring its liquidity ratio, and in response altered Bank Rate almost 200 times over 1880–1913.

While the Reichsbank also generally moved its discount rate inversely to its liquidity ratio, other central banks often violated rule (2). Discount-rate changes were of inappropriate direction, or of insufficient magnitude or frequency. The Bank of France kept its discount rate stable, choosing to have large gold reserves, with payments imbalances accommodated by fluctuations in its gold rather than financed by short-term capital flows. The United States, lacking a central bank, had no discount rate to use as a policy instrument.

Reason for stability: credible commitment to convertibility

From the late 1870s onward, there was absolute private-sector credibility in the commitment to the fixed domestic-currency price of gold on the part of Britain, France, Germany, and other important European countries. For the United States, this absolute credibility applied from about 1900. That commitment had a contingency aspect: convertibility could be suspended in the event of dire emergency; but, after normal conditions were restored, convertibility and honouring of gold contracts would be re-established at the pre-existing mint price – even if substantial deflation was required to do so. The Bank Restriction and greenback periods were applications of the contingency. From 1879, the ‘contingency clause’ was exercised by none of these countries.

The absolute credibility in countries’ commitment to convertibility at the existing mint price implied that there was zero ‘convertibility risk’ (Treasury or central-bank notes non-redeemable in gold at the established mint price) and zero ‘exchange risk’ (alteration of mint parity, institution of exchange control, or prohibition of gold export).

Why was the commitment to credibility so credible?

1. Contracts were expressed in gold; abandonment of convertibility meant violation of contracts – anathema to monetary authorities.
2. Shocks to economies were infrequent and generally mild.
3. The London capital market was the largest, most open, most diversified in the world, and its gold market was also dominant. A high proportion of world trade was financed in sterling, London was the most important reserve-currency centre, and payments imbalances were often settled by transferring sterling assets rather than gold. Sterling was an international currency – a boon to other countries, because sterling involved positive interest return, and its transfer costs were much less than those of gold. Advantages to Britain were the charges for services as an international banker, differential interest return on its financial intermediation, and the practice of countries on a sterling (gold-exchange) standard of financing payments surpluses with Britain by piling up short-term sterling assets rather than demanding Bank gold.
4. ‘Orthodox metallism’ – authorities’ commitment to an anti-inflation, balanced-budget, stable-money policy – reigned. This ideology implied low government spending, low taxes, and limited monetization of government debt. Therefore, it was not expected that a country's price level...
would get out of line with that of other countries.
5. Politically, gold had won over paper and silver, and stable-money interests (bankers, manufacturers, merchants, professionals, creditors, urban groups) over inflationary interests (farmers, landowners, miners, debtors, rural groups).
6. There was a competitive environment and freedom from government regulation. Prices and wages were flexible. The core countries had virtually no capital controls, Britain had adopted free trade, and the other core countries had only moderate tariffs. Balance-of-payments financing and adjustment were without serious impediments.
7. With internal balance an unimportant goal of policy, preservation of convertibility of paper currency into gold was the primary policy objective. Sterilization of gold flows, though frequent, was more ‘meeting the needs of trade’ (passive monetary policy) than fighting unemployment (active monetary policy).
8. The gradual establishment of mint prices over time ensured that mint parities were in line with relative price levels; so countries joined the gold standard with exchange rates in equilibrium.
9. Current-account and capital-account imbalances tended to be offsetting for the core countries. A trade deficit induced a gold loss and a higher interest rate, attracting a capital inflow and reducing capital outflow. The capital-exporting core countries could stop a gold loss simply by reducing lending abroad.

Implications of credible commitment

Private parties reduced the need for balance-of-payments adjustment, via both gold-point arbitrage and stabilizing speculation. When the exchange rate was outside the spread, gold-point arbitrage quickly returned it to the spread. Within the spread, as the exchange value of a currency weakened, the exchange rate approaching the gold-export point, speculators had an ever greater incentive to purchase domestic with foreign currency (a capital inflow). They believed that the exchange rate would move in the opposite direction, enabling reversal of their transaction at a profit. Similarly, a strengthened currency involved a capital outflow. The further the exchange rate moved toward a gold point, the greater the potential profit opportunity in betting on a reversal of direction; for there was a decreased distance to that gold point and an increased distance from the other point. This ‘stabilizing speculation’ increased the exchange value of depreciating currencies, and thus gold loss could be prevented. Absence of controls meant such private capital flows were highly responsive to exchange-rate changes.

Government policies that enhanced stability

Specific government policies enhanced gold-standard stability. First, by the turn of the 20th century, South Africa – the main world gold producer – was selling all its gold output in London, either to private parties or to the Bank of England. Thus the Bank had the means to replenish its gold reserves. Second, the orthodox-metallism ideology and the leadership of the Bank of England kept countries’ monetary policies disciplined and in harmony. Third, the US Treasury and the central banks of the other core countries manipulated gold points, to stem gold outflow. The cost of exporting gold was artificially increased (for example, by increasing selling prices for bars and foreign coin) and/or the cost of importing gold artificially decreased (for example, by providing interest-free loans to gold importers).
Fourth, central-bank cooperation was forthcoming during financial crises. The precarious liquidity position of the Bank of England meant that it was more often the recipient than the provider of financial assistance. In crises, the Bank would obtain loans from other central banks, and the Bank of France would sometimes purchase sterling to support that currency. When needed, assistance went from the Bank of England to other central banks. Also, private bankers unhesitatingly made loans to central banks in difficulty.

Thus, ‘virtuous’ interactions were responsible for the stability of the gold standard. The credible commitment to convertibility of paper money at the established mint price, and therefore to fixed mint parities, were both a cause and an effect of the stable environment in which the gold standard operated, the stabilizing behaviour of arbitrageurs and speculators, and the responsible policies of the authorities – and these three elements interacted positively among themselves.

Experience of periphery

An important reason for periphery countries to join and maintain the gold standard was the fostering of access to core-countries’ capital markets. Adherence to the gold standard connoted that the peripheral country would follow responsible macroeconomic policies and repay debt. This ‘seal of approval’, by reducing the risk premium, involved a lower interest rate on the country’s bonds sold abroad, and very likely a higher volume of borrowing, thereby enhancing economic development. However, periphery countries bore the brunt of the burden of adjustment of payments imbalances with the core (and other western European) countries. First, when the gold-exchange-standard periphery countries ran a surplus (deficit), they increased (decreased) their liquid balances in the United Kingdom (or other reserve-currency country) rather than withdraw gold from (lose gold to) the reserve-currency country. The monetary base of the periphery country increased (decreased), but that of the reserve-currency country remained unchanged. Therefore, changes in domestic variables – prices, incomes, interest rates, portfolios – that occurred to correct the imbalance were primarily in the periphery.

Second, when Bank Rate increased, London drew funds from France and Germany, which attracted funds from other European countries, which drew capital from the periphery. Also, it was easy for a core country to correct a deficit by reducing lending to, or bringing capital home from, the periphery. While the periphery was better off with access to capital, its welfare gain was reduced by the instability of capital import. Third, periphery-countries’ exports were largely primary products, sensitive to world market conditions. This feature made adjustment in the periphery take the form more of real than financial correction.

The experience of adherence to the gold standard differed among periphery groups. The important British dominions and colonies successfully maintained the gold standard. They paid the price of serving as an economic cushion to the Bank of England’s financial situation; but, compared with the rest of the periphery, gained a stable long-term capital inflow. In southern Europe and Latin America, adherence to the gold standard was fragile. The commitment to convertibility lacked credibility, and resort to a paper standard occurred. Many of the reasons for credible commitment that applied to the core countries were absent. There were powerful inflationary interests, strong balance-of-payments shocks, and rudimentary banking sectors. The cost of adhering to the gold standard was apparent: loss of the ability to depreciate the currency to counter reductions in exports. Yet the gain, in terms of a steady capital inflow from the core countries, was not as stable or reliable as for the British dominions and colonies.
Breakdown of classical gold standard

The classical gold standard was at its height at the end of 1913, ironically just before it came to an end. The proximate cause of the breakdown of the classical gold standard was the First World War. However, it was the gold-exchange standard and the Bank of England's precarious liquidity position that were the underlying cause. With the outbreak of war, a run on sterling led Britain to impose extreme exchange control – a postponement of both domestic and international payments – making the international gold standard inoperative. Convertibility was not suspended legally; but moral suasion, legalistic action, and regulation had the same effect. The Bank of England commandeered gold imports and applied moral suasion to bankers and bullion brokers to restrict gold exports.

The other gold-standard countries undertook similar policies – the United States not until 1917, when it adopted extra-legal restrictions on convertibility and restricted gold exports. Commercial banks converted their notes and deposits only into currency. Currency convertibility made mint parities ineffective; floating exchange rates resulted.

Return to the gold standard

After the First World War, a general return to gold occurred; but the interwar gold standard differed institutionally from the classical gold standard. First, the new gold standard was led by the United States, not Britain. The US embargo on gold exports was removed in 1919, and currency convertibility at the pre-war mint price was restored in 1922. The gold value of the dollar rather than pound sterling was the typical reference point around which other currencies were aligned and stabilized. The core now had two central countries, the United Kingdom (which restored gold in 1925) and the United States.

Second, for many countries there was a time lag between stabilizing the currency in the foreign-exchange market (fixing the exchange rate or mint parity) and resuming currency convertibility. The interwar gold standard was at its height at the end of 1928, after all core countries were fully on the standard and before the Great Depression began. The only countries that never joined the interwar gold standard were the USSR, silver–standard countries (China, Hong Kong, Indochina, Persia, Eritrea), and some minor Asian and African countries.

Third, the ‘contingency clause’ of convertibility conversion, that required restoration of convertibility at the mint price that existed prior to the emergency (the First World War), was broken by various countries, and even core countries. While some countries (including the United States and United Kingdom) stabilized their currencies at the pre-war mint price, others (including France) established a gold content of their currency that was a fraction of the pre-war level: the currency was devalued in terms of gold, the mint price was higher than pre-war. Still others (including Germany) stabilized new currencies adopted after hyperinflation.

Fourth, the gold coin standard, dominant in the classical period, was far less prevalent in the interwar period. All four core countries had been on coin in the classical gold standard; but only the United States was on coin interwar. The gold-bullion standard, non-existent pre-war, was adopted by the United Kingdom and France. Germany and most non-core countries were on a gold-exchange standard.

Instability of interwar gold standard
The interwar gold standard was replete with forces making for instability.

1. The process of establishing fixed exchange rates was piecemeal and haphazard, resulting in disequilibrium exchange rates. Among core countries, the United Kingdom restored convertibility at the pre-war mint price without sufficient deflation, and had an overvalued currency of about ten per cent. France and Germany had undervalued currencies.
2. Wages and prices were less flexible than in the pre-war period.
3. Higher trade barriers than pre-war also restrained adjustment.
4. The gold-exchange standard economized on total world gold via the gold of the United Kingdom and United States in their reserves role for countries on the gold-exchange standard and also for countries on a coin or bullion standard that elected to hold part of their reserves in London or New York. However, the gold-exchange standard was unstable, with a conflict between (a) the expansion of sterling and dollar liabilities to foreign central banks, to expand world liquidity, and (b) the resulting deterioration in the reserve ratio of US and UK authorities. This instability was particularly severe, for several reasons. First, France was now a large official holder of sterling, and France was resentful of the United Kingdom. Second, many more countries were on the gold-exchange standard than pre-war. Third, the gold-exchange standard, associated with colonies in the classical period, was considered a system inferior to a coin standard.
5. In the classical period, London was the one dominant financial centre; in the interwar period it was joined by New York and, in the late 1920s, Paris. Private and official holdings of foreign currency could shift among the two or three centres, as interest-rate differentials and confidence levels changed.
6. There was maldistribution of gold. In 1928, official reserve-currency liabilities were much more concentrated than in 1913, British pounds accounting for 77 per cent of world foreign-exchange reserves and French francs less than two per cent (versus 47 and 30 per cent in 1913). Yet the United Kingdom held only seven per cent of world official gold and France 13 per cent. France also possessed 39 per cent of world official foreign exchange. The United States held 37 per cent of world official gold.
7. Britain's financial position was even more precarious than in the classical period. In 1928, the gold and dollar reserves of the Bank of England covered only one-third of London's liquid liabilities to official foreigners, a ratio hardly greater than in 1913. UK liquid liabilities were concentrated on stronger countries (France, United States), whereas UK liquid assets were predominantly in weaker countries (Germany). There was ongoing tension with France, which resented the sterling-dominated gold-exchange standard and desired to cash in its sterling holding for gold, to aid its objective of achieving first-class financial status for Paris.
8. Internal balance was an important goal of policy, which hindered balance-of-payments adjustment, and monetary policy was influenced by domestic politics rather than geared to preservation of currency convertibility.
9. Credibility in authorities’ commitment to the gold standard was not absolute. Convertibility risk and exchange risk could be high, and currency speculation could be destabilizing rather than stabilizing. When a country's currency approached or reached its gold-export point, speculators...
might anticipate that currency convertibility would not be maintained and that the currency would be devalued.

10. The ‘rules of the game’ were violated even more often than in the classical gold standard. Sterilization of gold inflows by the Bank of England can be viewed as an attempt to correct the overvalued pound by means of deflation. However, the US and French sterilization of their persistent gold inflows reflected exclusive concern for the domestic economy and placed the burden of adjustment (deflation) on other countries.

11. The Bank of England did not provide a leadership role in any important way, and central-bank cooperation was insufficient to establish credibility in the commitment to currency convertibility. The Federal Reserve had three targets for its discount-rate policy: strengthen the pound, combat speculation in the New York stock market, and achieve internal balance – and the first target was of lowest priority. Although, for the sake of external balance, the Bank of England kept Bank Rate higher than internal considerations would dictate, it was understandably reluctant to abdicate Bank Rate policy entirely to the balance of payments, with little help from the Federal Reserve. To keep the pound strong, substantial international cooperation was required, but was not forthcoming.

**Breakdown of interwar gold standard**

The Great Depression triggered the unravelling of the gold standard. The depression began in the periphery. Low export prices and debt-service requirements created insurmountable balance-of-payments difficulties for gold-standard commodity producers. However, US monetary policy was an important catalyst. In 1927 the Federal Reserve favoured easy money, which supported foreign currencies but also fed the New York stock-market boom. Reversing policy to tame the boom, higher interest rates attracted monies to New York, weakening sterling in particular. The crash of October 1929, while helping sterling, was followed by the US depression. This spread worldwide, with declines in US trade and lending. In 1929 and 1930 a number of periphery countries –both dominions and Latin American countries – either formally suspended currency convertibility or restricted it so that currencies violated the gold-export point.

It was destabilizing speculation, emanating from lack of confidence in authorities’ commitment to currency convertibility, which ended the interwar gold standard. In May 1931 there was a run on Austria's largest commercial bank, and the bank failed. The run spread to other eastern European countries and to Germany, where an important bank also collapsed. The countries’ central banks lost substantial reserves; international financial assistance was too late; and in July 1931 Germany adopted exchange control, followed by Austria in October. These countries were definitively off the gold standard.

The Austrian and German experiences, as well as British budgetary and political difficulties, were among the factors that destroyed confidence in sterling, which occurred in mid-July 1931. Runs on sterling ensued, and the Bank of England lost much of its reserves. Loans from abroad were insufficient, and in any event taken as a sign of weakness. The gold standard was abandoned in September, and the pound quickly and sharply depreciated on the foreign-exchange market, as overvaluation of the pound would imply.

Following the UK abandonment of the gold standard, many countries followed, some to maintain their
competitiveness via currency devaluation, others in response to destabilizing capital flows. The United States held on until 1933, when both domestic and foreign demands for gold, manifested in runs on US commercial banks, became intolerable. ‘Gold bloc’ countries (France, Belgium, Netherlands, Switzerland, Italy, Poland), with their currencies now overvalued and susceptible to destabilizing speculation, succumbed to the inevitable by the end of 1936.

The Great Depression was worsened by the gold standard: gold-standard countries hesitated to inflate their economies, for fear of suffering loss of gold and foreign-exchange reserves, and being forced to abandon convertibility or the gold parity. The gold standard involved ‘golden fetters’, which inhibited monetary and fiscal policy to fight the Depression. As countries left the gold standard, removal of monetary and fiscal policy from their ‘gold fetters’ enabled their use in expanding real output, providing the political will existed.

In contrast to the interwar gold standard, the classical gold standard functioned well because of a confluence of ‘virtuous’ interactions, involving government policies, credible commitment to the standard, private arbitrage and speculation, and fostering economic and political environment. We will not see its like again.

Article

The so-called golden rule, or golden rule of capital accumulation, is a proposition about the consequences for national consumption – more broadly, for national welfare possibilities – of alternative paths of national wealth, and hence of national saving, in a closed economy. It developed out of the dynamic models of capital accumulation and output growth, generally in a setting of steady technical progress and demographic increase, begun in 1956 by R.M. Solow and T.W. Swan after some early explorations by Harrod, Domar and Robinson. Solow and Swan had shown that, provided diminishing returns to capital set in strongly enough (whether or not smoothly), there exists a state of steady growth corresponding to each possible value of the saving–output ratio, and, interestingly enough, this steady-state growth rate is independent of the value of the saving ratio – and often called the natural rate of growth. Hence, an upward shift of saving at each level of output, through increased private thrift or else...
higher taxes or lower spending by the government, cannot have a permanent, or non-vanishing, effect on the growth rate of output, only a transient effect.

If this theorem was the first law of the new ‘growth economics’, the golden rule of accumulation was the second law of growth economics. It states that the steady-growth state that gives the maximum path of consumption – the path layered on top of all the other steady-growth consumption tracks – is the one along which national consumption equals the national wage bill and thus national saving equals ‘profits’ (gross of interest in the present use of the term). Equivalently, the consumption-maximizing steady-growth path is the steady state along which the competitive rate of interest, which is the social rate of return to investment and to saving, is equal to the natural rate of growth. (To see the equivalence, divide profits and saving by capital.) Hence, a country (with any given history) that now plans for ever to equate saving to profits could not hope to achieve a sustainable increase in the consumption path by some date in the future through a shift of policy towards increased saving; very possibly, even a temporary increase of consumption would not result. The reason is that despite a boost to future output brought by greater accumulation, the increase in future investment would eat up the increase in future output – and then some.

The arrival circa 1960 of the golden rule result was a classic case of multiple discoverers. And discovery seems the apt word, since the golden rule theorem was just a simple insight about a set or sets of equations in existence for several years that was waiting to be noticed, not a creative vision of the world springing from an independent empirical sense; accordingly, many or most of the discoverers were fledgling, pre-flight theorists still working on the ground of existing models. The earliest publishers of the result were Phelps (1961), Robinson (1962), and Swan (1963). However, it quickly became apparent that there were also discoveries on the Continent by von Weizsäcker and Allais, and even within the tiny space of the Cowles Foundation at Yale there were additional independent discoveries by Beckmann and Srinivasan. Robinson coined the proposition ‘the neoclassical theorem’, but eventually Phelps's coinage ‘the golden rule’ became the standard. This was not a case of bad money driving out good, as will be explained.

The term ‘golden rule’ was something of a play on words. Mrs Robinson had dubbed states of steady growth as ‘golden ages’, so a proposition (if not exactly a maxim) about choosing among golden ages was natural to call a golden rule. In addition, there was also an allusion in the term to the biblical golden rule, do unto others as you would have them do unto you. The sense of that maxim, presumably, is that if one asserts a right to a certain policy, or treatment, from others, then in one's own treatment of others one must accord them the right to the same policy; so the choice of the rights to assert is subject to a reciprocity or cost constraint, which is a useful thing, for otherwise one would demand the most extreme sacrifices of others. Of course, this precept – the national saving policy, or national consumption function, that a future generation would have preceding ones follow, in view of its self-interests, it must likewise adopt on behalf of succeeding generations – does not by itself determine the just policy of national saving. Yet the golden rule perspective serves to alert us that there will be a limit to the austerity that future generations would ask of the present generation if they are obliged to practice the same austerity that they choose to preach. To make this effective, it should be noted, the saving policies from which society is to choose must be linear-homogeneous, and thus expressed in terms of saving as a ratio to output or profits or some related variable. (Otherwise, a future generation could piously call for lower consumption only at the present, comparatively low level of national income – and thus travel as a free rider.)
The meaning and indeed the significance of the golden rule becomes quite transparent in the special case of an economy in which the technology and the (working-age) population are constant, so that the natural rate of growth of the economy is zero. In this case the golden rule state is the Schumpeterian zero-interest stationary state; and since the net rate of return to investment is zero, gross profits are simply depreciation allowances and equal to gross investment, which is entirely replacement investment in a stationary state. Here it is abundantly clear why an alternative stationary state with a constant negative rate of interest would actually yield a lower path of consumption: the extra replacement investment would more than eat up the extra gross output, leaving an actual diminution of the net national product and consumption (to which NNP is equal). It is also perfectly clear that a society is not required as a matter of efficiency to aim for the Schumpeterian state; if the initial rate of return to investment is positive, it would take lower consumption in the present than would otherwise be possible on a sustainable basis (simply by consuming income) in order to move to the Schumpeterian state so that in the future a higher consumption level could be sustained than would otherwise be possible. Neither is such a move required as a matter of justice. From the utilitarian side there are economists who cheerfully discount the utilities of future people, and from the ‘maximin’ perspective it is obvious that present people would not optimally sacrifice to make better-off those who were not worse-off than they to begin with. The basic significance of the golden rule, then, is as a warning against national policies of over-saving, or counterproductive austerity. The golden rule theorem is simply a generalization to a growing economy of these observations.

Further results on the inefficiency entailed by exceeding, so to speak, the golden rule in certain respects were later obtained. It was shown with the help of T.C. Koopmans that keeping the capital–output ratio indefinitely in excess (by a non-vanishing amount) of the golden rule level would be dominated in terms of consumption, and thus utility, by another path, feasible from the same initial conditions, along which the capital–output ratio is always ‘epsilon’ smaller (Phelps, 1965; 1966). A much more general analysis came later from D. Cass in 1972 in which the borderline between efficient and dynamically inefficient paths is systematically examined.

‘But the golden rule path could be the social optimum, couldn't it? Certainly it is very beautiful, and not obviously unjust!’ There was a tendency among some to regard it as the optimum at least provisionally, for working purposes. However, any budding claims that may have existed for the ‘optimality’ of the golden rule path met with an objection by I.F. Pearce (1962). Start there at T₁, Pearce said, and end there at T₂. Then, if there is steady population growth, so the golden rule interest rate is positive (being equal to the population growth rate), it will increase the integral of total utility to save more now and less later, causing the capital stock to arch over its golden-rule track, since more saving will increase output. There could be no denying this, although some utilitarians prefer to sum the per capita utility of people over time (or the utility of per capita consumption), which suggests there is a maximin impulse in their otherwise utilitarian hearts; from this angle it would not be preferable to deviate along Pearce's arching detour. Then, using the per capita utility version of utilitarianism, P.A. Samuelson (1967) took up the cudgels with a revision of the Pearce argument: if there is steady technical progress, so the golden rule interest rate exceeds the population growth rate, it will increase the integral of per capita utility to cause the capital stock to arch above its golden-rule track since more saving will increase per capita output – as long as the interest rate remains above Samuelson's 'biological' level, which is the population growth rate. Again, it is nolo contendere from the golden rule side. Yet maximin advocates might object that if
the per capita utility received by succeeding generations is rising, and unavoidably so, so that the oldest generation extant is always the worst-off, the detour from the golden rule path proposed by Samuelson would presumably entail some belt-tightening by the oldest generation along with the others in order to produce the consumption splurge for the benefit of some younger or future generations – hence a reduction in *minimum* per capita utility across generations. That cannot be a maximin improvement and is indeed a maximin worsening. Thus goes the maximin rejoinder to the turnpike ‘refutation’ of the golden rule.

Article

Goldfeld was born in Bronx, New York, and received his undergraduate training in mathematics at Harvard University. He obtained a Ph.D. in economics from MIT in 1963. Except for visiting appointments at Center for Operations Research and Econometrics (CORE) at the Université Catholique de Louvain, the University of California, Berkeley, and the Technion in Haifa, and a year as a member of the US Council of Economic Advisors, he spent his professional life at Princeton University, where he served as Provost from 1993 until his death. Goldfeld largely divided his professional interests between monetary economics and econometric methodology. In the former category are his early book (1966a) and two definitive papers (1973a) and (1976) that are models of careful empirical econometrics. They address the question of whether the money demand function is basically stable in the short run. In estimating the money demand function for the post-war period, Goldfeld exhaustively analyses specifications differing from one another in terms of the extent of aggregation, the type of lag structure and the types of variables included in the demand function. In (1973a), he finds no substantial short-run instability in the demand function. He also concludes that disaggregation by sector probably helps explain money demand. But the (1976) paper attacks the poor predictive performance of the money demand equation in the period following 1973: the equation consistently over-predicts money demand. An even more extensive and thorough analysis aimed at fixing this problem makes him suggest that a more fundamental rethinking of money demand is indicated. He also studied savings and loan associations and their behaviour with respect to rate setting and allocational efficiency (1970), forecasting and policy evaluation in large-scale econometric models (1971) and numerous related topics.

His methodological interests began with the construction of a new test for homoscedasticity (1965),
subsequently called the Goldfeld–Quandt test, followed in short order by an abiding interest in nonlinear estimation (1968) and computational econometrics (1966b). This led to the invention of the GRADX algorithm, which solves the maximization problem for non-concave functions by embedding them in a concave analogue. He then turned to the case of switching regressions: problems in which the parameters of a regression equation switch from one set of values to another, but at an unknown point in time (1973b) (hence making the Chow test inappropriate). The superficial similarity of these models to disequilibrium models, in which the observed quantity represents the short side of the market, led him to an abiding interest in models of the latter type, sometimes within the framework of financial institutions (1975; 1980). A reconsideration of the Suits agricultural model may contain the first proof of the unboundedness of a likelihood function for a disequilibrium model when sample separation is not known a priori (1975). Because of the relatively intractable nature of the econometrics when error terms are normally distributed in these models, he explored the properties of a new distribution called the Sargan distribution (1981).

In the last few years of his life, Goldfeld was much interested in the microtheoretic problems of socialist enterprises operating in the presence of a soft budget constraint, a concept derived from János Kornai (1979; 1980; 1982). In the models, firms can undertake ‘whining’ when they face losses and bail-outs permit them to continue operating. These models confirm Kornai's conjecture that the expectation of bail-outs will lead to larger input demand than in the standard competitive case (1988; 1990). Embedding the possibility of ‘whining’ in a multi-firm case in which inputs are rationed and whining is intended to induce a more generous input allotment leads to the determination of a Nash equilibrium in whining (1990).

Goldfeld had enormous range and creativity and was a precise, careful and methodical worker as well as a much-loved teacher of both undergraduates and graduate students. His premature death was a great loss to the profession.

Born in Brussels, Goldsmith studied in Berlin (Ph.D., 1927). He emigrated to the United States and served on the US Securities and Exchange Commission (1934–41), the War Production Board (1942–7) and as a member of the Senior Staff, National Bureau of Economic Research (1953–78). He was a Professor at New York University (1956–61) and at Yale University (1962–73; Emeritus, 1973 onwards). He pioneered the measurement of national and sector saving, investment, wealth, and balance sheets.

In the 1930s Goldsmith initiated Securities and Exchange Commission estimates of saving, obtained by a new method: subtracting additions to liabilities from additions to assets. During 1947–68 the Commerce Department national income accounts reported personal saving derived from the Securities and Exchange Commission series as an alternative to estimates obtained as income less consumption and as investment less corporate and government saving. The Federal Reserve Board then absorbed the Securities and Exchange Commission work into its flow-of-funds accounts. These had been started by Copeland in research partly paralleling Goldsmith's (Copeland, 1952, p. xvi).

A still more important breakthrough, in 1950, was Goldsmith's perpetual inventory method of estimating the stock and consumption of durable capital. The United States and other countries use it to obtain official national income and capital stock series. Goldsmith's monumental Study of Saving followed, providing balance sheets, saving, and wealth, for the nation and sectors. It featured broad scope, great detail, and series running back to the 1890s (to 1805 for reproducible wealth; in Goldsmith, 1951b). Goldsmith subsequently updated these series and introduced similar ones for other countries. Lifelong adherence to the principle of reproducibility, which calls for sufficient description of all estimates to enable the reader to reproduce them, increases the usefulness of Goldsmith's data.

Goldsmith wrote extensively about financial institutions and capital markets. He introduced the financial
interrelations and financial intermediation ratios (Goldsmith, 1966; 1969). In his later years Goldsmith studied pre-industrial economies (Goldsmith 1987).

Towards the end of the 1950s, Harry Johnson produced the following theorem on value theory:

Define a good as an object or service of which the consumer would choose to have more. Then the collection of goods he chooses when he has more money to spend (prices being constant) must represent more goods than that he chooses when he has less money to spend (since he could have had more of each separate good).

1. i. If his income rises, he buys more goods; this implies a presumption that normally the income effect is positive.
2. ii. If he chooses collection B when he could have had collection A for the same money (i.e. \( \Sigma p_b q_b = \Sigma p_a q_a \)), he does not choose A if he could have had B for less money, because that would mean collection B represented less goods than collection A, and conflict with the definition of goods. Hence, when A is chosen B must be at least as expensive (i.e. \( \Sigma p_a q_b \geq \Sigma p_a q_a \)). This establishes that the substitution effect is non-negative (by subtraction, \( \Sigma (p_b - p_a)(q_b - q_a) \leq 0 \)).

Hence we derive both parts of the law of demand from the definition of goods. The hypothesis from which we have deduced it is that goods are goods. (1958, p. 149)
The idea that definition of goods carried with it the whole of the theory of demand, that the explanation of the determination of the exchangeable value of ‘things’ was intimately bound up with the definition of the ‘things’ themselves, probably struck many of Harry Johnson's readers as amusing. Indeed, Johnson may even have had this end in mind – no doubt many in the profession were beginning to wonder whether the frequency with which reconsiderations of something apparently so obvious as the theory of demand were being undertaken was entirely necessary. However, it did not strike at least one of his readers as being just another amusing aphorism: Kelvin Lancaster, upon whose review of Hicks's *Revision of Demand Theory* Johnson was commenting when he produced his theorem, took it seriously. Eight years later in the *American Economic Review* Lancaster advanced the so-called characteristics theory of demand. The argument was a simple corollary of the Johnson theorem: if it is the aim of the theory of demand to determine the prices of goods, then one ought to specify as clearly as possible the goods which are being demanded. After all, on this line of reasoning one demands not just physical objects, but the qualities with which they are endowed; it is to their characteristics that the potential purchaser first turns his attention.

The interesting features of this little episode, however, are not exhausted in a consideration of the ideas to which it gave rise. Quite as important are the implications which follow upon the recognition of the fact that the kinds of questions which lie behind Johnson's theorem had been debated before in contexts where certain useful results were generated. At least since the time of Adam Smith, economists have struggled to be clear about what it is in the nature of the things which are daily exchanged on markets that gives rise to exchangeable value. When Smith discussed the famous water–diamonds paradox, and drew from it (however perilously) the conclusion that the theory of exchangeable value should focus upon what may be called the objective conditions of production of things, rather than upon the subjective conditions of their consumption, he was engaged in just such an endeavour.

Smith was followed in this project by Ricardo. In the opening passages of the *Principles*, by establishing a clear line of demarcation between scarce and reproducible commodities, Ricardo reached Smith's conclusion by a different route. Marx praised this passage from Ricardo and focused his attention exclusively upon what he termed the commodity form. Moreover, this was not exclusively a classical preoccupation. Later writers, to whom modern economics seems to owe much more, also took the question very seriously indeed. Having returned to Smith's original paradox, they applied the distinction between total and marginal utility and to their satisfaction resolved it. This deprived Smith's original conclusion of its validity and allowed neoclassical writers to rebuild the theory of exchangeable value upon the basis of the subjective conditions of consumption of goods. Marshall was very clear about this at the beginning of the second chapter of Book II of his *Principles*.

The questions that Johnson's theorem prompts, therefore, include also those which were raised in these widely publicized and not insignificant debates of the 19th century over the distinction in the theory of value between those physical objects whose main characteristic is that they can be said to be in short supply, and those whose quantity may be increased by reproduction on an extended scale. To what extent, if at all, the choice of terminology by earlier writers reflects these differences is the subject matter of an investigation into goods and commodities.

**Etymological preliminaries**

In English the word *good* derives from the Old English word *gōd*. It is related also to the Old Frisian
goods and commodities: The New Palgrave Dictionary of Economics

gōd, the Old High German guot, the Old Saxon gōd, and the Old Norse gödr. The word is defined in the Oxford Dictionary of English Etymology as ‘the most general adjective of commendation’. The substantive plural form, goods, while sharing the origins, seems not to have appeared in English until the 13th century with a meaning much as it has today: objects or things which confer some advantage or produce some desirable effect upon their owner. Two further points may be noted. The first is that although there exists a genitive singular in Old Norse, no Teutonic language seems to have possessed a substantive plural form. Its usage in this manner probably derives from the Latin bona. The second is that despite the standard O.E.D. classification of goods as indeclinable, a substantive singular form has become common among economists.

In both modern French and German, the adjectives bien and gut share the meaning and sense as good in English (the German sharing the same Old Teutonic origins). The substantive plurals biens and Güter likewise share meaning and sense, together with the partial Latin origin of the English.

James Bonar's definition of the term goods in the original edition of this Dictionary – that ‘by the plural (Goods) is denoted concrete embodiments of usefulness’ – suggests that nothing of substance had been altered in the definition of the word even after it had been co-opted into the formal terminology of economic theory. Furthermore, Bonar's statement that goods are the physical embodiment of the metaphysical quality of good, seems to apply across all three languages. Of course, given that a substantive singular form is now in common usage, that part of Bonar's definition which went on to argue that the substantive singular commodity ‘is employed by economists to represent the missing singular of goods’, must be abandoned.

The word commodity is of entirely different origin and meaning. Its roots are in Latin and it is defined in the Oxford English Dictionary as ‘a thing produced for use or sale, an article of commerce, an object of trade’.

Commodities

Questions as to the essential properties of the things exchanged in a market economy, though they had arisen in the work of earlier economists, took on an entirely new dimension with the commencement of the systematic study of exchangeable value in the last half of the 18th century. Following immediately upon the definition of wealth as the ‘annual production’ of the system, and the analysis of the effects of progress in the division of labour on the ‘proportion between annual production and consumption’, Adam Smith had confronted the issue of the valuation of this ‘quantity of commodities annually circulated’. The problem was to establish, in the first instance, the sphere within which exchangeable value was to be examined. His answer, though failing to take into account conditions of relative scarcity, illustrates just as clearly as Johnson's theorem how an apparently neutral choice of language may be the bearer of certain theoretical precepts upon which an entire argument rests.

Perhaps even more importantly, Smith seems to have established not only the formal framework for the theory of value, but also the very language in which it was transmitted in orthodox circles right down to the time of Ricardo. That argument is sufficiently familiar not to have to be rehearsed here – the essential ingredient that is relevant to us is its rejection of the notion that the ‘utility of some particular object’ has anything to do with determining exchangeable value and that, instead, the exchangeable value of an object is to be explained in terms of what Smith variously called the ‘toil and trouble of obtaining it’ or its ‘difficulty and facility of production’.

These objects are quite consistently called by Smith commodities and not goods. The terminology and the theoretical construct seem to match quite well. If one is to follow Smith into an investigation of the relationship between conditions of production and relative prices, the usage of the term goods would be less than apposite. This, of course, is not to say that the familiar word goods does not crop up from time to time in the Wealth of Nations (opening the book at random would quickly disprove such a strong assertion). Nor is it to claim that Smith even bothered to take the time to explain his pattern of usage. But a determinate pattern there surely is.

Consider, for example, the discussion of the water–diamonds paradox, a passage where goods appears twice. This very short passage is followed by a carefully constructed paragraph setting out in a quite formal and purposeful way the project for the remainder of Book One. In that particular place, the term commodities is used exclusively. Indeed, the following three chapters, on real and nominal price, the component parts of price, and natural and market price, adhere fairly rigidly to this pattern of formal usage. The index, which was added to the original in its third edition of 1784, contains a lengthy entry under commodities but not one for goods. What is also interesting is that as between the two words, goods usually appears in those more discursive passages of the Wealth of Nations, whereas commodities is reserved for passages of a more formal, theoretical kind.

A remarkable parallel is to be found in the third edition of Ricardo's Principles. There, in the first paragraphs of the chapter on value, Ricardo makes a significant attempt to define just what it is that is important in the nature of those objects whose prices are determined on markets. At the same time, it should be noted, he replaces Smith's argument as to why exchangeable value is to be investigated in the sphere of production. The argument is pure Ricardo. Utility is ‘essential to exchangeable value’, objects which contribute in no way towards ‘gratification’ would be ‘destitute of exchangeable value’, but it does not determine it. Two conditions then remain to determine exchangeable value – Smith's difficulty and facility of production and, what Smith had passed over, scarcity. There follows Ricardo's famous twofold classification of commodities: those which are currently reproduced (produced commodities) and those which are fixed in quantity (scarce commodities). The exchangeable value of the former, when competition operates without restraint, is to be investigated in terms of the available methods of production. Relative prices of the latter depend upon the ‘wealth and inclinations of those who are desirous of possessing them’. Ricardo restricts the investigation to produced commodities and his use of terms resembles the pattern one discerns in the Wealth of Nations.

This particular argument was taken up subsequently by two writers who stand in contrasting positions with respect to this classical conception of the framework for the analysis of exchangeable value – John Stuart Mill and Karl Marx. Both built quite self-consciously on the work of Smith and Ricardo. But as it happens, while Mill was effectively to put in place ideas (which admittedly had been in the air for some time) that were quite dramatically to modify the classical position, Marx was to revivify it. How closely terminological conventions reflect these factors is a question of some importance in the present context. To begin with, let us turn to the German language, and to Marx, who claimed that Ricardo's argument for restricting the domain of the theory of value and distribution to the sphere of produced commodities had been ‘formulated and expounded in the clearest possible manner’ (1859, p. 60). Quite unlike Ricardo, Marx not only consistently avoided the use of term Güter (goods) – it is hardly possible to forget that the first chapter of Capital bears the title Wares – but actually considered the theoretical consequences of these terminological conventions in the Contribution to the Critique of Political Economy. Though not especially satisfying in itself, the theoretical argumentation of the Critique is
simple enough: ‘use-value as such, since it is independent of the determinate economic form, lies outside the sphere of political economy’ (1859, p. 28).

Goods

As the basis of the theory of value shifted away from the old classical idea of production as a circular process, towards the newer and different idea of an economic process resembling a one-way street – from ‘factors of production’ to ‘goods’ – there began simultaneously a retreat from the examination of exchangeable value in terms of the objective conditions surrounding the production of commodities, and an advance towards a theory of value grounded in the subjective conditions surrounding the consumption of goods. Of course, this was not entirely an unprecedented idea (the work of Lauderdale and Bailey comes to mind), what is different is the fact that these notions are now placed on a firmer theoretical footing than had hitherto been the case and that they come to form the mainstream of the discipline.

The orientation thereby imparted to the theory of exchangeable value by the economists in the vanguard of this change took as its starting point precisely those passages of the *Wealth of Nations* which had been so important in establishing the conceptual apparatus of the earlier classical economists. But the lesson that was drawn from them was not that which had been drawn by Smith. They, too, were keenly interested in the properties of the actual objects of market exchange, but from Smith's water–diamonds paradox they did not reach the classical conclusion, but rather one that held that the joint conditions of scarcity and utility would act to determine relative prices. As Pareto was eloquently to put it, economics became the study of equilibrium between man's tastes and the obstacles to satisfying them.

Exchangeable value, to borrow Jevons's terminology, would be determined by the final degree of utility. The 1870s were, of course, the years in which the basic provisions of the new constitution of economics were laid down almost simultaneously in Britain, France and Germany. Precursors had been sought out and honoured by those in the vanguard of the new theory, and the battle against the ‘noxious influence of authority’, as Jevons put it, already promised success – even the sterner opposition of the historical school was beginning to seem less formidable. Yet despite these quite rapid developments, in the initial years of the marginal revolution the language and usage in English economics seems to have remained essentially as it had been in the classical period. An example may serve to highlight the point.

William Stanley Jevons, who by the second edition of his *Theory of Political Economy* in 1879 had succeeded in substituting ‘economics’ for the older term ‘political economy’ in everything but the title of his book, retained the substantive *commodities* even though it was to their want-satisfying qualities that he wished to defer in his explanation of exchangeable value. Usage of the term *goods*, which conveys with greater accuracy the theoretical conceptions at the base of this new approach to the theory of value, appears to have been consciously avoided by Jevons. There is a particularly interesting passage from the *Theory of Political Economy* that illustrates the degree to which Jevons grappled with the language in which to express his theory:

> It will be allowable … to appropriate the good English word *discommodity*, to signify any substance or action which is the opposite of *commodity*, that is to say, *anything which we desire to get rid of* … Discommodity is, indeed, properly an abstract form signifying inconvenience or disadvantage. (1871, p. 114, italics in original)
It is impossible to resist the temptation to add that ‘the good English word’ *discommodity* is of Latin origin, and that the formal introduction of the simple Old English word *goods* at this juncture would have relieved Jevons of the need to conduct such linguistic exercises (see also, Jevons, 1882, p. 11). Nevertheless, the example is sufficient to indicate that in the English language at least, *goods* was not at this time in formal use in theoretical economics.

Despite this, however, the appearance of the term *goods* in the formal literature of economics is inextricably linked with the rise of the neoclassical theory of exchange and demand. But to see how this is so, it is necessary to turn to the writings of German economists of the new school. In the German neoclassical literature, quite precise definitions were given for the formal usage of the substantives *Gut* and *Güter*. Carl Menger's *Grundsätze der Volkswirtschaftslehre* (1871) provides a particularly striking example of this:

> Diejenigen Dinge, welche die Tauglichkeit haben in Causalzusammenhang mit der Befriedigung menschlicher Bedürfnisse gesetzt zu werden, nennen wir Nützlichkeiten, wofern wir diesen Causalzusammenhang aber erkennen und es zugleich in unserer Macht haben, die in Rede stehenden Dinge zur Befriedigung unserer Bedürfnisse tatsächlich heranzuziehen, nennen wir sie Güter. (1871, pp. 1–2)

Menger, in fact, went so far as to devote an exceedingly long footnote (printed as an appendix to the *Werke* edition of the *Grundsätze*) to the history of the usage of this term in this sense. How and when the equivalent term entered the formal language of English economics – and when it might be said to have established itself – is not a difficult question to answer. Alfred Marshall's *Principles* (1890) seems to be the innovator.

In a passage from the second edition of the *Principles* dating from 1891, Marshall remarked that lacking any short term in common use to represent all desirable things, that is ‘things that satisfy human wants’, he proposed ‘to use the term *Goods* for that purpose’ (1961, I, p. 54, italics in original). In the second edition Marshall appended a footnote to the effect that he intended to replace the singular *commodity* with the term *good*, and gives as explicit justification for this the correspondence between his usage and that of the German economists (see 1961, II, p. 185e). This appears to be the first systematic application of the term *goods* in the formal terminology of economic theory – what is more, its usage is derived from the German. Note that a substantive singular form also appears.

It would seem reasonable to conclude, therefore, that it is from this source (that is, from Marshall's *Principles*) that the term *goods* gained wide circulation in economic theory. The date by which it might be reckoned to have established itself would appear to be around the mid-1890s, as it was in the fourth edition of the *Principles* in 1898 that Marshall chose to delete the footnote alluded to in the previous paragraph. This would accord broadly with the date at which the original edition of this *Dictionary* appeared containing James Bonar's entry under the heading *goods*. It is interesting to note that by the end of the 1920s the term had been so fully absorbed into the language of economic theory that Robbins chose to omit from the English edition of Wicksell's *Lectures* a paragraph where the question of this terminology is discussed. According to Robbins's editorial note, this paragraph was ‘of no interest to English readers’ (Wicksell, 1934, vol. 1, p. 15 n.l).
The originators of the modern theory of exchange and demand, nevertheless, had established a terminology through which to convey one of the basic tenets of their argument. Not only did they appreciate that goods are goods, but they expended a considerable amount of time and energy establishing that the subjective conditions of consumption were the appropriate place to locate the analysis of exchangeable value.

Characteristics

This brings us back to Harry Johnson's theorem. The grounding of a theory of exchangeable value upon the notion of *goods* was taken in certain to require a closer specification of the want-satisfying qualities of the 'things' which are daily exchanged on markets – since these are, in the final analysis, the *goods* which form the subject of the examination. When one contemplates the kinds of developments in the theory of exchange which might contribute towards the fulfilment of this requirement, nearly all of them seem to entail a widening of the gap between the actual 'things' which are exchanged on markets, and their want-satisfying characteristics which are the real subjects of demand. This, of course, is the direction in which the characteristics theory of demand has already taken us. Its problematic, of course, is to establish a transformation from characteristics to the actual objects through which these characteristics are transmitted. In the language of Lancaster, what is required is a well-defined mapping from the characteristics space to the goods space – since in the end the prices that are thrown up on markets are attached to actual objects and not to their characteristics. The theory of separable utility functions has been of immense assistance in this regard.

However, if the classification of these characteristics could be rendered sufficiently fine, then a concomitant implication would seem to be that the idea of securing a theory of the prices attached to actual objects exchanged on markets would need to be sought in some other direction. Otherwise, we should be left with a theory of exchange and demand which made no contact, even at an abstract theoretical level, with the material realities of market exchange in modern economies. We should certainly have a theory of *goods*, but to what form of economic organization such a theory could be held to apply, if any, is not at all obvious.

So that such speculations should not be thought to be idle, it is interesting to note that language is not only a vehicle for the transmission of theoretical conceptions; it is often the vehicle through which a whole array of structural and cultural data about social interaction is conveyed. Exchange in different kinds of societies frequently embodies these complex social relations – so much so that the familiar idea of economists of the modern school that a universally applicable analysis of exchange is somehow desirable, or even possible, would seem to be fraught with pitfalls.

Article
Gordon was born 26 July 1908 in Washington, DC, and died 7 April 1978 in Berkeley, California. He was a policy-oriented economist whose research style was quantitative but not econometric, and whose influence was felt not only through his basic research but also as a dedicated and tireless public servant. After his formative years as graduate student and instructor at Harvard University, 1929–38, he accepted a position at the University of California (Berkeley), where he remained until his retirement from teaching in 1976.

His early work in industrial organization culminated in the influential volume on *Business Leadership in the Large Corporation* (1944), which is noteworthy for its pioneering use of empirical data in the field. Another major strand is his work on unemployment, its structural and cyclical causes, and the goal of full employment (1962; 1967).

His lifelong research interests were primarily focused, however, on business cycles and their causes. He championed the quantitative-historical method of cycle analysis over the National Bureau of Economic Research (Burns–Mitchell) and econometric modelling (Cowles Commission) approaches (1949), and he devoted much of his career to implementing his approach in studies of the business fluctuations of the interwar period (1951) and before and after the Second World War (1955a; 1969; 1974). His eclectic analysis of the causes of business cycles emphasized the Schumpeter–Hansen distinction between major and minor business cycles (1956) and attributed the major cycles to the appearance and exhaustion of investment opportunities in particular industries (1955b).

He combined a formidable talent for economic analysis with a sense of historical and institutional relevance and was impatient with the tendency he discerned in the profession at large to favour rigour over relevance in economic theorizing. This impatience was expressed at an early stage with regard to price theory (1948), reiterated in his presidential address to the American Economic Association on...
Rigor and Relevance in a Changing Institutional Environment’ (1976), and repeated in his last piece on ‘A Skeptical Look at the “Natural Rate” Hypothesis’ (1978).

His contributions to the public weal were many and lasting, but two in particular may be cited. In 1956–59 Gordon undertook a massive study of business education jointly with James E. Howell for the Ford Foundation, and their 1959 report provided the stimulus for a radical reorientation of MBA programmes in graduate business schools toward the use of analytical methods drawn from economics, statistics, and the behavioural sciences. He also served as chair of the President's Committee to Appraise Statistics on Employment and Unemployment in 1961–62, which led to important reforms in the nation's statistics in this vital area.

Gorman, W.M. (Terence)

Charles Blackorby, Daniel Primont and R. Robert Russell
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

W.M. (Terence) Gorman was a theorist's theorist who nonetheless thought himself to be very practical. His contributions were brilliantly original – both in conception and in technical execution – but they often were a difficult read. We sketch below two of his lifelong interests – aggregation over agents and aggregation over commodities – and discuss briefly a few of his other contributions. We hope this brief outline will encourage others to peruse his works in more detail.

M.; Hotelling's lemma; indirect utility functions; interpersonal utility comparisons; Le Chatelier principle; marginal product of capital; price aggregation; profit functions; Roy's theorem; separability; two-stage budgeting

Article

1 Introduction

W.M. Gorman lived from 1923 to 2003. He graduated from Trinity College, Dublin, in 1948 in economics and a year later in mathematics. He held posts at the University of Birmingham, Oxford University, and the London School of Economics. Among many honours, he was the president of the Econometric Society in 1972, a fellow of the British Academy, and an honorary foreign member of the American Academy of Arts and Sciences and of the American Economic Association. (For a more detailed discussion of Gorman's career and work, see Honohan and Neary, 2003.)

Gorman was interested in economics interpreted very broadly. He read history, philosophy, mathematics, and statistics. Nevertheless, most of his work was very abstract and many readers found it difficult to follow. We begin here by discussing his long-standing interest in two kinds of aggregation, over agents and over commodities, before considering some of his other contributions.

2 Aggregation across agents

Gorman's first published paper (Gorman, 1953) provided necessary and sufficient conditions for the existence of a representative consumer. That is, given that each consumer in society has well-behaved preferences and demand functions,
when can aggregate demand, $\sum h x^h$, be generated by the demands of an aggregate agent so that

$$x = \sum_h x^h = f(p, m),$$

(2.2)

where $m = \sum h m_h$? He demonstrated that a necessary and sufficient condition is that consumers have affine parallel Engel curves,

$$x^h = a(p) m_h + b^h(p),$$

(2.3)

so that the demands of the aggregate consumer can be written as

$$x = a(p)m + b(p),$$

(2.4)

where $b(p) = \sum h b^h(p)$. In a later paper, Gorman (1961) provided a closed form representation of the preferences of consumer with parallel affine Engle curves: the indirect utility functions can be written as

$$V^h(p, m_h) = A(p) m_h + b^h(p)$$

(2.5)

and the indirect utility function of the representative consumer can be written as

$$V(p, m) = A(p)m + B(p),$$

(2.6)

where $B(p) = \sum h B^h(p)$. Using Roy's theorem, the reader can easily check that (2.3) and (2.4) are derived from (2.5) and (2.6) respectively. The intuition behind this result is straightforward: if we take a dollar away from consumer 1 and give it
to consumer 2, aggregate demand cannot change, because total income has not changed; the two consumers therefore must have identical marginal propensities to consume. There have been many attempts to generalize this notion of a representative agent (see, for example, Muellbauer, 1976) but all suggest that aggregate demand for the $i$th commodity can be written as

$$x_i = \sum_{j=1}^{J} a_{ij}(p) b_j(m, z),$$

(2.7)

where $z$ is a vector of characteristics. Gorman (1981) demonstrates that utility maximization requires that the rank of the matrix with elements $a_{ij}$ be less than or equal to 3. Note that the idea of a representative consumer given in (2.3) entails that the matrix have rank 2. This proved that there is not much more that could be done to generalize this idea.

Over the course of the 1960s a battle raged between the US Cambridge and the English Cambridge over – to put it crudely – whether the marginal product of capital was a meaningful aggregate concept (see Fisher and Monz, 1992, for an extensive discussion of this issue). Gorman (1968a) approached this problem in the dual, using profit functions. His argument in favour of using the dual was that it was important to model problems in the appropriate variables. When thinking about capital aggregation he noted that the individual agents all face the same prices. Hence he thought the problem should be attacked using profit rather than production functions.

In the simplest terms, suppose that each firm has a profit function given by

$$n^f(p, k^f) = \max_{y^f} \left\{ p \cdot y^f \ \middle| \ y^f \in T^f(k^f) \right\} \text{ for } f = 1, \ldots, F,$$

(2.8)

where $k^f$ is a vector of the quasi-fixed factors of firm $f$ and $T^f(k^f)$ is the technology set of the firm for each fixed value of the $k^f$. In this context, the marginal product of capital only makes sense if there exists an aggregate profit function that can be written as

$$n(p, k) = \max_y \left\{ p \cdot y \ \middle| \ y \in T(k) \right\},$$

(2.9)

where $k$ is a scalar measure of the aggregate capital stock. Gorman showed that a necessary and sufficient condition for (2.9) is that

$$n^f(p, k^f) = \alpha(p) \varphi^f(k^f) + \beta^f(p) \text{ for } f = 1, \ldots, F,$$

(2.10)
so that the aggregate capital stock is given by

\[ k = \sum_{f} \varphi^f (k^f), \]

(2.11)

thus demonstrating that the marginal product of capital is not likely to be a meaningful concept very often. (For the implied restrictions on the technology sets and production functions, see Blackorby and Schworm, 1984.)

The intuition for this result is a little less straightforward. Think of \( \alpha (p) \) as a measure of bolted-down capital of firm \( f \). Then, \( \alpha (p) \) is clearly the marginal product of capital in firm \( f \) and (2.10) requires this be the same in every firm so that the aggregate profit function can be written as

\[ \pi(p, k) = \alpha(p)k + \beta(p) \]

(2.12)

where \( k \) is given by (2.11) and \( \beta(p) = \sum_{f} \varphi^f (p) \).

3 Aggregation across commodities

Gorman's best-known paper in this area (1959a) was written in response to a paper by Strotz (1957) on two-stage budgeting. Suppose that a consumer (or any organization with a well-behaved objective function and an expenditure constraint) wants to simplify its purchasing decisions as follows: first it wants to allocate funds optimally to broad categories of commodities and then later make the detailed calculations of how to spend the funds within any particular category. For example, a consumer might first decide how much money to budget for food and then later decide exactly how to allocate the food budget to particular commodities. The latter decision turns out to be equivalent to the separability of the commodities in each category, whereas the former hinges on a notion of price aggregation. (For more on two-stage budgeting and separability, see separability.)

Separability seemed a natural assumption to Gorman; it allowed the researcher to focus on a particular group of commodities without having to worry very much about anything else. In Gorman (1968b), however, he showed that this could have previously unknown implications. Suppose that one assumed that two groups of commodities were separable from their complements so that the utility function could be written as

\[ U(x) = \tilde{U}(U^A(x^A), x^C) \text{ and } U(x) = \tilde{U}(U^B(x^B), x^D). \]

(3.1)

Suppose in addition that some of the commodities in group A are not in group B, some are in both A and B, and the others are in B but not in A. Gorman showed that this implied that the utility function could in fact be written as
where the variables in \( a \) are those that are in A and not in B, those in \( b \) are in B but not in A, and those in \( c \) are in both groups. This surprising result can be taken in two ways: (1) perhaps too much separability is a dangerous thing but (2) on the other hand this theorem provides a fundamental and clean way of modelling additivity. Ever attuned to different ways of looking at things, Gorman (1970), in a paper published only in 1995, noted that if a quasi-concave utility function could be written additively, as would often be required to study intertemporal or uncertain events,

\[
U(x) = \sum_{s=1}^{S} U^s(x^s),
\]

(3.3)

then at most one of the functions \( U^s \) could fail to be concave. Thus, for example, if the \( U^s \) functions were the same as in expected utility theory (that is, linear transformations of one another), then quasi-concavity would imply concavity. Again this can be taken two ways – as an easy way to obtain concavity or as the danger of too much separability.

4 General interests

Gorman was well known for having widely circulated and widely cited but unpublished papers. Perhaps, the best known of these was ‘A Possible Procedure for Analysing Quality Differentials in the Egg Market’, a 1956 working paper of the Iowa Agricultural Experiment Station. (This paper was eventually published as Gorman, 1980. A more complete discussion can be found in Honohan and Neary, 2003.) Suppose that it is not the commodities that consumers want but rather the characteristics embodied in them. Thus type \( i \) egg would contain \( a_i \) of characteristic A, \( b_i \) of characteristic B, and so on. Further, Gorman assumed that if one bought \( x_1 \) of type 1 egg and \( x_2 \) of type 2, then the total amount of characteristic A would be \( a_1x_1 + a_2x_2 \). Thus, at arbitrary prices only two types of eggs would be purchased if there were only two characteristics that were relevant and three types if three characteristics were relevant, except in the degenerate case where relative prices were just right. Then the consumer would be indifferent between two or three or more types of eggs. Gorman argued that equilibrium prices should not contain any arbitrage opportunities and hence the degenerate case would be the normal one. This then suggested an agenda for empirical work that he and students pursued over the years. (Not very much of this research actually surfaced, although a 1959 University of Birmingham working paper entitled ‘Demand for Fish: an Application of Factor Analysis’ and his 1972 presidential address to the Econometric Society, ‘A Sketch for the Demand for Related Goods’, were widely cited for some time.)

Although Gorman wrote and published little in welfare economics, what he did write demonstrated a profound understanding of the issues involved. In order to avoid the known problem with the Kaldor (1939) compensation principle (namely, that situation B could be preferred to situation A by the Kaldor compensation criterion and that A could be preferred to B by the same criterion), Scitovsky (1941) had proposed a new test that required that B should be preferred to A if B was preferred by the Kaldor compensation test and A was not preferred to B by the same test. In Gorman (1955) he demonstrates in a very elegant manner that the Scitovsky criterion is intransitive; that is, that B could be preferred to A by the Scitovsky criterion, C preferred to B by the same criterion, and then that A could be preferred to C by the same test. In a rather more philosophical vein, Gorman (1959b) presents a series of arguments that might lead one to think that social indifference curves are convex. In this he was clearly aware of the problems of interpersonal comparisons of utility and the idea of diminishing marginal utility for each individual. Even now this makes for a thought-provoking read.
Although Gorman did very little research in general equilibrium, when preparing a paper for a Festschrift in honour of Ivor Pierce he felt that only a general equilibrium paper would be appropriate. Gorman (1984) prepared an analysis of the Le Chatelier principle in general equilibrium. To give the reader the flavour of his elegant argument, let \( \Pi(p) \) and \( \pi(p) \) be the long-run and short-run profit functions of a firm. It seems natural to assume that

\[
\Pi(p) \geq \pi(p).
\]

(4.1)

Suppose that at \( p = \bar{p} \) we are at a long-run equilibrium, so that

\[
\Pi(\bar{p}) = \pi(\bar{p}).
\]

(4.2)

Thus, the price vector \( p = \bar{p} \) minimizes the difference between long-run and short-run profits, \( \Pi(p) - \pi(p) \). The second-order condition for this minimization problem is given by

\[
\sum_i \sum_j \Pi_{ij}(\bar{p}) \theta_i \theta_j \geq \sum_i \sum_j \pi_{ij}(\bar{p}) \theta_i \theta_j.
\]

(4.3)

By Hotelling's lemma, this implies immediately that

\[
\frac{\partial \bar{x}_i}{\partial p_j} \geq \frac{\partial \bar{x}_i}{\partial p_j},
\]

(4.4)

that is, the long-run response of commodity \( i \) to a change in its price is greater than or equal to the short-run response – the Le Chatelier principle.

Technically, much of Gorman's work was difficult; he frequently employed transformations of variables and functions with such speed that the reader felt, if not lost, at least dizzy. In Gorman (1976) he wrote what he thought of as a reasonable introduction to some of these tools and called the paper 'Tricks with Utility Functions'. We conclude with a discussion of one of these tricks and the lesson that Gorman thought could be learned from it.

Gorman begins his discussion of equivalent adult scales (equivalence scales) with a quote from a former schoolmaster who said 'When you have a wife and a baby, a penny bun costs threepence'. Consider a family of type \( a=(a_1, \ldots, a_n) \) whose utility function could be written – after Barten (1964) – as

\[
U_a = U^a(x) = U(x^a),
\]
where the adjusted consumption vector,

\[ \chi^a = \left( \frac{\chi_1}{a_1}, \ldots, \frac{\chi_N}{a_N} \right), \]

(4.6)
corrects for the number of equivalent adults. Note that the second equal sign implies that all households have the same utility function but defined on the adjusted variables. The expenditure function dual to \( U^a \) in (4.5) is given by

\[ E^a(u_a, p) = \min_{\chi^a} \left\{ p_1 x_1 + p_2 x_2 + \ldots + p_N x_N \left| U^a(\chi) \geq u_a \right. \right\} = \min_{\chi^a} \left\{ a_1 p_1 \chi_1^a + \ldots + a_N p_N \chi_N^a \left| U(\chi^a) \geq u_a \right. \right\} = E(u_a, p^a), \]

(4.7)

where \( p^a = (a_1 p_1, \ldots, a_N p_N) \) and \( E \) is the expenditure function dual to \( U \) in (4.5). Thus, for a family of three bread-equivalent adults ‘a penny bun costs threepence’. The adjusted compensated demand for good \( i \) is

\[ x_i^a = E_i(u_a, p^a), \]

(4.8)

so that the ordinary compensated demand is

\[ x_i = a_i E_i(u_a, p^a). \]

(4.9)

From this, the compensated demand elasticities can be written as

\[ \xi_{ij} = \delta_{ij} + \alpha_{ij}, \]

(4.10)

where \( \delta_{ij} \) is the Kronecker delta and
at a fixed \( u_a \) is the compensated elasticity with respect to family size. It is easy from here to calculate the uncompensated elasticities as well. From this Gorman concludes that ‘Were the theory true, and were the sample to include a great enough variety of family types, we could use them to calculate the price elasticities from survey data. As long as everyone faces the same prices, we need not even know what they are’. If one had tried to do this analysis, as Barten did, working only with (4.5) the simplicity of this model would not have been exposed.

This paper had dozens of such ‘tricks’, techniques that use either duality or separability arguments, and we recommend them to the reader.

Article

Gossen was born in Düren (between Aachen and Cologne) on 7 September 1810; he died in Cologne on 13 February 1858. Little is known about his life, partly because the inconspicuous bachelor did not attract attention, partly because most of those who had known him were dead by the time he became famous, partly also because his literary remains, scant as they must have been, are lost. The principal biographical source is the essay by Walras (1885). The available facts are admirably surveyed by Georgescu-Roegen (1983), on whose masterly introduction to the English translation of Gossen's book the following life sketch is mostly based.

Gossen's father was a tax collector under Napoleon and subsequently the Prussian administration; later he managed his wife's estate near Godesberg. Hermann obtained a good high-school education, showing ability in 'elementary mathematics', but his mathematical training never went beyond that level. Since his father insisted on a government career in the tradition of his forebears, his university studies in Bonn and Berlin concentrated on law and government.

In 1834, Gossen entered the civil service as a 'Referendar' (junior law clerk) in Cologne. While he seems to have been a well-mannered young man, the performance of his duties left much to be desired. He simply had no interest in a government career and loved the good things in life. There were complaints and reprimands, and the promotion to the rank of 'Regierungsassessor' came rather later than usual. Finally, in 1847, though his superiors seem to have shown considerable sympathy, he had no choice but to resign.

The transition to a new career was perhaps eased by his father's death, which spared him recriminations about his failure and provided him with the means for a new start. Gossen went to Berlin, where he seems to have sympathized with the liberal revolution, and then returned to Cologne as a partner in a
new accident insurance firm. He soon withdrew from the firm, but continued to devise grandiose insurance projects.

Living with his two sisters, Gossen now devoted most of his energies to developing the unorthodox ideas he had expressed in his civil service examination papers into his magnum opus. The preface suggests that he hoped this would not only make him the Copernicus of the social universe but also open the door to an academic career. In 1853 an attack of typhoid fever undermined his health, and the disappointment about the fate of his book depressed him. Death came from pulmonary tuberculosis. He seems to have been an amiable, sincere and idealistic human being with broad interests, including music and painting. Brought up a Catholic, he developed into an enthusiastic hedonist. Dreaming of reforming the world, he lacked the force to conquer it.

The Entwickelung der Gesetze des menschlichen Verkehrs was published in 1854 at Gossen's expense by the publisher Vieweg in Brunswick. Very few copies were sold and the book remained unnoticed for years. Shortly before his death, Gossen withdrew it from circulation and the unsold copies were returned to him. After the author had become famous, Vieweg's successor, Prager, bought this stock from Gossen's nephew, a professor of mathematics by the name of Hermann Kortum, and put it on the market again with a new title page, as a 'second edition', in 1889. There is an Italian translation by Tullio Bagiotti and there is now, since 1983, a careful English translation by Rudolph C. Blitz, nicely divided into chapters. The manuscript of a French translation by Walras was apparently lost.

The first known references to Gossen's book were by Julius Kautz (1858/60), but they only show that their author did not understand the problems Gossen had solved. Slightly more understanding was shown by F.A. Lange, but again in no more than a footnote. Fortunately, Kautz's reference was seen by Robert Adamson, who was able to get hold of a copy and reported its content to Jevons. In the second edition of The Theory of Political Economy (1879) Jevons included a generous acknowledgement of Gossen's priority 'as regards the general principles and method of the theory of Economics', which became the ignition point of Gossen's posthumous fame. Though Gossen's name became famous, his book remains largely unread to this day.

At the level of individual behaviour, Gossen's basic theoretical problem concerns optimization with limited resources (references are to the 1889 edition; they are followed by the corresponding references to the English translation, marked T). Resources are first visualized as time (p. 1 f.; T ch. 1). The given lifetime has to be allocated to enjoyable activities in such a way that lifetime enjoyment or, in modern terminology, utility, is maximized.

For a given activity, marginal utility is assumed to be a declining function of the time spent on it. In Gossen's words, 'The magnitude of a given pleasure decreases continuously if we continue to satisfy this pleasure without interruption until satiety is ultimately reached' (p. 4f.; T p. 6). This is the postulate Wilhelm Lexis (1895) christened 'Gossen's First Law'. In itself, it was neither new nor profound. W.F. Lloyd had expressed it 20 years earlier just as clearly, it had a long ancestry reaching back to Bentham, the French 'subjectivists', Daniel Bernoulli, and the scholastics, and it is essentially commonplace. To simplify, Gossen assumes marginal utility curves to be linear. It is important to note that Gossen's curves do not describe the decline in the marginal utility of a good as its quantity increases, but the decline in the utility from the marginal unit of resources as the quantity of resources is increased. While this facilitated the analysis in some respects, it became a crucial handicap in others. Gossen realized that each of these marginal utility functions must be thought of as being derived by solving a suboptimization problem, inasmuch as time allocated to a given activity must be spent in the most
enjoyable way, probably with interruptions. However, his analysis of this difficult sub-problem, though original and suggestive, remained incomplete and unsatisfactory, leaving much to do for future research on the allocation of time.

Gossen recognized at once that a necessary condition for the optimal allocation of resources is the equality of the marginal utilities in different activities. This is ‘Gossen's Second Law’, which he had printed in heavy type: ‘The magnitude of each single pleasure at the moment when its enjoyment is broken off shall be the same for all pleasures’ (p. 12; T p. 14). This theorem is Gossen's principal claim to fame. It was the key that opened the door to a fruitful analytical use of the First Law and thus initiated the ‘marginal revolution’ in the theory of value.

The third stage of Gossen's analysis is reached with the introduction of exchange (p. 80 f.; T ch. 7). Gossen begins with the bilateral case. He immediately perceives that there are many different opportunities for mutually beneficial exchange, but his discussion of these possibilities is, understandably, inconclusive. As a necessary condition for optimal exchange he postulates that the marginal utilities must be equalized between individuals for each product. While this formulation requires both cardinality and interpersonal comparability of utility, its economic substance, since it can be expressed in terms of ‘marginal rates of substitution, is independent of these assumptions. The concept of a ‘contract curve’, however, is not used. The statement that each individual would usually be willing to forego a portion of what he receives suggests some notion of consumer's surplus.

The analysis is finally extended to market exchange, where each individual can exchange goods and effort at parametrically given prices, expressed in a common numéraire called money. We thus end up with the optimization problem that became the banner of the ‘marginal revolution’. The ‘Second Law’ can then be expressed by the condition that ‘the last atom of money creates the same pleasure in each pleasurable use’ (p. 93f.; T p. 109).

The solution to this problem determines the individual's market demand and supply for each product and effort. Gossen also shows how the value of intermediate products can sometimes be derived from that of the final goods, thereby foreshadowing Menger's theory of ‘imputation’, but he is careful to note that the market mechanism works even where imputation fails (p. 24f.; T p. 28f). If prices are specified at random, aggregate demand and supply will generally differ. Gossen explains how this exerts pressure on prices until all markets are cleared. Prices are thus endogenously determined by general equilibrium. This argument, though concise, is presented in verbal form only. The mathematical formulation of general equilibrium, foreshadowed by Cournot, had to wait for Walras.

In the fourth stage, Gossen introduces rent (p. 102 f; T chs 8–12). If the profundity of an economist can be gauged by his treatment of rent, he comes out near the top. The worker is assumed to own a specific piece of land. Suppose he is now offered the use of land at a superior location, owned by another individual. This does not affect his utility curves, but for the amount of effort for which the marginal utility is just zero he can now earn a higher income. At the same time the marginal disutility curve becomes flatter because the same total enjoyment is now spread over a higher income. In the absence of rent, the superior location would, of course, promise higher income. However, moves to superior locations are not free, but cost rent. This means that at the new location the individual has to earn a certain amount before he can even begin to buy commodities.

What is the maximum rent an individual is willing to pay for a superior location? This ‘warranted rent’ is reached at the point where total utility at the superior location is equal to the total utility at the original location. Gossen shows algebraically that with rent at the warranted level, superior locations are
associated with higher earned income and higher consumption.
While Gossen developed a novel and fruitful way to incorporate rent into a general equilibrium framework, his theory of rent is less rich than von Thünen's, published 28 years before. Gossen was no better in reading his predecessors than the later ‘marginalists’ were in reading Gossen. The fifth stage introduces capital and interest (p. 114; T ch. 13). The basic question concerns the highest amount of present utility that could be sacrificed for a piece of land with a given annual rent, continuing into the distant future. Gossen finds the answer by discounting the utility of each future rent payment at the appropriate rate of psychological time preference (as we would call it), reflecting uncertainty of expectations (pp. 30, 115; T pp. 35, 134). This promising idea is not successfully exploited, however, and the adaptation of the land paradigm to capital goods remains sketchy. Gossen thinks in terms of land and labour, while capital goods are played down (p. 172; T p. 194). He also makes an effort to determine the optimal amount of saving by the condition that the highest price the individual is willing to pay for a source of rent should be equal to the market price, but he seems to confuse average and marginal concepts and the sense of his argument remains obscure.
In an effort to interpret everyday observations in the light of his theory, Gossen offers an elaborate discussion of the effect of price changes on demand and expenditure. This discussion anticipates a lot of later work on demand elasticities, but it is also cumbersome. The reason is that Gossen's analytical engine, while permitting a brilliantly simple determination of the optimal budget at given prices, is ill suited for the analysis of price change. Since Gossen's curves, as observed above, relate the marginal utility of expenditure to expenditure, they have to be redrawn after each price change. The insights which Marshall's apparatus made so easy to communicate, remained virtually incommunicable for Gossen. This may be one of the main reasons why his achievement, though at the highest intellectual level, remained sterile. If he had read Cournot, his fate might have been different.
The second part of Gossen's book is largely devoted to social philosophy and policy. It shows its author as a passionate libertarian. Through free markets, mankind would succeed without effort where all socialist planning must fail, namely in reaching the highest possible happiness. Abhoring all forms of protection, Gossen was in favour of free trade, the protection of property rights and a liberal education for both sexes. To prevent fluctuations in the value of money, he advocated a metallic currency and the abolition of paper money. That he also asked for restrictions on child labour and government sponsorship of credit unions seems to indicate that he knew externalities and market imperfections when he saw them. Competitive equilibrium was for him much more than an economic theory or an ideology; it was the gospel, revealing the perfection of a benevolent creator. For him, the ‘invisible hand’ was not a didactic metaphor, but religion itself. Today, this apotheosis of competition, in language closer to a revival meeting than to scientific discourse, strikes one as bizarre.
Major sources of inefficiency, Gossen thought, were distortions in the allocation of land, preventing land from actually being used by the potentially most efficient user. To correct this defect, he proposed that the government use borrowed money to buy land on the free market and then lease it to the highest bidder (p. 250 f.; T ch. 23). Since governments differ from individuals by (1) being immortal, (2) having a higher credit rating, and (3) a lower time preference, such a scheme, he argued, would actually improve government wealth, and the initial debt could eventually be repaid out of rising rent income. For a given year, the scheme would be viable if the price paid by government for a piece of land did not exceed the sum of the rent and the annual increase in the value of land, capitalized at the market rate of interest. However, Gossen was not a ‘land socialist’; he was not concerned about ‘land monopoly’ and
the ‘socialization of rent’. His objective was the correction of a market imperfection without any limitation of property rights.

Gossen, though perhaps not quite a genius, had a brilliant, original and precise mind. With his one book, he moved constrained optimization into the centre of the theory of value and allocation, where it has since remained. With respect to economic content, his was probably the greatest single contribution to this theory in the 19th century. He failed, however, to develop the basic principle into a usable analytical engine. As a consequence, the so-called ‘founders’ of the modern theory of value had to rediscover those principles before they could proceed with their engineering work.

French economist, merchant and government official, Gournay was born at St. Malo in 1712. After a long career as merchant, spent largely in Cadiz (1729–44), his partner's death in 1746 permitted his retirement two years later from active trade and his entry into public life and more serious research into economics. Gournay has been traditionally associated with the propagation in France of free trade ideas such as deregulation of colonial trade, abolition of the guilds and of the system of government inspection of manufactures, aspects of his work illustrated by the important place generally assigned to him in the history of the phrase, laissez faire, laissez passer (Schelle, 1897, pp. 214–17). Turgot (1759, pp. 30–2) has noted, however, that his free trade position should be qualified and in addition that, unlike the Physiocrats, he accorded an important role in economic development to industry and trade as well as agriculture. He has therefore sometimes been described as the founder of a separate non-Physiocratic free trade school, whose members, among others, included Turgot, Morellet and Trudaine. Apart from Observations sur l'agriculture, le commerce et les arts de Bretagne (1757), only his notes accompanying the translation of Child (1754), now edited by Tsuda (1983), appear to have survived. His long friendship with Turgot exerted some influence on the latter's economics, partly because Turgot accompanied Gournay on his tours of inspection of industry between 1753 and 1756. Gournay's most important contribution to French economics seems to have been the encouragement he gave to the study of English economics literature. With Butel-Dumont he had himself translated Child and Culpeper (1754), he encouraged Forbonnais to abridge King's The British Merchant, Turgot to translate one of Tucker's pamphlets and, most importantly, may have been responsible for the publication of Cantillon's Essay in 1755 (Morellet, 1821, pp. 36–7). His death in 1759 provided the occasion for Turgot's eulogy on which much of the information about his life and work is based, though as Ashley (1900, p. 306)
warns, there are reasons for being hesitant in accepting Turgot's eulogy (1759) ‘as evidence of Gournay's opinions’.

government budget constraint

Eric M. Leeper and James M. Nason
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The government budget constraint is an accounting identity linking the monetary authority's choices of money growth or nominal interest rate and the fiscal authority's choices of spending, taxation, and borrowing at a point in time and across time. The intertemporal links create a rich set of possible outcomes from standard macro policy experiments. Taking the government budget constraint seriously can overturn some widely held beliefs about policy effects.

Article

The government budget constraint is an accounting identity linking the monetary authority's choices of money growth or nominal interest rate and the fiscal authority's choices of spending, taxation, and borrowing at a point in time. Whenever borrowing is the source of some fiscal financing, the government budget constraint also serves to link current monetary and fiscal choices to expected future monetary and fiscal policy variables. This intertemporal dimension creates a rich set of possible impacts of routine macro policy actions, as current or future policies can be expected to adjust to satisfy the government budget, along with other equilibrium conditions. Taking the government budget constraint seriously can overturn some widely held beliefs about policy effects.

The notion that current government policy has intertemporal implications goes back to Barro (1974), who revived ideas associated with Ricardo (1821). Traditional Keynesian models, in contrast, mostly ignored the impact of the government budget constraint on allocations and prices until the work of Christ (1967), 1968 see Sims (1998) for a review and extensions). Hansen, Roberds and Sargent (1991)
show that identification of the responses of allocations and prices to changes in the government budget constraint require specification of the economic primitives of preferences, technology and market structure.

The modern treatment of the government budget constraint begins with Sargent and Wallace (1981). They show that, when the primary fiscal surplus is fixed, an open-market sale of debt, and contraction of base money, produces higher future inflation. This stunning result arises because, with fiscal policy fixed, faster money supply growth is the only policy expected to balance future government budget constraints. A related but different mechanism by which the government budget constraint can restrict the equilibrium price level, namely, the ‘fiscal theory of the price level’, is developed by Leeper (1991), Sims (1994), Woodford (1995); 2001 and Cochrane (1999), among others. That theory demonstrates that, under certain assumptions on policy behaviour, debt-financed cuts in lump-sum taxes can stimulate aggregate demand, in apparent contradiction of Ricardian equivalence.

This article uses endowment and growth economies to study the restrictions the government budget constraint imposes on the intertemporal trade-offs between current and future monetary and fiscal policies. The endowment economy allows us to depict the policy trade-offs associated with a bond-financed tax cut, holding government spending fixed. We show that the effects of policy changes depend on current and expected future monetary and fiscal policies that are consistent with the government budget constraint at each date. Although we illustrate these points for a bond-financed tax cut, analogous results hold for an open-market operation. Implicit in the analyses is that the expected discounted value of real government debt has no value at the infinite horizon; that is, a transversality condition for government debt holds at the infinite horizon. This is a sufficient condition for an equilibrium to exist.

Model primitives

The models are variations of Sidrauski (1967) and share the following features: perfect foresight, a representative, infinitely lived household with utility defined over consumption, \( C_t \), and real balances, \( M_t / P_t \), \( U(C_t, M_t / P_t) = u(c_t) + \nu(M_t / P_t) \), and nominal one-period government bonds, \( B \), paying net nominal interest of \( i \). The models also have in common two equilibrium conditions that stem from optimal household choices: a portfolio balance expression

\[
\frac{\nu'(M_t / P_t)}{u'(c_t)} = \frac{i_t}{1 + i_t'},
\]

(1)

and optimality of bond choices, a Fisher relation, represented by the Euler equation
where \( \beta \) is the household's discount factor.

The structure of the government balance sheet, revenue sources, and expenditure process is also common across the models we examine. The government chooses sequences of \( \{ M_t, B_t, T_t, Z_t \} \) to finance purchases of goods and services, \( g_t \), and transfer payments, \( z_t \), to satisfy the government budget constraint

\[
g_t + z_t = T_t + \frac{M_t - M_{t-1}}{r_t} + \frac{B_t - (1 + i_{t-1})B_{t-1}}{r_t},
\]

where \( T_t \) denotes total tax revenues. Government spending is specified as shares of output: \( g_t = \gamma_t^g v_t \) and \( z_t = \gamma_t^z v_t \). The government budget constraint (3) has the present value form

\[
\frac{B_{t-1}}{P_{t-1}} = \mathbb{E}_t \sum_{j=0}^{\infty} \prod_{i=0}^{j} \left( \frac{\pi_{t+j}}{1 + i_{t+j+1}} \right) \left[ T_{t+j} - g_{t+j} - z_{t+j} + s_{t+j} \right],
\]

where \( s_t = (M_t - M_{t-1}) / P_t \) is seigniorage revenues. To arrive at (4), the infinite-horizon transversality condition for debt from the household's optimization problem has been imposed:

\[
\lim_{q \to \infty} \mathbb{E}_t \beta^q u'(c_{t+q}) \prod_{j=0}^{q} \left( \frac{\pi_{t+j}}{1 + i_{t+j+1}} \right) \frac{B_{t+q}}{P_{t+q}} = 0.
\]

This is the relevant sufficient condition because it forces the household to expect that it cannot postpone consumption, hold government bonds for ever, and raise lifetime utility (see Becker and Boyd, 1997, for good economic intuition). It is important to note that in stochastic models the transversality condition need not hold always and everywhere along equilibrium paths, as it does in perfect foresight equilibria. Rather, it holds only in expectation (see Kamihigashi, 2005, for discussion and examples).
It is useful to study an endowment economy because it draws out the role of the government budget constraint in macroeconomic analyses. The household budget constraint is

\[
\zeta_t + \frac{M_t + B_t}{p_t} \leq \nu_t + z_t + \frac{M_{t-1} + (1 + i_{t-1})B_{t-1}}{p_t},
\]

(5)

where \( y \) is the endowment of goods each period and we have set \( T_t = 0 \), for all \( t \), so \( z_t > 0 ( < 0) \) represents lump-sum transfers (taxes). Output and government purchases are constant, so \( \nu_t = y \) and \( g_t = s^G \nu \), which implies that in equilibrium consumption is a constant share of GDP, \( c_t = c = (1 - s^G)y \). Thus, the equilibrium real interest rate equals a constant, \( 1 / \beta \), the Fisher relation reduces to \( 1 + i_t = \beta^{-1} \pi_{t+1} \) (where \( \pi_{t+1} = P_{t+1}/P_t \)), and money demand varies only with the nominal interest rate, \( v'(M_t/p_t) = u'(\zeta) [i_t/(1 + i_t)] \).

We focus on circumstances in which the economy is in a stationary equilibrium at dates \( s > t \), but starts from a different equilibrium at date \( t \). Denote money growth by \( \rho_t = M_t/M_{t-1} \). Assume tax and monetary policies are fixed in the future stationary equilibrium: \( s^Z_s = s^Z \) and \( \rho_s = \rho \) for \( s > t \); at date \( t \), however, policies may be different: \( s^Z_t \neq s^Z \) and \( \rho_t \neq \rho \).

In the stationary equilibrium with constant real money balances, inflation depends only on money growth, \( \pi = \rho \), which implies the Fisher relation is \( 1 + i_s = \beta^{-1} \rho_{s+1} \), \( s \geq t \). Stationary real money balances become \( M_s/p_s = h(\rho_{s+1}) \), for dates \( s \geq t \).

We derive two versions of the government budget constraint that describe the trade-offs among current and future monetary and fiscal policies that arise in equilibrium. By imposing equilibrium prices on the government budget constraint (3), we obtain

\[
\frac{h(\rho)}{\nu} \left[ 1 - \frac{1}{\rho_t} + \frac{B_t}{M_t} - \frac{1 + i_{t-1}}{\rho_t} \frac{B_{t-1}}{M_{t-1}} \right] = s^G + s^Z_t.
\]

(6)

For given future expected policies, expression (6) reports the feasible trade-offs among current (date \( t \)) policies, when initial liabilities are \( (M_{t-1}, (1 + i_{t-1})B_{t-1}) \). On the assumption that future policy is anticipated (i.e., \( 1 + i = \beta^{-1} \rho \)), the government budget constraint is
along the equilibrium path for dates $s > t$, given $B_t / M_t = B / M$. Note that the bond–money ratio is constant in the stationary equilibrium. Conditional on the state of government indebtedness, equation (7) describes the trade-offs among future policies that are consistent with equilibrium.

Policy analysis

In the policy experiments we consider, government purchases, $s^G$, are held fixed. The experiments take the form of an initial cut in taxes at date $t$ (negative $s^Z_t$ becomes larger in absolute value), which is financed by sales of nominal bonds. We consider three alternative responses of current and future policies that satisfy (6) and (7). The analysis traces the effects of each specification of policy behaviour on the price level and inflation.

Policy 1

For policy experiment 1, suppose current and future money growth, $(\rho_t, \rho)$, are held fixed. This policy, together with the money demand relation, (1), and Fisher relation, (2), peg the nominal interest rate at $1 + i = \rho / \beta$ and fix equilibrium real balances at $h(\rho)$. Neither the initial price level, $P_t$, nor the stationary inflation rate, $\pi$, changes. A reduction in taxes today is consistent with equilibrium if nominal debt expands to satisfy the government budget constraint (6) with fixed money growth. This raises $B_t / M_t$, which, by the government budget constraint (7), forces future taxes to rise sufficiently to service the new, higher level of government indebtedness. This mix of policies yields Ricardian equivalence: the timing of taxes and debt is irrelevant for equilibrium allocations and prices. The policies also imply monetary policy is independent of fiscal considerations, as the quantity theory of money maintains. Of course, as this exercise illustrates, the quantity theory requires specific fiscal behaviour.

Policy 2

In the second experiment, the central bank credibly pegs the nominal interest rate by fixing future money growth, $\rho$, and the fiscal authority credibly fixes future taxes. Can this be an equilibrium? With future policies fixed, the anticipated budget constraint (7) implies current policies cannot alter government indebtedness in the future, which is summarized by $B / M$. Since the expansion in nominal debt cannot be transformed into future higher real debt, $P_t$ must rise in proportion to $B_t$. However, a pegged nominal interest rate fixes real money balances. The result is that the current money stock must expand in proportion to the increase in prices, which ensures $B_t / M_t$ is unchanged in the date $t$ budget constraint (6).
The central bank loses control of the current money stock and the price level in this experiment. Changes in these variables are governed by fiscal needs that are beyond the central bank's direct control. A pegged nominal rate subordinates current monetary policy to fiscal needs, but this is not 'monetization of deficits' in the usual sense of printing money to purchase newly issued government debt. Instead, the expansion in money is a passive adjustment of the money supply to clear the money market at the prevailing interest rate and price level. The monetary expansion is given by \( dM_t = dB_t / (B_t / M_t) \), making clear that monetary accommodation varies inversely with the level of indebtedness. This exercise corresponds to the fiscal theory of the price level as described by Leeper (1991), Sims (1994), and Woodford (1995). The precise result relies on government debt being sold at par, as Cochrane (2001) observes. If government debt is sold at a discount, bond prices may absorb some of the adjustment to equilibrium, which pushes the price level effects into the future.

**Policy 3**

The third experiment has the central bank fix current money growth, \( \rho_t \), while the fiscal authority continues to hold future taxes, \( s^Z \), constant. It remains feasible for current policy to imply more debt in the future because the anticipated increase in debt service forces future money growth and inflation to rise. The date \( t \) response is seen in a higher nominal interest rate and reduced real money balances driven by an increase in \( P_t \) to clear the money market, which follows from a fixed \( M_t \). Beyond date \( t \), debt service is financed by higher inflation and seigniorage – 'inflation tax' on nominal assets – revenues. Again, with future net-of-interest fiscal deficits held fixed at \( s^G + s^Z \), monetary policy is constrained by fiscal needs. In this case, the central bank loses control of future inflation. Sargent and Wallace (1981) employ these assumptions about policy in their classic ‘unpleasant monetarist arithmetic’ example.

**A growth economy**

A growth model with elastic capital supply, inelastic labour supply, and a distorting income tax extends the analysis by adding interesting intertemporal margins. The model consists of a representative household, a firm that produces the single consumption good, and a government (see, Gordon and Leeper (2006) for related analysis). Assume physical capital depreciates completely after one period. Output is allocated to consumption, capital, \( k_t \), and government purchases of goods, with the technology \( f(k_{t-1}) \) generating output, \( V_t \), where \( f(0) = 0 \), \( f'(k_{t-1}) > 0 \), and \( 0 < f''(k_{t-1}) \). Capital share's of production is denoted by \( \sigma \). The economy is closed with the aggregate resource constraint

\[
C_t + K_t + G_t = f(k_{t-1}).
\]

\[(8)\]

A competitive firm rents capital at rate \( r \) from the household and pays taxes levied against sales of
government budget constraint: The New Palgrave Dictionary of Economics

goods, which determine the profit function, \( D_t = (1 - \tau_t) y_t - (1 + r_t) k_{t-1} \). Profit maximization yields the after-tax factor price \( 1 + r_t = (1 - \tau_t) f'(k_{t-1}) \).

The household supplies labour inelastically, owns the firm, and receives factor payments. Subject to the budget constraint

\[
c_t + k_t + \frac{M_t + B_t}{P_t} \leq (1 + r_t) k_{t-1} + D_t + z_t + \frac{M_{t-1} + (1 + i_{t-1}) B_{t-1}}{P_t},
\]

(9)

the household maximizes the expected discounted value of its infinite horizon utility function, given \( P_t, i_t, \tau_t \), and the initial conditions \( (k_{-1} > 0, M_{-1} + (1 + i_{-1}) B_{-1} > 0) \). Government behaviour is unchanged from the endowment economy, but tax revenue is \( T_t = \tau_t (1 + r_t) k_{t-1} \).

Equilibrium

We recover an explicit characterization of the model’s equilibrium with \( u(c_t) = \ln(c_t) \) and 
\( v(M_t / P_t) = \ln(M_t / P_t) \). After imposing transversality conditions for capital, debt and money, equate the supply and demand for capital to find the solution

\[
k_t = \left(1 - \frac{1}{\eta_t}\right) (1 - s^G_t) f(k_{t-1}),
\]

(10)

\[
\eta_t = E_t \Sigma_{j=0}^{\infty} (\sigma \beta)^j \Pi_{j=0}^{i-1} \left( \frac{1 - \tau_{t+j+1} + 1}{1 - s^G_{t+j+1}} \right).
\]

Money market equilibrium sets money supply to money demand to yield

\[
\frac{M_t}{P_t} = c_t \mu_t,
\]

(11)

where

\[
\mu_t = E_t \Sigma_{j=0}^{\infty} \beta^j \Pi_{j=0}^{i-1} \frac{1}{\rho_{t+j+1}}.
\]

Note that \( \eta \) and \( \mu \) completely summarize what agents need to
know to form rational expectations. Since eqs. (8) and (10) imply a decision rule for consumption, equilibrium real balances can be expressed in terms of their opportunity cost, $1 / \mu_t = i_t / (1 + i_t)$, the transactions they help finance, $c_t + k_t$, and expected fiscal policies:

$$\frac{M_t}{P_t} = \frac{1}{\eta_t} \left( \frac{i_t}{1 + i_t} \right)^{-1} c_t + k_t. \tag{12}$$

With $c + k$ serving as a scale variable, expression (12) is a conventional money demand function except for the dependence on expected fiscal policies. Expectations about future fiscal policies are essential to tie down the equilibrium. This is a key to the dynamics of the growth model and the impacts of fiscal policy on the current equilibrium.

Equilibrium requires that current and future policies satisfy the government's budget constraint and that agents' expectations of policy are consistent with equilibrium. This creates interactions between current and future policies. As before, we distill the analysis down to two periods – now and the future. Fix current and future government spending shares, $\{s^G_t, s^I_t\}$, for all $t$, and assume future money growth and tax rates are constant $\rho = \rho, \tau = \tau, s > t$. Current policies, however, may differ: $\rho_t \neq \rho, \tau_t \neq \tau$.

The government budget constraint can be expressed entirely in terms of current and expected policies. In period $t$, the constraint is

$$\left[ \frac{\rho_t - 1}{\rho_t} + \frac{B_t}{M_t} - \frac{1 + i_{t-1}}{\rho_t} \frac{B_{t-1}}{M_{t-1}} \right] \mu_t \eta_t = \frac{s^G_t + s^I_t - \tau_t}{1 - s^G_t}. \tag{13}$$

Given policy expectations are embedded in $\mu_t / \eta_t$ and initial government indebtedness is summarized by $(1 + i_{t-1})B_{t-1} / M_{t-1}$, expression (13) reports the equilibrium trade-offs among current policies. Equilibrium trade-offs between current and future policies are given by the state of government indebtedness. We use the budget constraint (13) to develop this idea for the growth model. Shift the timing of eq. (13) forward one period and assume future interest liabilities are correctly anticipated at $t$ by substituting the expression for the equilibrium nominal return $1 + i_t$. Given the bond–money ratio is constant at $B / M = B_t / M_t$ in the stationary equilibrium, there can be no net additions to debt in the future. Dropping the time subscript for variables dated $t + 1$ and imposing equilibrium yields
Equation (14) describes the trade-offs among future policies that are consistent with fixed $\mu_t/\eta_t$ being an equilibrium. The trade-offs represented by eqs. (13) and (14) tie together current policies and expectations of future policies. Any change in policy at date $t$ that requires a change in $\mu_t/\eta_t$ must be accompanied by a change in policy in the future that is consistent with revised values of $\mu_t/\eta_t$, conditional on the level of government debt $B/M$.

Policy analysis

As for the endowment economy, we study the current and future responses of fiscal and monetary policy to a date $t$ debt finance tax cut in the analysis that follows.

Policy 1

Hold current and future money growth fixed at $(\rho_t, \rho)$. This policy pegs the nominal interest rate by fixing $\mu_t$ but it does not fix real money balances unless $\eta_t$ is also constant. Since new debt issued to finance the tax reduction raises $B_t/M_t$, a higher level of debt is carried into the future. To clear the government budget constraint in the future, budget constraint (14) implies future taxes must rise. Higher taxes reduce the return on capital (a lower $\eta$) and induce substitution from real to nominal assets, which includes money. Equilibrium in the money market requires the current price level to fall. The source of the non-Keynesian reduction in inflation is the link between current policy (that is, the fiscal expansion) and the expectation that future policy will expand government debt.

Policy 2

Fix both future money growth and future taxes at $(\rho, \tau)$. By assumption, all future policies are constant in the face of the current tax cut. Current policies must adjust to ensure the real value of debt in the future is unchanged, as was true when this policy was applied to the endowment economy. The real value of debt remains unchanged because the current money stock rises by the amount that the current budget constraint (13) dictates is needed to maintain the pre-tax cut level of $B_t/M_t$. The monetary expansion necessary to maintain equilibrium is sufficient to produce additional future seigniorage (that is, the level of the money supply rises). Since the fixed rate of money growth is just enough to pay for the increased debt service and with equilibrium real money balances fixed by constant future policies, (12) predicts the current price level rises in proportion to the increase in $M_t$. Gordon and Leeper (2006) label this ‘the canonical fiscal theory exercise’.

The implications of the fiscal theory contrast with the tax cut of policy 1. The bond-financed tax cut is pure fiscal policy in the sense that it is independent of the path of the money stock. It also reduces
nominal spending and the price level. An essential aspect of the fiscal theory is that the current money stock adjusts passively to clear the money market, raising nominal demand and the price level. If the policy authorities peg the nominal interest rate and fix future taxes without reference to the rest of the economy, higher prices are inevitable consequences of a tax cut. This is an illustration of the fiscal theory.

Policy 3

The fiscal authority holds future taxes constant and the central bank fixes current money growth. If future money growth rises sufficiently to generate the seigniorage revenue to service the new debt, an expansion in current debt can be carried into the future. Expected inflation increases, which lowers the expected return on money (that is, $\mu$ falls), decreases money demand, raises the price level, and contributes to higher future inflation. The change in future money growth depends, of course, on future $B / M$, which drives the change in debt service.

Concluding remarks

The equilibria described in this article can easily be couched in terms of arbitrary sequences of policy variables. It has become increasingly popular, however, to endow policy authorities with simple rules that make the policy instrument a time-invariant function of only a few variables that are not directly related to the actions of other policy institutions (that is, the interest rate–monetary policy rules studied in Taylor, 1999). Although this approach has the advantages of being interpretable and tractable, it runs the risk of oversimplifying policy behaviour. For example, it is difficult to square simple time-invariant policy functions with the observation that policy regimes can, and do, change, sometimes because of the interactions of different policymakers.

A natural extension of simple rules allows feedback parameters to take on finitely many values (‘regimes’) whose evolution is governed by a Markov process. Relative to simple rules, this extension produces a far richer set of expectations of future policy variables, a generalization that can overturn some of the principles guiding macro policy research that have been obtained from simple rules (see Davig, Leeper and Chung, 2004, and Davig and Leeper, 2005).

Markov switching of policy rules has also generalized the test of the long-run sustainability of fiscal policy proposed by Hamilton and Flavin (1986). Davig (2005) finds expansionary and contractionary regimes in US government debt that nonetheless yield a stochastic process for discounted debt with an unconditional expected value equal to zero in the long run.

Theoretical work that takes seriously the restrictions imposed by the government budget constraint has established some important and surprising results. In light of these theoretical findings, it is remarkable how little applied work on monetary and fiscal policy treats the government budget constraint with equal seriousness. This is an open area of research.

ceiling velocity; commodity-reserve monetary standard; flexible exchange rates; German hyperinflation; Graham, F. D.; international trade theory; Mill, J. S.; protection; tariffs; Taussig, F. W.; terms of trade; velocity of circulation

Article

Graham was born in Halifax, Nova Scotia, and died in Princeton, New Jersey. He is known mainly for his work in the theory of international trade, and especially for his attack on classical and neoclassical trade theory. He received his doctorate from Harvard, where he came under the influence of Taussig. After teaching at Rutgers and Dartmouth, he joined the Princeton faculty in 1921, becoming a full professor in 1930. In addition to undergraduate teaching, he taught the Princeton graduate courses in international trade and in monetary theory.

In a path-breaking article (1923b), Graham argued that J.S. Mill, by using a two-country, two-commodity model, had reached erroneous conclusions concerning the effect of changes in international demand on the commodity terms of trade. Mill had reasoned that, within the limits set by comparative cost (limits which he – but not Graham – regarded as improbable cases), an increase in a country's demand for imports would worsen the country's terms of trade. Retaining Mill's assumptions of free trade, costless transportation and constant cost per unit of output, Graham concluded that, when a given commodity is produced by more than one country, the cost structures of the affected countries are locked together and that, therefore, changes in international demand do not affect the equilibrium terms of trade so long as the same commodities continue to be produced by the same countries; instead, within possibly wide limits, international adjustment takes place through shifts in output, the limits occurring when commodities disappear from, or are added to, national production schedules.

To illustrate these points, Graham devised a multi-country, multi-commodity model, with all variables expressed in real terms. Operating with assumed national opportunity-cost ratios, national productive capacities and national demand functions, he was able to derive, by a trial-and-error process using simple arithmetic, an equilibrium solution specifying the commodity terms of trade and each country's
consumption, production (if any) and exports or imports of each commodity. In his final work, *The Theory of International Values* (1949), he developed these ideas at length, using illustrations with as many as ten countries and ten commodities. Because of the assumption of costless transportation, domestic (non-traded) goods do not appear in the trade model, but Graham examined their role in international adjustment in his earliest article (1922) and in his 1949 treatise.

Although the Graham model, which assumes full employment, can be used to demonstrate that national and world real output are maximized under free trade, Graham was not a doctrinaire free trader. In an early article (1923a), he made a case for permanent protection for decreasing-cost industries. The article was attacked on various grounds by Knight (1924) and others, but Graham retained the argument in his book, *Protective Tariffs* (1934), which, while critical of most arguments for tariffs, included a chapter on ‘Rational Protection’.

In the field of money, Graham's major work was his treatise (1930) on the German hyperinflation after the First World War. Perhaps his most significant conclusion was the concept of ‘ceiling velocity’. He found that, in the German case, monetary velocity reached an upper limit which was about 25 times the pre-war normal; thereafter, the German price level rose at approximately the same rate as the German money supply.

Graham had a passionate interest in economic policy. He was an early advocate of flexible exchange rates (on a managed basis), and during the Great Depression he devised various plans to promote recovery. Later, he advocated a commodity-reserve monetary standard as a means of achieving price-level stability and full employment.

An iconoclast with a caustic wit, Graham was an unusually stimulating teacher and had a profound influence on his students, two of whom – T.M. Whitin and L.W. McKenzie – extended his work on the trade model. In a 1953 article which illustrated the model geometrically, Whitin concluded that Graham's work ‘anticipated linear programming models by many years’, and McKenzie, in a powerful 1954 article employing a theorem from topology, demonstrated what Graham firmly believed but was never able to prove: that his trade model yields an equilibrium for any continuous demand functions and that this solution is unique for the demand functions which Graham actually used.

J.; Granger-causality; Haavelmo, T.; long memory models; maximum likelihood; nonlinear time series; non-stationary variables; reduced rank regression; spectral analysis; spurious regressions; time series analysis; vector autoregressions

Article

Clive Granger is one of the best-known time-series econometricians of our time. He has contributed to many areas in econometrics. They include the analysis of non-stationary time series, causal relations between economic variables, long memory, nonlinearity, forecasting economic time series, modelling stock prices and volatility, and price formation.

The most important concept that Granger has introduced to econometrics is cointegration. It can be viewed as an extension to non-stationary time series of Nobel Laureate Trygve Haavelmo's formulation of an economy as a system of simultaneous stochastic relationships that laid the foundations to modern...
time-series econometrics. The origins of the concept may be traced to a paper in which Granger and his associate Paul Newbold consider regressing a random walk series on another independent random walk series (Granger and Newbold, 1974). They pointed out that the classical t-test in such a regression may often suggest a statistically significant relationship between variables although none exists. This result suggested that many relationships found between non-stationary economic variables in static econometric models of the time could in fact have been spurious. It called for a more careful analysis of non-stationary economic time series, and Granger and Newbold also strongly emphasized the importance of dynamic models instead of static ones that did not take the dynamic properties of economic variables into account.

A solution to this spurious regression problem was to model the relationships between economic variables in first differences. This, however, created a problem because these relationships were generally expressed in levels, not differences. Granger's solution to this problem (Granger, 1981) may be illustrated by the following regression equation:

\[
y_t = \alpha + \beta x_t + \varepsilon_t,
\]

(1)

where \(y_t\) is the dependent variable, \(x_t\) the single exogenous regressor, and \(\{\varepsilon_t\}\) a white-noise, mean-zero sequence. Granger used the concept of degree of integration of a variable. If variable \(Z_t\) can be made approximately stationary by differencing it \(d\) times, it is called integrated of order \(d\), or \(I(d)\). Weakly stationary random variables are thus \(I(0)\). Many macroeconomic variables can be regarded as \(I(1)\) variables: if \(Z_t \sim I(1)\), then \(\Delta Z_t \sim I(0)\). Assume now that both \(x_t \sim I(1)\) and \(y_t \sim I(1)\) in eq. (1). Then generally the linear combination \(y_t - \beta x_t \sim I(1)\) as well. There is, however, one important exception. Many macroeconomic variables can be regarded as \(I(1)\) variables: if \(Z_t \sim I(1)\), then \(\Delta Z_t \sim I(0)\). It has to do with the fact that for an equation such as (1) to be meaningful it has to be balanced, a concept Granger employed in his work. An equation is balanced when its right-hand and left-hand sides are of the same order of integration. Rewrite (1) as

\[
y_t - \beta x_t = \alpha + \varepsilon_t.
\]

If \(\varepsilon_t \sim I(0)\), then \(y_t - \beta x_t \sim I(0)\), that is, the linear combination \(y_t - \beta x_t\) has the same statistical properties as an \(I(0)\) variable. There exists only one such combination so that coefficient \(\beta\) is unique. In this special case, variables \(x_t\) and \(y_t\) are called cointegrated. This notion generalizes to more than two variables.

The importance of cointegration in the modelling of non-stationary economic series becomes clear in the Granger representation theorem that was first formulated in Granger and Weiss (1983). Consider the following bivariate vector autoregressive (VAR) model of order \(p\):
\[ x_t = \sum_{j=1}^{p} \gamma_{1j} x_{t-j} + \sum_{j=1}^{p} \delta_{1j} \Delta y_{t-j} + \epsilon_{1t} \]

\[ y_t = \sum_{j=1}^{p} \gamma_{2j} x_{t-j} + \sum_{j=1}^{p} \delta_{2j} \Delta y_{t-j} + \epsilon_{2t} \]

where \( x_t \) and \( y_t \) are I(1) and cointegrated, and \( \epsilon_{1t} \) and \( \epsilon_{2t} \) are white noise. The Granger representation theorem states that in this case the system can be written as:

\[ \Delta x_t = \alpha_1 (y_{t-1} - \beta x_{t-1}) + \sum_{j=1}^{p-1} \gamma_{1j} \Delta x_{t-j} + \sum_{j=1}^{p-1} \delta_{1j} \Delta y_{t-j} + \epsilon_{1t} \]

\[ \Delta y_t = \alpha_2 (y_{t-1} - \beta x_{t-1}) + \sum_{j=1}^{p-1} \gamma_{2j} \Delta x_{t-j} + \sum_{j=1}^{p-1} \delta_{2j} \Delta y_{t-j} + \epsilon_{2t} \]

where at least one of parameters \( \alpha_1 \) and \( \alpha_2 \) deviates from zero. Both equations of the system are balanced since \( y_{t-1} - \beta x_{t-1} \sim I(0) \). System (2) is now in error-correction form where \( y_{t} - \beta x_{t} = 0 \) defines a dynamic equilibrium relationship between the two economic variables, \( y \) and \( x \). While the system consists of two equations, it only has a single equilibrium relationship. More generally, if the system has \( n \) variables, the number of these cointegrating relationships is less than \( n \). System (2) in disequilibrium but has a built-in tendency to adjust itself towards the moving equilibrium. The coefficients \( \alpha_1 \) and \( \beta_2 \) represent the relative strength of this adjustment at any given time. In applications, the equilibrium or long-run relationship represents an economic theory proposition,
where the remaining variables and parameters describe the short-term dynamic behaviour of the system.

It may be mentioned that linear combinations of non-stationary variables had appeared in dynamic econometric equations prior to Granger's work. Phillips (1957), who coined the term 'error correction', and Sargan (1964) had employed them, but they did not, however, consider the statistical implications of introducing such components into their models.

A first test for cointegration appeared in Granger and Weiss (1983). The idea is best seen from eq. (1). Variables $x_t$ and $y_t$ are cointegrated if $\varepsilon_t \sim I(0)$. Estimate parameter $\beta$ by ordinary least squares and apply a standard unit root test to the residuals. A rejection of the null hypothesis suggests cointegration.

A method for estimating parameters of systems with cointegrated variables was still needed to make the concept applicable. Granger, working jointly with Robert Engle, developed a two-stage estimation method for VAR models with cointegration (Engle and Granger, 1987). Consider the following $n$-dimensional VAR model of order $p$:

$$
\Delta x_t = \alpha \beta' x_{t-1} + \sum_{j=1}^{p-1} \Gamma_j \Delta x_{t-j} + \varepsilon_t (t = 1, \ldots, T)
$$

where $x_t$ is an $n \times 1$ vector of I(1) variables, $\alpha \beta'$ is an $n \times n$ matrix such that the $n \times r$ matrices $\alpha$ and $\beta$ have rank $r$, $\Gamma_j, j = 1, \ldots, p-1$, are $n \times n$ parameter matrices, and $\varepsilon_t$ is an $n \times 1$ vector of white noise with a positive definite covariance matrix. If $0 < r < n$, the variables in $x_t$ are cointegrated with $r$ cointegrating relationships $\beta' x_t$. If the variables in $x_t$ are cointegrated, the parameters of (3) can be estimated in two stages. First estimate $\beta$ or, more precisely, the cointegrating space ($\beta$ up to a multiplicative constant) using a form of least squares. Then, holding that estimate fixed, estimate the remaining parameters by maximum likelihood. The estimators of $\alpha$ and $\Gamma_j, j = 1, \ldots, p-1$, are consistent and asymptotically normal. This solution is based on the fact that the least squares estimator of $\beta$ is superconsistent: its rate of convergence is faster than that of the estimators of the other parameters. Engle and Granger (1987) also contains a rigorous proof of the Granger representation theorem.

This paper by Engle and Granger is one of the most cited papers in time series econometrics (200 citations annually since its appearance), and it was followed by a flood of applications. Cointegration strongly contributed to the popularity of VAR models suggested by Sims (1980) as a convenient tool for modelling economic variables without strong assumptions originating from economic theory. The ultimate refinement of the statistical theory of cointegrated variables was provided by Søren Johansen (see Johansen, 1995, for a summary) who derived the maximum likelihood estimator of $\beta$ or, more precisely, the space spanned by the $r$ cointegrating vectors in (3), using reduced rank regression. He also considered tests for determining the cointegration rank $r$. It may be mentioned that Granger originally (Granger, 1981) defined cointegration using tools from spectral analysis. In fact, in 1964 he wrote an
early book on the topic jointly with Michio Hatanaka. The book that became a Citation Classic was based on the work carried out when Granger was visiting Princeton University on a Harkness fellowship in the early 1960s.

Granger also undertook very influential research concerning causal relationships between variables. He moved away from deterministic causality (‘if A then B’) to stochastic one in which time plays a decisive role. Granger's causality definition (Granger, 1969) is based on the prediction accuracy of a stationary variable \( y \). If \( y \) can be predicted more accurately with a set of other variables than without them, then these variables are said to cause. This is an operational definition that makes it possible to test the null hypothesis of no causality between economic variables with statistical methods. This may be done in either a single-equation or a system framework. For this reason this concept of causality, nowadays called Granger-causality, has become very popular in applied work. Most of the available tests, however, test for in-sample predictability, whereas Granger has always emphasized the fact that his definition pertains to out-of-sample forecasting and the (non)existence of causality should be tested accordingly. Granger-causality has become an important tool in economic research and policymaking and is also being used in other areas than economics. For more information, see Hendry and Mizon (1999). Granger (1986) established a link between causality and cointegration. If \( y \) and \( x \) are cointegrated then there is Granger-causality at least in one direction between these variables.

Granger has also been instrumental in starting the econometric research on processes with long memory. They have the property that their autocorrelations as a function of the lag length decay at a slower rate than autocorrelations of a linear autoregressive–moving average process in which the decay rate is exponential. Granger and Joyeux (1980) defined a new concept, fractional integration, and showed how fractionally integrated processes, stationary or non-stationary, can have long memory. A stochastic variable \( y_t \) is fractionally integrated series of order \( d \), \( I(d) \), where \( d \) need not be an integer, if \( x_t \) in

\[
x_t = (1 - L)^d y_t
\]

where \( L \) is the lag operator: \( L y_t = y_{t-1} \), is an I(0) variable. Choosing \( d = 1 \) yields the standard case where \( y_t \sim I(1) \). Time series models based on fractional integration have since become popular in econometrics, and long memory in volatility has received plenty of attention in financial econometrics.

Granger is one of the first econometricians interested in nonlinear time series and wrote (1978, with Allan Andersen) a book on bilinear time series models. The bilinear model has not found much application in economics, but the book has stimulated more research in this area. Granger has since expanded his interests in nonlinear models, among other things, by generalizing cointegration, originally a linear concept, into nonlinear cointegration. He has also written a book on nonlinear econometric modelling (1993, with Timo Teräsvirta).

Economic forecasting has been one of Granger's main interests throughout his career. He observed (Bates and Granger, 1969) that combining forecasts from different models often improves the forecast accuracy compared with forecasts from individual models, and proposed forecast weighting schemes for this purpose. This work has prompted a large literature that is still growing. He wrote a book (1970, with
Oskar Morgenstern) on forecasting stock markets before that became a topic of broad interest, and a classic textbook with Paul Newbold on economic forecasting (Granger and Newbold, 1977). Another forecasting topic that has attracted Granger's interest is the evaluation of forecasts and the role of the forecaster's cost function in both parameter estimation and model evaluation, and he has made important contributions in this area.

One may argue that Granger's research is principally focused on conditional mean models, but he has also contributed to the analysis of conditional variance models. He has extended the standard model of generalized autoregressive heteroskedasticity (GARCH) model into the power GARCH model (Ding, Granger and Engle, 1993), intended to improve the modelling of volatility in financial time series such as return series of sufficiently high (intra-daily, daily, weekly) frequency. He has also indicated the potential for statistical modelling of the decomposition of stock return series into a sign process with little or no autocorrelation and an absolute return one with strong dependence structure. He has considered forecasting volatility of financial return series, a topic that is of great importance to investors who consider volatility to be a measure of risk (Poon and Granger, 2003).

A representative collection of Granger's scientific papers can be found in Ghysels, Swanson and Watson (2001).

Granger–Sims causality

G.M. Kuersteiner
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The concept of Granger–Sims causality is discussed in its historical context. There follows a review of the subsequent literature that explored conditions under which the definitions of Granger and Sims are equivalent. The relationship to the potential outcomes framework is explored in light of recent developments in the literature.

Article

Granger–Sims causality is based on the fundamental axiom that ‘the past and present may cause the future, but the future cannot cause the past’ (Granger, 1980, p. 330). A variable $x$ then is said to cause a variable $y$ if at time $t$ the variable $x_t$ helps to predict the variable $y_{t+1}$. While predictability in itself is merely a statement about stochastic dependence, it is precisely the axiomatic imposition of a temporal ordering that allows us to interpret such dependence as a causal connection. The reason is that correlation is a symmetric concept with no indication of a direction of influence, while ‘the arrow of time imposes the structure necessary’ (Granger, 1980, p. 349) to interpret correlations in a causal way.

1 Definitions
A more precise definition of Granger causality can be given as follows. Assume that all relevant current information is measured in a vector $X_t = (V_t, X_t, Z_t)$ which is observed at equally spaced discrete points in time $t$. (The assumption of discrete time can be relaxed but is maintained here for expositional convenience. Almost all empirical work is in the context of discrete time models.) Denote by $Y_t^j$ all information contained in $V_j$, $j = \{s, \ldots, t\}$ with equivalent definitions for $X_t^j$ and $Z_t^j$. (In more formal terms, the expression ‘information contained in’ can be replaced by ‘sigma field generated by’; see Florens and Mouchart, 1982, for precise definitions.) Then $x_t$ does not Granger cause $Y_{t+1}$ if

$$P\left(V_{t+1} \in A \left| Y_{-\infty}^t, X_{-\infty}^t, Z_{-\infty}^t \right.\right) = P\left(V_{t+1} \in A \left| Y_{-\infty}^t, Z_{-\infty}^t \right.\right)$$

(CI)

for all $t$ and for any set $A$ for which the conditional probabilities are well defined. It is worth noting that no assumptions of stationarity are needed for this definition. It is common to use the shorthand notation $V_{t+1} \perp X_{-\infty}^t \mid Y_{-\infty}^t, Z_{-\infty}^t$, $\forall t$, which states that $V_{t+1}$ and $X_{-\infty}^t$ are independent conditional on $Y_{-\infty}^t, Z_{-\infty}^t$. This form of the definition, which imposes a conditional independence restriction on the joint distribution of the process $X_t$ (see Dawid, 1979, for a formal definition and alternative equivalent representations), is similar to the definition used by Granger (1980). It is more general than the original formulations of Granger (1963; 1969), which are based on prediction error variances: Let $E(Y_{t+1} \mid X_{-\infty}^t)$ denote the optimal predictor of $Y_{t+1}$ based on $X_{-\infty}^t$, $\varepsilon_{t+1} = Y_{t+1} - E(Y_{t+1} \mid X_{-\infty}^t)$ is the prediction error and $\sigma^2(Y_{t+1} \mid X_{-\infty}^t)$ the variance of $\varepsilon_{t+1}$. Then, according to Granger (1969), $x_t$ does not cause $Y_{t+1}$ if

$$\sigma^2(Y_{t+1} \mid Y_{-\infty}^t, X_{-\infty}^t, Z_{-\infty}^t) = \sigma^2(Y_{t+1} \mid Y_{-\infty}^t, Z_{-\infty}^t).$$

(PV)

The conditional independence definition (CI) has the advantage that it does not depend on a particular risk function and is easier to relate to other definitions of causality in stochastic environments such as Suppes (1970) and Rubin (1974). The formulation based on conditional independence was later used and refined in theoretical work by Chamberlain (1982), Florens and Mouchart (1982; 1985), Bouissou, Laffont and Vuong (1986) and Holland (1986). The advantage of the prediction error variance definition, (PV) which goes back to Wiener (1956), on the other hand, is that it is easier to implement in
statistical tests and has consequently received considerable attention in applied work. In an influential paper, Sims (1972) showed in the context of covariance stationary processes and restricted to linear predictors that in the case of a bivariate system $X_t' = (X_t, Y_t)$ the definitions of Granger (1963; 1969) are equivalent to parameter restrictions of the moving average or distributed lag representations of $X_t$. When $X_t$ is covariance stationary it can be represented as

$$X_t = \sum_{j=0}^{\infty} a_j u_{t-j} + \sum_{j=0}^{\infty} b_j v_{t-j}$$

$$Y_t = \sum_{j=0}^{\infty} c_j u_{t-j} + \sum_{j=0}^{\infty} d_j v_{t-j}$$

where $a_j$, $b_j$, $c_j$ and $d_j$ are constants and $u_t$ and $v_t$ are mutually uncorrelated white noise processes. Sims (1972) shows that the condition ‘$x_t$ does not Granger cause $y_{t+1}$’ is equivalent to $c_j$ or $d_j$ being chosen identically zero for all $j$. Furthermore, if $X_t$ has an autoregressive representation, then

$$x_t = \sum_{j=0}^{\infty} \pi_j v_{t-j} + \varepsilon_t$$

where the $\pi_j$ are parameters and $\varepsilon_t$ is an unobservable innovation. Strict exogeneity of $y_t$ in the context of this model is defined as the condition that $y_t$ and $\varepsilon_s$ are independent for all values of $t$ and $s$. Sims then shows that the residuals from a projection of $x_t$ onto $v_{t-j}$, $j \geq 0$ are uncorrelated with all past and future $y_t$ if an only if $x_t$ does not Granger cause $y_{t+1}$. In other words, it follows that the condition ‘$x_t$ does not Granger cause $y_{t+1}$’ is equivalent to the condition that $y_t$ is strictly exogenous. The relationship between Granger non-causality and strict exogeneity, first discovered by Sims (1972), is further discussed by Engle, Hendry and Richard (1983). Hosoya (1977) shows that this relationship continues to hold in a bivariate setting when processes are not necessarily stationary and have deterministic components, a situation not originally consider by Granger (1969). The strict exogeneity restrictions discussed in Sims (1972) have become known in the literature as ‘Sims non-causality’. In more general terms, and in the context of the process $X_t$, the absence of Sims causality of $x_t$ for $y_{t+1}$ is defined as a conditional independence restriction where

$$P(x_t \in A|Y_{-\infty}^{\infty}, X_{-\infty}^{t-1}, Z_{-\infty}^{t}) = P(x_t \in A|Y_{-\infty}^{t}, X_{-\infty}^{t-1}, Z_{-\infty}^{t})$$

(S)
for all \( t \) or equivalently as \( Y_{t+1} \perp X_t | Y_{-\infty}^t, X_{-\infty}^{t-1}, \mathbf{Z}_{-\infty}^t, \forall t \). This definition appears in Florens (2003) and Angrist and Kuersteiner (2004) and is closely related to Chamberlain (1982) except that here additional information contained in \( \mathbf{Z}_{-\infty}^t \) is allowed for.

The equivalence between the Granger and Sims notions of causality extends beyond the prediction criterion for covariance stationary processes to definitions of non-causality based on conditional independence restrictions, but, as discussed below, in models with time-varying covariates \( z_t \) Sims causality is more appealing and easier to link to the potential-outcomes causality concepts widely used to analyze randomized trials and quasi-experimental studies. Sims (1977, p. 30) emphasizes the use of strict exogeneity restrictions for model identification in structural models and notes that these restrictions can often be related to decision rules of economic agents. Granger non-causality, on the other hand, is a restriction of the reduced form. Structural vector autoregressions (VARs) provide an example of this difference where Sims non-causality imposes restrictions on the impulse response function of structural innovations (Sims, 1986, p. 9, discusses the nature of structural innovations and mentions explicitly that they may include random fluctuations of policies) while Granger non-causality imposes restrictions on the reduced form VAR representation of the model. That the two are in general not equivalent will be discussed in Section 3.

2 Motivation and interpretation of Granger–Sims causality

In order to understand the significance of the original definition of Granger–Sims causality in Granger (1963; 1969) and Sims (1972), it is useful to briefly review the preceding debate in the literature. Simon (1953) defines causality as ‘properties of a scientist’s model’. Asymmetric functional relationships between variables are given causal interpretations but Simon emphasizes that no notion of time is needed for this definition. In the context of linear systems of equations Simon's definition of causal relationships is equivalent to a block recursive structure of the equations. Simon (1953, p. 65) emphasizes the need for a priori knowledge about the system to identify the block recursive structure.

Wold (1954) and Strotz and Wold (1960) strengthen this definition of causality to require a model to be fully recursive. If the model has three variables \( a, b \) and \( c \) then recursiveness means that \( a \) can be solved without knowing \( b \) and \( c \), the solution for \( b \) generally depends on \( a \), and the solution for \( c \) depends on both \( a \) and \( b \). Such a system then is interpreted to have a causal relationship where \( a \) causes \( b \) and \( a \) and \( b \) both cause \( c \). Wold (1954, p. 166) writes: ‘The relationship is then defined as causal if it is theoretically permissible to regard the variables as involved in a fictive controlled experiment.’ The idea is that, because \( a \) does not depend on \( b \) an \( c \), it can in principle be controlled or changed by an experimenter. In the terminology of Wold (1954, p. 166), \( a \) is the cause and \( b \) and \( c \) are the ‘effect variables’. Wold (1954) discusses the distinction between randomized experiments in the sense of R. A. Fisher and non-experimental observations. In the latter case causal interpretations depend on ‘subject-matter theory’ (Wold, 1954, p. 170) to identify recursive structures. In other words, a priori assumptions about the structure of the model replace randomized experiments as the source of identification. This approach remains popular to this day for the identification of structural VARs where recursive relationships based on a casual appeal to economic theory are imposed. Orcutt (1952) discusses causal
Granger–Sims causality: The New Palgrave Dictionary of Economics

chains or triangular systems but also mentions the possibility of using temporal structures to identify causal links. Basmann (1963) criticizes the recursive identification schemes of Wold and argues in favour of more general structural economic models to identify causal relationships. Both Granger and Sims voice scepticism about identifying restrictions which can in general not be tested but have to be accepted a priori. Granger (1980, p. 335) writes,

[i]f these assumptions are correct or can be accepted as being correct, these definitions may have some value. However, if the assumptions are somewhat doubtful, these definitions do not prove to be useful.

And Sims (1972, p. 544; see also 1977, p. 33) notes,

[i]f one is willing to identify causal ordering with Wold's causal chain form for a multivariate model, and if enough identifying restrictions are available in addition to those specifying the causal chain form, one can test a particular causal ordering as a set of overidentifying restrictions. The conditions allowing such a test are seldom met in practice, however.

The great advantage of Granger's definition of causality is that it is directly testable from observed data. Granger (1969) gives operational definitions and discusses testable parameter restrictions in linear time series specifications. The strict exogeneity restrictions derived by Sims (1972) are particularly revealing of the power of the flow of time as the identifying force behind uncovering causal links between time series. On the assumption that $x_t$ is strictly exogenous, then, if $x_t$ does not cause $y_t$ it must be conditionally independent of future outcomes $y_{t+j}$. On the other hand, if conditional correlations between future outcomes $y_t$ and current values of $x_t$ are detected, they must be due to a causal influence of $x_t$ on $y_t$, because, by assumption, the possibility of a causal link between events determining $y_{t+j}$ that lie in the future and current observations of $x_t$ have been excluded and thus cannot be the source of the observed correlation.

As Granger (1963; 1980) notes, the notion of causality has a long and controversial tradition in philosophy. Some treatments discussing relationships to econometric and statistical practice include Pearl (2000) and Hoover (2001). Holland (1986) discusses the causality definitions of David Hume, John Stuart Mill and Suppes (1970) in the context of Rubin's (1974) causal model. Holland points out that Hume's criteria for causality include the axiom of temporal precedence as well as the requirement of a 'constant conjunction' between cause and effect. (See Hoover, 2001, p. 8, for more discussion of Hume's concept of 'constant conjunction'.) Suppes (1970) proposes a probabilistic theory of causality where he replaces constant conjunction with the requirement that one event is the cause of another if the appearance of the first event is followed with high probability by the appearance of the second, and there is no third event that we can use to factor out the probability relationship between the first and second events. (Suppes, 1970,
The definition of Suppes has some parallels to Granger's definition, notably the requirement of temporal succession, the fact that there are no restrictions on what can be a cause and the fact that causes are defined through their effect on the conditional distribution of the effect variable. Finally, Holland attributes the idea of identifying causal effects through experimentation to Mill. Experimentation has since played a central role in the statistical analysis of causality, although Granger (1980, p. 329) mentions it only in passing and does not rely on it in his definition of causality. An important consequence of an experimental concept of causality is that, as Holland (1986, p. 954) writes, ‘causes are only those things that could, in principle, be treatments in experiments’. As discussed in Section 4, this is a critical difference to the concept of Granger causality which does not restrict possible causes. Feigl (1953) discusses various aspects of the definition of causality that have appeared historically in philosophy and attempts to extract what he calls a ‘purified’ definition of causality. Zellner's (1979) critique of the concept of Granger causality is centered on Feigl's definition according to which ‘[t]he clarified (purified) concept of causation is defined in terms of predictability according to a law’ (Feigl, 1953, p. 408). Feigl (1953, p. 417) continues to note that ‘[p]rediction may be analyzed as a form of deductive inference from inductive premises (laws, hypotheses, theories) with the help of descriptions or existential hypotheses’. Zellner (1979, p.12) writes: ‘predictability without a law or set of laws, or as econometricians might put it, without theory, is not causation.’ In other words, the causality concept put forward by Feigl is based on a priori theoretical assumptions used to generate predictions, while the Granger–Sims notion of causality replaces these a priori restrictions with the axiom of temporal priority. Feigl (1953, p. 417) notes that causal relationships can be defined even when cause and effect are contemporaneous. According to Feigl, a more important distinction between cause and effect lies in the controllability of the cause as opposed to the effect, which leads Feigl to recommend experimental methods as the best way to identify causal factors. In light of Feigl's work Zellner's main critique of Granger–Sims causality is that it is not based on economic theory to identify causes. (Leamer, 1985, also strongly rejects the idea of conducting causal inference without relying on a priori theory.) In a reply to Zellner, Sims (1979, p. 105) notes that Feigl's definition is at least as ambiguous as the term ‘causality’ itself and that it is so general that it encompasses many other definitions of causality.

Zellner also criticizes three more specific features of Granger causality. First, the requirement that the information set needed to define relevant conditional distributions contain all available information makes the definition non-operational. Zellner (1979, p. 33) writes, ‘Granger does not explicitly mention the important role of economic laws in defining the set of “all relevant information”’ and emphasizes that additional assumptions beyond statistical criteria are necessary to implement tests for Granger non-causality. Second, the limitation to stochastic phenomena and the assumption or axiom of temporal priority of a cause is unnecessarily restrictive compared with other definitions of causality, such as the one of Feigl (1953), which does not rely on these restrictions. And finally, the use of the prediction error variance as a criterion for predictability and the reliance on an optimal predictor, which according to Zellner may both not be well defined, is too restrictive. As far as this last point is concerned it should be noted that more general definitions of Granger–Sims causality proposed by Granger (1980), Chamberlain (1982) and Florens and Mouchart (1982), which are based on conditional independence
restrictions of the joint distribution, do not have the problems that Zellner mentions because these
distributional restrictions can be formulated for any process with well-defined conditional distributions.
Zellner further points out that economic theory can play a role in providing overidentifying restrictions
that allow directions of causality to be imposed. Sims (1979) objects to this last suggestion on the
grounds that a test for causality based on overidentifying restrictions is always a joint test of the
correctness of such restrictions and the hypothesis of interest and is thus never conclusive. On the other
hand, strict exogeneity and thus Granger non-causality, as pointed out by Sims (1977, p. 30, 33)
provides overidentifying restrictions that can be tested for. The scepticism about untestable identifying
restrictions is forcefully expressed in Sims (1980).
The role of economic theory in identifying parameters of interest in empirical studies remains one of the
most controversial issues in econometrics and empirical economics to date. The debate over the correct
definition of causality hinges on what individual researchers are prepared to assume a priori, be it
restrictions on the temporal direction of cause and effect or fundamental structures that govern the
interaction between economic variables. Granger (1980) does not dispute the potential usefulness of a
priori theoretical restrictions in identifying causal relationships but emphasizes the potential for
misleading inference should these restrictions turn out to be incorrect.

The problem of specifying the correct information set is recognized by Granger (1969), where it is
suggested to restrict the set of all available information to the set of relevant information. Granger
(1980) discusses a number of examples that illustrate the sensitivity of a causal relationship between two
variables to additional information in the conditioning set. This problem is also mentioned by Holland
(1986). It seems, however, that, even though specification issues are of great importance in applied
work, this is not a fundamental limitation of the causality concept put forward by Granger. Moreover,
correct specification of relevant conditioning variables is a common problem in most statistical
procedures applied to economic data and thus not specific to procedures testing for causality. At the
same time, the argument in favour of guidance from economic theory when designing such procedures is
probably strongest when it comes to selecting the relevant variables that need to be included in the
analysis, a point elaborated in more detail below.

Further problems of interpretation are discussed in Granger (1980). Simultaneity occurs if \( x_t \) causes
\( y_{t+1} \) and \( y_t \) causes \( x_{t+1} \). In a bivariate system of equations this form of feedback, as Granger (1969)
defines it, typically leads to other inferential problems as discussed in Sims (1972). In particular, the
lack of exogeneity in this case invalidates conventional regression methods and complicates the
interpretation of reduced form parameters such as in VARs. Furthermore, Granger causality is not a
transitive relationship: if \( x_t \) causes \( y_{t+1} \) and \( y_t \) causes \( z_{t+1} \) then \( x_t \) does not necessarily cause \( z_{t+1} \).
Granger (1980, p. 339) gives the following example. Assume that \( \xi_t \) and \( \eta_t \) are mutually independent i.i.d.
sequences and that \( x_t = \xi_t, y_t = \xi_{t-1} + \eta_t \) and \( z_t = \eta_{t-1} \). Then, because \( y_t = x_{t-1} + \eta_t \) it is clear
that \( x_t \) causes \( y_{t+1} \). In the same way, \( y_t \) causes \( z_{t+1} \) but \( x_t \) does not cause \( z_{t+1} \) if the conditioning set
contains only \( x_{-\infty} \) and \( z_{-\infty} \), which is the typical assumption in bivariate statements of causality. At
the same time, \( x_t \) does cause \( z_{t+1} \) in this example when the information set is enlarged to
\( (x_{-\infty}, y_{-\infty}, z_{-\infty}) \) because now the innovation \( \eta_{t-1} \) can be recovered from \( \eta_{t-1} = y_{t-1} - x_{t-2} \).
This example shows that the concept of Granger–Sims causality can be sensitive to the specification of
conditioning information.

3 Equivalence and non-equivalence of Granger and Sims causality

Since the original contributions of Granger (1963; 1969) and Sims (1972), which were mostly cast in terms of forecast error criteria, there has been a sizeable literature concerned with extensions of the basic definition and establishing a number of equivalence relationships. While the conditional independence formulation of Granger causality goes back at least to Granger (1980, p. 330), a formal analysis of the equivalence with a corresponding definition of Sims causality was first obtained by Chamberlain (1982) and Florens and Mouchart (1982). It turns out that the condition for Granger non-causality, which in its more general form can be stated as $\forall t+1 \perp X_{-\infty}^t \mid Y_{-\infty}^t$, does imply the generalized form of Sims non-causality formulated as $\forall t+1 \perp X_{-\infty}^t \mid Y_{-\infty}^t$, but the reverse implication does not hold generally. Florens and Mouchart (1982) give a counter-example of a nonlinear process where Sims non-causality holds but Granger non-causality does not hold. As Florens and Mouchart (1982) point out, the two conditional independence relationships are equivalent for Gaussian processes where lack of covariance is equivalent to independence. Chamberlain (1982) shows, on the other hand, that a generalized form of Sims non-causality, stated as $\forall t+1 \perp X_{-\infty}^t \mid Y_{-\infty}^t$, is equivalent to $\forall t+1 \perp X_{-\infty}^t \mid Y_{-\infty}^t$ under a mild regularity condition limiting temporal dependence. Florens and Mouchart (1982) obtain a very similar result for slightly different definitions of the conditioning sets. General statements of this result can also be found in Bouissou, Laffont and Voung (1986). These authors define additional causality relationships: global non-causality (C) is defined as $\forall t + 1 \perp X_{-\infty}^t \mid Y_{-\infty}^t$, Granger non-causality of order $k$ ($G_k$) is defined as $\forall t + 1 \perp X_{-\infty}^t \mid Y_{-\infty}^t$, and Sims non-causality of order $k$ ($S_k$) is defined as $\forall t + 1 \perp X_{-\infty}^t \mid Y_{-\infty}^t$ where $X_{t-k}$ is any subset of $X_{-\infty}$. It is then shown that ($G_k$), ($S_k$) and (C) are all equivalent for all $k$, a result that is also stated in Florens and Mouchart (1982, p. 580).

Pierce and Haugh (1977) propose an alternative definition of Granger causality in the context of linear processes. If $H(Y_0, U)$ is the linear projection of $Y_{t+1}$ on $\{Y_0, U\}$ where $\{Y_0, U\}$ is the closed linear span of all the variables generating $Y_0$ and the initial conditions $U$, then $y_t$ does not Granger cause $Y_{t+1}$ if the innovations $Y_{t+1} - H(Y_0, U)$ and $X_{p+1} - H(X_0, U)$ are uncorrelated for all $p \leq t$. Florens and Mouchart (1985) show that this definition is equivalent to covariance-based definitions of Granger and Sims causality under some additional regularity conditions. Generally speaking, the results of this early literature show that Granger causality between two processes $x$ and $y$ is equivalent to appropriate definitions of Sims causality not only in a mean squared prediction error sense but more generally in terms of restrictions on appropriate conditional distributions of the joint process. It should also be noted that these equivalence results continue to hold when both $x$ and $y$ are vector valued processes.
The situation changes, however, quite markedly when an additional set of covariates \( z \) is added to the analysis. In this situation Granger non-causality defined as \( Y_{t+1} \perp X_{-\infty}^t, Y_{-\infty}^t, Z_{-\infty}^t, \forall t \) in general is not equivalent to Sims non-causality defined as \( Y_{t+1} \perp X_{-\infty}^t, Y_{-\infty}^{t-1}, X_{-\infty}^t, Z_{-\infty}^t, \forall t \). This result seems to have been first obtained by Dufour and Tessier (1993) for the linear case and also appears in Florens (2003) and Angrist and Kuersteiner (2004) and in the biostatistics literature in Robins, Greenland and Hu (1999). Simple examples can be constructed where \( x \) Granger-causes \( y \) but does not Sims cause \( y \) as well as cases where \( x \) Sims causes \( y \) but does not Granger cause \( y \). In related work Lütkepohl (1993) and Dufour and Renault (1998) show that, in general, (G1) does not imply (C) if the information set contains \( z \).

To illustrate the result of Dufour and Tessier (1993), assume that \( X_t = (\chi_t, x_t, z_t) \) and that \( \chi_t \) can be represented as linear functions of present and past structural innovations \( e_t \). To simplify the exposition assume that for \( C(L) = A(L)^{-1} \) where \( A(L) \) is a matrix of lag polynomials of finite order and \( L \) is the lag operator, it holds that \( X_t = C(L) e_t \). Also assume that the diagonal blocks of \( C(0) \), partitioned according to \((y_t, x_t, z_t)\), are full rank. The reduced form VAR representation of \( \chi_t \) then is \( \pi(L)X_t = u_t \) with \( u_t = C(0) e_t \) and \( \pi(L) = C(0) A(L) \). As was discussed before, Sims non-causality imposes zero restrictions on off-diagonal blocks of \( C(L) \) while Granger non-causality imposes zero restrictions on corresponding off-diagonal blocks of \( \pi(L) \). Now note that when \( \chi_t \) contains only \( y_t \) and \( x_t \), the partitioned inverse formula implies that off-diagonal blocks of \( A(L) \) are zero if and only if corresponding blocks of \( C(L) \) are zero. Because the latter can hold only if corresponding blocks of \( C(0) \) are zero, it follows that \( \pi(L) \) has zero off-diagonal blocks if and only if corresponding blocks of \( C(L) \) are zero. This is the result of Sims (1972). On the other hand, when \( X_t = (\chi_t, x_t, z_t) \) the partitioned inverse formula for matrices partitioned into three blocks shows that \( C(L) \) having off-diagonal blocks no longer implies that corresponding blocks of \( A(L) \) are necessarily zero as well. Thus the equivalence between Sims and Granger causality no longer holds when additional time varying covariates are included in the analysis. In Section 4, applications in monetary economics are discussed where this situation arises naturally.

4 The connection between Granger–Sims causality and potential outcomes

The notion of causality that has become standard in micro-econometrics is based on Rubin's (1974) concept of potential outcomes, which at its core uses experimental variation to identify causal relationships. The potential outcomes model has been extended to and applied in observational studies. Observational studies are situations where no experimental assignments of actions were used. Examples are medical trials where experiments might be unethical or many economic policy questions where experiments may be unethical or too expensive to carry out. The importance of experimental evidence was recognized in econometrics dating back to Haavelmo (1944). Wold (1954) similarly discusses controlled experiments as a way to uncover causal relationships. Orcutt's (1952, p. 305) notion of causality is closely related to the idea of potential outcomes and is defined in terms of consequences of actions:
Thus when we say that $A$ is the cause of $B$, we often mean that if $A$ varies, then $B$ will be different in a specified way from what it would have been if $A$ had not varied.

Orcutt (1952, p. 309) goes on to discuss policy actions as a substitute for unavailable experimental evidence to identify causal relationships in observational data, an idea explored in more detail below. For expositional purposes, assume that a certain action or treatment $D$ can be either given or not given to individual $i$. The causal question in this context is whether the treatment has an effect on an outcome variable of interest measured by $y$. It is convenient to define $D_i = 1$ if the treatment is given and $D_i = 0$ if the treatment is not given. The potential outcome $y_i(0)$ is defined as the outcome for individual $i$ that would have occurred if the treatment had not been given and $y_i(1)$ as the outcome that would have occurred in the case the treatment had been given. The absence of causality of $D$ for $y$ then is defined as the situation where $y_i(0) = y_i(1)$. This condition is referred to as the ‘strong null hypothesis of no causal effect’. Usually this condition cannot be directly tested because $y_i(0)$ and $y_i(1)$ are not both observed for the same individual. Instead, the observed measurement takes the form

$$y_i = D_i y_i(1) + (1 - D_i) y_i(0)$$

(PO)

Potential outcomes may depend on a list of covariates $z_i$. Covariates capture characteristics of the outcome variable that are not directly related to the experiment but that need to be taken into account when assessing the outcome. An identification condition is needed to proceed to testable restrictions. Formally one imposes the condition $y_i(0), y_i(1) \perp D_i z_i$, which is sometimes referred to as selection on observables. This condition is automatically satisfied if $D_i$ is randomly assigned in an experiment. In observational studies the condition essentially states that actions by individuals or policymakers cannot be based on unobservable information. The ‘selection on observables’ condition implies that

$$P(y_i(j) \in \mathcal{A} z_i) = P(y_i(j) \in \mathcal{A} D_i z_i)$$

for all $j$ and the null hypothesis implies that

$$P(y_i \in \mathcal{A} D_i z_i) = P(y_i \in \mathcal{A} z_i)$$

which is identical to Granger’s condition of no causal effect, a result that is discussed in Holland (1986).
The power of the identifying restriction lies in the fact that it is formulated independently of the null hypothesis of no causal relationship. To be more precise, the identifying restriction imposes conditional independence of $D$ from $y_i(0)$ and $y_i(1)$ but not from $y_i$. The latter holds only when the null is true. This is an important difference from Sims (1977, p. 30), who writes that ‘Causality is an important identifying restriction on dynamic behavioral relations’. In other words, Sims imposes the null to identify certain structural models. Another important difference between this model of causality and the less specific definition of Granger–Sims causality is that the form of the causal link between $D$ and $y$ is of a simple functional form specified in (PO). This particular structure is what allows the interpretation of measured correlations as causal links.

Identification conditions thus lead to testable implications of Rubin's potential outcome framework that are identical to the Granger–Sims definition of non-causality. Nevertheless, causality in Rubin’s context is closely related to experiments and counterfactuals: causal effects of a treatment are measured by comparing unobservable counterfactuals under treatment and non-treatment. On the other hand, Granger–Sims causality does not rely on the notion of treatment. It has been applied to studying such phenomena as the temporal link between interest rates and inflation, variables that are endogenously determined and where it is hard to imagine that an experiment or even a policy intervention is available for causal inference. Orcutt’s idea of using policy variation can, however, still be implemented if instead of market interest rates one focuses (in the United States) on the federal funds target rate, a variable that is directly set by the policymaker. Under the additional assumption that all systematic aspects of the policy depend on observable information, it is possible to generate pseudo-experimental variation even in the interest rate example. These ideas are now explored in more detail.

The potential outcomes framework in its original form is in many ways too limited to be directly applicable to macroeconomic questions of causality where the Granger–Sims concept of causality has been mostly applied. The two main limitations of the potential outcomes approach are that it does not allow for dynamic treatments or policies and that usually the stable unit treatment assumption of Rubin (1980) is imposed. The latter rules out general equilibrium effects of treatments and is not satisfied in a macroeconomic context. Angrist and Kuersteiner (2004) propose an extension of the potential outcomes framework that overcomes these limitations (also related is the work of White, 2006). Consider an economy that is described by $\chi_t = (y_t, D_t, z_t)$ where $y$ is a vector of outcome variables, $D$ is a vector of policy variables and $z$ is a vector of relevant covariates not already included in $y$. Potential outcomes $y_{t,j}^*(d)$ are defined as values the outcome variable $y_{+,j}$ would have taken if at time $t$ the policy had been set to $D_t = d$. It is probably useful to discuss the nature of the potential outcome $y_{t,j}^*(d)$ in a context where one has a dynamic general equilibrium model describing the evolution of the process $\chi_t$ as a system of stochastic difference equations. Then $y_{t,j}^*(d)$ has to be thought of as a specific solution of that model indexed against a specific decision rule $d$ of some policymaker. It is helpful, but not necessary, to assume that the model has a strong solution, in the sense of stochastic process theory, such that the strong null of no causal effect can be represented as the restriction $\forall t, j\{d\} = \forall t, j\{d'\}$ for all possible values of $d$. It should be clear from this description that $y_{r,j}^*(d)$ is a possibly highly complex function of all the inputs that go into the model, including policy decisions taken at times different from $t$. Solving for $y_{r,j}^*(d)$ explicitly is not necessary for the definition of a causal link between $D$ and $y$, a feature that is
very much in the spirit of Granger and Sims. All that is needed is an identifying restriction that allows us to interpret observed correlations as causal links. A sufficient condition is

\[
\forall t, j(d) \perp D_t y_{-\infty}^t, D_{-\infty}^{t-1}, z_{-\infty}^t, \forall t, \forall j > 0.
\]

(ID)

Under the sharp null of no causal effect where \( \forall t, j(d) = \forall t+j \) it then follows immediately that 
\[
\forall t+j \perp D_t y_{-\infty}^t, D_{-\infty}^{t-1}, z_{-\infty}^t.
\]

This is the same as the condition for Sims non-causality. As discussed earlier, it is generally not equivalent to Granger non-causality. The form of the testable restriction depends critically on the form of (ID). At least in cases where \( D \) is a decision variable of a policymaker, this restriction leading to Sims causality seems plausible. This can be seen easily in the context of linear models where the identification assumption leading to Sims non-causality is identical to the restriction that policy innovations are independent of all future innovations affecting the outcome variables.

In order to better understand the nature of the identifying assumption (ID) it is useful to consider a specific example. The notion of Granger causality was applied to the question of a causal link between monetary policy and real economic activity, starting with Sims (1972), and thus has a long tradition in the empirical macro literature. Most of the early empirical literature has investigated this question using linear regressions of some measure of monetary aggregates or interest rates and various measures of real economic activity. In an important methodological contribution, Romer and Romer (1989) use information from the minutes of the Federal Open Markets Committee to classify US Federal Reserve policy into times of purely anti-inflationary monetary tightening and other periods. Times of tight monetary policy are called Romer dates. The idea then is to measure average economic activity following Romer dates and to compare these measurements to average economic activity at other times.

While the argument that Romer dates are exogenous has been criticized (see for example Hoover and Perez, 1994; Shapiro, 1994; Leeper, 1997), the basic premise of the approach of Romer and Romer (1989) remains valid. It is to use a behavioural theory or policy rule for a policymaker to construct policy innovations which serve as exogenous variation that can be used to evaluate the effectiveness of the policy in question (Jorda, 2005, emphasizes the importance of exogenous variation to identify causal relationships). Angrist and Kuersteiner (2004) analyse the consequences of allowing for additional covariates \( z \) in the policy model to capture information about nominal macroeconomic variables such as the inflation rate. These variables are clearly relevant for policy decisions of the Federal Reserve and thus constitute relevant conditioning information in the sense of Granger (1969). At the same time these nominal variables are not part of the null hypothesis of no causal effects on real economic activity and thus cannot be subsumed into the \( y \)-process. As discussed earlier, under these circumstances reduced form regressions based on Granger's notion of non-causality cannot be used to test for Sims non-causality.

Generally speaking, a model of the policymaker, in this case the Federal Reserve, is a conditional
Granger–Sims causality: The New Palgrave Dictionary of Economics

probability distribution \( P(D_t \in \mathcal{A}_{t-1}, D_{t-1}^{t-1}, Z_{t-1}^{t-1}) \). An example of a policy model for the Federal Reserve in the context of the Romer and Romer data was developed by Shapiro (1994). The fundamental identifying assumption then is that this model is correct, especially in the sense that the conditional probability of \( D_t \) does not depend on \( y_{t,r}j(d) \). This condition will be satisfied when two criteria are met. All relevant information that the policymaker used to decide on the policy \( D_t \) is included in the model and the problem at hand is of a nature where the policymaker does not foresee the future. This is the way Granger's fundamental axiom of 'the arrow of time' plays a role to provide identifying assumptions in this setting. If these conditions are met then all random deviations of the policy \( D_t \) from what is predicted by the model are conditionally independent of \( y_{t,r}j(d) \). Random deviations could be due to the variation over time in policymakers’ beliefs about the workings of the economy, decision-makers’ tastes and goals, political factors, and the temporary pursuit of objectives other than changes in the outcomes of interest (for example, monetary policy that targets exchange rates instead of inflation or unemployment), and finally harder-to-quantify factors such as the mood and character of decision-makers. It is then precisely these random deviations from prescribed policies that help to identify causal links. In other words, it is not the systematic or predictable policy changes that are helpful to answer causal questions but the deviations from prescribed rules. The reason for this is that the causal model used here does not provide enough structure to disentangle causal links from endogenously varying policy variables. The situation is quite similar to the analysis of impulse response functions in structural VAR models where identification is driven by the independence of structural innovations. Impulse response analysis can thus be viewed as a special case of the potential outcomes model when \( \chi \), is a linear process.

The potential outcome framework has the advantage that it focuses on exogenous variation and puts the identification discussion at the centre of causal inference. It helps to clarify the source of identifying variation in an analysis of Granger–Sims causality. A priori arguments for the identifying exogeneity restrictions can be based on institutional settings such as the introduction of new legislation, on procedural details as in the Romer and Romer (1989) example, or on behavioural models derived from economic theory. At the same time the potential outcome approach to identification is limited in the sense that its most natural areas of application lie in the analysis of policy effectiveness. It is less suited to analyse causality between variables that are jointly determined in equilibrium.

A point made by Granger (1980) is also relevant here. The analysis of causality is not necessarily relevant for the analysis of controlled processes. To illustrate the issue, consider the linearized Lucas model of McCallum (1984), where in an overlapping generations framework price setting happens in isolated markets based on local information. McCallum shows that random innovations to the money stock affect unemployment because agents cannot completely distinguish between real price changes in their markets and price changes due to variation in the supply of money. A test of conditional independence between money and employment for data generated by this model would find evidence of a causal relationship in the sense of Sims. At the same time, any attempt by the monetary authority to systematically exploit this relationship through a systematic policy rule would fail in this model because agents fully incorporate predictable actions of the policymaker and do not respond to nominal changes in prices. This example shows that a statistical definition of causality may indicate the existence of a causal relationship that does not lend itself to policy intervention and control. Whether individual researchers
are willing to call such a finding a causal relationship hinges upon their notion of causality and is likely to be controversial.

The situation is reversed in some models where the monetary authority can fully control output through appropriate policy rules. For the purpose of illustration consider the model by Rudebusch and Svensson, which 'consists of an aggregate supply equation that relates inflation to an output gap and an aggregate demand equation that relates output to a short term interest rate' (1999, p. 205). Monetary policy is conducted by setting the nominal interest rate, and affects output and inflation with a one period lag. In this model it is possible for the monetary authority to fully stabilize output such that deviations from a fixed steady state level are serially uncorrelated. On the assumption that the policy rule is augmented with an independently distributed policy innovation (this assumption is necessary for statistical identification of test procedures, see Sims, 1977, p. 39), it follows that a test for Granger causality will not be able to reject the null of no causal relationship running from interest rates to output. At the same time, a test for Granger non-causality of output for interest rates will be rejected because the interest rate setting rule depends on past output. In this example, the direction of causality in the statistical sense of Granger goes in the opposite direction of what the model indicates.

On the other hand, a test of the conditional independence restriction (S) for Sims non-causality of interest rates for output will be rejected, thus revealing the influence of the policymaker on output. Sims (1977, p. 36) considers a similar reversal of the direction of Granger causality in models where a policy variable is controlled. While Sims considers a bivariate model where both Granger and Sims causality are equivalent, the model of Rudebusch and Svensson considered here has three equations, which explains why the concepts of Granger and Sims causality do not lead to the same conclusions. A test of (S) in this model is thus able to identify the direction of causality even when variables are controlled, at least when the test is based on the assumption that the policy model is correctly specified and the policy innovation is thus identified. However, even in this case, the measured causal effects are those of random deviations from the policy rule. As discussed earlier, attempts to exploit these effects with systematic policy actions may not be feasible due to the reactions of rationally forward-looking agents.

A related issue is the problem of analysing causal effects of systematic changes in the policy rule, a problem discussed in Sims (1977, p. 30). Without additional structure such questions seem to be hard to address, and it remains an open question to what extent evidence gained from causal inference based on notions of Granger–Sims causality can be used to investigate them.

5 Summary

This article explores the notion of Granger–Sims causality as a concept of statistical predictability. The definition is appealing because it does not require a priori theoretical restrictions but rather is formulated in terms of a directly testable implication on the distribution of observed data. The simplicity of this approach to causality has led to extensive applications in areas such as macro-econometrics, where notions of causality that rely on the possibility of carrying out experiments are difficult to apply. Difficulties with a purely statistical concept of causality, however, arise when it comes to interpreting the nature of detected causal relationships. Without additional assumptions regarding the exogeneity of one or more input variables, it seems difficult to link the statistical causality concept with the more
fundamental distinction between cause and effect. The latter distinction is fundamental to the analysis of controllability of outcome variables and thus central to many questions in the social sciences. As discussed above, there is clearly a distinction between a causal link between two variables and the possibility of controlling an output by manipulating certain inputs. Equilibrium effects which are at the core of economic analysis may, for example, pre-empt policy changes through the agent’s rational anticipation of just these policy changes. Perceived causal relationships thus may not be exploitable for policy purposes even if they can be reliably identified in the history of an economy. The analysis of causality and controllability in dynamic equilibrium models thus remains a central topic of research.

Abstract

Graphs are used in economics to depict situations in which agents are in direct contact with each other. The use of graph theory enables one to understand the basic properties of the communication network in an economy or market. Typical questions include: how does the structure of a network affect economic outcomes and the welfare of the individuals involved? What happens if agents can choose those with whom they interact? How will networks evolve over time? Theoretical results, economic applications and empirical examples are given.

Article

At first sight it might seem that the rather abstract mathematical theory of graphs would be of little relevance for economics. That this is not entirely the case is largely due to developments since the early 1980s. Economists have become interested in the structure of the relations between individuals, firms and groups and their importance for economic activity. These relations can be viewed as a graph, and the properties of the particular graph will have specific implications for the economic outcomes in the situation modelled. A simple example may help. Consider a competitive economic market. Agents receive prices from a central source and do not communicate with each other. This can be represented as a star. The centre which emits the prices is often thought of as the ‘Walrasian auctioneer’. However, in many economic situations the organization may be very different, and it is of interest to know what consequences this may have. For example, in an ordinary $n$ person game everyone is conscious of what
every other player is doing, and this situation could be represented by a complete graph in which there is a link between every pair of players.

While accounts of the use of networks in economics can be found elsewhere (see Goyal, 2006; Jackson, 2004 for excellent surveys), the question for this article is the extent to which graph theory has helped economists answer the questions they analyse.

**Basic concepts in graph theory**

First, a few definitions are necessary to set the stage. Think of a set $V$ of nodes, (or economic entities), each pair of the nodes will be linked $v(ij) = 1$ or not $v(ij) = 0$, by an edge. If there are $N$ nodes then a simple graph can be represented by its adjacency matrix with each element $v(ij)$ being 1 or 0 depending on whether $i$ and $j$ are linked. Obviously, other considerations could be included. For example, if the graph is directed, $v(ij) = 1$ does not imply $v(ji) = 1$; an obvious example of this would be an input–output system where a good $i$ enters into the production of $j$ but not vice versa. An undirected graph, on the other hand, has a symmetric adjacency matrix, and here a simple example would be that of co-authors of papers. The degree, $d(v)$, of a vertex $v$ is the number of edges with which it is incident. Two vertices are adjacent if they are incident to a common edge. The set of neighbours, $N(v)$, of a vertex $v$ is the set of vertices which are adjacent to $v$. The degree of a vertex is the number of neighbours it has, or formally, the cardinality of its neighbour set.

A path is an alternating sequence of vertices and edges, with each edge being incident to the vertices immediately preceding and succeeding it in the sequence and with no repeated vertices. The length of a path is the number of edges in the sequence defining the walk. If $u$ and $v$ are vertices, the distance from $u$ to $v$, written $d(u,v)$, is the minimum length of any path from $u$ to $v$. In an undirected graph, this is obviously a metric. The diameter, $diam(G)$ of the graph $G$ is the maximum value of $d(u,v)$, where $u$ and $v$ are allowed to range over all of the vertices of the graph.

A graph is complete, or a clique, if every pair of vertices are adjacent. The typical $n$ person game can be thought of as involving a complete graph since all players are in contact with each other. This is the other extreme from the star of the competitive model.

**Economic applications**

With these concepts in mind we can now ask how they may help in analysing economic problems. If we think about situations in which agents or firms are linked through a network, then there are three basic questions. How does the structure of a network affect economic outcomes, which structures are ‘efficient’, and which graph structures or topologies are likely to be found? In a number of applications very different graph structures may govern economic interaction. A first and important distinction is between exogenous and endogenous graphs. In the former the agents are taken as already linked, and one examines the consequences of the way in which they are linked. One can think of the distinction often made in spatial economics between agents situated on a line or on a lattice. In the latter case the number of neighbours would be four or eight depending on how one constructs the links. In more general networks, the sort of question asked is: how fast will information travel, or how quickly will an epidemic of opinion or innovation grow? The two important characteristics here will be the connectivity
of a graph and a measure of the maximum distance between two nodes, the *diameter* of the graph. Another important notion is that of a *neighbourhood* and the burgeoning literature on externalities and spillover effects has come to pay attention to the structure of neighbourhoods and the idea that individuals in certain neighbourhoods may become isolated from the global network (see Durlauf, 2004). The important thing here is that neighbourhoods are not necessarily geographical but are determined by the network of interpersonal relations. The architecture of the graph will have important consequences for the allocation of resources and distribution of wealth in an economy.

One can also pose such questions as: how vulnerable is a network to the removal of links? This too is closely tied to the *connectivity* of the graph. This sort of problem has been extensively looked at in the operations research literature, where the vulnerability of a railroad or communications network to a bombing attack was studied over a long period after the Second World War (see, for example, Frank, 1967). The same techniques have been applied to the problems of power outages in electricity networks, but this sort of analysis has, for the moment, made few inroads into the economics literature. This problem has also been studied in the context of stochastic networks, as discussed below.

The notion of *vertex degree* is obviously applicable to matching problems and many matching problems can be thought of as finding a bipartite graph satisfying certain efficiency criteria. Wherever there is a limit to the number of agents who can interact, possibly for institutional reasons, this translates into the idea that the degree of a node is constrained.

While these observations give some idea of the use of graph theoretic concepts in economics, there are rather few examples of contributions which draw directly on graph theory. Indeed, it would be fair to say that most of the relevant contributions use concepts from this theory for notational rather than for analytical reasons. An example of a contribution which makes direct appeal to results from graph theory is that of Corominas-Bosch (2004). She looks at buyers and sellers linked by an exogenous network. The outcomes will depend on who is linked to whom, and players choose strategies depending on those chosen by those that they are linked with. She then uses a theorem on the partitions of bipartite graphs in order to analyse the sort of networks of connections that will produce the Walrasian outcome. What is the competitive outcome in this framework? If buyers outnumber sellers, all the surplus goes to the sellers and, conversely, if sellers outnumber buyers all the surplus goes to the buyers. When the numbers are equal the surplus is split ‘evenly’ between buyers and sellers. She shows that, given certain conditions, either the whole group of players will implement the competitive solution or the group will partition into groups of players in sub-graphs, each of which will implement the competitive solution. In other words, the graph will partition into sub-graphs, each reflecting the overall relationship between buyers and sellers, and the competitive solution will be implemented in each sub-graph. Thus, what Corominas-Bosch shows is the relation between the architecture of the graph of relations and the efficiency of the outcome.

Another example is that of Anderlini and Ianni (1996), who study the long-run properties of learning from neighbours. In their model, at each step the players play a game with one of their $m$ neighbours, who is chosen at random with probability $1/m$. This is repeated and the final result described. Where is graph theory useful here? The idea that one can, in fact, draw at random at each point in time a one-to-one matching of players is simple, but it is not obvious that the structure of the exogenously given links will permit this. The authors wish to limit the structure of relations between individuals to guarantee that it can be done. The situations in which each member of a group is linked to another single member of...
the same group are considered. Sub-graphs of this type are called 1-factors. Obviously, the number of such matchings depends on the underlying graph structure, which is taken as exogenous. Recall that Anderlini and Ianni (1996) require, in the original graph, that the vertex degree of all agents shall be \( m \). However, it is known from graph theory that certain graphs of this sort may permit no such matching, that is, may have no 1-factor. To handle this, Anderlini and Ianni assume that their graph is the product of \( m \) 1-factors, so as to guarantee that they can randomly rematch their players at each stage. Once they can do this they can show whether the learning process used by the agents converges. Here, managing a rather natural, but technical, problem in a rematching game involves graph-theoretic tools.

Much of the literature in economics has focused on undirected graphs, although in some situations such as input–output matrices the direction is clearly important, since production processes are not reversible. Evstigneev and Taskar (1995), although working in a stochastic context, have modelled some economic equilibrium problems using directed graphs but, as they indicate, the task is made difficult by the fact that some of the mathematical tools which make the undirected case tractable are not available for directed graphs.

Up to this point we have considered the agents as located in a given graph. However, one of the most interesting challenges in examining an economy is to include the evolution of the network structures themselves. If one wants to proceed to a theory of endogenous network formation, a first step might be to find out which organizations of individuals are stable. Thus one would look for ‘rest points’ of a dynamic process of network evolution. Such rest points would be arrangements, or networks, which would not be subject to endogenous pressures to change them. This, as it stands, is not a well-formulated concept. More of the rules under which agents operate have to be spelled out. The dynamics of the system will be defined by the way in which links are formed. Good surveys of the literature on this subject (see network formation), are available and, once again, although the terms from graph theory are widely used, there is little evidence of the use of graph theoretic results, at least in the deterministic case, to prove economic propositions. In many cases, well-known architectures such as the star turn out to be efficient, and it is not difficult to see why. With \( n \) agents such a graph has diameter 2 and only \( n–1 \) links. Thus it is an efficient way of organizing links if links have any costs. The problem is to show that such a structure will emerge as a result of a well-specified interaction process.

**Stochastic graphs**

Paradoxically, it is in the case where the economic graph structure is considered to be stochastic that more appeal has been made to graph-theoretic results, such as those developed by Erdos and Renyi (1960).

There are different ways of defining a stochastic graph. The simplest one is that used by Erdos and Renyi themselves in which the 1’s and the 0’s of the adjacency matrix are replaced by probabilities, so that the edge \( e(ij) \) exists with probability \( p(ij) \), and so the adjacency matrix is now composed of probabilities and if the graph is undirected the matrix will be symmetric, that is, \( p(ij)=p(ij) \). (This tool was developed in economics by Kirman, Oddou and Weber, 1986; Durlauf, 1990; and Ioannides, 1990.) An alternative and more general possibility is to have a probability distribution over all possible adjacency matrices.

An interesting and useful fact is that the graph representing the links through which interaction takes
place may become surprisingly highly connected as the number of agents increases, provided that the probability that any two individuals are connected does not go to zero too fast. To understand what is meant by this, consider a result of Bollobas (1985). He shows that, if the probability that any two agents know each other in a graph $G$ with $n$ nodes, $P^n(i,j)$ is greater than $\frac{1}{\sqrt{n}}$ for all $i$ and $j$ and for all $n$, then as $n$ becomes large it becomes certain that the diameter of the graph, $D(G^n(P^n(i,j)))$ will be at most 2. More formally,

$$\lim_{n \to \infty} \text{Prob}(D(G^n(P^n(i,j))) \leq 2) = 1$$

In other words, any two individuals will be sure to have a ‘common friend’ if the graph is large enough. Thus, as was observed in Kirman, Oddou and Weber (1986), one should say on encountering someone with whom one has a common friend, ‘it’s a large world’. This somewhat surprising result suggests that, as sociologists have long observed empirically, relational networks are likely to be much more connected than one might imagine.

It was this sort of result which led to the first use of stochastic graphs in economics in Kirman (1983). The application there was very simple. The core of an exchange economy is defined as that set of allocations that no coalition can improve upon, in the sense that no coalition could redistribute its own resources and do better than in the allocation proposed. A classic result, originally due to Edgeworth, shows that, if the set of agents becomes large – that is, we consider a sequence of economies with each economy having more agents than the previous one – then the core shrinks to the competitive equilibria. A standard objection to this is that it is highly implausible that all coalitions should form. The question then is: what may happen if agents communicate only with a certain probability, and only coalitions of agents who are closely linked can form? Suppose that there are $n$ agents and that they can communicate with a fixed probability, so that $P^n = P$. Furthermore, for reasons which are obvious, assume that the probability does not decrease too fast with $n$, that is, $P_n \geq \frac{1}{\sqrt{n}}$. Now we know that it suffices to have large coalitions form for Edgeworth’s result to hold. The question that remains is: if $n$ becomes large, will the large coalitions be able to form if we place some restriction on how closely the agents have to be linked to form a coalition? Suppose that we allow coalitions to form only if the maximal distance between two agents (the diameter of the sub-graph defined by the coalition) is less than or equal to 2. Now, since the links are drawn at random, the set of allocations is itself a random variable. What we can hope for is that the probability that the core of such a random economy will be different from the set of competitive equilibria converges to zero. As should be clear, it is enough, given our assumptions, to use Bollobas’s result directly to obtain this result.

In general, the property of increasing connectivity is of interest, as noted, in economic models, since the connectivity determines how fast information or a ‘technological shock’ diffuses and how quickly an epidemic of opinion or behaviour will occur. It is important to note that the result just evoked depends crucially on the fact that the actors in the network are linked with uniform probability or, slightly more
generally, that the pair of agents with the lowest probability of being linked should still be above the lower bound mentioned.

**Emerging graphs**

The dynamic evolution of the state of the individuals linked in a graph-like structure is particularly interesting since the stable configurations of states, if there are any, will depend on the graph in question, and some of the results from other disciplines (see Weisbuch, 1990) can be evoked in the context of economic models.

This ‘small world’ problem discussed above is related to, but rather different from, that studied by Watts (2000), since he looked at networks which evolve as the links are modified stochastically. In other words, he does not consider a realization of a graph drawn from a family of graphs with given probability but, rather, starts with a given graph and shows how structure and, in particular, connectivity may emerge as links are replaced by other links. What he examines is a situation in which agents have a fixed number of links with others, that is, the vertex degree of the graph is a constant. For example, they might all be situated on a circle and be linked only with their immediate neighbours. Then one of the existing links is drawn at random and replaced with a new link. This may be to any agent, in particular one to whom the distance was great in the original graph. Adding such links drastically increases the connectivity of the graph. This procedure is repeated and what emerges is a typically clustered structure in which closely linked individuals in a small group are linked to other groups through one or two links.

In a pure random graph of the Erdos-Renyi (E-R) (1960) type, distances are short, as we have seen, but there is almost no clustering. However, in the sort of small world graphs studied by Watts the situation is different: distances are still short but there is a great deal of clustering. Here the few long links between different groups keep the distance down but most of the interaction is within small groups. This sort of clustering is observed in many empirical situations in economics. In this case the pure random E-R graph is used as a benchmark, but the analysis is self-contained and does not exploit results developed in stochastic graph theory itself.

An example of the direct use of stochastic graph theory concerns the degree distribution which, in the case where the set of agents is finite, just specifies the proportion of agents who have each vertex degree $k$, and which we can denote by $P(k)$. In the E-R case this distribution is Poisson, but more general degree distributions have been considered by Newman, Strogatz and Watts (2001), for example. There are two large classes of stochastic graphs. The first is composed of those which have a degree distribution which peaks at a particular $k$ and then declines exponentially for large $k$. The classic E-R model and the Watts ‘small world’ model fall into this category. They are relatively homogeneous. The other class is characterized by a degree distribution which decays as a power law, that is,

$$P(k) = k^{-\gamma}.$$  

In this class the probability that a node has a very large number of links is much higher than for the
The graphs in this class are referred to as ‘scale free’ networks. A first reason for being interested in this division is spelled out by Albert, Jeong and Barabasi (2000). They show that scale-free networks are very robust to error but very vulnerable to attack. The reason for this is simple. Since in such networks the majority of nodes have a very small number of links, random failure of nodes will have rather little impact. The measure of the impact of the failure of nodes is taken here to be the change in the diameter of the graph. However, in E-R graphs, since all nodes have essentially the same number of links, each node contributes equally to the diameter. Thus removing any node will have the same impact. The diameter of the remaining graph will increase progressively and faster than if the same thing is done in the scale-free class. The vulnerability to attack is now clearly in inverse relation to the robustness to errors. Since in the scale-free networks there are nodes with a very large number of links which, as a result, contribute much to the connectivity of the network, an ‘enemy’ will simply choose one of these nodes as his target and have much more effect than he would on an E-R network. As an illustration, Albert, Jeong and Barabasi (2000) show that the removal at random of 2.5 per cent of the nodes in the World Wide Web, whose degree distribution is well fitted by a power law (see Faloutsos, Faloutsos and Faloutsos, 1999), has no significant effect on its diameter. However, the removal of 2.5 per cent of the most connected nodes in an E-R graph increases the diameter by a factor of 6.

The degree distribution is of interest for other reasons. It permits one to work out the average number of neighbours at distance $m$ from the agents in a graph. This number can be calculated for each $m$ and, if this sequence converges, there cannot be a giant component and all the agents will belong to small connected components in the graph. If this number diverges, however, there will always be a giant component containing many agents and smaller connected sets. There is a crucial level of the ratio of the average number of neighbours at distance 1 to the average number at distance 2 which determines which of these situations applies. This value will depend on the degree distribution. Such threshold values play an important role in Erdos and Renyi’s work. Newman’s interest has tended to focus on networks of co-authors and citations, and the obvious interest here is the extent to which there is a large disciplinary, or interdisciplinary, network, and the extent to which there are fragmented self-referential networks. It is clear, however, that the same ideas could be applied to trading groups or to firms and sectors.

From the empirical evidence one can form an estimation of the degree distribution in a particular network, and one can then examine the distribution of different sized components and pose the question as to the relation between the two and its consistency with the asymptotic predictions. The degree distribution has been used in another context by Galeotti et al. (2006). They study the results for games played on networks and where payoffs depend on the players’ own actions and those of their neighbours, and examine the influence of three features (whether the games involve strategic substitutes or complements, negative or positive externalities, and incomplete or complete information). It is the latter aspect that is of interest here. They say that an agent has incomplete information if a player knows only his own degree and the degree distribution, and complete information if he knows the degree of every player. Under incomplete information they show, for example, in games with positive, (negative) externalities, expected payoffs from a game are increasing (decreasing) in degree. This is in contrast with earlier results of Bramoullé and Kranton (2007), where in a public goods game players with higher degrees earn worse payoffs. The key difference from the result just mentioned is that the implicit assumption in their paper is that there is complete information.
The assumptions underlying the model developed by Galeotti et al. (2006) are that the players all believe that the graph in which they are situated is drawn from a family of networks that has two properties:

1. (i) the probability of any node having \( k \) links is \( P(k) \); and
2. (ii) the degrees \( k_i(g) \) and \( k_j(g) \) of any two players \( i \) and \( j \) are stochastically independent.

This is interesting since it harks back to the ‘configuration’ model described in Bollobas (1985). (Ioannides, 2006, describes the case where the degrees of neighbouring agents are no longer independent, and develops the theory of Markov random graphs, which allow for dependence between neighbouring nodes.)

Another idea developed by Galleoti et al. (2006) is that of looking at the results for games played on different graphs, in particular where the degree distribution of one is more or less ‘spread out’ than the other. Slightly more formally, one looks at whether one distribution first order stochastically dominates (FOSD) the other or vice versa. In such cases for particular games, they are able to show a relationship between the payoff for a player with a given vertex degree when a particular type of game is played on a graph \( g \) and the payoff when the game is played on another graph \( g' \). If \( g \) FOSD another graph \( g' \), then the payoff is higher under \( g \) than under \( g' \). Unfortunately, no such unambiguous results are available under more general changes in the degree distribution.

**Conclusion**

Economists are often accused of the wholesale borrowing of results from various branches of mathematics and using them even in inappropriate contexts. The growing literature on the importance of networks in economics seems to provide a counter-example. Although many of the concepts and even the notation of mathematical graph theory are used, rather little of the formal structure has been imported, and most of that has been concentrated on stochastic graphs. Many results in the economic literature have, however, been proved *ex nihilo*, and one could argue that economists have in this modest way added to the graph theory literature.

graphical games

Michael Kearns
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Graphical games and related models provide network or graph-theoretic means of succinctly representing strategic interaction among a large population of players. Such models can often have significant algorithmic benefits, as in the NashProp algorithm for computing equilibria. In addition, several studies have established relationships between the topological structure of the underlying network and properties of various outcomes. These include a close relationship between the correlated equilibria of a graphical game and Markov network models for their representation, results establishing when evolutionary stable strategies are preserved in a network setting, and a precise combinatorial characterization of wealth variation in a simple bipartite exchange economy.

Keywords

computation of equilibria; correlated equilibrium; dynamic programming; evolutionary game theory; evolutionary stable strategies; exchange economies; graphical economics; graphical games; network structure

Article

Graphical games are a general parametric model for multi-player games that is most appropriate for settings in which not all players directly influence the payoffs of all others, but rather there is some notion of ‘locality’ to the direct strategic interactions. These interactions are represented as an undirected graph or network, where we assume that each player is identified with a vertex, and that the payoff of a given player is a function of only his or her own action and those of his or her immediate neighbours in the network. Specification of a graphical game thus consists of the graph or network, along with the local payoff function for each player. Graphical games offer a number of representational and algorithmic advantages over the normal form, have permitted the development of a theory relating network topology to equilibrium properties, and have played a central role in recent results on the
computational complexity of computing Nash equilibria. They have also been generalized to exchange economies, evolutionary game theory, and other strategic settings.

**Definitions**

A graphical game begins with an undirected graph or network $G = (V, E)$, where $V$ is the set of players or vertices, and $E$ is a set of edges or unordered pairs of vertices/players. The assumed semantics of this graph are that the payoffs of players are determined only by their local neighbourhoods. More precisely, if we define the neighbour set of a player $u$ as $N(u) = \{v: (u,v) \text{ is in } E\}$, the payoff of $u$ is assumed to be a function not of the joint action of the entire population of players, but only the actions of $u$ itself and the players in $N(u)$. Complete specification of a graphical game thus consists of the graph $G$, and the local payoff functions for each player. Note that at equilibrium, it remains the case that the strategy of a player may be indirectly influenced by players arbitrarily distant in the network; it is simply that such influences are effected by the propagation of the local, direct payoff influences.

In the case that $G$ is the complete network, in which all pairs of vertices have an edge between them, the graphical game simply reverts to the multi-player normal form. However, in the interesting cases the graph may exhibit considerable asymmetry and structure, and also be much more succinct than the normal form. For instance, if $|N(u)| \leq d$ for all players $u$, then the total number of parameters of the graphical game grows exponentially only in the degree bound $d$, as opposed to exponentially in $n$ for the normal form. Thus when $d$ is much smaller than $n$ (a reasonable expectation in a large-population game with only local interactions), the graphical game representation is exponentially more parsimonious than the normal form. Qualitatively, one can think of graphical games as a good model for games in which there may be many players, but each player may be directly and strongly influenced by only a small number of others. Graphical games should be contrasted with other parametric models such as congestion and potential games, in which each player has global influence, but often of a highly specific and weak form. They can also be viewed as a natural generalization of more specific network-based games studied in the game theory and economics literature (Jackson, 2007).

**Computational properties**

In addition to the aforementioned potential for representational parsimony, graphical games permit a family of natural and sometimes provably efficient algorithms for the computation of Nash and other equilibria. It should be emphasized here that by ‘efficient’ we mean an algorithm whose running time is a ‘slowly’ growing function of the number of parameters of the graphical game representation (which may be considerably more challenging than a slowly growing function of the number of parameters in the normal form representation, which may be much larger). As is standard in computer science, ‘slowly’ growing typically means a polynomial function (ideally of low degree). For instance, in the special case that the graph structure is a tree (or can be modified to a tree via a small number of standard topological operations involving, for instance, the merging of vertices), there is an algorithm running in time polynomial in the number of parameters that computes approximations to (all) Nash equilibria of the given graphical game (Kearns, Littman and Singh, 2001.) This algorithm is based...
on dynamic programming, and is decentralized in the sense that communication need take place only between neighbouring vertices in the network. In even more restrictive topologies, efficient algorithms for computing exact Nash equilibria are known (Elkind, Goldberg and Goldberg, 2006). For non-tree topologies, a generalization of this algorithm known as NashProp (Ortiz and Kearns, 2002) has been developed that is provably convergent, but has weaker guarantees of computational efficiency. Provably efficient algorithms have also been developed for computing correlated equilibria (again in the sense of the computation time being polynomial in the number of parameters) for general graphical games (Papadimitriou, 2005; see also Kakade et al., 2003). These algorithmic results are in sharp contrast to the status of computing equilibria for games represented in the normal form, where the results are either negative or remain unresolved. Graphical games have also proven valuable in establishing computational barriers to computing Nash equilibria efficiently, and certain classes of graphical games have been shown to be just as hard as the normal form in this regard (Daskalakis and Papadimitriou, 2005; 2006; Daskalakis, Goldberg and Papadimitriou, 2006; Schoenebeck and Vadhan, 2006).

Extensions of the model

Since the introduction of graphical games, a number of related models have been introduced and studied. In each case, the model again begins with an undirected network in which the edges represent the pairs of participants that are permitted to interact directly in some strategic or economic setting. For instance, the model known as graphical economics (Kakade, Kearns and Ortiz, 2004) provides a network generalization of the classical exchange economies studied by Arrow and Debreu and others. As in the classical models, each consumer has an initial endowment over $k$ commodities, and a subjective utility function describing his or her preferences over bundles of commodities. However, unlike the classical model, not all pairs of consumers may engage in trade. Instead, each consumer or vertex $u$ may only trade with his or her neighbours $N(u)$, and there is no resale permitted. Equilibria in prices and consumption plans can still be shown to always exist, but now the equilibrium prices may need to be local, in the sense that two consumers may charge different prices per unit for the same commodity, and these prices may depend strongly on the network topology. This introduces variation in equilibrium wealth dependent on a consumer's position in the overall network (see below). As with graphical games, the graphical economics model permits efficient computation of equilibria under certain topological restrictions on the network. More recently, a network version of evolutionary game theory (EGT) has also been examined (Kearns and Suri, 2006). In classical EGT, there are random encounters between all pairs of organisms; in the network generalization, such encounters are restricted to the edges of an undirected network. Thus the evolutionary fitness of an organism represented by vertex $u$ is once again determined only by the strategies of its neighbours $N(u)$. More than one reasonable generalization of the evolutionary stable strategy (ESS) of classical EGT is possible in the network setting. As with graphical games, both graphical economics and the network EGT model revert to their classical counterparts in the special case of the complete graph over all participants, and thus represent strict generalizations, but which are most interesting in cases where the underlying graph has some non-trivial structure.
Network structure and equilibrium properties

Aside from the algorithmic properties discussed above, one of the most interesting aspects of the various models under discussion is their ability to permit the study of how equilibrium properties are influenced by the structure or topology of the underlying network, and indeed there is a growing body of results in this direction.

In the case of graphical games, a tight connection can be drawn between the topology of the underlying graph $G$ of the game and the structure of any minimal (in a certain natural technical sense) correlated equilibrium (CE), regardless of the details of the local payoff functions. Among other consequences, this result implies that CE in graphical games can be implemented using only local, distributed sources of randomization throughout the network in order effect the needed coordination, rather than the centralized randomization of classical CE. The result also provides broad conditions under which the play of two ‘distant’ players in the network may be conditionally independent – for instance, at CE, the play of vertices $u$ and $v$ is always conditionally independent given the pure strategies of any vertex cutset between them (Kakade et al., 2003).

In the graphical economics model, for certain simple cases one can give precise relationships between equilibrium wealth, price variation and network structure. For instance, in the case of an arbitrary bipartite network for a simple two-commodity buyer-seller economy with symmetric endowments and utilities (thus deliberately rendering network position the only source of asymmetry between consumers), there is no price or wealth variation at equilibrium if and only if the underlying network has a perfect matching sub-graph between buyers and sellers. More generally, a purely structural property of the network characterizes the ratio between the greatest and least consumer wealth at equilibrium. These structural results have been applied to analyse price and wealth variation in certain probabilistic models of buyer–seller network formation. For instance, it has been shown that whereas truly random networks with a certain minimum number of edges generally exhibit no variation in prices or wealth, those generated by recent models of social network formation such as preferential attachment lead to a power-law distribution of wealth (Kakade et al., 2004).

In the networked EGT setting, it has been proven that even networks with rather sparse connectivity (in which each organism directly interacts with only a small fraction of the total population), but in which the connections are formed randomly, classical ESS are always preserved, even if the initial locations of the invading population are arbitrary. Alternatively, if the network is arbitrary but the initial locations of the invading population are selected randomly, classical ESS are again preserved (Kearns and Suri, 2006). Related network models include those of Blume (1995) and Ellison (1993).

Graunt was born on 24 April 1620 in Hampshire and died on 18 April 1674 in London. At the age of 16 he was apprenticed to his father as a haberdasher of small wares, but remarkably little is known of his life before he published his *Natural and Political Observations Made upon the Bills of Mortality* in 1662. Graunt had formed a friendship with William Petty, who came from a social and economic background similar to his own and who may have drawn Graunt's attention to the data in the London Bills of Mortality. Six months after the publication of the *Natural and Political Observations* Graunt was made a fellow of the Royal Society, in whose foundation Petty had been greatly involved. The publication of this volume had an immediate impact; a second edition was published the same year and two others in 1665. Graunt subsequently fell into disgrace following his conversion to Catholicism and he died in poverty despite generous help from Petty. The latter's own work, especially that on urban growth, owed much to methodologies initiated by Graunt.

It has been claimed that the *Natural and Political Observations* 'created the subject of demography' (Glass, 1963) as it involved the first truly analytic study of births and deaths within a population precisely situated in space and time. To do this Graunt employed the Bills of Mortality (Greenwood, 1948) and the records of christenings in 17th-century London in order to investigate mortality and population growth in the city. The study's most outstanding qualities are revealed by the search for regularities and configurations in mortality and fertility along with a critical and very insightful appreciation of the quality of the data. He was greatly concerned to establish mortality rates by age and through this interest he came remarkably close to constructing the first formal life table. Using the cause of death evidence in the Bills of Mortality, Graunt without any information whatsoever on ages proceeded to estimate the extent of mortality in infancy and childhood by selecting those causes of death which he guessed would only affect children 'under four or five years old'. To these he added half of the deaths from smallpox and measles which he thought would fall upon children under six, along
with slightly less than one third of the plague victims. From these assumptions he derived an estimate suggesting that 36 per cent of all deaths occurred to children under six years. Similar principles were employed to estimate that seven per cent of deaths through ‘ageing’ could be attributed to those over 70 years. He then proceeded to take these not implausible estimates of mortality at young and old ages to construct an elementary life table which unfortunately was flawed by the unrealistic assumption that above age six the deaths in each specified age period amounted to about three-eighths of the survivors at the beginning of the period. Nonetheless, what Graunt had evolved was an outstanding innovation and was very soon taken up and developed by others. Graunt's interests in the *Natural and Political Observations* were innovative in other respects; he attempted to calculate the size and rate of growth of 17th-century London, the incidence of plague mortality (Sutherland, 1963; 1972), and sex ratios at birth and levels of maternal mortality, and he made some highly believable estimates of the levels of immigration to London that were needed to sustain the city's remarkable growth in the 17th century.

**Selected works**

1662. *Natural and Political Observations … upon the Bills of Mortality*. There was a further edition later in 1662, and the plague of 1665 called forth a third edition in the early summer and a fourth edition in November (printed in Oxford) of that year.

The importance of countries' economic size in explaining trade patterns was recognized in an equation first proposed by Tinbergen (1962). Tinbergen proposed that the volume of trade between countries would be similar to the force of gravity between objects. Suppose that two objects each have mass $M_1$ and $M_2$, and they are located distance $d$ apart. Then, according to Newton's universal law of gravitation, the force of gravity $F_g$ between these two objects is:

$$F_g = G = \frac{M_1 M_2}{d^2},$$
where $G$ is the gravitational constant, $M_1$ and $M_2$ the mass of the two objects, and $d$ the distance between them. The larger each of the objects are, or the closer that they are to each other, then the greater is the force of gravity between them.

The equation proposed by Tinbergen to explain trade between countries is very similar to Newton's law of gravity, except that instead of the mass of two objects we use the gross domestic product (GDP) of two countries, and instead of predicting the force of gravity we are predicting the amount of trade between them. So the gravity equation in trade is:

$$\text{Trade} = \frac{A \cdot GDP_1 \cdot GDP_2}{d^\gamma},$$

(1)

where trade is the amount of trade (that is, imports, exports, or their sum total) between two countries, GDP$_1$ and GDP$_2$ their gross domestic products, $d$ the distance between them, and $A$ a constant. We use the exponent $\gamma$ on $d^\gamma$ rather than $d^2$ as in Newton's law of gravity, because we are not sure of the economic relationship between distance and trade.

While Tinbergen (1962) showed that the gravity equation worked well empirically, it was some years before the theoretical foundation of this equation was known. The earliest contribution is Anderson (1979), followed by Bergstrand (1985; 1989) and Helpman (1987). All these authors suppose that countries produce different goods. That result might be due to the underlying assumption of monopolistic competition, in which case every firm produces a different product variety from every other firm. It follows that firms in different countries also produce different product varieties (which we label as different goods). But that is not the only model where countries produce different goods. That result also applies in a perfectly competitive model where there are more goods than factors, and some differences in factor prices or technologies across countries (Bhagwati, 1972; Davis, 1995).

Along with country specialization in different goods, let us add the assumption that the utility function of the representative consumer is homothetic, so that the income elasticities of demand are unity (that is, the share of demand spent on each good does not vary with income). In that case, we can follow Helpman (1987) and derive a simple gravity equation. Let $i, j=1, \ldots, C$ denote countries, and let $k=1, \ldots, N$ denote goods. Let $\gamma_k^i$ denote country $i$'s production of good $k$. Assume that prices are the same across all countries due to free trade and no transport costs, and normalize the prices at unity, so $\gamma_k^i$ actually measures the value of production. Total GDP in each country is $\gamma^i = \sum_{k=1}^N \gamma_k^i$, and world GDP is $\gamma^w = \sum_{i=1}^C \gamma^i$.

Let $s_j^i$ denote country $j$'s share of world expenditure. If we assume that trade is balanced in each country, then $s_j^i$ also denotes country $j$'s share of world GDP, so that $s_j^i = \gamma_j^i / \gamma^w$. Then with all countries
producing different goods, and with identical and homothetic demand across countries, the exports from country $i$ to county $j$ of product $k$ are given by:

$$x_k^j = s^j y^j_k.$$  

(2)

Summing over all products $k$, we obtain:

$$x^j = \sum_k x_k^j = s^j \sum_k y^j_k = s^j y^j = \frac{y^j y^i}{Y^j}.$$  

(3)

So this simple model gives us a gravity equation like (1), where $A = 1 / Y^j$. The gravity equation in (3) omits a distance term, however. Notice that, if instead we solve for $x^j$ then we get $y^j y^i / Y^j$, which is exactly the same as (3). So in this very simple model, bilateral exports equal bilateral imports (that is, trade is balanced between every pair of countries).

The key limitation of the gravity equation (3) is that it assumes no transport costs. Since transport costs will depend on the distance between countries, by introducing them we will also introduce a distance term into the gravity equation. But allowing for transport costs means that the prices of goods will differ across countries, since a distant country will have higher c.i.f. prices (that is, including cost, insurance and freight charges). In that case we need to re-derive the gravity equation while allowing for different prices. To do so requires us to introduce an explicit demand structure into the model. A commonly used demand within the monopolistic competition model arises from constant-elasticity-of-substitution (CES) preferences. In that case the demand for a good $i$ exported by that country-to-country $j$ is:

$$c^{ij} = \left( \frac{p_{ij}}{P^j} \right)^{-\sigma} \left( \frac{y^j}{P^j} \right).$$  

(4)

where $\sigma > 1$ is the elasticity of substitution, $p_{ij}$ the c.i.f. price of the good exported from $i$ to $j$, and $P^j$ refers to country $j$'s overall price index, defined as:
\[ p^j = \left( \sum_{i=1}^{c} N_i^j (p^{ij})^{1-\sigma} \right)^{1/(1-\sigma)}, \]

(5)

where \( N_i^j \) is the number of goods produced in country \( i \) and exported to \( j \).

To obtain total exports from country \( i \) to \( j \), we add up over all \( N_i^j \) goods produced in country \( i \) and exported to \( j \), obtaining \( \chi^{ij} = N_i^j p^{ij} \), or from (4) and (5),

\[ \chi^{ij} = N_i^j \left( \frac{p^{ij}}{p^j} \right)^{1-\sigma}. \]

(6)

Equation (6) is not quite a gravity equation because it does not have the GDP of the exporting country \( i \). There are several methods that can be used to introduce that variable into (6).

One method is to solve for the number of products \( N_i^j \) in the exporting country, by using a free entry condition from the monopolistic competition model. In the simplest monopolistic competition model, with one factor of production and CES preferences, the number of products will be proportional to GDP, so that \( N_i^j \propto Y_i^j \). We can also introduce transport costs into (6) by writing the c.i.f. prices as:

\[ p^{ij} = T^{ij} p^i, \]

(7)

where \( p^i \) is the f.o.b. (free on board) price from country \( i \) and \( T^{ij} \geq 1 \) is the transport costs from country \( i \) to \( j \). By substituting these relations into (6), and taking natural logs, we obtain:

\[ \ln(\chi^{ij}) = a + \ln(Y_i^j Y_j^i) + (1-\sigma) \ln(T^{ij}) + (1-\sigma) \ln(p^i / p^j). \]

(8)

Baier and Bergstrand (2001) estimate a gravity equation like (8), using price data for the term...
ln(\(\frac{p^i}{p^j}\)), and splitting the term ln\(T^{\tilde{ij}}\) into tariffs and transport costs. They use data for Organisation for Economic Co-operation and Development (OECD) countries, and take differences between the averages in 1958–60 and 1986–88 to express all the variables as changes over time. The resulting linear regression has an \(R^2\) of 0.40, so they are able to explain nearly one-half of the growth in exports between OECD countries.

A second method to convert (6) into a gravity equation is to solve for the f.o.b. prices \(p^i\) in each exporting country. Anderson and van Wincoop (2003) argue that an implicit solution for the f.o.b. prices is:

\[
\tilde{p}^i = \left(\frac{s^i}{N^i}\right)^{1/(1-\sigma)} \tilde{p}^i,
\]

in which case the price indexes are solved as:

\[
(\tilde{p}^j)^{1-\sigma} = \sum_{i=1}^{C} s^i \left(\frac{T^{\tilde{ij}}}{\tilde{p}^i \tilde{p}^j}\right)^{1-\sigma}.
\]

If we substitute (9) into (6), we obtain the gravity equation:

\[
\chi^{\tilde{ij}} = s^i \gamma^j \left(\frac{T^{\tilde{ij}}}{\tilde{p}^i \tilde{p}^j}\right)^{1-\sigma} = \left(\frac{\gamma^i \gamma^j}{\gamma^w}\right) \left(\frac{T^{\tilde{ij}}}{\tilde{p}^i \tilde{p}^j}\right)^{1-\sigma}.
\]

So we obtain a gravity equation like (1), where the transport costs \(T^{\tilde{ij}}\) can depend on distance \(d^{\tilde{ij}}\). The ‘constant’ \(A\) in the gravity equation (11) is \(A = \langle \tilde{p}^i \tilde{p}^j \rangle^{\sigma-1} / \gamma^w\), which depends on the price indexes of the exporting and importing country. So the important lesson from Anderson and van Wincoop is that the ‘constant’ term must vary with the importer and exporter (and if multiple years are used in the data, then it should also vary with time).

Anderson and van Wincoop apply their version of the gravity equation to Canada–US trade. McCallum (1995) originally estimated a gravity equation for trade between ten Canadian provinces, and trade.
between those provinces and 30 US states, using 1988 data. An updated version using 1993 data, which also includes trade between US states, is as follows (with standard errors in parentheses):

\[
\ln X^i_j = 2.75 \text{Canada} + 0.40 \text{US} + 1.13 \ln y^i + 0.97 \ln y^j - 1.11 \ln d_{ij},
\]

(12)

\[R^2 = 0.85, \quad N = 1511.\]

The first variable appearing on the right of (12), ‘Canada’, is an indicator variable equal to 1 for trade between Canadian provinces, and zero otherwise. The second variable, ‘US’, is an indicator variable equal to 1 for trade between US states, and zero otherwise. The remaining variables are GDPs of the exporting province or state, both of which have coefficients close to unity, and distance, with a coefficient close to minus 1.

Since the variables in (12) are in natural logs, we can take the exponential of the indicator coefficients to obtain \(e^{2.75} = 16\) and \(e^{0.4} = 1.5\). Thus, the estimates imply that cross-provincial trade within Canada is 16 times greater than cross-border trade with the United States, whereas cross-state trade within the United States is only 1.5 times greater than cross-border trade. (Using data from 1988, McCallum had found that cross-provincial trade within Canada was 22 times greater than cross-border trade.) The very large magnitude of the ‘border effect’, leading to much more trade within Canada than across the border, is very surprising!

Before we try to explain where this border effect might come from, we should check that the estimates in (12) are reliable. In particular, this estimate does not incorporate the price indexes \(\hat{p}^i\) and \(\hat{p}^j\) that appear in (11). If we incorporate these terms, the estimate for 1993 from Anderson and van Wincoop (2003) is:

\[
\ln (X^i_j / y^i y^j) = -1.65 \text{Border} - 0.79 \ln (d_{ij}) + \ln (\hat{p}^i)^{\sigma - 1} + \ln (\hat{p}^j)^{\sigma - 1},
\]

(13)
Notice that Anderson and van Wincoop (2003) keep the GDPs on the left of (13), by dividing both sides of (11) by $(Y_iY_j)$. On the right, they include an indicator variable ‘Border’ equal to 1 for cross-border trade, and zero otherwise, rather than the separate Canada and US indicator variables. In addition, they include the price indexes $(\hat{p}^i)^{-1}$ and $(\hat{p}^j)^{-1}$ on the right. Those price indexes are computed from the formula in (10), where the transport costs used in that formula are:

$$\ln(T^{ij}) = -1.65 \text{Border} - 0.79 \ln(\sigma^{ij}).$$

Thus, we use the estimated coefficients of the border and distance from (13), substitute these into (14) and (10) to compute the price indexes $(\hat{p}^i)^{-1}$ and $(\hat{p}^j)^{-1}$, use these price indexes in the regression (13) to get a new coefficients of the border effect and distance, use those again in (14) and (10) to get new price indexes, and iterate on this procedure until it converges.

The estimated ‘border effect’ from (13) is $e^{1.65}=5.2$. So, on average, the Canada–US border leads to five times more trade within the United States and Canada than cross-border trade. This procedure does not directly give an estimate of the separate Canada and US border effects, but that can be obtained from an extra calculation using (10) and computing what trade within each country would be with and without the border effect. Anderson and van Wincoop (2003) conclude that trade within Canada is 10.5 times higher than cross-border trade due to the border effect, which is smaller than the estimate of 16 times obtained from regression (12) (or the original estimate of 22 times from McCallum, 1995). In addition, trade within the United States is 2.6 times higher than cross-border trade due to the border effect.

This procedure due to Anderson and van Wincoop requires custom programming to compute the price indexes from (10). Feenstra (2004, ch. 5) notes that a linear regression can be used instead, by estimating the price indexes in (13) using fixed effects, that is, using indicator variables for each exporting region and each importing region whose coefficients are the estimated price indexes $(\hat{p}^i)^{-1}$ and $(\hat{p}^j)^{-1}$. That approach gives results very similar to (13), and is easier to compute, so using fixed effects for importing and exporting regions can be considered the preferred estimation method.

The use of fixed effects in the gravity equation has now become common practice, and makes a difference. For example, Rose (2000) estimates a gravity equation across a broad sample of countries, some of which belong to a currency union. The indicator variables for members of the currency union take on a surprisingly large value, implying that a currency union increases trade between its members by three times, or 200 per cent! That result seems too large. Rose and Wincoop (2001) include fixed
effects for exporting and importing countries, and subsequent papers have also included the fixed effects while allowing them to vary over time (as needed when multiple years are included in the estimation). Baldwin (2006a; 2006b) surveys these papers, and concludes that a currency union increases trade by nearly two times, or 100 per cent. But the impact of the euro on trade is much lower – in the range of eight to 15 per cent.

The use of fixed effects does not necessarily lower the indicator variable coefficients. In another application, Rose (2004) estimates the impact of World Trade Organization (WTO) membership on trade between countries, and finds that it is surprisingly small. He added together exports and imports, using $\ln(X_{ij} + X_{ji})$ as the dependent variable (which is appropriate only in the simplest gravity model without price effects, as in (3)), and using a single set of country fixed effects. But Subramanian and Wei (2003) argue that, when the $\ln X_{ij}$ is used as the dependent variable and both exporter and importer fixed effects are included, the WTO has a substantial effect on imports, especially for the industrial countries.

Along with included fixed effects in the estimation (and allowing them to vary over time), another very important estimation issue is how ‘zero's’ are treated in the data. Notice that we use the natural log of exports as the dependent variable in the gravity equation, so when exports are zero the natural log cannot be computed. Common practice has been to omit those observations, as was done in (12) and (13). In order to incorporate the zero trade flows, Silva and Tenreyro (2006) recommend that estimation be performed as if the dependent variable had a Poisson probability distribution. The Poisson distribution is ordinarily applied to ‘count’ data, that is, the non-negative integers 0, 1, 2, 3, … But it can still be used as the estimation method for a continuous, non-negative dependent variable like $X_{ij}$. In that case the zero trade values can be included.

An alternative approach to incorporate zero trade values is advocated by Helpman, Melitz and Rubenstein (2007). They first model the *reason* why countries might not trade with each other, that is, because of fixed costs of exporting to another country. That model leads to a selection equation for whether countries trade or not, followed by a gravity equation when trade is positive. This two-equation system is estimated using a modified Heckman procedure (that is, one equation for whether a country has positive trade or not, and a second equation explaining the amount of trade). They argue that the estimates from the two-equation system are quite different from a single equation approach that ignores the zero trade flows.

We conclude by noting that the gravity equation is more general than we have indicated so far, in several respects. First, it can be derived even for trade in homogeneous goods (so that countries produce the same good). Eaton and Kortum (2002) derive a gravity equation in a general model with homogeneous goods and many countries, while Evenett and Keller (2002) and Feenstra, Markusen and Rose (2001) also obtain this equation in more specialized settings. Second, the gravity equation can also be used with dependent variables other than trade. For example, Eaton and Tamura (1994) and Head and Ries (2005) derive and estimate a gravity equation that uses foreign direct investment as the dependent variable. Engel and Rogers (1996) estimate a gravity equation that use the variance in prices across cities as the dependent variable, and find that crossing the Canada–US border adds as much to the volatility of prices as adding 2,500 miles between cities. These examples illustrate the many applications of the gravity equation, which will continue to be a widely used empirical tool in international economics.

Abstract

Basic gravity models state that economic interactions between two geographically defined entities are proportional to the size of these entities and inversely related to the distance between them. They have great empirical explanatory power. The impact of distance is strong and not diminishing over time. Extended gravity models incorporate borders and contiguity effects and more sophisticated interaction cost measures. They can be theory grounded, which makes each country's location vis-à-vis the rest of the world play a role in the bilateral relationship. Various empirical approaches have been proposed to tackle the econometric issues at stake in these more sophisticated frameworks.

Article

The simplest gravity model states that economic or social interactions between two geographically defined economic entities are proportional to the size of these entities and inversely related to the distance between them. The system of interactions that results from these bilateral relationships shapes the spatial organization of the global economy. Initially borrowed from the universal law of gravitation that Newton established in 1687 for heavenly bodies, this model has undergone many refinements in economics, in particular in order to better match some underlying theoretical models and data. Some of the first applications were proposed by social physicists such as Ravenstein (1885) for migration flows, and Reilly (1931) for consumers' shopping behaviour. Stewart (1947), an astronomer, suggested that the
gravity models: The New Palgrave Dictionary of Economics

The gravity law could be applied to a very wide class of social interactions. Tinbergen (1962) initiated what continued to be the main application of gravity models, namely, the study of the determinants of trade.

The basic framework

Typically, country i's exports to country j, \( F_{ij} \), are modelled as a function of the distance between these countries, \( d_{ij} \), and of their economic mass, \((M_i, M_j)\), which is most often proxied by their GDPs. Thus a basic gravity trade model estimates parameters \( \alpha \), \( \beta \), and \( \delta \) (expected to be positive) such that

\[
F_{ij} = C \frac{M_i^\alpha M_j^\beta}{d_{ij}^\delta} \varepsilon_{ij}
\]

where \( G \) is a constant and \( \varepsilon_{ij} \) an error term capturing what is left unexplained by the model. \( M_i \) can be interpreted as the supply of the good traded and \( M_j \) the demand, while \( d_{ij}^\delta \) captures trade costs, which encompass all costs incurred in transferring goods. These costs add to the price of goods when they are not sold locally and are assumed to increase with spatial distance. Alternatively, if \( F_{ij} \) is the number of migrants from i to j, regional populations are often more relevant as measures of \( M_i \) and \( M_j \), while \( d_{ij}^\delta \) reflects a moving cost. Similar interpretations can be proposed for other kinds of flows.

According to gravity models, proximity is the main engine of trade, of migration or of any precisely defined social interaction between spatially distinct economic entities. This could appear as an obsolete view of the world if one believes in the 'death of distance', as touted by popular accounts. However, Disdier and Head's (2008) meta-analysis over 1,467 estimations of \( \delta \) on trade flows indicates an average value around 0.9: halving distance increases trade by 45 per cent. These authors report even larger \( \delta \)'s for recent periods, which means that the distance decay effect has actually increased in recent years.

In addition to the reliable estimates of the impact of distance they lead to, the success of gravity models is due to their great explanatory power for flows, and this holds true whatever the geographical scale (countries, large or small regions), the period of study or the goods considered. This makes gravity one of the most stable relationships in economics and a useful predictive tool. It can be also used for obtaining predictors of variables used in a second stage to explain income, productivity, or growth dispersion across space (for example, Redding and Venables, 2004).

A wide range of applications

Gravity models are applicable to many other endogenous quantities in addition to trade flows. We have...
Gravity models have been extended to control for economic factors that would directly capture trade costs. Large data-sets on trade agreements or on transport costs are now available. The fraction of the population sharing the same language is used to capture closeness of tastes or reduced information costs. More generally, the positive role of business and social networks (among migrants from the same country or among firms belonging to the same business groups) on trade is currently being studied. These measures reduce the impact of distance, borders, and contiguity, without completely eliminating them. Naturally, not all the reasons why space matters for interactions have yet been identified. Extensive references on trade costs proxies and the various applications of gravity models can be found in Anderson and van Wincoop (2004) and in Combes, Mayer and Thisse (2008, ch. 5).

Extended frameworks and the role of the rest of the world

The bilateral nature of the gravity model is somewhat surprising. One would expect the actual location
of the respective economies vis-à-vis the rest of the world to matter also. Trade between Australia and New Zealand is certainly much larger than it would be if these countries were not so isolated. But nothing in basic gravity models takes this into account. Similarly, if the relationship results from equilibrium between supply and demand, the absence of the goods prices in the model is also striking. Moreover, economists have long been challenged by the strong empirical support of gravity models and, simultaneously, their lack of theoretical foundations. Therefore, from Anderson (1979) on, a number of approaches have been proposed to derive the gravity relationship from fully specified theoretical models. Anderson and van Wincoop (2004) show that for trade flows the class of models that can be used is fairly large. They are based on either comparative advantage or on imperfect competition; the most popular uses monopolistic competition. They all lead to specifications more complex than (1) but such microfoundations significantly improve the understanding of gravity models and of their underlying mechanisms. Their main feature is that the interactions between two economic entities, such as regions, do depend on their location relative to other areas because of interesting price effects. Indeed, in an economy with more than two regions and costly trade, the supply, demand and price of goods traded between two given economies depend on the relative costs of all firms and consumers to access all the markets. For instance, if Australia and New Zealand reduced their trade costs to all other developed countries, the price of the goods they exchange bilaterally would increase relative to the price of all other goods, which would reduce their bilateral trade. On the other hand, the overall saving in trade costs and the increase in competition it induces would also imply a greater purchasing power, which would increase trade with all partners, including bilateral trade. Interestingly, in these models local incomes can be shown to be function of the area's market potential. This potential takes a form similar to the economic version proposed by Harris (1954), which is reminiscent of gravitational or electric potentials, which must be enriched by price effects again. This is the sum of all regions' income discounted by trade costs and weighted by complex price effects.

Econometric issues

Unfortunately, such formulations modify (1) in ways that make estimation more cumbersome. Typically the equation becomes nonlinear in some unknown parameters (such as price elasticity) that must be estimated simultaneously with the impact of trade costs. Various approaches, detailed in Feenstra (2004, ch. 5), have been proposed to deal with that difficulty. The first one consists of using nonlinear estimation procedures. Another solution takes as the left-hand-side variable the ratio of the bilateral flow to the flow to a reference destination, which makes the right-hand-side variables depend again on the origin and destination only. People sometimes use real price data, but these rarely match their exact definitions in the theoretical model. The least data-demanding strategy, which remains compatible with a large number of theory-grounded approaches, consists in estimating fixed effects for each origin and destination. However, the impact of the determinants of the fixed effects, the mass of the economies and their locations for instance are no longer identified.

Other econometric problems remain. First, the fact that each country trades with many destinations induces correlations between error terms, and therefore possible heteroskedasticity biases. More problematic are the zero trade flows towards a large number of destinations that often characterize many countries, which may induce selection biases. Santos Silva and Tenreyro (2006) propose a pseudo-
maximum likelihood estimator to deal with both issues. The literature based on heterogeneous firms and
the presence of fixed export costs might help provide more theory-grounded approaches to these
problems (Helpman, Melitz and Rubinstein, 2008). The fact that economic masses and prices are
simultaneously determined with trade flows might also bias the estimations. Appropriate instrumental
procedures should help, however. Last, the trade cost proxies might themselves be endogenous. For
instance, new infrastructure can be built in response to an increase of trade flows, trade agreements may
be signed preferably between privileged trade partners and networks may emerge once trade is large.
This is more difficult to handle and these possible reverse-causality biases have yet to be really
investigated.

Hence, the long history of gravity models does not prevent them from stimulating a lot of current
research, both theoretical and empirical. Microfounded frameworks move the model further and further
away from Newton's law, adding a lot to the understanding of the mechanisms shaping spatial
interactions. Additional challenges lie ahead.

Great Depression (mechanisms)

Lee E. Ohanian
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article summarizes the theoretical framework and the diagnostic procedures that economists use to construct and test theories of depressions and booms, and also summarizes recent applications of these procedures to well-known depressions.

Keywords

balanced growth; banking crises; Euler equations; Great Depression; growth models; optimal growth theory; real business cycles.

Article

Depressions – prolonged periods in which output and employment fall 15 per cent or more below their long-run trend levels – are pathological. These episodes are particularly bizarre in economies like that of the United States, in which aggregate variables are almost always within a couple of percentage points of their long-run trend values (Leamer, 2004). Economists have long recognized that these abnormal episodes are strongly at variance with standard economic theory. For this reason, economists have not used equilibrium models, or, for that matter, any optimizing framework to investigate these episodes. And the reason why optimizing theories have been eschewed seems straightforward – what could equilibrium models tell us about episodes that appear to defy equilibrium reasoning? Prescott (2002) refers to the omission of theory from studies of depressions as a virtual ‘taboo.’

The omission of theory from analysis of depressions and crises comes at a cost, as it limits the tools with which economists can investigate these pathologies and thus limits the extent to which we can understand them. Since the late 1990s, however, macroeconomists have begun to use theory to investigate depressions, with a focus on the application of optimal growth theory developed by Cass (1965) and Koopmans (1965). Obviously, the steady state growth path of the Cass–Koopmans model – by definition – fails to reproduce any depression episode. But economists are beginning to learn about
the pathology of depressions as deviations from standard economic theory, much as a physician learns about illness by assessing deviations of a patient's vital signs from normality. The deviations of depressions from optimal growth theory are providing valuable diagnostic information that are used as the first step in developing and testing theories of depression. The remainder of this article describes these 'depression diagnostics', their application, and the new theories of depression that are being developed as a result of the use of these diagnostics.

The motivation behind the approach is that abnormal periods of macroeconomic activity – whether depressions or booms – lead to a proliferation of possible theories, and thus far there has been no systematic approach in the literature to shed light on which theories are the most promising. The diagnostic approach summarized here provides a simple method for identifying promising classes of theories. The idea of using optimal growth theory to diagnose depressions was initially used in Cole and Ohanian (1999), and the approach was further developed by Chari, Kehoe and McGrattan (2002), Cole and Ohanian (2002), and in particular by Chari, Kehoe and McGrattan (2007). The diagnostic method documents the deviations of the standard growth model, and then turns those deviations on their head to direct researchers to particularly promising classes of models.

To summarize the procedure, I begin with the following deterministic optimal growth model, which is given by:

\[
\max \sum_{t=0}^{\infty} \beta^t \{ \ln(C_t) + \varphi \ln(1 - L_t) \} N_t
\]

where \( \beta \) is the household discount factor, \( C \) is consumption, \( L \) is hours worked, and \( N \) is population.

The maximization is subject to the resource constraint, and the deterministic laws of motion for technology \( (X_t) \) which grows at the constant rate \( \gamma \), and population \( (N_t) \) which grows at the constant rate \( n \):

\[
Y_t = F(K_t, (X_tL_t) + (1 - \delta)K_t \geq C_t + K_{t+1}, K_0 \text{ given}
\]

\[
X_t = (1 + \gamma)^t X_0, X_0 \text{ given}
\]

\[
N_t = (1 + n)^t N_0, N_0 \text{ given}
\]
While this example uses logarithmic preferences, one can use other functional forms for utility. To induce stationarity, all variables are divided by population, and all variables that grow along the steady state growth path are detrended by the exogenous productivity factor $(1+\gamma)$. The stationary, per-capita variables are denoted with lower-case variables. Standard dynamic programming techniques can be used to solve for the first-order conditions. The equations that characterize the planner's optimum, and that form the basis of the diagnostic procedure, are given by:

\[
\frac{\psi}{1-l_t} = \frac{F_{lt}}{c_t} \\
(1+\gamma)(1+n)c_{t+1}/c_t = \beta[F_{kt+1} + 1 - \delta] \\
y_t = c_t + (1+\gamma)(1+n)k_{t+1} - (1-\delta)k_t \\
y_t = F(k_t, x_0, l_t)
\]

The first of the four equations listed above governs the household's allocation of time between market and non-market activities. The second equation, often called the Euler equation, governs the household's allocation of income between consumption and savings. The third equation is the resource constraint, and the fourth equation is the production function. Given parameter values, a functional form for the technology, and time series observations on output, consumption, labour, and investment, we construct the following percentage deviations between theory and data that will form the basis of the diagnostics:

\[
\begin{align*}
\epsilon_{lt} &= \{\psi / (1-l_t) / (F_{lt} / c_t)\} - 1 \\
\epsilon_{kt} &= \{(c_{t+1} / c_t) / (\beta[F_{kt+1} + 1 - \delta])\} - 1 \\
\epsilon_{yt} &= \frac{y_t - c_t - l_t}{y^* - c^* - l^*} - 1,
\end{align*}
\]

where starred variables are steady state values, and
I denote these as the labour deviation, \( \varepsilon_{lt} \), the Euler deviation \( \varepsilon_{kt} \), the National Income and Product Accounts (NIPA) deviation \( \varepsilon_{yt} \), and the productivity deviation \( \varepsilon_{zt} \). With the exception of the NIPA equation, each of these deviations is constructed as the percentage difference between the left-hand side and the right-hand side of each equation. The NIPA deviation is normalized relative to a steady state value. Note that, along the steady state growth path, all of these deviations are equal to zero by construction.

The next step is to choose parameter values and functional forms. Regarding parameterization, it is often convenient to choose values so that the deviations are equal to zero immediately before the episode of interest. Thus, given values for consumption, hours worked, and the technology, the parameter value for \( \phi \) is chosen so that \( \varepsilon_{lt} = 0 \) prior to the episode. Similarly, given values for consumption, capital, hours worked, and the depreciation rate, the parameter value for \( \beta \) is chosen so that \( \varepsilon_{kt} = 0 \) prior to the period of interest. Regarding functional forms, the application here uses log preferences over consumption and leisure, though other forms can certainly be used. For the production function, it is common to use Cobb–Douglas.

For heuristic purposes, I have described the procedure in a deterministic economy. The extension to a stochastic economy is fairly straightforward, and is presented in detail in Chari, Kehoe and McGrattan (2007). In summary, the procedure is modified for stochastic environments so that the measured deviations are modelled as a vector stochastic process, which is typically specified as a vector autoregression (VAR) and which for simplicity is represented here as a first-order process. The vector \( W \) is a 4×1 vector containing the four deviations previously defined above. The VAR is given by:

\[
W_t = \varphi W_{t-1} + \varepsilon_t, \quad E(\varepsilon \varepsilon') = \Omega
\]

The labour, NIPA, and productivity deviation are measured exactly the same way as in the deterministic case. Measuring the Euler deviation, however, requires evaluating the expectation of the right-hand side of the Euler equation. This can be accomplished by log-linearizing the planner's conditions, and then solving the resulting linear system. The linearized model can then be used to forecast the right-hand side of the Euler equation, which implicitly defines the stochastic Euler deviation.

Chari, Kehoe and McGrattan (2007) show that, given this procedure of measuring the deviations, the model economy is able to reproduce (up to numerical solution error) any observed sequences of fluctuations of the endogenous variables, given the sequences of these deviations and an initial value of the capital stock, population, and technology. Consequently, any fluctuation of an actual economy from its balanced growth path value is entirely accounted for by one or more of these deviations within the growth model. This insight transforms the growth model into an accounting framework, and as such the procedure can document the relative importance of each deviation for understanding fluctuations.
this, the investigator calculates the solution of the model using just one deviation at a time, or a subset of the four deviations. Chari, Kehoe and McGrattan (2007) conducted this type of analysis to show that the labour deviation and the productivity deviation account for virtually all of the Great Depression through 1933.

It is important to recognize that the interpretation of the deviations at this stage of analysis differs from that in the business cycle literature. For example, real business cycle models typically identify the Solow residual, or some variant of that residual, as a primitive shock. The diagnostic framework summarized here does not necessarily place this type of identifying interpretation on these deviations. Rather, the focus here is to provide clues to researchers for the class of models to consider. In the case of a productivity deviation, the key point of the diagnostic is that it informs researchers that a successful theory will be one that can be mapped into a growth model with this feature. A shift in the aggregate technology set is one interpretation of this deviation, but there are other interpretations as well, including theories based on the mismatch of resources across plants which impacts the Solow residual (see Restuccia and Rogerson, 2007), a distortion in relative prices that leads firms to shift their input mix, which also impacts the Solow residual (see Chari, Kehoe and McGrattan, 2007), or changes in government regulations (see Hansen and Prescott, 1993).

To concretely illustrate the use of this diagnostic approach further, suppose an investigator calculated these deviations, and found they were all roughly zero with the exception of the labour deviation. This information narrows the class of theories so that it would be admissible to include only those that feature some mechanism that changes the rate at which households value their time with respect to the measured wage, but leaves all other margins within the growth model unchanged. Models in this class include those with time-varying taxes on labour income, time-varying subsidies to non-market time, such as changes in unemployment benefits, changes in the incentive to accumulate human capital, and changes in union or monopoly power. The diagnostics presented in this hypothetical example also exclude several classes of models, including models of productivity shocks, models with government spending shocks, and models with time-varying taxes on capital income or investment, as the margins on which these factors operate are not distorted.

This example of a large labour distortion, but no other large distortions, not only illustrates how the method can be applied, but also happens to be the outcome of the procedure when the tools are applied to two well known and puzzling depressions, in the United States between 1933 and 1939 and the United Kingdom between 1921 and 1929. These episodes have long been considered puzzling because of their long duration, and because standard economic fundamentals were reasonably healthy during this period. In particular, the US money supply grew quickly after 1933, productivity growth was rapid after 1933, and there were no bank runs. All of these factors should have fostered a rapid recovery in the United States, yet hours worked in the United States recovered very little after the 1933 trough. In the United Kingdom, productivity growth was at its trend level during the 1920s, and the economy should have been poised for a significant post-First World War recovery.

During both of these episodes $\varepsilon_{lt}$ was very large, but other deviations were small. Specifically, the marginal rate of substitution fell well below the wage in both of these depressions. In the United States, the real wage was as much as 100 per cent above the marginal rate of substitution, while total factor productivity was near trend in both episodes, and the intertemporal consumption-savings Euler equation was undistorted. The diagnostic thus establishes that the key depressing factors in these episodes severely affected the labour market but did not depress productivity, nor did they distort the household's
intertemporal first-order condition governing the consumption savings decision. Cole and Ohanian (1999, p. 6) used this diagnostic information to focus on theories which could substantially distort the household's time allocation decision. Perhaps the most obvious factor that distorts this decision is changes in labour and consumption tax rates, as these taxes change the incentive to work and thus impact this first-order condition. The authors ruled this factor out based on empirical grounds, because changes in labour and consumption taxes were relatively small during this period in both countries.

For the United States, the next factor they considered was government policies that impact the labour market, and major labour market policies were adopted in both countries just prior to these episodes. In the United States, President Roosevelt introduced the National Industrial Recovery Act in 1933 that permitted industrial firms to cartelize and raise prices provided that they also raised wages. Relative prices and real wages in these sectors jumped significantly after the adoption of these policies, and employment and output remained low throughout the 1930s. This led Cole and Ohanian (2004) to develop a dynamic insider–outsider model in which firms were able to collude provided they reached a wage agreement with their workers. The model accounted for about 60 per cent of the post-1933 depression, and was consistent with the behaviour of wages and prices in both the industrial and non-industrial sectors of the economy. The insider–outsider model developed by Cole and Ohanian maps into a standard growth model with a large labour deviation, but the other deviations are roughly zero.

For the United Kingdom, Cole and Ohanian (2002), following work by Benjamin and Kochin (1974), noted that the United Kingdom adopted a very generous unemployment policy after First World War. Initially, benefits were available to those who worked for only one day in total, could be received indefinitely, and provided generous payments. At one point, the benefits paid were equal to about four per cent of GNP. Cole and Ohanian developed a model in which the policy reduced hours worked by about 15 per cent and distorted the household's first-order condition governing time allocation, but did not affect the other margins in the growth model.

In both of these episodes, the substantive finding from the diagnostic procedure led to the development of theories in which government policies distorted labour markets and significantly reduced hours worked, but did not significantly distort the incentive to save. The most provocative issue that has arisen in this diagnostic literature regards the importance of distortions to the capital market as a source of depression in the United States in the 1930s. Bernanke (1983), in a very influential paper, argued that banking panics led to a longer and deeper depression, using regression analysis that demonstrated that banking variables were statistically significant in an output equation that also included a measure of monetary shocks. Chari, Kehoe, and McGrattan (2007) show that some optimizing models that feature the financial intermediation channel emphasized by Bernanke, including Carlstrom and Fuerst (1997), map into a growth model with a substantial Euler equation deviation. However, the empirical Euler deviation is small during this period, leading Chari, Kehoe, and McGrattan to conclude that financial frictions theories that operate through the specific channel emphasized in Carlstrom and Fuerst are not quantitatively important for the Great Depression. This finding was a surprise to many economists, and is leading to new research in this area (see Christiano and Davis, 2007; Primaceri, Schaumber and Tambaloti, 2006).

It is likely that this procedure will be used not only in business cycles, but in a variety of applications. Lu (2007) uses the procedure to study Taiwan since the 1950s, and finds a very large Euler deviation.
Given this finding, and the fact that the spread between deposit and lending rates in Taiwan declines from about 12 per cent in 1950 to about two per cent in 2003, she develops a model of technological advances in financial intermediation efficiency that can account for the decline in the saving–lending spread and the Euler deviation, and finds that this development led to a significant increase in Taiwanese per-capita income.

Great Depression, monetary and financial forces in

Satyajit Chatterjee, P. Dean Corbae
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We survey papers that seek model-based answers to the following questions regarding the Great Depression. What caused the worldwide collapse in output from 1929 to 1933? Why was the recovery from the trough of 1933 so protracted for the United States? How costly are Depression-like episodes in terms of welfare? Was the decline in output preventable? The papers point to: an important, but not exclusive, role of monetary factors in causing the decline; counterproductive labour market interventions in making the recovery slow; uninsured risk of unemployment in making Depression-like episodes costly; timely provision of liquidity as a preventive policy.

Keywords

certainty; debt-deflation hypothesis; depressions; dynamic stochastic general equilibrium (DSGE) model; financial intermediation; gold standard; Great Depression; liquidity preference; monetary and financial forces in the Great Depression; monetary base; money multiplier; multiple equilibria; sticky wages; total factor productivity

Article

What caused the worldwide collapse in output from 1929 to 1933? Why was the recovery from the trough of 1933 so protracted for the United States? How costly was the decline in terms of welfare? Was the decline preventable? These are some of the questions that have motivated economists to study the Great Depression.

Cole and Ohanian (1999) document that US per capita GNP fell 38 per cent below its long-run trend path (of two per cent per annum growth) from 1929 to 1933. Real per capita non-durables consumption fell nearly 30 per cent, durables consumption fell over 55 per cent, and business investment fell nearly 80 per cent. On the input side, total employment fell 24 per cent and total factor productivity (TFP) fell 14 per cent. On the nominal and financial side, the GNP deflator fell 24 per cent; per capita M1
(currency plus deposits) fell 30 per cent; M1 velocity fell 32 per cent; the per capita monetary base rose 9 per cent; the currency–deposit ratio rose over 160 per cent (Friedman and Schwartz, 1963, Table B3); the loan–deposit ratio fell 30 per cent (Bernanke, 1983, Table 1); and ex post real commercial paper rates rose from six per cent in 1929 to a peak of 13.8 per cent in 1932.

What caused the Depression? For the United States, Friedman and Schwartz (1963, p. 300) argued that it was the decline in the stock of M1 – a consequence of Fed tightening and of a fall in the money multiplier induced by banking panics. According to Eichengreen (1992), international adherence to the gold standard transmitted the US monetary contraction to other industrialized countries. Specifically, high interest rates and low prices in the United States attracted foreign inflows of gold (in 1932 the United States and France held over 70 per cent of the world gold reserves), which the Fed largely sterilized (that is, sold domestic government debt and bought money). The outflow of gold from foreign countries implied that gold-backed money supplies of those countries had to decline in order to meet their cover ratios. Further evidence (see Bernanke and James, 1991, Table 4) of the importance of the gold standard in transmitting the contraction comes from the experience of countries like Britain, which suspended the gold standard in 1931 and recovered by 1932; from Spain, which never was on it and had a much less severe contraction than those on the gold standard; and from France, which was one of the last major countries to leave it and still faced declining industrial production past the 1933 trough. As Bernanke (1995, p. 3) puts it: ‘The new gold-standard research allows us to assert with considerable confidence that monetary factors played an important causal role, both in the worldwide decline in prices and output and in their eventual recovery.’

However, much of this evidence is problematic in that it is in the nature of correlations between endogenous variables – a fact that makes it challenging to establish causality. Did the decline in M1 cause the decline in aggregate output or – as Temin (1976) argued early on – did M1 and aggregate output decline in response to some other common shock? If the ‘monetary-cum-exchange-rate-policy’ explanation is indeed correct, we ought to be able to demonstrate its correctness in a reasonably calibrated, dynamic stochastic general equilibrium (DSGE) model. To paraphrase Lucas (1993, p. 271): ‘If we know what a depression is, we ought to be able to make one.’ The challenge of ‘making’ a depression has been taken up by various researchers and constitutes a noteworthy recent development in depression research.

The conventional explanation of why money affected output is sticky nominal wages – goods prices fell as a result of the monetary contraction but nominal wages adjusted slowly and the ensuing increase in the real wage depressed the demand for labour. One significant contribution to evaluating this conventional explanation is by Bordo, Erceg and Evans (2000). They calibrate a one-sector stochastic macro model with four-quarter nominal wage rigidity and find that 70 per cent of the output decline from 1929 to 1933 can be accounted for by feeding in the negative innovations to the actual M1 money supply process during that period.

Although the findings of Bordo, Erceg and Evans are striking, there are some unresolved issues. One is that the real-wage rise in the model was chosen to mimic the actual real-wage rise in the manufacturing sector while there is some indirect evidence that non-manufacturing real wages actually fell during the 1929–33 downturn. Cole and Ohanian (2000) re-examine the sticky-wage hypothesis in a multisector model and find much less support for it.

A second unresolved issue is that Bordo, Erceg and Evans do not take into account the evidence on
aggregate labour productivity and TFP, both of which declined between 1929 and 1933. Ohanian (2002) argues that only about a third of the decline in labour productivity and/or TFP can be plausibly accounted for by mismeasurement of factor inputs. By itself, a decline in TFP could account for a substantial fall in aggregate output, consumption and investment. Unless a decline in TFP can be viewed as an endogenous response to the monetary shock (through, for example, aggregate increasing returns), the decline leaves less scope for a purely monetary explanation. Using a DSGE model where money is non-neutral due to imperfect information, Cole, Ohanian and Leung (2005) show that the decline in M1 accounts for only one-third of the decline in output from 1929 to 1933, while the effect of an exogenous decline in TFP accounts for two-thirds. They use a misperceptions model of monetary non-neutrality because such a model generates less of a counterfactual movement in labour productivity than a model with nominal wage rigidities.

Sticky wages and monetary misperceptions are not the only mechanisms through which money can affect real output. Irving Fisher (1933) pointed out that the unanticipated fall in prices during 1929–33 led to bankruptcies because it increased the real value of nominal debt of households, firms, and financial intermediaries. This ‘debt-deflation’ hypothesis was analysed by Mishkin (1978) for households and formalized by Bernanke and Gertler (1989) for firms. More generally, Bernanke (1983) argued that the reduction in borrower net worth increased the cost of obtaining external finance, while bank failures and tightened credit standards hampered the efficient allocation of capital. However, a quantitative DSGE model featuring this mechanism has yet to be implemented for the Great Depression. Such a model holds out the promise of explaining some portion of the puzzling decline in TFP during 1929–33 as an endogenous response to a misallocation of capital.

One of the most striking facts of the Depression was the reduction in the money multiplier from 1929 to 1933 associated with the flight from bank deposits to currency. Cooper and Corbae (2002) construct a model in which households have the option of saving in the form of currency or bank deposits, and in which bank deposits ultimately fund working capital for businesses. Because of increasing returns in the intermediation technology associated with fixed verification costs, their model admits multiple equilibria. In the good equilibrium the return on bank deposits is high, households hold small amounts of currency, and output is high. In the bad equilibrium, the return on bank deposits is low, households substitute into currency, and output is low. A shift from the good to the bad equilibrium replicates many of the salient nominal changes that occurred between 1929 and 1933. Although not quantitative, their work formalizes the idea that output, credit and money supply responded negatively to a loss in confidence – much as Irving Fisher (1933, p. 343) suggested it did.

Why was the recovery from the trough of 1933 so protracted for the United States? As noted by Cole and Ohanian (1999), aggregate US output was still below trend in 1939. The answer cannot be the gold standard or M1 because the United States left the gold standard in 1933 and the US money stock recovered rapidly thereafter. One explanation offered is that the National Industrial Recovery Act (NIRA) encouraged businesses to accept high real wages of industrial workers. Cole and Ohanian (2004) embed labour bargaining into a DSGE model and quantitatively explore the effect of the NIRA, giving more weight to workers in the bargaining process post 1933. Their model is reasonably successful in producing a slow recovery. Adverse labour market interventions also appear to have played a role in other industrialized countries such as Germany, France, the UK and Italy (Kehoe and Prescott, 2002).
per cent in the United States but it is not known how this decline was distributed across households. Chatterjee and Corbae (2006) analyse how households that can self-insure against uninsured earnings losses would fare through a depression. They found that the welfare cost of living in a world with a small likelihood of a Depression-like event is quite large – somewhere between one and seven per cent of consumption in perpetuity depending on the completeness of asset markets. Much of this cost is associated with the increased variability of individual consumption streams.

Was the Depression preventable? First, if the ‘monetary-cum-exchange-rate-policy’ explanation is correct, the right monetary policy could have prevented the decline. Christiano, Motto and Restagno (2003) estimate a DSGE model with many shocks but find that a liquidity preference shock inducing households to hold currency instead of deposits played the most important role in the contraction phase of the Depression. They then specify a policy rule that raises the monetary base as a function of liquidity shocks, and run a counterfactual experiment where they find that output would have declined only six per cent if such a reaction function had been in place. Second, if a portion of the decline in output was the result of a banking collapse stemming from a shock to confidence, then – as shown by Cooper and Corbae (2002) – an announcement by the monetary authority that it stands ready to supply liquidity to the banking system might have moderated the decline. Finally, with regard to the slow recovery in the United States, the only credible explanation offered is adverse labour market intervention. If this explanation is correct, we know what not to do to prolong a severe decline in output.

Great Depression

Peter Temin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The world depression of the 1930s was the greatest peacetime economic catastrophe in history. There had been hard times before, but never without war, natural disaster or pestilence. The massive and long-lasting unemployment and hardship of the 1930s was a pathology of industrial society, caused by a malfunctioning of the economic system. Adherence to gold-standard policies led to a set of currency crises in 1931 that turned a bad recession into the Great Depression.

Article

Magnitude

Figure 1 shows the fall in industrial production during the Great Depression in the four largest national economies at that date. Industrial production declined by almost half in the United States and Germany. It fell more slowly and continuously in France, and paused rather than fell in Great Britain. National incomes did not fall as far as industrial production since services did not contract as much, but they decreased sharply: real per-capita GNP in the United States fell by one-third. National experiences in the depression varied greatly, but very few countries in the world escaped the economic hardship of the 1930s. One task for any account of the Great Depression is to explain its worldwide impact.

Figure 1
Figure 2 shows the fall in wholesale prices for the same four countries. Prices fell at the same time as production, by the same amount or more. Unemployment grew dramatically in almost all countries. Rates for the four largest economies are shown in Table 1. Only in the United Kingdom were unemployment rates approximately as high in the 1920s as in the 1930s, due to depressed conditions in Britain during the 1920s and a mild depression in the 1930s. Other countries for which we have data fit the more common pattern of higher unemployment in the 1930s.

Unemployment meant distress in the 1930s, most visible in Europe and North America. Diets in Europe became very monotonous despite the presence of home-grown vegetables in some areas. Families ate meat only rarely, starches were the basis of most diets, and sugar frequently was replaced by cheaper saccharine. Even this poor diet consumed almost all the family income. Families with children bought milk, most families bought coal for heat, but there was little money left over for clothes and other expenses. Shoes in particular were a problem. Families typically could not afford to replace shoes that had worn out, and so they were patched and patched again. Some families even restricted the activities of their children to save the wear and tear on their shoes.

While spending was channelled into food, and food into bread and coffee, personal travel was reduced to journeys to local neighbourhoods and villages. Trips to towns and town
centres had been increasing during the 1920s, to go to the theatre, do Christmas shopping, or attend school. With unemployment, the money to undertake these journeys vanished. Even tram and train fares became a burden, and people relied more heavily on their bicycles. The isolation of rural villages, alleviated by the railways and the prosperity after the First World War, reappeared in the depression.

Unemployed men were exceedingly idle; an increase of apathy reduced all forms of recreational activity. Men passed their time doing essentially nothing; when asked, they could not even recall what they had done during the day. They sat around the house, went for walks – walking slowly – or played cards and chess. Most men went to bed early; there simply was no reason to stay awake. Women were far more active. They spent time cooking, mending clothes to make them last longer, and managing their budgets. Men contributed less to the running of the household than before, sometimes not even turning up on time for meals, and women had the full responsibility for maintaining the household. Even though women previously had struggled to complete their housework after working, they uniformly would have preferred being back at work.

Sociologists observed that most European unemployed families were resigned to their condition. Such families were hanging on, preserving as much of their life and family as they could on their meagre budgets. All their activity was dedicated to getting by; no thought was given to the future. Some families still planned as before, but others collapsed entirely into mental and physical neglect and conflict.

Beyond Europe and North America, the story of destitution was the same, although the workers’ issues typically were more related to physical survival. Rural families in Asia and Africa suffered from the low prices that their crops received in the depressed world markets. They do not seem to have lapsed into idleness like unemployed urban workers, but rather continued to produce crops in the hope of increasing their incomes. Consumers in India, no longer able to afford imported cloth, gave a boost to domestic, beleaguered handloom weavers. Workers in Latin America retreated from cities and organized agriculture back into the countryside, and little is known of their living conditions. Latin American governments divided into active states that tried to insulate their economies from the outside world and passive states that waited for better times. Governments were surprisingly stable under this economic stress, but they collapsed in some countries, ranging from Germany to Burma.

Analysis

The first question to ask about this contraction is whether the shocks that produced it were demand or supply shocks. The simultaneous fall in production and prices indicates that the shocks were demand shocks, that the economies of the world were moving down along their upward-sloping aggregate supply curves in response to downward shifts of aggregate demand curves. The apathetic reaction to unemployment in the Great Depression confirms the hypothesis that the depression was due to a demand shock. Had it been due to a supply shock, families would have been unemployed by choice, happy with their extra leisure. The psychological depression also put great strain on the social structure, and even the political structure in some countries. It was in soil such as this that the noxious weed of National Socialism grew in Germany.

A second question about the Great Depression is how so many countries could have had negative demand shocks at the same time. The answer is that all these countries were adopting deflationary policies according to the dictates of the gold standard. The gold standard was characterized by the free flow of gold between individuals and countries, the maintenance of fixed values of national currencies in terms of gold and therefore each other, and the absence of an international coordinating or lending organization such as the International Monetary Fund. Under these conditions, the adjustment mechanism for a deficit country was deflation rather than devaluation – that is, a change in domestic prices instead of a change in the exchange rate. Lowering prices and possibly production as well would reduce imports and increase exports, improving the balance of trade and attracting gold or foreign exchange. (This is the price-specie-flow mechanism first outlined by Hume in 1752.)

A recession began at the end of the 1920s in the United States and Germany. Both countries began to contract economically, at least partly as a result of central bank pressure. The initial downturns appear to be independent in each country, but their economies were connected, and it is hard to be sure about this. In any case, it was gold-standard policies that transformed the downturn into the Great Depression and pulled the rest of the world down. The choice of deflation over devaluation was the most important factor determining the depth of the Great Depression. The choice was seen clearly and supported by contemporaries in all industrial countries who insisted that the way out of depression was to cut wages and thereby the costs of production and the prices of goods and services. Devaluation was not a respectable option.

Less developed countries were less likely to be on the gold standard than those in Europe or North America. They suffered from the depression nonetheless because of their ties to gold standard countries. As industrial countries reduced their demand for imports, exports from less developed countries declined. As industrial countries stopped exporting capital, less developed countries found their balance of payments deteriorating further. A few countries, such as Spain and Japan, devalued their currencies early and avoided the worst of the depression, but many more countries were not in a position to do this or where it would have had a large effect.

A third question that economists ask about the Great Depression is why the fall in demand was not absorbed entirely in falling prices. In other words, why did prices not fall more and production less than shown in Figures 1 and 2? The relative stability of wages caused production and employment to fall; falling prices and wages did not absorb the full brunt of the fall in demand. Falling prices also put pressure on financial institutions, whose failures reduced production as well.

Governments and central banks could not easily deflate their economies in the aftermath of the First World War. Workers, who had borne the burdens of international stability mutely in the past, expected and even demanded a voice in policy after their sacrifices during that war. The inability of economic policymakers to force wages down rapidly created the conditions for the Great Depression. The political strains generated by attempts to lower wages caused investors to fear for the stability of the gold standard even as policymakers
struggled to maintain it. One reason the gold standard worked well before 1914 was that labour had no voice. The spread of democracy both cast doubt on the monetary authorities’ commitment to the gold standard and reduced price flexibility.

Banks failed right and left in the midst of deflation and currency crises. Widespread banking failures were restricted to countries on the gold standard, showing that the strain of the gold standard was the principal cause of bank distress. All banks suffered as economic activity and prices declined, but the diversion of central banks from the support of commercial banks to the defence of the currency made the difference between banks in difficulty and banking crises. The German government took over the country's great banks in June and July 1931; American banks were allowed to fail continuously as economic decline continued. It seems that a slow crisis was more destructive of economic activity than a rapid one, though there are not enough observations to test this hypothesis.

Narrative

The narrative of the Great Depression properly begins with the First World War. The dislocations of the war and the peace agreements meant that many adjustments had to be made in the international economy. Strains were evident in the immediate aftermath of the war, resulting in hyperinflations in several countries, most notably Germany. The response was to return to the gold standard in the mid-1920s in the hopes of regaining pre-war stability. Alas, the cure proved worse than the disease.

Federal Reserve policy became contractionary at the start of 1928 in order to combat speculation in the New York stock market and to arrest a gold outflow begun in part by previous financial ease. The gold outflow was a prominent determinant of the policy change, even though it was tiny relative to US reserves. The Federal Reserve's primary aim in 1928 and 1929 was to curb speculation on the stock exchange while not depressing the economy. Even though this policy did not impede stock-market speculation, it reduced the rate of growth of monetary aggregates and caused the price level to turn down. The monetary stringency was even tighter than it seems from examining the aggregate stock of money because the demand for money to effect stock-market transactions rose, leaving less for other activities.

The German economy was heavily dependent on imported capital in the 1920s. Popular history regards the capital imports as a necessary offset to Germany's outflow of war reparations payments; they were needed to solve the transfer problem. The reality was quite different. Germany managed to avoid paying reparations by a variety of economic and political manoeuvres that succeeded in postponing its obligations until they could be repudiated entirely. The capital inflow therefore represented a net increase in the resources available to the German economy. The Reichsbank paradoxically worried that this capital inflow was unhealthy and acted to curtail it, sharply reducing the amount of credit available on the German market at the end of the 1920s. The capital flow from the United States to Germany ceased at the end of the 1920s, but the downturn in Germany preceded this fall and derived largely from German economic policies.

At its inception, the Great Depression was transmitted internationally by a gold-standard ideology, a mentality that decreed that external economic relations were primary and that speculation like the booming stock markets in New York and Berlin was dangerous. As the American, British and German economies contracted, they depressed other economies through the mechanism of the gold standard. These countries reduced their imports as they contracted, reducing exports from other countries. They also reduced their capital exports or increased their capital imports in response to the tight credit conditions at the end of the 1920s.

A bad recession turned into the Great Depression in the summer and autumn of 1931. A series of currency crises led both to what we now regard as perverse policy responses and to failures of financial institutions. A warning came in May 1931 when the main bank of Austria, the Credit Anstalt, failed, taking the Austrian schilling with it. This was a preview of things to come, but not a cause of them. The German mark had been under pressure since the German recession began in the late 1920s and the Weimar government began to run increasingly large deficits. They were covered by foreign lending, of which the American Young Plan was the most famous. The Weimar government, however, scared its foreign creditors by a series of statements for domestic consumption about a customs union with Austria and a possible repudiation of First World War reparations. The Reichsbank lost reserves precipitously in late May, and free trading in the mark was suspended in July 1931.

The British government found itself in similar trouble as its deficits followed Germany's. The Bank of England, unwilling to raise the bank rate above six per cent and further depress the domestic economy, abandoned the gold standard, floated the pound, and devalued in September 1931. The Federal Reserve, facing similar problems and adverse speculation, chose to raise its discount rate by 200 basis points in October 1931. This dramatic measure saved the dollar but killed the domestic economy. It was, however, loudly applauded by the American financial community as the correct gold-standard action.

The effects of fixed exchange rates can be seen in a comparison of Figures 1 and 2. Figure 1 shows that industrial production in four major countries declined at quite different rates. Figure 2 shows that the rate of decline in prices in the same four countries was strikingly similar. The fixed exchange rates of the gold standard led to uniform changes in prices even though other factors affected the change in production. The standard deviation of price changes was smaller than the standard deviation of production changes for 21 countries on the gold standard in 1930–2, as shown in Table 2. The standard deviation of price changes was smaller than the standard deviation of changes in the industrial production index in each year, even though the standard deviation of both series rose in 1932 as some countries abandoned gold. The final row of Table 2 shows the standard deviations in 1932 for seven countries that stayed on gold in 1932. Even though data for these countries are indistinguishable from the rest of the sample in 1930 and 1931, they are far more uniform in 1932.

Standard deviation of changes in 21 gold-standard countries, 1930–1932

Charles Kindleberger put forward a more international explanation in (1986). He argued that the lack of central bank leadership in the operation of the

financial community behind this perverse policy. This contractionary policy in the midst of rapid economic decline was the classic central bank reaction to a gold-standard crisis.

Even their story cannot separate the United States from the rest of the world. The Federal Reserve raised interest rates in October 1931 to defend the dollar, as noted above,

Even in the United States, with its vast economic resources and gold reserves, going off gold was a necessary prerequisite for economic expansion. Great Britain avoided the worst of

the Great Depression by going off gold in 1931, as shown in Figure 1. Spain avoided the depression by never being on the gold standard; Japan by a massive devaluation in 1932. At

the other extreme, the members of the gold bloc led by France endured contractions that lasted into 1935 and 1936. The single best predictor of the severity of the depression in

different countries is how long they stayed on gold. The gold standard was a Midas touch that paralysed the world economy.

Real wages stayed high in countries on the gold standard. Macroeconomic policies to preserve the value of the currency reduced prices faster than wages, and real wages stayed high

or even rose. Bank failures also were widespread in gold-standard countries, further depressing production. Both high real wages and bank failures show up as explanatory variables

for low incomes around 1935, and the prevalence of financial crises in countries on gold suggests that a counterfactual with more rapid deflation and no devaluations would not have

resulted in the maintenance of something close to full employment.

Complications

The influence of the gold standard determined the spread and the depth of the Great Depression, but the story has many dimensions not captured in this stark description. The

literature can be contentious, although apparently competing views may represent elements in a more comprehensive view.

One view of the Great Depression sees it as an American contraction that was transmitted to the rest of the world. In A Monetary History of the United States, 1867–1960 (1963),

Milton Friedman and Anna Schwartz argued that the Federal Reserve System in the United States acted with such ineptness that it plunged the world into depression. They attributed

this incompetence to the death of Benjamin Strong (president of the Federal Reserve Bank of New York) in 1928, and they describe several alternative monetary policies that they

argue would have eased or even eliminated the economic contraction.

Even their story cannot separate the United States from the rest of the world, however. The Federal Reserve raised interest rates in October 1931 to defend the dollar, as noted above,

even though the economy was contracting. Friedman and Schwartz characterized this action as an inept mistake, but they acknowledged the power of the gold standard to unite the

financial community behind this perverse policy. This contractionary policy in the midst of rapid economic decline was the classic central bank reaction to a gold-standard crisis.

Charles Kindleberger put forward a more international explanation in The World in Depression (1986). He argued that the lack of central bank leadership in the operation of the

restored gold standard was key to the spread of the Great Depression: the proposition summed up in the phrase ‘no longer London, not yet Washington’. The diminished financial

status of Great Britain meant that London was unable to act as sole conductor of the international orchestra – or, in more modern terminology, to operate as the ‘hegemon’ – while the

United States was not yet willing to take over this role despite the enormous improvement in its international economic standing.

Another factor which has been put forward as the primary explanation for the problems of the interwar period is the absence of international cooperation between the United States,

Britain, France and Germany. Barry Eichengreen, in Golden Fetters (1992), identified this behaviour as a central feature of the period, manifest particularly in the attempt of each of

the main powers to secure for itself a disproportionate share of the world's limited stocks of monetary gold. Prior to the collapse of the gold standard in 1931 their non-cooperative behaviour involved the imposition of tight monetary policies not only by countries in deficit, but also by those – notably the United States and France – which were in surplus. This added to the deflationary pressures on the world economy and increased the vulnerability of the weak currencies, such as the pound and the mark, to speculative attack.

Recovery

The world began to recover from the contraction in 1933, when the United States and Germany both abandoned the policies of the gold standard, but the Great Depression was far from over. Unemployment continued to be high in most countries, as indicated in Table 1. The world economy split up into competing currency and trading blocs, and domestic policies to combat the hardships of depression changed the role of government.

Unemployment continued to be high in most countries throughout the 1930s. Measures designed to help workers often perpetuated unemployment. The National Industrial Recovery Act of 1933 in the United States attempted to bring order to industries and income to workers by allowing industries to enforce codes of conduct that raised both prices and wages. Rising wages impeded the extension of employment, trading off the benefits to the unemployed for benefits to those working. Germany under the Nazis expanded government spending and, apparently, decreased unemployment dramatically. France and other members of the gold bloc continued to maintain contractionary policies in an effort to retain the convertibility of their currencies into gold. Only when France devalued in 1936 could its recovery begin.

Recovery, however slow and halting, did not approach the status quo ante. The world economy fragmented in the 1930s, and recovery took place within relatively isolated currency and trading blocs. The United States began the process of reducing world trade with the Smoot–Hawley tariff of 1930. The United Kingdom abandoned its tradition of free trade in 1932 in favour of protection for the British Commonwealth. Germany under the Nazis adopted a complex set of bilateral trading arrangements that reoriented its trade towards south-eastern Europe. International trade was much reduced, and international capital flows virtually disappeared.

Countries were changed internally as well. Governments became active in the economy as they attempted to reduce unemployment or ease the condition of the unemployed. Unions grew in many countries, helped both by legislation and by unemployment. Regulation grew as governments substituted direct controls for those of the market, and the world war that followed the Great Depression caused governments to take control even more firmly of their economies. The mixed economies and large governments that were typical of the last half of the 20th century were the legacy of the Great Depression and its aftermath.

It is not possible to separate the long-run effects of the Depression from those of the Nazis and the Second World War, but it is instructive to ask whether the Great Depression could have been avoided. There were indeed stresses on the world economy at the end of the 1920s, and the control mechanisms used in earlier times were not in good shape. The downturns in the United States and Germany would have produced a serious recession in the early 1930s in any case. The currency crises of 1931 then turned this recession into the Great Depression. If Germany and the United States had abandoned gold after Britain had chosen devaluation over further contraction, the world economy would have begun to recover two years earlier and before unbearable strain had been put on economic and political institutions.

Historians today debate how much freedom policymakers had in 1931. The German cabinet discussed devaluation after Britain left gold, but the memory of hyperinflation less than a decade before inhibited – if it did not preclude – an expansionary policy such as devaluation. The United States was not under the same economic pressure as Germany, but the Federal Reserve nonetheless raised interest rates sharply in late 1931 in response to gold outflows following Britain's devaluation. The Federal Reserve was following the dictates of the gold standard in actions that were applauded by the local financial community. It was a world tragedy – one that escalated from economics to politics and war – that the hold of the gold standard was so strong in the early 1930s that policymakers in the major economies chose to continue deflationary economic policies long after the need for expansionary measures was clear.

Great Divide

Erik Berglöf

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

commitment; compensation; crowding out; fiscal responsibility; Great Divide; policy reform; privatization; rule of law; transition

Article

The expression ‘Great Divide’ refers to the differences in institutional development apparent in the first decade of transition among the countries of central and eastern Europe and former Soviet Union following the collapse of Communism (Berglöf and Bolton, 2002). Figure 1 compares these countries in 1996, 2000 and 2005 using one measure of rule of law derived through questionnaires to businesses operating in a broad range of countries.

Figure 1
By the end of the first decade of transition in 2000, the Great Divide was visible in almost every measure of economic performance: gross domestic product (GDP) growth, investment, government finances, growth in inequality, general institutional infrastructure, and in measures of financial development. Gradually growth has picked up and macro-stability improved in the Commonwealth of Independent States countries, in large part thanks to favourable terms-of-trade changes as a result of price increases in energy and other raw materials. As indicated by Figure 1, institutional development has also progressed in most of these countries but still lags significantly on most dimensions, and there are examples of institutional regression, particularly in political institutions.

The Great Divide does not primarily refer to the depth and duration of the initial transitional recession, but rather to the more long-term institutional backwardness observed in parts of the region. Some countries (for example, Estonia, Latvia and Lithuania) had a deeper recession, but a less protracted turnaround accompanied by rapid institutional transformation.
Other countries (for example, Belarus, Turkmenistan, and Uzbekistan) did not attempt full-scale reform, and thus experienced neither initial decline nor substantial development in their institutions. The non-European transition countries China and Vietnam exhibit yet another pattern where broad, if incremental and partial, economic reform did not result in initial output decline.

The Great Divide represents one of the key puzzles of transition in that it cannot be immediately traced to the policies pursued. In fact, differences in policies among the more successful countries in Central and Eastern Europe were often more pronounced than those between some of these countries and those of former Soviet Union. A prominent, but by no means the only, example would be privatization policies, where the Czech model had more in common with that of Russia than with that of Poland.

Another, perhaps less puzzling, observation is the remarkable institutional convergence of economic systems in Central and Eastern Europe despite the diversity in terms of policies pursued. The emerging model of ownership and control of large firms is one with an owner with a large controlling share and a strong presence in day-to-day management of the firm. The financial systems are strongly dominated by commercial banks, increasingly foreign-owned, whereas stock markets on the whole remain volatile and illiquid. This convergence has been taking place even though the countries differ markedly in terms of policies when it comes to areas such as enterprise and bank privatization, bank recapitalization, stock market policies, and entry and exit of firms.

Both these observations, the emergence and persistence of the Great Divide and the convergence of economic systems in the front-runner countries in central and eastern European countries, suggest that initial conditions matter greatly for institutional development and economic growth. The relative importance of different initial conditions has been estimated by a large number of studies, but the influences of individual factors are often hard to disentangle. Broadly speaking, the Soviet legacy (the degree of integration into the economic and political system of the Soviet Union) and the prospect of membership in the European Union stand out as key in shaping the development of economic and political institutions.

Another key to understanding the origin of the Great Divide is to look at when and under what conditions it emerged. Typically, the differences in institutional development first became visible when the governments were faced with demands from different groups to be compensated for the adjustments in relative prices following pricing reforms. The ability of governments of transition economies to achieve fiscal and monetary responsibility, together with a commitment to refrain from bailing out failing banks or loss-making enterprises, determined whether economic and financial development took off.

Fiscal responsibility promotes both financial development and economic growth through two important channels: it limits the extent of crowding out of private investment by government borrowing and it makes credible the commitment of the government to maintain the macro-stability essential for private investment. In addition, it provides some guarantees that the returns from investment are not going to be taxed away in the future by excessively profligate governments desperately seeking tax revenues where they can find them. Of course, specific initial conditions and underlying country characteristics facilitate the emergence of fiscally sound governments capable of enforcing the rule of law.

green national accounting

Sjak Smulders
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Extending conventional national product measures, green national accounting provides better indicators of economic welfare and of the sustainability of welfare levels. The main theoretical result shows that in an undistorted economy net national product is proportional to welfare, provided some rather stringent conditions are met. With appropriately used shadow prices, the welfare effects of externalities and world market changes can be accounted for and sustainable income – the hypothetical level of consumption that can be sustained into the future – can be calculated. Practical approaches have been proposed to adjust conventional national income figures roughly in the spirit of the theoretical results.

Article

Green national accounting extends conventional national product measures to provide better indicators of economic welfare, as well as indicators of the degree to which welfare levels can be sustained. Conventional national accounts measure the size of the market or commercial activities, but do not necessarily measure very well (a) how these activities translate into welfare and (b) how non-marketed activities contribute to the welfare of citizens. A big part of the greening of national accounts...
concerns issues related to the environment. For example, production of certain goods that generate market value contributes to national income, but, if the production generates undesirable pollution as a by-product, the contribution to welfare might be actually negative. Conventional national accounts ignore the reduction in air quality since air quality is not traded on markets and is left out from conventional national accounts. As another example, consider the depletion of oil reserves. Oil companies' profits contribute to conventional national income, but the fact that fewer reserves will be available in future is left unaccounted, even though this may affect the welfare of future generations.

The aim of measuring economic welfare by a simple number is without doubt challenging, since it is inevitably related to the formal economic concept of individual utility and the theoretical problems of aggregating utility and interpersonal utility comparisons. The theoretical approaches to green accounting circumvent these problems by assuming a social welfare function and representative agents in highly stylized models. Because of lack of data and various other constraints, the more applied approaches to green accounting are only loosely rooted in formal theory and sometimes include issues of (intergenerational) income distribution on an ad hoc basis.

The focus of green accounting is much more on dynamic and intergenerational aspects than on intra-generational issues. It typically tries to measure to what degree the lifetime utility of the representative agent in a country increases over time, and to what degree it is higher than in other countries. It sometimes also tries to measure to what degree intra-temporal levels of utility of the representative agent in a country can be maintained over time, whether the economy is investing enough to maintain non-decreasing utility levels, and how much a country can consume more than another country when both of them would ensure utility levels of their inhabitants are not declining over time. The latter type of questions is often associated with ‘sustainability accounting’ as a particular branch of green accounting. Green accounting starts from a broad concept of economic welfare, which goes beyond welfare depending on just marketed produced goods. Thus, welfare is allowed to depend on health, environmental amenities, pollution levels, or availability of natural resources. Even altruistic preferences are allowed: utility levels of future generations may matter for the welfare objective of current generations. Society might care in particular for the utility levels of those generations that are worse off in future. The extreme case of this implies maximin preferences: only the generation with lowest utility levels gets a positive weight in the social welfare function and reductions in other generations' welfare do not count. This contrasts to utilitarian preferences, in which every generation gets a weight, and utility levels of generations further in future often get a lower weight because of a positive utility discount rate.

Welfare in an undistorted economy

A fundamental theoretical result concerns the measurement in undistorted competitive (and hence by construction welfare-maximizing) economies (Weitzman, 1976; 2003), which we will refer to as the Weitzman principle. Consider a society that manages to maximize its own social welfare function, either because there are no externalities or because all existing externalities are internalized by appropriate policy. In such an economy, green net national product (NNP) can be calculated and this measure is proportional to total welfare. Moreover, green net investment can be calculated and a positive (negative) value of this measure always implies an increase (decrease) in instantaneous welfare. To start with, we consider the simplest model economy (as in Weitzman, 1976), in which a single
consumption good is produced from a single capital good, representative agents maximize utility discounted at a constant rate, and the social welfare function is the sum of individual utilities. Then the sum of the value of consumption and net investment, valued against market prices, is proportional to welfare. Note that this sum is equal to the conventional NNP number for this economy. In this model economy, NNP reflects intertemporal welfare: consumption reflects instantaneous utility, whereas investment reflects how current economic activity contributes to future utility.

Extending conventional income to ‘green’ income is needed if the welfare function has ‘unconventional’ arguments like environmental quality and health (see, for example, Asheim and Buchholz, 2004). These arguments can be seen as alternative forms of consumption, not consumption of conventionally produced goods but of natural resource services, health services, and so on. Then, in a perfect economy, according to the Weitzman principle, green NNP should be calculated as the value of all ‘consumption’ activities that matter for utility plus the value of net investment in all ‘capital’ stocks that matter for production capacity. Both ‘consumption’ and ‘capital’ are broad comprehensive measures here, with the former including for example consumption of environmental resource services and the latter including any variable that determines the production capacity for the generation of comprehensive consumption. Accordingly, the relevant capital goods, or assets, include not only physical capital and resource stocks, but also all kind of other state variables like public health (in economies that have a preference for health or in which health determines workers productivity), atmospheric pollution stocks, physical characteristics of the soil determining absorption of pollution and regeneration of nature, institutional capital and social norms subject to erosion and development.

As a special result of the Weitzman principle, the Hartwick rule can be derived (Hartwick, 1977). The rule says that, if society wants to maintain a constant utility level over time, it has to invest the returns to non-renewable resources in other assets such that total green net investment (the comprehensive measure of investment) is zero. Hence, in accordance with the Weitzman principle, in such an economy green NNP equals the sustainable level of utility (as well as green consumption, since green net investment is zero). As a result it is a measure of sustainability: comparing two different economies that are both undistorted and maximize maximin preferences, we can say that the country with higher green NNP can maintain indefinitely a higher welfare level than the other.

Caveats

The above results must be interpreted with care and are more limited than might seem at first sight. The important caveat is that an economy with zero green net investment is not necessarily able to maintain a constant utility level for its representative agent over time and can thus be unsustainable (Asheim, Buchholz and Withagen, 2003). This may be the case, for example, in an economy that is dependent on a non-renewable resource and that is maximizing a utilitarian welfare function with constant discount rate rather than a maximin welfare function. Such an economy might optimally consume growing amounts initially, but eventually consume declining amounts, which of course is always inefficient for maximin preferences. The key insight from the Hartwick rule is that a necessary, but not sufficient, condition for maintaining constant welfare over time is sufficient investment (Pezzey, 2004).

The Weitzman principle applies only when changes in production capacity depend solely on investment choices. Alternatively, production capacity, that is, the possibility to generate consumption, might
change over time due to events beyond control of the economy. Three important examples are exogenous technological change, world price changes, and geological or climatic changes. If technology improves over time or the world market price of export goods increases, an economy's welfare can improve even when green net investment (as defined above) is negative. Formally, welfare is now proportional to the sum of comprehensive consumption and net investment, augmented with a term capturing the (properly valued and discounted) benefits from improved technology and world market prices that will accrue to the economy in future (Sefton and Weale, 1996). The latter term can be labelled the ‘value of time’, whereas the sum of green NNP and the value of time is ‘augmented NNP’ (Pezzey and Toman, 2002). In the case of global warming or other negative environmental developments because of purely geological or climatic reasons, there might be a negative time premium and sufficiently positive green net investment is needed to keep welfare constant.

Externalities and sustainable income

The Weitzman principle is derived for welfare-maximizing economies. How can we measure welfare in economies that do not actually maximize welfare? Similarly, how can we measure sustainable income (consumption) levels in economies that do not actually sustain constant consumption levels?

One theoretically possible way is to construct a hypothetical income figure that represents the level of welfare or sustainable consumption, respectively, that would arise if the economy made the switch from being distorted to being welfare maximizing or sustainable, respectively. This requires a measurement of the total wealth of the economy, consisting of all assets valued at their corresponding shadow prices, which depend on the exact welfare function.

The problem when putting this into practice is that actual prices observed in the distorted economy have no direct relation to the shadow prices needed to calculate wealth. In the presence of externalities, market prices do not reflect certain social costs and benefits, so that the sum of consumption and net investment at market value misses some contributions to welfare. As an alternative to calculating wealth against shadow prices as indicated above, one may augment the market value of comprehensive consumption and net investment with the net present value of the marginal externality along the competitive path (Aronsson, Löfgren and Backlund, 2004). Obviously, such an augmentation term in green accounting is also hard to calculate in practice.

Green national accounting in practice

Given these theoretical results, how feasible is welfare and sustainability measurement in practice? The results suggest that we need (a) comprehensive accounting of consumption and investment activities, (b) the right (shadow) prices, and (c) additional forward-looking augmentation terms to capture exogenous or uninternalized developments over time. It has been concluded that (b) and (c) are insurmountable impediments to practical green accounting: fully correct green accounting is impossible and any method ignoring the problems associated with (b) and (c) is bound to produce biased numbers. At the other side of the debate it has been argued that national accounting has always been imperfect and indicative only (Cairns, 2002). According to this view the task is to focus on making national accounts more comprehensive – and satisfy at least requirement (a) – carefully delineating consumption and net
investment, and applying corrections to prices where reasonable and feasible. Furthermore, the value of non-marketed activities has to be imputed rather than observed. A host of methods is available to impute prices, which use hedonic pricing, contingent valuation methods, and travel cost approaches. The resulting practical approaches differ with respect to what to include in national accounts and how to determine values and prices. Among them ‘genuine savings’ (GS), a comprehensive net investment measure, is the best-known and closest to theory (Pearce and Atkinson, 1993). Most GS correct conventional measures of investment for consumption of resources, damages from pollution, and investment in education. GS is often found to be positive in Europe and Japan (thanks to high savings and investment in education) and negative for Africa and oil-producing countries (due to the depletion of oil reserves). The latter results are quite sensitive to the way resource depletion is accounted for. GS figures should be interpreted with care: since the GS calculation ignores ‘value of time’ terms and uses market prices rather than shadow price, GS is not a true measure of welfare increases. Persistent negative rates of GS are likely to result in decreases in welfare (unless exogenous technological change is significant), but with positive rates of GS nothing definitive can be said. So GS can be used to measure only unsustainability.

Another well-known indicator is the index of sustainable economic welfare (ISEW, initiated by Daly and Cobb, 1989). It is an extended measure of green NNP (and therefore aimed at measuring welfare) that starts from conventional income, adds changes in environmental quality, imputes value of non-marketed activities (particularly household work), subtracts consumption expenditures that do not directly contribute to welfare (such as health and pollution abatement expenditures), and weighs on an ad hoc basis remaining expenditures by a measure of income inequality. For different components different valuation methods are used so that consistency is not always guaranteed. Shadow prices or opportunity costs are rarely used to value damages. The large number of adjustment to NNP also raises the question why certain components are still omitted (for example, the value of leisure time is not included while household work is, and investment in education and technological change are omitted). Calculations of ISEW for richer countries show that ISEW has grown considerably more slowly than conventional NNP over recent decades. This result is not robust, however, for changes in the specific composition of the index and the valuation assumptions (Neumayer, 2003).

Because of the main problem of determining correct prices for non-marketed goods and for dealing with externalities, but also because of the limited substitution between natural resources and conventional man-made inputs, it is often argued that purely physical indicators are useful to measure the state of the environment and economic welfare and to supplement (rather than adjust) more conventional measures. Since no attempts are made to monetize and the common denominator is missing, different physical indicators cannot be easily aggregated to overall welfare: improvement in one indicator cannot be compared with gains elsewhere and the costs of securing improvements cannot be determined. The sustainability gap indicator is an example (Ekins and Simon, 1999). Since welfare is critical dependent on air quality, a minimum level of air quality can be defined that is needed to maintain welfare at a reasonable level, and it can be measured how far society is from this standard; the exercise can be repeated for other critical natural resources.

Another popular example is ‘ecological footprint’, which measures the amount of land that is needed to generate the consumption of a country, including the land needed to assimilate the waste generated and undo climatic change from carbon dioxide emissions by means of carbon sequestration (Wackernagel...
and Rees, 1996). If for the world as a whole the ecological footprint exceeds available land, the economy is said to be unsustainable. A problem here is how to aggregate over different land uses. Similar measures, with a similar aggregation problem, keep track of varieties of material resource flows. It is unlikely that the theory of green accounting can in the end be fully applied. Instead, a combination of different indicators and imperfect theory-based measures of welfare could – together with the caveats from theory – provide a useful information system to put conventional national income systems into proper perspective.

The second son of Sir Richard Gresham, merchant, Sir Thomas Gresham was educated at Gonville Hall, Cambridge, apprenticed to his uncle Sir John Gresham, also a merchant, and admitted a member of the Mercers' company in 1543. In 1551 or 1552 he became royal agent or king's factor at Antwerp, in which post he received 20 shillings a day, and which he retained with few intervals during three reigns until 1574, employed in spite of his Protestant views even by Mary. His business was to negotiate royal loans with Flemish merchants, to buy arms and military stores, and to smuggle into England as much bullion as possible. He succeeded in raising the rate of exchange from 16•s. to 22•s. in the £, and is said to have saved in this way 100,000 marks to the crown and 300,000 to the nation. His operations greatly benefited English trade and credit, though the government could not be induced to pay its debts as punctually as Gresham would have liked. He did not hesitate to remonstrate with and advise Elizabeth and Cecil; but he was so useful and trustworthy that he was never seriously out of favour, except just after Mary's accession. On Mary's death he advised Elizabeth to restore the base money, to contract little foreign debt, and to keep up her credit, especially with English merchants. Later he taught her how to make use of these English merchants when political troubles in the Netherlands curtailed her foreign resources; at his suggestion the Merchant Adventurers and Staplers were forced by detention of their fleets to advance money to the state; but as they obtained interest at 12 per cent instead of the legal maximum of 10, and the interest no longer went abroad, the transaction proved advantageous to all parties and increased Gresham's favour. His journeys to and from Antwerp were very frequent, but in his later years he entrusted most of his public work to his agent, and is not known to have been at Antwerp after 1567. In 1554 he was sent to Spain to procure bullion, a very difficult task in which he was only partially successful; and in 1559 he was employed as ambassador to the Duchess of Parma, regent of the Netherlands; it was on this occasion that he was knighted.

In addition to his public services he continued throughout his life to do the work of 'the greatest
merchant in London’. He was, in the language of the day, a banker and goldsmith, with a shop in Lombard Street, as well as a mercer; but he was a considerable country gentleman besides, with estates, chiefly in Norfolk, where his father held considerable property, and with several country houses besides the house in Bishopsgate which he built and bequeathed to London as Gresham College. He twice entertained Queen Elizabeth as his guest. His wealth was mainly earned by his private business, but he cannot be acquitted of enriching himself at the public expense by at least one dishonourable manœuvre; and he habitually forwarded his schemes by bribery. The money so gained he applied to public uses, his only son having died young: the foundation of the royal exchange, of Gresham College, and of eight almshouses, and the establishment of the earliest English paper-mills on his estate at Osterley, show the breadth of his interests, his liberality, his charity, his culture, and his commercial enterprise.

Gresham's Law

François R. Velde
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article recounts the origin of Gresham's Law, discusses its theoretical and empirical problems, and presents several refinements that have been proposed.

Keywords

assignats; asymmetric information; bimetallism; exchange rate indeterminacy; good and bad money; Giffen, R.; Gresham, T.; Gresham's Law; legal tender; seigniorage

Article

Gresham's Law, which holds that 'bad money drives out good money', is as problematic as it is well-known. It predicts that, when two monies are in use but one is of lower quality or lower intrinsic value than the other, the former will be used as medium of exchange to the exclusion of the latter. The law implicitly relies on the monies circulating for the same value in spite of their intrinsic differences. The key question is: why would they?

Origin of Gresham's Law

Gresham's Law is one of the 'laws' bequeathed to us by 19th-century political economists eager to uncover laws of nature just like physicists. Henry Dunning Macleod (1855–56, vol. 2, p. xxxvi; 1858, p. 477; 1896, p. 38), the man who named it, described it successively 'an unerring law of nature', 'a fundamental and universal law in Economies, which has been found to be true in all countries and ages', and 'this great Law, which is as well and firmly established as the Law of Gravitation'. Perhaps it should have been named Macaulay's Law, for it was Lord Macaulay (1850–61, vol. 4, p. 620) who gave the law its familiar form: 'where good money and bad money are thrown into circulation together, the bad money drives out the good money.' Macaulay also noted that the phenomenon had
been described in the fifth century bc by the playwright Aristophanes, who in *The Frogs* (718–733) compared the prevalence of bad politicians with the replacement in use of high-quality gold and silver coinage by inferior copper coins. Macaulay dismissed the playwright's explanation based on preferences but thought the verses worth quoting in the original Greek. MacLeod quoted Aristophanes, too, albeit in English, but he decided to credit the first person he thought to have explained the law properly: Sir Thomas Gresham, a financier in 16th-century England. Gresham's letter to Queen Elizabeth I on her accession, urging her to restore a good quality coinage after the debasements of her predecessors, had recently been published by Burgon (1839, vol. 1, p. 483).

Wolowski (1864, p. lix) soon drew attention to earlier formulations of the law in monetary tracts of Nicholas Copernicus (written between 1519 and 1528) and Nicole Oresme (written between 1355 and 1357), although the relevant passage in Oresme's tract was later shown to be an anonymous addition of the late 15th century (Bridrey, 1906, pp. 263–5). Later, Fetter (1932) pointed out that Gresham never stated anything remotely approaching his law: the famous letter to Queen Elizabeth I merely stated that the price of the English pound sterling abroad had declined after Henry VIII's debasement of the silver currency and that gold had been exported on that occasion. The somewhat arid search for the first person to state the law is often led astray towards descriptions of the phenomenon in some particular instance (such as the aftermath of a debasement), or of a related phenomenon (such as clipping, culling, and exporting of good coins). On this score, Copernicus's claim of priority is solid, since he wrote as a general proposition that ‘introducing a new, worse money while the old, better one remains not only depreciates the latter, but, I would say, expels it’ (Wolowski, 1864, p. 56).

Be that as it may, MacLeod's coinage popularized by Jevons (1875) soon gained universal currency and, being taken at face value, this ‘law’ has been driving critical thinking out of circulation ever since.

The problems with Gresham's Law

In the usual laconic formulation of the law, ‘bad money drives out good money’, every single word cries out for clarification. What is ‘money’, what is ‘good’, what is ‘bad’, and what does ‘driving out’ mean? The nature of the law, empirical regularity or theoretical proposition, is just as uncertain.

The law, being so vague, has been applied to a wide variety of pairs of monies: freshly minted and worn or full-bodied and clipped versions of a given coin; original and debased version of a given coin; a coin and a similar but lighter coin of the same metal; coins of different metals; metallic and paper money; paper monies of different issuers; securities of varying risk characteristics; and so on. The process of ‘driving out’ is taken to mean that one money replaces the other in some monetary function either completely or partially, but also that the coins circulate alongside but not at par (Fetter, 1932). In formal models, Gresham's Law is often invoked to compare outcomes across equilibria (for some parameter values, two monies circulate, and for others only the bad one does) rather than the dynamic process suggested by the words ‘drive out’.

As a theoretical proposition, the law seems to run against basic economic intuition. Bad apples do not drive out good apples, they fetch a lower price. Why the good money could not circulate at a premium is a puzzle that the mere invocation of the law occults. Friedman and Schwartz (1963, p. 27 n.) note that the law is often misused because it ‘applies only when there is a fixed rate of exchange between the two [monies]’. This raises the question: what fixes the exchange rate? In this version, the law relies on a
postulate about prices, which economists are in the business of explaining.
As an empirical regularity, the law would have been more compelling if counter-examples had not been ignored as carefully as examples have been collected. One need only go to the original inventors of the law to find instances of selective empirics. Lord Macaulay invoked it as a general proposition to explain the state of the English coinage in 1695, a time when high-quality milled money was driven out by worn and clipped hammered money. He does not explain, however, why the law failed to apply in the previous 30 years throughout which milled and hammered coins coexisted (see Sargent and Velde, 2002, ch. 16). Sir Thomas Gresham himself was baffled by the fact that, after Henry VIII's debasements, testoons containing 40 grains of silver circulated alongside testoons containing 20 grains, and at the same value (De Roover, 1949, p. 93). Other counter-examples are easily found. High-quality currencies have dominated lower-quality competitors in international trade since the days of the Florentine florin and the Venetian ducat. Rolnick and Weber (1986) have documented numerous other violations of the law. Finally, the vast literature documenting collapses in real balances during hyperinflations surely testifies to the fact that (very) bad money will be driven out by almost anything else.

Refinements of Gresham's Law

Several refinements of the law have been proposed, and three are considered here. One force that might fix the exchange rate is legal-tender laws. A law conferring legal tender status on a money states that a debtor is discharged of his debt by tendering that money (in the correct amount) to the creditor. It is up to the creditor to accept or refuse, but should he refuse he has no further legal recourse against the debtor. The argument that legal-tender laws can be sufficient to uphold Gresham's Law runs as follows. Suppose that two currencies, one intrinsically worth less than the other, are given equal legal tender by enforceable laws: say, one dollar coin is worth 90 per cent of the other in intrinsic content. Debtors will then discharge their debts with the bad money, and reserve the good money for other purposes. The bad money displaces the good one, at least in repayment of debts.
A first difficulty is that legal-tender laws typically apply to the discharge of debts, not to circulation in general. But – if we set this aside – while the law forces the creditor to take the bad dollar in payment, it usually does not force the debtor to tender only bad dollars, or the creditor to accept good dollars at face value. The debtor owing $100 could offer the creditor a choice between 100 bad dollars and 90 good dollars (on the assumption that the transactions costs of such an offer are not too high, as they might be if the relative price is an inconvenient fraction; see Rolnick and Weber 1986).
To shore up Gresham's Law requires unusually strong legal tender laws, such as the two examples given by Selgin (2003). In the first example, on 11 January 1776 the Continental Congress resolved to protect the paper money it was issuing, the continental, by declaring that

if any person shall hereafter be so lost to all virtue and regard for his country, as to refuse to receive said bills in payment, or obstruct or discourage the currency or circulation thereof, and shall be duly convicted [...] such person shall be deemed, published, and treated as an enemy of his country, and precluded from all trade or intercourse with the inhabitants of these colonies.
In the second example, the French revolutionary government defended its paper currency, the assignat, by decreeing on 11 April 1793 that trading specie for the assignat at anything but par, and setting or offering different prices for payment in assignats or specie, would be punished by six years of imprisonment. A law of 5 September 1793 added that such acts committed with counter-revolutionary intent were punishable by death.

Such examples, however, are too infrequent to sustain Gresham's Law with any kind of generality. They also tend to occur in periods of turmoil when the force of the legal-tender laws is questionable. The Continental Congress's resolution, which Nussbaum (1950, p. 567) finds 'of dubious legal significance', did not prevent the continental from quickly depreciating below par. In the French case, the assignat was already trading at less than half the price of gold coins, according to the Treasury's own records, and never traded above thereafter. These strong laws succeeded in propping up the demand for these paper currencies, but certainly not at anything like par.

A second refinement was proposed by Walker (1877, pp. 193–5) following Ricardo, and was endorsed by Giffen (1891) and by Palgrave (1894–99, vol. 2, p. 262). Bad money will drive out good money only when the sum of the two is in excess of the wants of trade. This refinement can be made more precise as follows (see Sargent and Smith, 1997, for a formalization of these ideas).

Suppose that the objects used as money have alternative uses: for example, a coin could be melted down and consumed as metal. Monetary objects may be worth more as money than in their next-best use if their supply is restricted in quantity (by government control over the issue), or unrestricted but at a markup over their alternative value (unlimited minting with a seigniorage charge). Furthermore, these monetary objects, although differing in their alternative values, may have the same value as money if they provide exactly the same monetary services, that is, their relative exchange rate is constant but the level indeterminate. Here, the force that keeps the exchange rate fixed is the Kareken and Wallace (1981) result on indeterminacy. The common value of these monetary objects, as money, will depend on the overall demand for monetary services (the ‘needs of trade’), and the total supply of these objects. These conditions may change so as to drive down the value of the objects in monetary use. For example, additions of some monetary objects to the money supply will, if the money demand remains constant, drive down the value of all monetary objects at the same time. If the value falls low enough, the objects with the most valuable alternative use will be the first to be removed from monetary use: the ‘best money’ will be driven out.

Three points should be noted about this qualified version of Gresham's Law. The foregoing reasoning described one possible equilibrium, but does not rule one where Gresham's Law would fail (such as one money circulating and all the others in their alternative use). Second, the best money can be driven out by the addition of any monetary object to the money supply, not necessarily the worst. Finally, this version depends crucially on the expectations that holders of the monetary objects may have about future rates of return on the different objects: if the value of money is expected to fall further, why would agents persist in holding balances in those objects whose value will fall further than others?

The third refinement arose from the growing importance of asymmetric information in economics. In his famous paper, Akerlof (1970, p. 489) noted the analogy between ‘lemons’ driving out good cars from the market and Gresham's Law, although he thought that, in the latter case, ‘both buyer and seller can tell the difference between good and bad money.’ Velde, Weber and Wright (1999) and Dutu, Nosal and Rocheteau (2005) have explored the role of asymmetric information about coinage. Gresham's Law can
make an appearance in such models because of a ‘lemons effect’. Good and bad coins will fetch the same price in trades when the seller cannot recognize or be convinced of the quality of the coin being traded, and this may lead to fewer or no trades involving good coins. When both parties do know the difference, they will trade both good and bad coins, with the latter at a premium. This argument, however, rationalizes Gresham's Law only when good and bad coins are hard to distinguish, for example during medieval debasements in which debased coins were almost identical to the original ones (and thus hard to distinguish) but contained less silver. In most of the cases for which Gresham's Law has been cited, such as milled and hammered money, gold and silver, metal and paper, the monies were clearly distinguishable, and this refinement of Gresham's Law would not apply.

It should now be apparent that trying to salvage Gresham's Law in its lapidary and universal form is hopeless. The phrase would be more useful, not as a general law that excuses the user from providing an explanation, but as a class of outcomes that may or may not obtain, depending on the model's assumptions or the historical episode's circumstances.

**Gresham's Law and bimetallism**

Since Gresham's Law owes its fame to its role as an argument against bimetallism during the extensive debates of the late 19th century, a word on this topic is in order. Bimetallism – that is, the concurrent circulation of gold and silver currency at a constant exchange rate – would always be defeated by Gresham's Law: whichever metal was cheaper on the market than at the legal rate would always displace the other. Its application in this context is misplaced. As has been shown (Walras, 1977, p. 339; Velde and Weber, 2000), bimetallism is a stable monetary system in which exogenous fluctuations (in supply, monetary or non-monetary demand) are accommodated by fluctuations in the relative shares of the two metals in circulation. An increase in the supply of gold need not result in any change in the relative price of the metals, as long as enough gold can be taken out of, and enough silver added to, non-monetary uses, keeping the ratio of marginal utilities constant. This process of displacement of one money by the other takes place precisely as long as the two monies are substitutes at a constant relative price, meaning that neither one can be said to be ‘worse’ than the other.

Article

Zvi Griliches was one of the most important and influential empirical economists of the second half of the 20th century. His research contributions were wide-ranging and seminal, and through his students, collaborators and colleagues he greatly affected the conduct of empirical research in economics.

Zvi Griliches was born in Lithuania to a well-educated Jewish family. At age 11, along with his parents and sister, Griliches was moved into the ghetto in German-occupied Kaunas, where he remained until 1944, when he and his father were separated from his mother and sister and were sent to Dachau concentration camp. His father died there from starvation, and his mother died from typhus in the Stutthof concentration camp. In May 1945 Griliches was liberated by General Patton’s 3rd US Army. After spending a year in Germany, he attempted to go to Palestine, but was prevented by the British
from entering, and was held for nine months in an internment camp on Cyprus. He arrived in Palestine in September 1947.

Griliches then spent three years in several kibbutzim, focusing much of his spare time on learning English and mathematics. Although he never went to high school, he taught himself sufficiently well to pass an external high-school equivalence examination in 1950. After studying history for a year at the Hebrew University, Griliches applied for and was awarded a scholarship by the University of California at Berkeley, where he chose agricultural economics as his major field of study. Griliches completed Berkeley's undergraduate degree requirements in two years, took his first econometrics course from George Kuznets (Simon's brother), and earned his Master's degree in 1954, at which time he transferred to the University of Chicago, where he completed his Ph.D. in 1957, writing a seminal dissertation on the economics of the diffusion of hybrid corn. After 15 years at Chicago, in 1969 Griliches moved to Harvard. In the late 1970s, he became the first Director of the National Bureau of Economic Research's Program on Technological Progress and Productivity Measurement. Elected to the National Academy of Sciences in 1975 and President of the American Economic Association in 1993, Griliches also served as co-editor of *Econometrica* for a decade, and won the John Bates Clark Medal at age 35. He died from cancer in 1999. Further details on his life are found in Lerner (2004) and Trajtenberg and Berndt (2001).

Griliches' lifelong research focus involved detailed analyses on the role of technological change as a principal driver of long-run economic growth, and included examination of the determinants of the diffusion of new technologies, the measurement of physical, human and R&D capital, the role of education, and the contribution of R&D to productivity growth. Griliches devoted a great deal of attention throughout his career to properly measuring various inputs and outputs, and adjusting prices for quality change. Although economic growth theory in the late 1950s emphasized the role of disembodied technological progress and ‘manna from heaven’, Griliches (1957; 1958; 1960a) instead developed the view that technological progress is itself an economic phenomenon amenable to economic analysis. In formulating this theme and building supportive empirical evidence, Griliches and his collaborators enlarged considerably the set of econometric tools and procedures now commonly employed by empirical economic researchers. These econometric tool innovations included the use of distributed lags (1961b; 1967a; 1984a), procedures for dealing with measurement error and unobservable variables (1974; 1975; 1977; 1978), and with discrete count data (1984b).

Much of Griliches' early empirical research focused on measuring inputs, outputs and productivity in agriculture (1960a; 1964), but later on it extended to other sectors of the economy, particularly the service sectors (1992; 1994a; 2000a). The theoretical framework integrating these measurement issues involved use of the production function (1964; 1967b; 1969; 1970; 1971). He initially focused on measurement of physical capital inputs (1963; 1966; 1984a), but subsequently on issues involving measurement of labour input that generated several influential strands of research. One important literature involved establishing relationships between quality-adjusted labour inputs, education, and rates of return to schooling (1975; 1979; 1986a; 1997; 2000b). A related literature examined complementarity between physical capital and skilled labour (1969; 1977; 1994b).

In addition to examining the relationships among outputs and labour and capital inputs, a great deal of Griliches' research focused on the special role of R&D, differences between private and social returns to R&D, and the impact of R&D on productivity growth (1958; 1964; 1980; 1994; 1998). This research then led to a more detailed analysis of R&D, including a host of important studies that examined the extent to which patents served as a useful indicator of inventive activity generated by R&D (1986b;
Another of Griliches' seminal contributions involved reviving intellectual and policy interest in the use of hedonic multivariate regression techniques to adjust observed prices for changes in observed and unobserved quality over time. In large part this research reflected Griliches' scepticism about measuring productivity growth as the 'residual', which in its simplest form simply subtracted the growth of traditionally measured inputs from the growth of outputs. To what extent, he reasoned, could what goes into that residual ('a measure of our ignorance') reflect instead measurement and specification errors, rather than technological and other quality change? This led Griliches to undertake empirical analyses initially linking prices of new automobiles to observed characteristics (1961a), as well as prices of used automobiles to operating cost characteristics, such as fuel efficiency and gasoline prices (1986d).

Subsequent research examined the extent to which traditionally constructed government price statistics for certain high-technology goods such as personal computers overstated price inflation (or understated price deflation) by failing to incorporate fully the quality attribute improvements that were embodied in new goods (1993a; 1995). Yet another strand of this hedonic price research extended into prescription pharmaceuticals (1996), where problems of a new goods bias and oversampling of older goods were particularly important (1993b; 1994c). Adjusting measures of medical price inflation for changes in outcomes from medical treatments was a focus of Griliches' work with collaborators just prior to his death in 1999 (2000a).

Griliches' interest in price measurement led to his being appointed a member of both the 1960–61 Stigler Commission (resulting in 1961a), and the Boskin Commission of 1995–96, each of which provided influential and thoughtful recommendations on price measurement issues facing the U.S. Bureau of Labor Statistics. Although he was also named a member of the National Academy of Science Panel on the Conceptual, Measurement and Other Statistical Issues in Developing Cost-of-Living Indexes (1999–2001), because of his ill health and subsequent death in late 1999 he was unable to contribute directly to the final report.

The gross substitute assumption is used to establish the existence and uniqueness of an equilibrium and to prove the equilibrium to be stable for a dynamic adjustment system for prices. The gross substitute assumption also implies results of comparative statics, that is, results on the displacement of equilibrium that follows from shifts in demand or changes in initial stocks. The concept of gross substitutes was introduced by Mosak (1944) in the context of a pure trading model. A definition with wider application is the one used by Morishima (1964).

**Article**

The assumption that goods are gross substitutes is applied to a set of excess demand functions \( e_i(p_1, ..., p_n), i = 1, ..., n \), where \( p_i \) is the price of the \( i \)th good and \( e_i \) is the excess demand for the \( i \)th good. The concept was introduced by Mosak (1944) in the context of a pure trading model. However, his definition required that \( \partial e_i / \partial p_j \) have the same sign as the substitution term in the Slutsky equation as well as be of positive sign. That is, the income effect should not overbalance the substitution effect. At about the same time Metzler (1945) said simply that the \( j \)th good is a gross substitute for the \( i \)th good if \( e_{ij} = \partial e_i(p) / \partial p_j > 0 \) holds, and this has been the meaning used in later papers when the functions \( e_i \) have been assumed to be differentiable.

A definition with wider application is the one used by Morishima (1964). By this definition the \( j \)th good
is a gross substitute for the $i$th good if $e_i(p) < e_i(p')$ whenever $p \leq p'$, $p_j < p_j'$, $p_k = p_k$ for $k \neq j$. We will say that the assumption of gross substitutes holds if $e_i(p) < e_i(p')$, $i = 1, \ldots, n$, for all $p$ and $p'$ such that $p \leq p'$, $p \neq p'$, and $p_j = p_j'$. If $e(p)$ is differentiable, this assumption implies that the $n \times n$ matrix $[e_{ij}(p)]$ has positive off-diagonal elements for all $p$ in the interior of the domain of $e(p)$. A matrix with this property and a negative diagonal is often referred to as a Metzler matrix. We will say that the assumption of weak gross substitutes holds if the condition $e_i(p) < e_i(p')$ is replaced by the weak inequality $e_i(p) \leq e_i(p')$. In the case of differentiable $e(p)$ it is implied by the assumption of weak gross substitutes that $[e_{ij}(p)]$ has non-negative off-diagonal elements. That these assumptions are not empty is shown by the case of excess demands defined by Cobb–Douglas utility functions of the form

$$U(x) = \prod_{i=1}^{n} x_i^a_i$$

where $\sum a_i = 1$. The excess demand function for a consumer in a pure exchange economy, holding initial stocks $\bar{x}$, is $e_i(p) = (a_i \sum_{k=1}^{n} p_k \bar{x}_k / p_i) - \bar{x}_i$ so $e_i(p) = a_i \bar{x}_j / p_i \geq 0$ for $i \neq j$. If the initial stock of every good is positive for the whole market, the assumption of gross substitutes is satisfied.

A price vector $p$ is said to be an equilibrium of the set of demand functions if $e(p) \leq 0$. The gross substitute assumption is used to establish the existence and uniqueness of an equilibrium and to prove the equilibrium to be stable for a dynamic adjustment system for prices. The gross substitute assumption also implies results of comparative statics, that is, results on the displacement of equilibrium that follows from shifts in demand or changes in initial stocks.

The following assumptions will be made on $e(p)$.

- (B) $e(p)$ is defined for all $p > 0$, and $p^0 \rightarrow p$ where $p_i = 0$ for $i \in I, p \neq 0$ implies $\sum_{i \in I} e_i(p) \rightarrow \infty$. Also $e(p)$ is bounded below.
- (C) $e(p)$ is single-valued and continuous for $p > 0$.
- (H) $e(\lambda p) = e(p)$ for any $\lambda > 0$, that is $e(p)$ is positively homogeneous of degree 0.
- (W) $\sum_{i=1}^{n} p_i e_i(p) = 0$, that is, $e(p)$ satisfies Walras’s Law.

The example of Arrow–Hahn (1971, pp. 29–30), where demand is derived from the utility function $u(x) = x_1^{1/2} + x_2^{1/2} + x_3^{1/2}$ where $x$ is the consumption bundle, shows that assumption B cannot easily be improved.

**Uniqueness**

The existence of a positive equilibrium under assumptions B, C, H, and W does not require an assumption of gross substitutes (see Debreu, 1970). However, if there should exist an equilibrium price $p$ when gross substitutes is assumed, $p > 0$ must hold. This follows from the fact that $p_i = 0$ for some $i$, and $p \neq 0$, is inconsistent with assumption H in that case, since it must at the same time be true, for $\lambda > 1$, that $e_i(\lambda p) = e_i(p)$ and $e_i(\lambda p) > e_i(p)$. Thus $e(p)$ cannot be defined at such a $p$. 

http://www.dictionaryofeconomics.com.proxy.library.csi.c...edu/article?id=pde2008_G000119&gto=B&result_number=693|2|9|1|2009-1-2 0:39:02
Make the assumption that all goods are gross substitutes. Assume that two equilibria exist, say $p$ and $p'$ where $p' \neq \lambda p$ for any $\lambda > 0$. By assumption H we may choose $p$ and $p'$ so that $p_i = p'_i$ for some $i$ and $p_j \leq p'_j$ for $j \neq i$. Then by gross substitutes $e_i(p) < e_i(p')$. But $p$ and $p' > 0$ and assumption W implies that $e_i(p) = e_i(p') = 0$, which is a contradiction. Thus an equilibrium price vector is unique up to multiplication by a positive number.

Consider a partition of the goods into two non-empty subsets $I$ and $J$. Say that the excess demand functions are connected if for any such partition $p_i = p'_i$ for all $i \in I$ and $p_j < p'_j$ for all $j \in J$ implies that $e(p) \neq e(p')$. Then by a similar argument, uniqueness of equilibrium may be seen to hold when weak gross substitutes and connectedness are assumed. Strictly speaking, connectedness need only hold at an equilibrium point.

If weak gross substitutes is assumed without connectedness, uniqueness may fail. However, it may be shown that the set of equilibrium price vectors is convex (McKenzie, 1960). Arrow and Hurwicz (1960) proved that the weak axiom of revealed preference holds between any equilibrium price vector $p$ and any non-equilibrium price vector $p'$ when weak gross substitutes is assumed. This means that $0 = p' e(p) = p' e(p')$ implies $p e(p') > p e(p) = 0$. In other words, $p e(p') > 0$. Suppose $p$ and $p'$ are both equilibria and consider $p'' = \alpha p + (1 - \alpha) p'$ for $0 < \alpha < 1$. If $p''$ is not an equilibrium $p'' e(p'') = \alpha p e(p'') + (1 - \alpha) p' e(p'') > 0$ which contradicts assumption W, Walras's Law. Thus $p''$ is an equilibrium and the set of equilibria is convex.

**Comparative statics**

The modern approach to the comparison of equilibria after a shift of demand was begun by Hicks (1939). The fact that the Hicksian theorems hold locally when the excess demand functions satisfy the gross substitute assumption was proved by Mosak (1944). A global treatment of comparative statics in this context was given by Morishima (1964). Assume weak gross substitutes. Let demand shift from the $i$th good to the $j$th good. Let $p$ and $p'$ be the old and new equilibrium prices, $e$ and $e'$ the old and new excess demand functions. Then

$$p'_i e'_i(p) + p'_j e'_j(p) = \sum_{i=1}^{n} p'_k e'_k(p) > 0, \quad \text{by the Weak Axiom}.$$ (1)

On the other hand,
Multiply (1) by $p_i$ and (2) by $p_j$ and subtract to obtain $p_i p_j' - p_j p_i' > 0$, or $p_j' / p_j > p_i' / p_i$. Thus the price of the $j$th good increases relative to the price of the $i$th good.

Assume that all goods are gross substitutes. Then a shift in demand from the $i$th good to the $j$th good raises the price of the $j$th good relative to all other goods and lowers the price of the $i$th good relative to all other goods. These results are immediate from the fact that the good that rises in price relative to some goods and falls relative to none must experience a fall in demand and the good that falls in price relative to some goods and rises relative to none must experience a rise in demand. But only the $j$th good can absorb a rise and only the $i$th good can absorb a fall and still have demand equal to 0 after the shift has occurred. All other goods have zero excess demands at the old equilibrium prices after the shift, and the excess demands at the new equilibrium prices must also be zero. The same results follow from weak gross substitutes if any subset of the excess demand functions with $n - 1$ members is connected.

If the $e_i(p)$ are assumed to be continuously differentiable, the local theory of comparative statics is equivalent to determining the sign pattern of the inverses of the principal submatrices of order $n - 1$ of the Jacobian $[e_{ij}]_{i,j = 1, \ldots, n}$. The gross substitutes assumption implies that $e_{ij} > 0$ for $i \neq j$. Then either assumption H or W implies that the inverses of these submatrices have all elements negative.

Choose the $n$th good as numeraire, and choose units so equilibrium prices $p_i = 1$, all $i$. Then $\frac{d p_i}{d \alpha} = - (\frac{[e_{ij}]_{mn}}{h})_{ih}^{-1}$ if $\partial e_h(p, \alpha) / \partial \alpha = 1$. This is minus the $i$th element of the $h$th column of the inverse matrix of the submatrix where the $n$th row and column are omitted. Thus $\frac{d p_i}{d \alpha} > 0$, and it may be shown that $\frac{d p_h}{d \alpha} > \frac{d p_j}{d \alpha}$ for $i \neq h$ or $n$. If weak gross substitutes is assumed but the Jacobian and its $n - 1$ principal minors are indecomposable the same conclusions follow.

The local results may be extended to the case where there is a numeraire and the goods other than the numeraire may be partitioned into two non-empty subsets with indices in $I$ and $J$, such that $e_{ij} > 0$ for $i \neq j$ and $i$ and $j$ in the same subset, while $e_{ij} < 0$ for $i$ and $j$ in different subsets. If the principal minors of $[e_{ij}]$ of order $n - 1$ have dominant diagonals, at equilibrium with the equilibrium prices as multipliers, the shifts of demand raise the price of the good to which demand has shifted and also the prices of all other goods in the subset of the partition to which it belongs, while lowering the prices of the goods in the other subset. Also the beneficiary of the demand shift has the largest change in equilibrium price in absolute value. These results are seen to follow from those for gross substitutes by considering the matrix formed by pre- and post-multiplying a principal minor of $[e_{ij}]$ by a diagonal matrix $D$ with $d_{ii} = 1$ for $i \in I$ and $d_{jj} = -1$ for $j \in J$. This case was first analysed by Morishima (1952). The gross substitute case and the Morishima case may be shown to be the only sign patterns for a Jacobian matrix of the demand functions with all elements non-zero which allow the inverse matrix to be signed without quantitative information (see Bassett, Habibagahi and Quirk, 1967).
Stability

Since weak gross substitutes implies the weak axiom of revealed preference which in turn implies local stability of the tâtonnement for both the usual price adjustment models, with and without a numeraire (Arrow and Hurwicz, 1958), there is no special advantage for gross substitutes in local analysis of stability. However, for global results on stability the gross substitute assumptions are the only ones known with much plausibility. In order to use the weak axiom the adjustment must be, after proper choice of units,

(I) \[ p_i = e_i(p), \]

for all goods other than the numeraire, if any, where \( \dot{p}_i = \partial p_i / \partial t \), and (I) must hold globally. Excess demand is now assumed to be continuously differentiable. In order to use the other major possibility, a dominant diagonal for the matrix of demand elasticities, assuming a numeraire, the adjustment process

(II) \[ p_i = p_i e_i(p), \]

is used for the non-numeraire goods (see Arrow and Hahn, 1971, p. 293). While (II) may be more reasonable than (I) for a global adjustment rule it is also very special. On the other hand, when weak gross substitutes is assumed, stability may be proved for the adjustment rule

(III) \[ \dot{p}_i = h_i(p), \]

for all goods other than the numeraire, if any. The only special requirements placed on \( h_i(p) \) are that it should be continuously differentiable and have the sign of \( e_i(p) \). The adjustment rule III was proposed by McKenzie (1960) and global stability was proved using as a Lyapunov function the value of positive excess demand, \( V[\rho(t)] = \sum_{i \in P} \rho_i e_i(p), \rho = \{i e_i(p) \geq 0\} \). The tâtonnement is shown to converge to the convex set of equilibrium prices. If the excess demand functions are connected, the equilibrium is unique.

Arrow and Hurwicz (1962) proved that the convergence of process III with weak gross substitutes is, in fact, to a particular equilibrium price vector, which will depend on the initial prices. This is clear once it is recognized that the goods whose prices are highest relative to some equilibrium price cannot be in
excess demand and their prices cannot rise, and *mutatis mutandis* for the prices which are lowest. Thus the prices during tâtonnement cannot retreat from any equilibrium price vector. In the case of gross substitutes this line of argument is very simple and effective, since the prices actually fall and rise respectively.

In the theory of tâtonnement prices are revised according to excess demand but no trading occurs until equilibrium is reached. However, the stability of the adjustment process for a pure exchange economy is not lost if trading occurs at market prices, so long as the excess demand that drives the tâtonnement is determined by the maximization of utility by each trader under a budget equal to the value of the stocks he currently holds (Negishi, 1961). The crucial fact is that trading at market prices has only second-order effects on excess demand. However, the price to which the process converges now depends on initial conditions and the course of trading.

It was pointed out by Rader (1972) that the production sector of the economy is unlikely to satisfy the gross substitute assumption in the demand for factors. As a consequence it seemed that the range of application of the gross substitutes assumption was effectively confined to pure trading economies. However, Rader was able to prove a local stability theorem assuming gross substitutes only for households. The production sector is made up of a finite number of firms with strictly convex production possibility sets. The key to the argument is that \( p[e^H] = 0 \) at equilibrium, where \( e^H(p) \) is household excess demand. This is established by differentiating Walras's Law \( p e^F(p) + p e^H(p) = 0 \) to give

\[
 e^F(p) + e^H(p) + p[e^F] + p[e^H] = 0.
\] (3)

Since the first two terms sum to 0 at equilibrium, and the third term is 0 by profit maximization, (3) implies \( p[e^H] = 0 \). Then the Jacobian of the adjustment system I with a numeraire is negative definite at equilibrium and local stability follows.

**Generalizations**

Mukherji (1972) pointed out that some gross substitute theorems carry over if the weak gross substitute pattern is established in a transformed goods space. In particular, if there exists a matrix \( S \) such that \( S^{-1}[e_{ij} + e_{ji}]S \) is indecomposable with off-diagonal elements non-negative, the tâtonnement is locally stable for the process I, with or without a numeraire. Also a rise in demand for the \( i \)th good causes the \( i \)th equilibrium price to rise. Ohyama (1972) shows that similar results follow if there is a stochastic matrix \( G \) which is positive definite and \( G[e_{ij}] \) or \( G[e_{ij} + e_{ji}] \) satisfies the conditions above. Uzawa (1960) proved that a discrete tâtonnement defined by \( P_i(t + 1) = \max\{0, p_i(t) + f_i(t)\} \) where \( f_i(t) = \beta_i(e_i[p(t)]) \) is globally stable when the Weak Axiom holds and \( \beta_i > 0 \) is sufficiently small. He
assumes a numeraire and some additional differentiability and nonsingularity conditions. Howitt (1980) defines a generalized gross substitute notion where \( e(p) \) is allowed to be a convex valued correspondence rather than a function. This assumption of generalized gross substitutes holds if

1. (a) for all \( p, p' > 0 \), if there is a partition of indices for goods into non-empty subsets \( I \) and \( J \) where \( p_i' = p_i \) for all \( i \in I \) and \( p_j' > p_j \) for all \( j \in J \) than \( \sum_{i \in I} p_i x_i' > \sum_{i \in I} p_i x_i \) for all \( x' \in e(p) \), \( x' \in e(p') \);
2. (b) strict inequality holds in (a) if \( p \) is an equilibrium.

Howitt proves that the equilibrium price vector is unique and globally stable for the price adjustment process

\[
(IV) \quad \dot{p}_j \in e(p),
\]

under generalized gross substitutes, when assumptions C, W, and H hold and an equilibrium exists. Excess demand \( e(p) \) is assumed to be upper semi-continuous. He applies his result to the linear economy described by Gale (1976) and shown to satisfy gross substitutes by Cheng (1979).

Arrow and Hurwicz (1962) extended the adjustment process III to include expected prices. Let \( q \) represent expected prices. Then their process with adaptive expectations is

\[
\dot{p}_j = h_j(p, q), \quad \text{if} \quad p_j > 0 \quad \text{and} \quad h_j(p, q) > 0, \quad = 0, \quad \text{otherwise}
\]

\[
(V) \quad \text{sign } h_j(p, q) = \text{sign } e_j(p, q), \quad \text{or} = 0 \quad \text{if } i \text{ is a numeraire}
\]

\[
\dot{q}_i = a_i(q_i - p_i)
\]

They prove global stability for this process under weak gross substitutes with some auxiliary assumptions. Arrow and Hahn (1971) give a proof of global stability with an assumption of gross substitutes and assumptions B, C, H, and W. By the gross substitute assumption in this context is meant that \( \frac{\partial e_i(p, q)}{\partial p_j} > 0 \) for \( i \neq j \), and \( \frac{\partial e_i(p, q)}{\partial q_j} > 0 \) for all \( j \). The adjustment function \( h_i \) is assumed to be continuously differentiable.
Arrow and Hahn also prove a global stability theorem for a model in which expected prices \( q_i \) are given as functions \( q_i(p) \) of current prices. This is in accord with models of temporary equilibrium. They prove global stability for adjustment process II with a numeraire, assuming gross substitutes for \( e(p, q) \) and the Hicksian elasticity of substitution \( \varepsilon_j = \frac{d}{d \log p_j} \log q_j \leq 1 \), which is consistent with Hicks's presumption when the strict inequality holds (see Hicks, 1939, p. 251).

In this model of the tâtonnement for temporary equilibrium \( q(p) \) is presumably the expected price on the assumption that \( p \) is an equilibrium price. It is not so clear how to justify adaptive expectations in the tâtonnement setting.

Article

Herschel I. Grossman was born in Philadelphia on 6 March 1939. He obtained a BA from the University of Virginia in 1960, a B.Phil. from Oxford in 1962, and a Ph.D. from Johns Hopkins in 1965. He joined Brown University's economics faculty in 1964. He died suddenly while attending a conference in Marseilles on 9 October 2004.

In the early 1970s Grossman, in cooperation with Robert J. Barro, produced path-breaking research on the foundations of Keynesian macroeconomics. Barro and Grossman's main joint contribution was the article ‘A General Disequilibrium Model of Income and Employment’ (1971a). This was the first formalization linking the labour market and the output market in a general-disequilibrium setting with exogenous wage rate and price level, in which labour demand is constrained by output sales while the demand for goods is constrained by sales in the labour market. Generalized excess supply implied a Keynesian demand-multiplier effect. The analysis also shed light on cases of generalized excess demand, such as in socialist economies with artificially low prices. This work unified complementary strands of the literature – particularly, Patinkin (1965, ch. 13) and Clower (1965) – within a coherent choice-theoretic framework, and for many years was the most cited article ever published in the American Economic Review. Barro and Grossman summarized and extended their analysis in the landmark book Money, Employment, and Inflation (1976). Independent appraisals of the non-market-clearing paradigm and its limits were given by Barro (1979) and Grossman (1979). See also Grossman's entry on Monetary Disequilibrium and Market Clearing in the first (1987) edition of The New Palgrave: A Dictionary of Economics.

In his subsequent work Grossman became increasingly interested in understanding the foundations of economic policy and the effects of conflict on the economy, and made innovative contributions to political economy and the economics of appropriation (see Kolmar, 2005, for a survey). Building on
Haavelmo (1954), Grossman modelled conflict as an economic activity by agents allocating resources over various uses, including the uses for appropriative conflict itself. His contributions in this area comprise theories of governments as kleptocracies (1990; 1994a; 1999), insurrections (1991), appropriation and land reform (1994b), effective property rights (1995), anarchy, predation and the state (2002), and many others.

Grotius (de Groot), Hugo (1583–1645) : The New Palgrave Dictionary of Economics

Grotius (de Groot), Hugo (1583–1645)

P.G. Stein
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

combinations; contract theory; Grotius (De Groot), H.; natural law; private property; usury

Article

Legal theorist, philosopher and theologian, Grotius was born in Delft on 10 April 1583 and died in Rostock on 28 August 1645. An infant prodigy, Grotius entered the University of Leyden at the age of 11, and at 15 was hailed by Henry IV of France as ‘the miracle of Holland’. Deciding on a legal career, he had become Advocate General of Holland, Zealand and West Friesland by the age of 24. In this period he wrote a treatise on the Law of Prize, of which the part dealing with freedom of the seas (Mare Liberum) was published in 1609. Because of his support for the moderate Arminians against the Calvinists, he was in 1619 imprisoned in Loevestein castle, and while there wrote an introduction to the law of Holland (Inleidinge tot de Hollandsche Rechtsgeleertheyd, published in 1631) and a tract on the truth of the Christian religion, the first of many theological writings. After two years, his wife arranged his escape in a chest ostensibly holding books, and thereafter he lived mainly in France, where he served for ten years as ambassador of Sweden.

Grotius' greatest work is De iure belli ac pacis (On the law of war and peace), published in 1625 and widely translated (six editions appeared in English before 1750). Written during the upheavals of the Thirty Years War, it laid down certain fundamental principles of law which purported to have the certainty of mathematics and absolute validity in all times and in all places. These principles both provided a standard for measuring the validity of the positive law of any state and also formed the basis for governing the relations between states. The work had enormous influence on the ethical and legal thought of the 17th and 18th centuries and is regarded as the beginning of ‘the law of nature and of nations’, the forerunner of modern international law.

Grotius built on the learning of late scholastic writers on natural law, such as Suarez, but he tried to make it independent of theological doctrine, so that amid the factionalism of the Reformation its principles would be unaffected by conflicting religious views. For him these principles could be proved in two ways: a priori, by logically deducing them from the rational and social nature shared by all
mankind, and a posteriori, by showing that they were generally accepted by the consensus of writers – at least in more civilized nations – through the ages. For when many writers ‘at different times and different places affirm the same thing as certain, that ought to be referred to a universal cause’, which must be either correct conclusion drawn from the principles of nature or common consent (Prolegomena, sec. 40). Grotius concentrated on the latter approach, and dealt particularly with property and contract, the area of law of most concern to market societies and to nation states dealing with each other at arm's length.

Relying on the Bible narrative and on accounts of American Indians, he envisaged a primitive state of nature in which everything was held in common. When primitive simplicity gave way to specialization in agriculture and cattle raising, the conflicts that arose led first to division of lands among nations and then to division among families; thus community of property was replaced by private property. ‘This happened not by a mere act of will … but rather by a kind of agreement, either expressed, as by a division, or implied, as by occupation’ (De iure belli II. 2, 21–5).

His doctrine of contracts was loosely based on Aristotle. He tolerated monopolies but condemned combinations to raise prices or to prevent the movement of goods by fraud or force. Although the law of nature did not forbid usury, divine positive law forbade it for Christians. However, Grotius adopted the canonist distinction between usury, which was forbidden, and receiving interest, which was permissible, if the rate was reasonable as in the positive law of Holland.

group selection

Arthur J. Robson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Group selection’ is the biological term for the possibility that a characteristic that is beneficial to the group but possibly costly to the individual is evolutionarily successful. Although logically possible, it is generally viewed with scepticism by biologists. It is not problematic that group selection would favour an equilibrium whose payoffs dominated those of another, because there is then no conflict with individual selection within each group. Group selection might reject inefficient equilibria in a repeated game, for example. Since human societies can support rather arbitrary outcomes as equilibria, group selection could play a role in human evolution.

Article

It is uncanny how close Darwin (1859) came to the modern view of biological evolution, given that detailed understanding of the mechanics of genetic inheritance lay in the future. Darwin understood how mutations might arise randomly rather than in response to circumstances. Further, he espoused the modern dogma concerning the separation of the germ line (sex cells) and the somatic line (all other bodily cells). Under this dogma, which explicitly contradicts the earlier biologist Lamarck, only those characteristics present in the germ line, not those acquired during the individual's lifetime, are genetically inherited by offspring. If a germ line characteristic produces a somatic or behavioural attribute that is best suited to the ecological or social circumstances of the individual (yielding the most offspring), then the attribute and the underlying genetic characteristic will become more common. Darwin typically emphasized that a particular variation would spread if this variation led to greater
reproductive success for individuals and were inherited by their descendants. However, Darwin also strayed occasionally into what would now be called ‘group selection’, especially when he was considering the implications of his theory for humans (Darwin, 1871, p. 166). Thus, he thought an individual human might engage in behaviour that is beneficial to the survival of a group, even if this behaviour had a fitness cost to the individual. It is of interest that Darwin refers to humans in particular, since it is still sometimes argued that group selection might be important for our own species.

The group selection debate in biology

There is a ‘folk wisdom’ appeal to group selection in biology. This mechanism was once invoked in popular accounts of natural selection. For example, the idea that a predator species is doing a prey species a favour by eliminating its weakest members involves an egregious form of group selection. The English experimental biologist Wynne-Edwards provided an especially explicit manifesto on group selection and became thereby a favourite target for those wishing to argue against it. In Wynne-Edwards (1962), for example, he argued that birds limit the size of their clutches of eggs to ensure that the size of the population does not exceed the comfortable carrying capacity of the environment.

These particular group selection arguments were effectively devastated by Williams (1966). If a new type of individual does not so obligingly limit her clutch, why would this more fertile type not take over the population, without regard for the standard of living? Indeed, there are compelling arguments why it is in the interests of the individual to limit her clutch size. For example, it might well be that, beyond a certain point, an increase in the number of eggs reduces the expected number of offspring surviving to maturity, because each egg then commands a reduced share in parental resources. A finite optimum for clutch size is then to be expected.

Dawkins (1976 and 1982, for example) has been even more insistent than Williams on rejecting group selection, going further in arguing for the primacy of the gene as a still lower-level unit of selection. There certainly are phenomena best understood at the level of the gene. Consider, for example, sickle-cell anemia. At the relevant locus, there exists a particular variant gene, a particular allele, that is. If one of the two alleles that are present at this locus is this variant gene, the individual has improved resistance to malaria. However, if both alleles are of this variant type, the red blood cells have a characteristic sickle shape. Such cells malfunction by not carrying adequate oxygen, implying increased mortality. Under sexual reproduction, there is no way of maintaining only the individuals who have exactly one copy of the variant gene. Rather, both alleles are maintained as a stable mixture, where each allele is present in individuals who have quite different fitnesses.

There are presumably a fair number of cases where the interests of the gene and the individual do not conflict. In any case, it is often difficult to give concrete form to the gene as the unit of selection, given our ignorance of the details of the transformation of genes into individuals, particularly for complex behavioural characteristics. (Grafen, 1991, advocates finessing such detailed questions on the genetic basis of individual variation. This is his so-called ‘phenotypic gambit’.) Hence, despite the theoretical primacy of the gene, we restrict attention here to the comparison between the individual level and the group level of selection.

In order to fix ideas, consider the following outline of the classic model that addresses the issue of individual selection versus group selection.
The haystack model

The following is a simplified account of Maynard Smith (1964). There are a number of haystacks in a farmer's field, each of which is home to two mice. Each pair of mice now play the Prisoner's Dilemma game, with the usual two choices: cooperate or defect. Payoffs for each individual take the concrete form of the number of offspring, but reproduction is asexual, with offspring inheriting their mother's choice of strategy. There are a number of subsequent stages of play, where the mice in each haystack are paired at random to play the Prisoner's Dilemma game. The number of individuals within the haystack choosing each strategy then grows in an endogenous fashion, as does the overall size of the group. Every so often, once a year, say, the haystacks are removed, and the mice are pooled into a single large population. Now pairs of mice are selected at random from the overall population to re-colonize the next set of haystacks, and excess mice die.

Maynard Smith's intention here was to give the devil his due, by building a model in which group selection might well have an effect. At the same time, he wished to show that the parametric assumptions needed to make group selection comparable in strength to individual selection would be unpalatable. In order for group selection to be effective there must be a mechanism that insulates the groups from one another. Only then can a cooperative group be immune to infection by a defecting individual, and maintain its greater growth rate. Even with the temporary insulation of each haystack in this model, cooperation will evolve only if there are sufficient rounds of play within each haystack, so that defectors from a particular haystack are likely to be eliminated when the groups are reformed.

A loose description of the problem with group selection is that it relies too heavily upon a group becoming extinct as a likely consequence of a choice that is bad for the group. There is clearly scope, in reality, for individual selection, since individuals die frequently; group selection is less plausible, since there may not be enough extinction of groups.

An example of group selection?

Despite the disfavour into which group selection has fallen in biology, there remain examples of cases that are challenging to explain otherwise. One of these concerns the interaction of the myxoma virus and European rabbits in Australia. (Lewontin, 1970, proposed a group selection interpretation of this case. Sober and Wilson, 1999, pp. 45–50, give a – somewhat partisan – view of the subsequent debate.) English rabbits were introduced into Australia in a misguided attempt to recreate the English countryside in Australia, but their numbers grew out of control, causing massive economic damage to farms there. The myxoma virus was first identified in South American forest rabbits, where it was only mildly virulent. When this South American strain was originally tested on Australian rabbits, however, it seemed an ideal solution to the rabbit infestation there, since it killed nearly the entire sample. Unfortunately, in the long run, after the South American virus had been present in the Australian rabbit population for a while, the rabbit mortality rate fell dramatically.

Why? Perhaps the most obvious explanation is that the rabbit population had been selected to have greater resistance to the virus, consistent with individual selection of rabbits. That this was true to some extent was demonstrated by the finding that the new Australian strain of the virus had a greater effect on laboratory-bred Australian rabbits than on the feral stock. However, this effect was not sufficient to
explain the entire drop in rabbit mortality. Indeed, both laboratory and wild strains of Australian rabbits were less susceptible to the new Australian strain of the virus than they were to the original strain imported from South America. The virus had evidently evolved to be less virulent as a result of its interaction with the Australian rabbit population.

This situation might be roughly mapped onto the haystack model as follows. Consider a group of viruses to be those infecting a given rabbit. The evolutionary success of this group might best be promoted by settling for a moderate level of mortality for the host rabbit. Whatever the other advantages to the virus of strategies that induce high mortality in the rabbit, the early death of the current host makes transmission to a new host difficult. However, prolonging the life of the host is a public good from the point of view of the infecting viruses. A strain of virus with a strategy that was more lethal to the host could then grow as a fraction of the group of viruses. As in the haystack model, however, if there were enough generations of the virus within each rabbit's lifetime, this conflict between the group and the individual might be resolved in favour of the group, as suggested by the data.

Selection among equilibria

When does group selection matter in biology? In theory, it could lead to different results than would individual selection, as in the Prisoner's Dilemma, and as it may in above example. In practice, the above example is atypical, and group selection is usually a rather weak force. There is, however, one compelling scenario in which group selection would operate robustly, in any species. This is as a mechanism to select among equilibria (Boyd and Richerson, 1990). Consider a population that is divided into various sub-populations, which are largely segregated from one another, so that migration between sub-populations is limited. Each sub-population plays the same symmetric game, which has several symmetric equilibria. Play of this game involves a random matching of the members of each sub-population. Individual selection ensures that some equilibrium is attained, within each sub-population. But group selection is then free to operate in a leisurely fashion to select the Pareto-superior equilibrium, since there is no tension here between the two levels of selection.

Group selection and economics

Why does group selection matter in economics? Group selection is the most obvious mechanism for generating preferences in humans that might make them behave in the social interest rather than that of the individual. At stake, then, is nothing less than the basic nature of human beings. As an economist, one should be sceptical of the need to suppose that individuals are motivated by the common good. Economic theory has done well in explaining a wide range of phenomena on the basis of selfish preferences, and so the view of the individual as the unit of selection is highly congenial to economists. Furthermore, to the extent that armchair empiricism suggests that non-selfish motivations are sometimes present, these seem as likely to involve malice as to involve altruism. For example, humans seem sometimes motivated by relative economic outcomes, which involve such a negative concern for others. Group selection is a blunt instrument that might easily ‘explain’ more than is true.

There are, nevertheless, some aspects of human economic behaviour that are tempting to explain by group selection. For example, we have a proclivity for trade that may go beyond myopic self-interest. As
Darwin, an astute observer of both human beings and the natural world, observed on one of his visits to Tierra del Fuego,

Some of the Fuegians plainly showed that they had a fair notion of barter. I gave one man a large nail (a most valuable present) without making any signs for a return; but he immediately picked out two fish, and handed them up on the point of his spear. (Darwin, 1845, ch. 10)

That is, human beings are often willing to trade with strangers they will likely never see again, as might be analogous to cooperating in the one-shot Prisoner's Dilemma. There is no shortage of reliable data showing that human beings are capable of such apparently irrationally cooperative behaviour, in appropriate circumstances. Whatever the underlying reasons for this, it is clearly significant, and may even help account for the prodigious economic and biological success of humans. Furthermore, identifying the underlying reasons would help shape a theory of such behaviour that remains falsifiable; such a theory might also predict what alternative circumstances might induce non-cooperative or antagonistic behaviour. Group selection is an obvious avenue to explore in this connection.

It is sometimes argued, in particular, that the structure of hunter–gatherer societies helps account for cooperative behaviour. Hunter–gatherer societies were composed of a large number of relatively small groups, and individuals within each group were often genetically related. Perhaps, so the argument goes, we acquired an inherited psychological inclination towards conditional cooperation in such a setting, partly perhaps as a result of group selection. These inclinations then carried over into modern societies, despite genetic relatedness now being essentially zero on average. Seabright (2004), for example, argues eloquently that human societies cannot function on myopic self-interest alone, but also that the trust needed for exchange in market economies sprang from adaptations to archaic small groups. It is hard to believe, however, that hunter–gatherers never encountered strangers. If there were good reasons to condition on this distinction, why would corresponding different strategies not have evolved?

A phenomenon that looms large in the case of human beings is culture, by which is meant the non-genetic transmission of behaviour, by imitation of peers, for example. Many attempts to derive cooperative behaviour have focused then on group selection in models of cultural transmission. We now turn to this literature.

### Cultural group selection and economics

A spectacular and famous example of cultural group selection features the Nuer and Dinka, who lived as neighbouring ethnic groups in 18th century southern Sudan (Kelly, 1985). Despite the similarity of their environment, these two groups differed in various economic and political respects. Perhaps the key difference was that Dinka lived in small groups, the size of which was related to the needs of their economic activity. The Nuer, on the other hand, organized their society according to a patrilineal system that bound many such smaller units together, over a greater geographic area. Over a period of 100 years, the Nuer expanded their territory at the expense of the Dinka, killing or assimilating their rivals. Nuer culture, that is, was selected over that of the Dinka.
Despite the apparently strong military advantages of the Nuer political system over that of the Dinka, it
seems plausible that any individual – Dinka or Nuer – would have had the incentive to play the
appropriate role within their society. It would not have been possible for an individual Dinka to shift
unilaterally to Nuer behaviour.

Human societies have the capacity to render a wide range of behaviour optimal for the individual. If a
society wishes to adopt a rather arbitrary rule, it may well have adequate sanctions to enforce this (Boyd
and Richerson, 1992). As described above, group selection can then be relied upon to select between
various equilibria. Boyd et al. (2003) make the important additional point that, because punishment is
needed only infrequently near full cooperation, the weak force of group selection can support
cooperation as an equilibrium, without the usual need for punishment of those who fail to punish, and so
on.

Group selection is uncontroversial as a mechanism for selecting an efficient outcome within each group.
But this does not directly explain observations, such as Darwin's, of our apparent willingness to trade
with strangers. The difficulty is stark: defection is a strictly dominant strategy in the one-shot Prisoner's
Dilemma game.

One stark option is that cooperation is hard-wired. Bowles, Choi and Hopfensitz (2003) argue that, if
behaviour is directly genetically controlled, cooperative behaviour may then be sustained in the presence
of culturally maintained institutions. These institutions, food-sharing for example, serve to reduce the
negative impact on individuals of cooperative behaviour. Group selection arises from conflict between
groups, with more cooperative groups emerging victorious in such conflict.

However, human strategic behaviour is genetically mediated in a complex and poorly understood way,
and is not always cooperative. Even if we did somehow acquire a genetic inclination to cooperate in
archaic societies, shouldn't we now be in the process of losing this inclination in modern large and
anonymous societies?

A recent revival?

Sober and Wilson (1999) push energetically for a rehabilitation of group selection within biology. They
argue that group selection is closely related to other well-accepted phenomena. For example, they argue
that kin selection – the widely accepted notion that individuals are selected to favour their relations –
should be regarded as a special case of group selection.

In its simplest form, kin selection is the argument that individuals should undertake actions that benefit a
relation if this benefit, when deflated by the degree of relatedness, exceeds the cost to the first
individual. (This is ‘Hamilton's rule’ as in Hamilton, 1964.) The empirical evidence in favour of kin
selection is overwhelming – mothers, human and non-human, routinely make large sacrifices in favour
of offspring. Even economists would exempt such interactions from the general presumption of selfish
behaviour.

Sober and Wilson certainly make the case that these phenomena can be viewed in an integrated fashion.
Indeed, it is a consequence of the ‘Price equation’ (Price, 1970) that what matters most fundamentally is
the likelihood that altruistic individuals will be preferentially matched with other altruistic individuals.
In the case of kin selection, this could be ensured by a mechanism to directly recognize relations – by
smell, for example – or by indirect but reliable methods, such as, for example, assuming that those who
are found in proximity to one's mother are relations. Bergstrom (2002) provides the best introduction to the literature on group selection for economists. He presents a unified and intuitive treatment of the literature, and also stresses the key role of assortative matching. Thus, for example, if the subgroups in the haystack model are dispersed after one round of the game, and then randomly recombined, there is no force to group selection. Only if the subgroups remain together for repeated play of the game is there effective assortative matching. Such a structure seems less compelling for non-relations than it is for relations. Despite the formal analogies between kin selection and group selection, acceptance of the former does not then require acceptance of the latter. In the end, a sceptical but not dogmatic view of the importance of group selection to human economic behavior seems warranted.

growth accounting

Francesco Caselli
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Growth accounting consists of a set of calculations resulting in a measure of output growth, a measure of input growth, and their difference, most commonly referred to as total factor productivity (TFP) growth. It can be performed at the level of the plant, firm, industry, or aggregate economy. This article discusses the theoretical interpretation of the growth-accounting exercise, problems of measurement, and main empirical results. It concludes with a (very selective) history of the field.

Keywords

growth accounting; input–output analysis; measurement error; national accounts; production functions; research and development; specification error; technical change; total factor productivity; vintage capital

Article

Growth accounting consists of a set of calculations resulting in a measure of output growth, a measure of input growth, and their difference, most commonly referred to as total factor productivity (TFP) growth. It can be performed at the level of the plant, firm, industry, or aggregate economy. Current growth-accounting practice tends to rely on the theoretical construct of the production function both as a guide for measurement and as a source of interpretation of the results. Apart from the existence of a production function linking inputs and outputs, the main assumption is that factors of production are rewarded by their marginal product. In continuous time, this permits a representation of output growth as a weighted sum of the growth rates of the inputs, and an additional term that captures shifts over time in the production function. The weights for the input growth rates are the respective shares in total input payments. Since data on the growth of output and individual input quantities cover discrete periods of time, a discrete-time approximation to the weights is required. Current practice tends to use simple averages of the input shares at the beginning and the end of each period. In the special case that the production function is of the translogarithmic form, this procedure actually results in an exact decomposition; otherwise it can be interpreted as a second-order approximation.
It is customary to group inputs into broad categories. When output is measured as value-added the broad categories are labour and capital. When output is total production one has to add materials, which are occasionally further broken down with further entries for energy and services (giving rise to the so-called KLEMS accounting framework). This kind of grouping allows one to speak of, for example, the ‘contribution of labour (capital, materials) to output growth’. However, this grouping masks an enormous heterogeneity of the underlying inputs. This heterogeneity is the source of a large share of the measurement problems in growth accounting. These problems are most severe in the measurement of the growth of capital input.

Capital inputs are heterogeneous within vintages (for example, tractors versus personal computers) and across vintages (computers produced in 2006 versus computers produced in 2007). Heterogeneity within vintages is best addressed by having as fine a disaggregation of capital types as the data will allow. The most important data constraint on disaggregation of capital types occurs in the construction of type-specific shares in total capital income, as these require type-specific estimates of rental rates, which in turn require type-specific estimates of depreciation rates, capital gains and tax treatment. Heterogeneity across vintages, also known as embodied technical change, or quality change, poses even more difficult problems. Most practitioners’ ideal solution to this problem is to put the measurement of the stocks of different types of capital on a constant-quality basis, by applying appropriate deflators reflecting quality change to the corresponding investment series. However, the availability and/or accuracy of such deflators, whose construction generally requires hedonic methods, is currently limited for most countries, industries and capital types. As a result there is a presumption that the growth rate of (the efficiency units embodied in) the capital stock is often understated.

Construction of indices of labour input growth have conceptually similar problems. However, aggregation across types (for example, female, white, high-school graduates, of age 40 to 45 versus male, black, college graduate of age 35 to 40) is simpler as average rental rates (that is, hourly wages) for reasonably fine categories are reasonably well observed (while in the case of capital goods they must be estimated). The vintage problem is typically bypassed by assuming that there is no quality change within narrowly defined categories.

Another difficult problem is how to turn the growth in input stocks into growth in the flow of input services, that is, how to account for variation in the rate of utilization of labour and capital. Measuring labour in hours is helpful, but an issue of utilization still remains if effort per hour is not constant, as is likely. For capital, various adjustments based on proxies for utilization have been proposed, a classic one being a measure of electricity consumption. But this approach to the problem of measuring utilization creates a deeper problem of interpretation, or at least a conflict with the estimate of rental rates. This is because the latter are constructed in a way that assumes them to be invariant to the rate of utilization. But in this case the opportunity cost of setting the utilization rate to 100 per cent all the time is nil, and there should be no variation in utilization. Some more systematic adjustment to the theoretical framework, such as endogenous depreciation or limited opportunity for substitution between capital and other inputs, is therefore required to fully solve the measurement and interpretation challenges posed by variable utilization.

At the plant, firm, and industry levels a choice can be made between accounting for total production or value added. The total production approach is attractive, because after all it is total production that ‘comes out’ of the production process. Furthermore, the conditions for existence of a well-defined production function for total output are far less stringent than the conditions for existence of a function
linking valued added to capital and labour inputs. On the other hand, the results of growth-accounting exercises based on total output are very sensitive to the degree of vertical integration, and this causes severe problems of interpretation.

At the country level value added is obviously the only meaningful concept of output, no matter how stringent the conditions for an aggregate valued-added function. Because of the well-known shortcomings of standard measures of valued added as indicators of the ‘want-satisfying’ capacity of the economy, some attempts have been made to augment such measures by estimates of non-market outputs, chiefly the output of the education sector. Accounting for the effects of economic activity on the natural environment is very probably the next frontier.

Among the outputs of the growth-accounting calculation the one to receive most attention is usually the difference between output and input growth. This is somewhat surprising because the interpretation of this quantity is fraught with difficulties, as underscored by the multitude of phrases used to refer to this difference: besides TFP growth, ‘multi-factor productivity’ growth, ‘(Solow) residual’, ‘measure of our ignorance’, ‘rate of technical change’, and growth in ‘output per unit of (total) input’, among others. What is sometimes misunderstood is the relationship between the difference and technical change. An economic unit can use additions to its capital and labour either to directly produce more output, or to devise ways to rearrange the existing capital and labour so as to produce more (constant-quality units of) output, the latter being the definition of research and development (R&D). If it does so by equating the marginal products of labour and capital between direct production of output and indirect production of output through R&D, the extra output produced thanks to R&D will be fully ‘accounted for’ by the measured growth in capital and labour inputs. Hence, TFP growth does not really measure technical change as this term is commonly understood. Furthermore, failures of TFP growth to accelerate in periods/industries/firms experiencing increases in R&D spending do not need to be puzzling.

For the same reasons, TFP growth can be identified neither with disembodied nor with embodied technical change. Embodied technical change in capital-using industries is a reflection of disembodied technical change in capital-producing industries, but neither need necessarily show up in the TFP numbers, as long as R&D costs have been properly accounted for.

So what does show up? Under the maintained theoretical assumptions, the cleanest interpretation – apart from weather shocks, and costless, instantaneous flashes of inspiration (if they were not instantaneous an opportunity cost of time would have to be imputed) or innovations stumbled upon by luck, none of which seems susceptible to vary much over time and space, or with government policy – is R&D externalities. If the units performing R&D fail to capture all the social return from it, other units will experience costless growth in output per input, and this will be detected by TFP growth. Under this interpretation, a link may indeed be found between R&D and TFP growth, and if so it would be possible to use the framework to advocate policies to encourage R&D. Other forms of externalities may also give rise to positive TFP growth.

But since TFP is a residual, it also picks up, as all residuals, errors of specification and measurement. We have already discussed mismeasured input growth, chiefly in terms of incomplete adjustment for quality change. A failure to account for quality change in output will push TFP growth in the opposite direction. Note that mismeasured quality change in capital results in lower TFP growth in capital-producing industries, higher TFP growth in capital-using industries, and somewhat ambiguous effects on TFP at the aggregate level, though the net effect is usually deemed to be positive.

Many economies are likely to be characterized by frictions to the efficient allocation of resources among
economic units, implying that marginal products of homogeneous inputs are not equalized. In these cases improvements in the allocation of resources will also result in positive TFP growth.

It is impossible to overestimate the interest that growth-accounting calculations have elicited. There must be very few industries and countries for which some kind of input–output data exists that has not been used for performing a growth accounting exercise. Indeed, several national statistical agencies explicitly include the output of growth-accounting calculations, including TFP growth, into the national accounts.

I am unable to provide here an overview of this immense body of work, and the reader will have to refer to the country/industry/period of interest on a case-by-case basis. However there are a couple of broad lessons that can be distilled here. First, over the medium to long term, the residual accounts for a relatively minor portion of overall growth in output. For example for the United States it is possible to explain about two-thirds of growth in (market) output per worker over the post-war period by changes in the quality and quantity of inputs. For countries experiencing exceptionally high growth rates, such as the Asian Tigers between 1960 and 1990, this share is even higher. To the extent that the residual picks up measurement and specification errors, this is tantamount to saying that the performance of the growth-accounting methodology is very good by the standards of empirical work in economics. This interpretation is reinforced by the fact that, again by and large, the role of the residual tends to be systematically smaller in studies deploying better quality data.

Over shorter horizons, however, TFP growth is harder to underplay. For example a slowdown in TFP growth ‘accounts’ for a large fraction of the slowdown in output growth observed between the mid-1970s and the mid-1990s. Not coincidentally, the root causes of that slowdown remain as mysterious as ever.

While growth-accounting calculations can be performed at various levels of aggregation, and their interpretation is perhaps easier the smaller the unit of analysis, the origins of growth accounting are macroeconomic. The earliest growth-accounting exercises (Stigler, 1947; Schmookler, 1952; Abramowitz, 1956 – the latter also coining the expression ‘measure of our ignorance’) were a direct byproduct of the development of US aggregate national account data. One exception was agriculture, for which early growth-accounting experiments date to 1948 (Barton and Cooper) and 1951 (Kendrick and Jones). Kendrick (1956; 1961) compiled the first large-scale growth-accounting calculations broken down by many industries. He also introduced the phrase ‘total factor productivity’.

Solow (1957) laid out the theoretical foundations of growth accounting (a previous contribution in this direction by Tinbergen, 1942, with attendant calculations, was discovered by the English-language literature only subsequently). Solow (1960) and Jorgenson (1966) worked out the implications of embodied technical change. Denison (1962) introduced corrections for changes in the composition of the labour force. Griliches and Jorgenson (1966) and Jorgenson and Griliches (1967) put aggregation of inputs and outputs on a solid theoretical basis, particularly by showing how to correctly estimate rental rates. They also pioneered empirical approaches to quality change and variable utilization. This programme was further refined by Christensen and Jorgenson (1969; 1970) for the aggregate economy, and Fraumeni, Gollop and Jorgenson (1987) for a broad set of industry-level calculations which has shaped the way US national accounts are now constructed, and whose methods are widely accepted to be the gold standard for the purposes of productivity measurement.

Christensen, Jorgenson and Lau (1973) developed the translogarithmic production frontier, and Diewert

Civil war is obviously damaging for both society and the economy. The social consequences are often difficult to measure: for example, people die as a result of disease and are traumatized through rape or experience as child soldiers. However, the consequences for the economy are much more amenable to quantification, and a key economic research issue has been to try to classify and quantify the economic damage.

There are three consequences of civil war for economic growth. The most obvious is the loss of growth experienced by the country during the war. War is destructive of both the capital stock and normal economic activity. In addition to inflicting purposive destruction, rebel forces typically prey on economic activity within their military reach, since they have no official sources of finance. Government forces may adopt the same tactics: typically, lines of command are too loose to prevent the diversion of military force into decentralized predation. In such circumstances citizens with assets radically reduce their investment and resort to capital flight abroad, and poorer citizens may similarly retreat into subsistence activities that are less vulnerable. The consequences of civil war for the growth of gross domestic product (GDP) have been estimated from time series regressions, a typical result being that the annual growth rate is reduced by around 2.3 percentage points (Collier, 1999). Since the typical civil war lasts around seven years, by the end of the conflict the country is around 15 per cent poorer than it would have been had it remained at peace.

The second consequence for growth is the legacy of war – effects that arise after the war has ended. Peace does not usually enable the economy to rebound swiftly to its previous growth path. Even if the post-conflict peace is secure the economy will take several years to rebuild its capital stock, and some costs, such as a loss of human capital, may be irreversible. More typically, the legacy of civil war creates major problems for economic recovery. The peace itself may be insecure: around 40 per cent of post-conflict situations revert to conflict within a decade. The breakdown in social order during civil war
allows opportunistic behaviour to become more prevalent. Both the high macro-risk of conflict reversion and the high micro-risk of being the victim of opportunism inhibit investment, and capital flight typically continues. These effects dampen and can potentially prevent post-conflict recovery. Often, post-conflict growth exceeds normal growth by around 1.1 per cent, so that after a war the economy needs about double the length of time of the civil war before it joins its long-term path (Collier and Hoeffler, 2004a). Until then the country is poorer than it would have been without the war, and so this shortfall should properly be counted as a cost. Because recovery is so slow, most of the costs of a civil war accrue after it is over. Aid accelerates growth during recovery and has been found to be particularly effective in post-conflict situations. This was indeed the original rationale for aid: the World Bank was initially going to be named the ‘International Bank for Reconstruction’.

The third consequence for growth is the effect of civil war on other countries. Typically, the adverse effects of a civil war spread far beyond the borders of the afflicted country: even countries that are not direct neighbours suffer significant reductions in growth (Murdoch and Sandler, 2002). Although the reduction in the growth rate of neighbours is much lower than that experienced by the country itself, because many countries are affected, the overall ‘spillover’ costs to neighbours arising from this loss of growth tend to exceed those experienced by the country itself.

Taken together, these consequences for growth have two important implications. One is that the true economic cost of civil war is massive even before one takes into account the social costs. By applying a conventional discount rate to the lost growth and allowing only for costs to direct neighbours, Collier and Hoeffler (2004b) estimate the value of the typical cost of a civil war in a low-income country at an astounding 64 billion dollars. The other implication is that most of these losses are externalities to the people taking the decisions at the time of the conflict: the losses accrue to neighbours and to a future generation. Hence, decisions to start civil wars are unlikely to reflect a true social calculus of the probable consequences of war.

growth and civil war: The New Palgrave Dictionary of Economics

growth and cycles

Gadi Barlevy
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

There is a long tradition in macroeconomics of treating growth and cycles as distinct phenomena. However, various economists have also recognized the virtue of incorporating the two forces into a single framework and to study the way they are related. This article reviews this literature, with emphasis on attempts not only to integrate growth and cycles into a single framework but also to endogenize growth, cycles, or both.

Keywords

capital accumulation; endogenous growth; growth and cycles; innovation; Kydland, F.; Prescott, E.; Ramsey model; research and development; risk; technical change; precautionary savings

Article

Growth and cycles are two key features that characterize real output per capita in most industrialized countries. Real output per capita grows systematically over time; and the rate at which it grows tends to fluctuate over time.
A long tradition in macroeconomics treats these two features as distinct. On the one hand, economists who study why output per capita consistently grew in most countries during the 20th century often ignore the fact that growth in any given country was uneven over time. Underlying this approach is the assumption that temporary fluctuations in economic growth are transitory and have no consequences for long-run growth. On the other hand, economists interested in cyclical fluctuations often abstract from long-run economic growth. In particular, various business cycle models have been devised in which output fluctuates around a constant level of output rather than a path that grows over time. This approach again reflects the view that long-run growth is driven by forces that are independent of the factors that drive booms and busts in economic activity. On this assumption, we can analyse why output deviates from its long-run trend without bothering to model the trend itself.
While this dichotomy has proven useful for exploring certain questions, economists have become
increasingly critical of this approach. Various attempts at integrating these two phenomena can be found in work on growth and business cycles from the late 1960s and early 1970s. Richard Goodwin's entry for growth and cycles in the first edition of this dictionary surveys some of this work (Goodwin, 1987, pp. 574–6).

Arguably, however, the article that contributed most to advancing the view that growth and business cycles should be analysed within a single model is Kydland and Prescott (1982). They argued that business cycles were driven not by short-run variations in aggregate demand, as most previous work had assumed, but by fluctuations in the same force that drives long-run growth, namely, technological progress. They started with the Ramsey (1928) growth model in which long-run growth is due to labour-augmenting technical change. But rather than assuming a constant rate of technical change, they allowed it to vary over time. This captures the notion that new ideas arrive sporadically, so productivity growth is inherently random. Households react to these shocks by varying their capital accumulation and labour supply.

Kydland and Prescott went on to argue that technology shocks could account for most of the volatility in US output during the post-war period. This claim remains controversial. However, even those who were sceptical of the claim that productivity shocks were responsible for business cycles were forced to acknowledge that temporary shocks could affect decisions relevant for long-run growth, such as capital accumulation, and conversely that the forces which shape long-run growth could have important short-run consequences. This implies that treating growth and cycles as distinct processes might overlook important connections between the two phenomena.

While Kydland and Prescott's paper was influential in promoting the view that growth and cycles should be modelled jointly, their model offered only limited insight into the connection between the two. This is because they modelled both long-run growth and fluctuations as exogenous: output per capita in their model grows because the economy is assumed to undergo technical change, and it grows in cycles because technical change is assumed to occur in cycles. As such, their model does not explain what drives technical change, why it should be inherently volatile, or whether growth and cycles might affect one another.

For example, Kydland and Prescott's model cannot tell us whether business cycles affect the rate of long-run growth. Are entrepreneurs more reluctant to undertake activities that lead to technical change in the face of macroeconomic volatility? Addressing this question requires us to model growth as an endogenous process rather than as the outcome of exogenous technical change. As another example, Kydland and Prescott asserted that technical change is inherently volatile. While this is undoubtedly true for any individual sector, it is not obvious why this volatility does not cancel out in the aggregate, resulting in a constant rate of technical change for the economy as a whole. Addressing this question requires us to model the underlying fluctuations in the rate of technical change as an endogenous outcome rather than as the result of an exogenous process. Fortunately, economists have since developed models in which either long-run growth or fluctuations, or both, are endogenous.

One line of research endogenizes growth while maintaining exogenous fluctuations. This approach allows us to study the effects of cyclical fluctuations on long-run growth. One of the first papers to tackle this question was Leland (1974), who built on previous work by Levhari and Srinivasan (1969). The latter studied the problem of a household deciding between consumption and saving given uncertain returns on its savings. Leland showed that this model could be reinterpreted as a representative
growth and cycles: The New Palgrave Dictionary of Economics

household economy with a linear technology for producing output from capital. Growth in this model was driven by capital accumulation, so shocks to productivity – the analogue of uncertain returns – affected growth by affecting average investment. Leland showed that the effect of cycles on growth depended on household attitudes towards risk. If the coefficient of relative risk aversion among households exceeded one, they would engage in more precautionary savings in the face of macroeconomic volatility, accumulating capital more rapidly. When relative risk aversion is below unity, macroeconomic volatility would induce households to accumulate less capital, leading to a slower rate of growth. Thus, whether cycles encourage or discourage long-run growth is ambiguous from a theoretical standpoint. Ramey and Ramey (1995) provided empirical evidence on the relationship between growth and cycles using cross-country evidence. They found that volatility is associated with slower growth. At the same time, they found that more volatile countries do not have lower investment rates, contradicting Leland's analysis on how volatility ought to affect growth. This contradiction was resolved by Ramey and Ramey (1991) and Barlevy (2004), who argued that volatility affects growth not by changing average investment but by making investment less volatile; more volatile investment lowers long-run growth because growth is concave in investment. Barlevy (2004) in particular argued that this channel implies that exogenous cyclical fluctuations would be associated with very large welfare costs.

A separate line of research proceeded in the opposite direction: it assumed long-run growth was exogenous, and examined whether fluctuations in the economy-wide rate of technical change could arise endogenously. For example, Shleifer (1986) developed a multi-sector model where in each period innovators in a fixed fraction of sectors develop more productive technologies. They could use these to earn profits for a limited period, after which rivals in their sector could copy the technology and drive profits to zero. If innovators implemented their ideas as soon as they came up with them, the rate of aggregate technical change would be constant. But Shleifer allowed firms to delay implementation, and showed that there exist equilibria where technical change occurs in spurts: innovators wait until there is enough innovation in other sectors before they implement their own ideas, so growth would be concentrated rather than spread out evenly over time. Shleifer's result emerges because in his model implementing new technologies exhibits strategic complementarities: when one firm implements a new technology, its owners earn excess profits which they use to purchase goods in other sectors. Firms that come up with a new technology might therefore prefer to wait until others come up with new ideas. Even though the economy arrives at new ideas at a constant rate, growth proceeds at an uneven rate in equilibrium.

A third line of research has sought to endogenize both long-run growth and fluctuations. For example, Francois and Lloyd-Ellis (2003) consider a modification of the Shleifer model where innovators choose how much research to undertake, rather than assuming the rate at which new ideas arrive is fixed exogenously. This allows them to examine whether implementation cycles can affect long-run growth. Since implementation cycles emerge endogenously, the connection between cycles and growth may be different from the way growth responds to exogenous shocks as in Leland's analysis. Francois and Lloyd-Ellis find that the equilibrium with cycles involves unambiguously higher average growth than the equilibrium in which innovators implement their new ideas immediately. This is because innovators earn higher profits when they coordinate implementation, providing them with more incentive to engage in research. However, welfare turns out to be lower in the presence of cycles, so
faster but more uneven growth is less desirable. Lastly, Francois and Lloyd-Ellis show that, if countries differ in research productivity, we would observe a negative correlation between growth and cycles across countries; countries that are less productive in research will grow more slowly and exhibit longer and larger deviations from average growth. This helps to reconcile their results with Ramey and Ramey's evidence, and points out an important caveat for interpreting the cross-country evidence on growth and cycles.

Other authors have used models where both growth and cycles arise endogenously to explore whether technical change occurs in spurts not because of implementation delays but because of fluctuations in innovation. That is, even if innovators implement their new ideas immediately, they might still choose to concentrate their research activity in particular periods. Examples include Bental and Peled (1996), Walde (2002), and Matsuyama (1999). All three describe models in which the economy alternates between capital accumulation and innovation. In the first two papers, successful innovation raises the marginal product of capital, inducing a shift towards capital accumulation until the return to capital is low enough for innovation to turn profitable again. Matsuyama develops a model in which the economy grows as the variety of goods produced increases. Profits depend on the ratio of capital to the number of goods, so successful innovation reduces the profitability of innovation rather than increase the returns to physical capital. But all three models imply that the amount of innovation, and thus the rate of technical change, fluctuates along the equilibrium path.

A central feature of these models is that the economy fluctuates between innovation and capital accumulation. However, empirical evidence suggests research and development activity is high when capital accumulation is high. Recent work by Comin and Gertler (2006) and Barlevy (2005) examines why research activity might vary positively with capital accumulation. However, both assume cycles are due to exogenous shocks rather than that they arise endogenously in equilibrium. It remains a question for future research whether innovation might fluctuate endogenously but still co-vary with capital accumulation.

growth and inequality (macro perspectives)

Vincenzo Quadrini
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article provides a review of studies that examine the relationship between economic growth and inequality. These studies are divided into two groups. The first emphasizes the channels through which inequality affects growth, while the second emphasizes the opposite channel, where economic growth affects inequality. Although several empirical studies find a significant correlation between inequality and growth, it is still an open question as to whether the correlation is driven by the first or the second channel.

Article

The study of ‘growth and inequality’ has a long tradition. One well-known relationship in economic development is the Kuznets curve. Kuznets observed that in the early stage of human development, when agriculture was the main economic activity, inequality in the distribution of income was relatively low. As the economy industrialized and the workforce moved towards industry and away from agriculture, the distribution of income tended to widen. At some critical point in the economy’s development, this tendency reversed. Although more recent evidence does not support the Kuznets curve hypothesis (see, for example, the widening income inequality observed in the United States starting in the early 1980s), the original empirical finding of Kuznets (1955) stimulated a large body of research activity.
Other evidence of the relationship between inequality and growth comes from more recent cross-country observations. Data collected during the 1980s and 1990s show that there is a great deal of variation across countries in the degree of income inequality and economic growth. Are the different growth rates related to the degree of inequality of each individual country? Several studies find, indeed, that there is a cross-country negative correlation between inequality and growth, that is, countries with greater income inequality tend to experience slower growth; see Benabou (1996) and Perotti (1996) for a review of the empirical studies. But correlation does not imply causation, and there are good reasons to think that the causation can go in both directions. In other words, slow growth could generate greater inequality and equality could lead to faster growth.

Inequality affecting growth

One of the channels through which inequality affects growth is through the political and institutional system. A new series of studies in the 1980s, pioneered by Romer (1986) and Lucas (1988), developed a new class of models in which government policies could have a significant impact on the long-term growth of the economy (endogenous growth models). Given the importance of government policies for long-term growth, it becomes important to understand the forces and mechanisms underlying the choice of policies. This work stimulated a new series of studies in political economy. These studies start from the observation that, in a democratic society, the fundamental mechanism underlying the choice of policies is the electoral system. Therefore, in order to understand how policies are selected, we need to study the policy preferences of the population and how these preferences are translated into voting preferences.

Many factors affect the voting preferences of a society. However, for policies that have a clear redistributive content, the position of the voter in the distribution of income or wealth plays an important role. If a person is poor, his or her tax payments are smaller than the benefits he or she receives from government expenditures. Consequently, his attitude towards redistributive policies is more favourable than someone at the top of the income distribution (he or she has to pay more taxes than the received benefits). If the distribution of income is very unequal, then there will be many voters favouring larger governments. Of course this would not be a problem for efficiency if taxes were not distortionary. But, in a standard endogenous growth model, taxes have a negative impact on investment and growth. Therefore, the main conclusion of this literature is that inequality impairs the economic potential of a country because voters will demand more redistribution through distortionary taxes; Persson and Tabellini (1994), Alesina and Rodrik (1994), Krusell and Rios-Rull (1996), Krusell, Quadrini and Rios-Rull (1996) are some examples.

These studies also demonstrate the importance of the institutional system. Although greater inequality implies a greater demand for redistributive policies, the way political preferences are aggregated and the way policies are ultimately chosen depend on the particular institutional framework. For example, whether the representative democracy works through a parliamentary or a presidential system could lead to different sizes of government and, through distortionary taxes, to different levels of economic growth; see Persson and Tabellini (2005) for an analysis of the economic effects of constitutions.

The predictions of the politico-economic literature are consistent with several empirical studies as they find a negative relation between inequality and growth. However, a deeper empirical investigation of
growth and inequality (macro perspectives) : The New Palgrave Dictionary of Economics

this channel poses some doubts. More specifically, the politico-economic channel can be divided into two sub-channels: a positive relation between ‘inequality’ and ‘redistributive policies’ and a negative relation between ‘redistributive policies’ and ‘growth’. Perotti (1996) shows that the negative effect of redistributive policies on growth is not a robust feature of the data. On the contrary, redistributive policies may even be positively associated with economic growth. How is this possible?

Several theories envision a beneficial effect of redistributive taxes. The key ingredient is the presence of financial constraints. Let us take the Shumpeterian view that entrepreneurship is central to economic growth. However, due to financial constraints and the lack of insurance markets, entrepreneurial investment is suboptimal. Under these conditions, redistribution may provide extra resources to constrained entrepreneurs and could facilitate more investments in growth-enhancing activities. At the same time, a redistributive system provides an implicit system of income smoothing (a person pays high taxes when he or she earns high profits but receives payments in case of losses), and therefore, it provides insurance. If entrepreneurs are risk averse, this encourages more investment. The issue of whether redistributive taxes increase or decrease entrepreneurial investment is still an open area of research.

A similar story applies to investment in education or human capital. If education is important for economic growth, but because of financial constraints households choose sub-optimal levels of education, then government transfers may allow for greater investment and growth. A more direct effect could be generated by financing public education, as in Glomm and Ravikumar (1992). Examples of studies that emphasize the importance of inequality for growth in the presence of financial constraints are Galor and Zeira (1993), Banerjee and Newman (1993) and Aghion and Bolton (1997).

Another group of studies emphasizes social conflict and expropriation. Greater inequality means that a larger group of individuals is at the bottom of the distribution and faces poor economic conditions compared to the rest of the population. Faced with poor economic conditions, people have strong incentives to expropriate either by ‘stealing’ or through ‘revolutions’. The risk of expropriation has two negative effects. First, it acts as an investment tax that discourages investment. Second, more resources are devoted to protect property rights, which detracts from resources devoted to productive and growth enhancing activities. An example of this kind of theory is Benhabib and Rustichini (1996).

Another theory of inequality affecting growth is that developed in Murphy, Shleifer and Vishny (1989). This theory assumes that there are technologies with increasing returns. These technologies become profitable only if the domestic market is sufficiently large, that is, there is a large demand for the goods produced with the new technologies. If wealth is highly concentrated the domestic market remains small (since there are not enough consumers who can afford these goods). As a result, these growth-enhancing technologies will not be implemented. However, the theory finds weak support in the data (see Benabou, 1996).

Growth affecting inequality

If we take the view that growth requires innovative risky activities and these activities cannot be easily insured, we would expect that faster growth is associated with greater *ex post* inequality. At the same time, a faster rate of innovation implies greater destructions of monopoly positions (creative destruction). This would generate lower inequality because the monopoly positions, which are the source
growth and inequality (macro perspectives) : The New Palgrave Dictionary of Economics

of high-income revenues, last for a shorter period of time. Therefore, it is not obvious whether faster innovation and growth create greater inequality. However, within this environment, faster growth generates higher mobility due to a higher turnover in the holding of monopoly positions. Therefore, even if growth leads to greater inequality, it also creates a healthier social environment. Long-term growth requires technological innovation and there is no doubt that new technologies affect different groups in different ways. Therefore, growth and inequality are intrinsically related. Since 1980, wage inequality among different education groups has been widening in almost all industrialized countries. Katz and Murphy (1992) show that this increase is due to a raising demand of skilled labour. Krusell et al. (2000) propose an explanation for the increasing demand of skilled labour based on the introduction and development of new technologies that are more complementary to skilled labour (skill-biased technologies).

Suppose that there are two types of workers, skilled and unskilled. The stocks of skilled and unskilled workers change slowly over time. Now suppose that there is the introduction of skill-biased technologies, that is, technologies that require more skilled labour than unskilled labour. This will lead to an increase in the demand for skilled workers. Given the limited increase in the supply, the wages of skilled workers will increase. On the other hand, the demand for unskilled workers will decline, which leads to a fall in the wages of these workers.

This is a compelling explanation for the increasing wage premium started at the beginning of the 1980s. However, it raises the question of why the ratio of skilled versus unskilled workers has not increased that much during this period, certainly not as much as we would expect given the size of the wage premium change.

The technological innovations introduced in the 1970s seem to have affected the economy in other respects. Greenwood and Jovanovic (1999) and Hobijn and Jovanovic (2001) believe that new information technologies required a level of restructuring that incumbent firms could not face. As a result, their stock market value dropped. This is another form of redistribution in the sense that the owners of incumbent firms lose market value to the owners of the new firms.

Policy considerations

Whether we concentrate on the first channel of causation—in which growth affects inequality—or to the second—in which inequality affects growth—there are no obvious policy recommendations. If we think that inequality has a negative impact on growth because society demands more redistributive policies (as in the standard political economy literature), then the constitutional system of electoral representation becomes central. Changing the constitutional system could lead to different political outcomes. However, changing the constitutional system is not easy. We could also think of reallocating resources once and for all to change the initial distribution. Although this is possible in theory, it is difficult from a political point of view.

If we concentrate on the opposite channel, in which growth impacts on inequality, and we are concerned about having an excessively unequal distribution of incomes, then we may consider possible redistributive policies. However, these policies may also have undesired effects on efficiency. If the tax system keeps the after-tax skill premium low, the incentive to acquire skills will be lower. But, because of skilled-biased technologies, more skills are required. This could also discourage the introduction of these technologies, which would impact negatively on growth. The equity–efficiency trade-off becomes
central to the analysis. The positioning of a society in this trade-off will depend on society preferences about the degree of inequality that is socially acceptable. These preferences are based on individual beliefs that are likely to depend on individual experiences and they change very slowly over time. The relationship between personal experience and beliefs is formalized in Piketty (1995); see also Quadrini (1999).

Abstract

Institutions are often viewed as a key determinant of economic growth. Much research inquires whether the institutions that influence economic outcomes are themselves determined by other factors. European colonization of the world provides a laboratory in which to investigate these issues since it exogenously imposed different institutions on otherwise identical societies. Colonies where Europeans settled had institutions that protected property rights, and have since prospered, while other colonies were given centralized repressive states that extracted resources from the population and have largely remained relatively poor. Choice of institutions reflects the distribution of political power in a society.

Article

A central question of economics is to understand why some countries are much poorer than others. Economists have long recognized that this relates to the fact that some countries have much less human capital, physical capital and technology than others, and use their existing factors and technologies much less efficiently. Nevertheless, these differences are only proximate causes in the sense that they pose the next question of why some countries have less human capital, physical capital and technology and make worse use of their factors and opportunities. This has motivated economists and social scientists more broadly to look for potential fundamental causes, which may be underlying these proximate differences across countries.

Institutions have emerged as a potential fundamental cause, contrasting, for example, with geographical differences or cultural factors. While geographic characteristics of countries and regions may lead to differences in the technology available to individuals or make their investments in physical and human capital more difficult, institutional differences, associated with differences in the organization of society, shape economic and political incentives and affect the nature of equilibria via these channels. There is vibrant research, both empirical and theoretical, attempting to understand the importance of institutions for economic outcomes. Since it is impossible to do justice to this burgeoning field in such a short article, my purpose here is not to survey the literature but to present some of the main conceptual issues that are useful for future work.

What are institutions?

Douglass North (1990, p. 3) offers the following definition: ‘Institutions are the rules of the game in a society or, more formally, are the humanly devised constraints that shape human interaction.’ Three important features of institutions are apparent in this definition: (a) they are ‘humanly devised’, which contrasts with other potential fundamental causes like geographic factors, which are outside human control; (b) they are ‘the rules of the game’ setting ‘constraints’ on human behavior; and (c) their major effect will be through incentives (see also North, 1981).

The notion that incentives matter is second nature to economists, and institutions, if they are a key determinant of incentives, should have a major effect on economic outcomes, including economic development, growth, inequality and poverty. But do they? Are institutions key determinants of economic outcomes or secondary arrangements that respond to...
other, perhaps geographic or cultural, determinants of human and economic interactions?

Much empirical research attempts to answer this question. Before we discuss some of this research, it is useful to emphasize an important point: ultimately, the aim of the research on institutions is to pinpoint specific institutional characteristics that are responsible for economic outcomes in specific situations (for example, the effect of legal institutions on the types of business contracts). However, the starting point is often the impact of a broader notion of institutions on a variety of economic outcomes. This broader notion, in line with Douglass North’s conception, incorporates many aspects of the economic, political and social organization of society. Institutions can differ between societies because of their formal methods of collective decision-making (democracy versus dictatorship) or because of their economic institutions (security of property rights, entry barriers, the set of contracts available to businessmen). They may also differ because a given set of formal institutions is expected to, and does, function differently; for example, they may differ between two societies that are democratic because the distribution of political power lies with different groups or social classes, or because in one society democracy is expected to collapse while in the other it is consolidated. This broad definition of institutions is both an advantage and a curse. It is an advantage, since it enables us to get started with theoretical and empirical investigations of the role of institutions without getting bogged down by taxonomies. It is a curse, since we can follow it up with a better understanding of the role of specific institutions, we have learned little.

The impact of institutions

There are tremendous cross-country differences in the way that economic and political life is organized. A voluminous literature documents large cross-country differences in economic institutions, and a strong correlation between these institutions and economic performance. Knack and Keefer (1995), for instance, look at measures of property rights enforcement compiled by international business organizations, Mauro (1995) looks at measures of corruption, Djankov et al. (2002) compile measures of entry barriers across countries, while many studies look at variation in educational institutions and the corresponding differences in human capital. All of these authors find substantial differences in these measures of economic institutions, and significant correlation between these measures and various indicators of economic performance. For example, Djankov et al. find that, while the total cost of opening a medium-size business in the United States is less than 0.02 per cent of GDP per capita in 1999, the same cost is 2.7 per cent of GDP per capita in Nigeria, 1.16 per cent in Kenya, 0.91 per cent in Ecuador and 4.95 per cent in the Dominican Republic. These entry barriers are highly correlated with various economic outcomes, including the rate of economic growth and the level of development.

Nevertheless, this type of correlation does not establish that the countries with worse institutions are poor because of their institutions. After all, the United States differs from Nigeria, Kenya and the Dominican Republic in its social, geographic, cultural and economic fundamentals, so these may be the source of their poor economic performance. In fact, these differences may be the source of institutional differences themselves. Consequently, evidence based on correlation does not establish whether institutions are important determinants of economic outcomes.

To make further progress, one needs to isolate a source of exogenous differences in institutions, so that we approximate a situation in which a number of otherwise identical societies end up with different sets of institutions. European colonization of the rest of the world provides a potential laboratory in which to investigate these issues. From the late 15th century, Europeans dominated and colonized much of the rest of the globe. Together with European dominance came the imposition of very different institutions and social power structures in different parts of the world.

Acemoglu, Johnson and Robinson (2001) document that in a large number of colonies, especially those in Africa, Central America, the Caribbean and South Asia, European powers set up ‘extractive states’. These institutions (again broadly construed) did not introduce much protection for private property, nor did they provide checks and balances against the government. The explicit aim of the Europeans in these colonies was extraction of resources, in one form or another. This colonization strategy and the associated institutions contrast with the institutions Europeans set up in other colonies, especially in colonies where they settled in large numbers: for example, the United States, Canada, Australia and New Zealand. In these colonies the emphasis was on the enforcement of property rights for a broad cross section of the society, especially smallholders, merchants and entrepreneurs. The term ‘broad cross section’ is emphasized here since, even in the societies with the worst institutions, the property rights of the elite are often secure, but the vast majority of the population enjoys no such rights and faces significant barriers to participation in many economic activities. Although investments by the elite can generate economic growth for limited periods, for sustained growth property rights for a broad cross section seem to be crucial (Acemoglu, Johnson and Robinson 2002; Acemoglu, 2003).

A crucial determinant of whether Europeans chose the path of extractive institutions was whether they settled in large numbers. In colonies where Europeans settled, the institutions were developed for their own future benefits. In colonies where Europeans did not settle, their objective was to set up a highly centralized state apparatus, and other associated institutions, to oppress the native population and facilitate the extraction of resources in the short run. Based on this idea, Acemoglu, Johnson and Robinson (2001) suggest that, in places where the disease environments made it easy for Europeans to settle, the path of institutional development should have been different from areas where Europeans faced high mortality rates.

In practice, during the time of colonization, Europeans faced widely different mortality rates in colonies because of differences in the prevalence of malaria and yellow fever. These mortality rates provide a possible candidate for a source of exogenous variation in institutions. The mortality rates should not directly influence output today but, by affecting the settlement patterns of Europeans, they may have had a first-order effect on institutional development. Consequently, these potential settler mortality rates can be used as an instrument...
for broad institutional differences across countries in an instrumental-variables estimation strategy.

The key requirement for an instrument is that it should have no direct effect on the outcome that is the object of interest (other than its effect via the endogenous regressor). There are a number of channels through which potential settler mortality could influence current economic outcomes or may be correlated with other factors influencing these outcomes. Nevertheless, there are also good reasons why, as a first approximation, these mortality rates should not have a direct effect. Malaria and yellow fever were fatal to Europeans who had no immunity, and thus had a major effect on settlement patterns, but they had much more limited effects on natives who, over centuries, had developed various types of immunities. The exclusion restriction is also supported by the death rates of native populations, which appear to be similar between areas with very different mortality rates for Europeans (see, for example, Curtin, 1964).

The data also show that there were major differences in the institutional development of the high-mortality and low-mortality colonies. Moreover, consistent with the key idea in Acemoglu, Johnson and Robinson (2001), various measures of broad institutions – for example, measures of protection against expropriation – are highly correlated with the death rates Europeans faced more than a century ago and with early European settlement patterns. They also show that these institutional differences induced by mortality rates and European settlement patterns have a major (and robust) effect on income per capita. For example, the estimates imply that improving Nigeria's institutions to the level of those in Chile could, in the long run, lead to as much as a sevenfold increase in Nigeria's income. This evidence suggests that, once we focus on potentially exogenous sources of variation, the data point to a large effect of broad institutional differences on economic development.

Naturally, mortality rates faced by Europeans were not the only determinant of Europeans' colonization strategies. Acemoglu, Johnson and Robinson (2002) focus on another important aspect, namely, how densely different regions were settled before colonization. They document that in more densely settled areas Europeans were more likely to introduce extractive institutions because it was more profitable for them to exploit the indigenous population, either by having them work in plantations and mines or by maintaining the existing system and collecting taxes and tributes. This suggests another source of variation in institutions that may have persisted to the present, and Acemoglu, Johnson and Robinson (2002) show similar large effects from this source of variation.

Another example that illustrates the consequences of difference in institutions is the contrast between North Korea and South Korea. The geopolitical balance between the Soviet Union and the United States following the Second World War led to separation along the 38th parallel. The North, under the dictatorship of Kim II Sung, adopted a very centralized command economy with little role for private property. In the meantime, South Korea, though far from a free-market economy, relied on a capitalist organization of the economy, with private ownership of the means of production and legal protection for a range of producers, especially those under the umbrella of the chaebols, the large family conglomerates that dominated the South Korean economy. Although not democratic during its early phases, the South Korean state was generally supportive of rapid development and is often credited with facilitating, or even encouraging, investment and rapid growth in Korea.

Under these two highly contrasting regimes, the economies of North and South Korea diverged. While South Korea grew rapidly under capitalist institutions and policies, North Korea has experienced minimal growth since 1950 under communist institutions and policies.

Overall, a variety of evidence paints a picture in which broad institutional differences across countries have had a major influence on their economic development. This evidence suggests that to understand why some countries are poor we should understand why their institutions are dysfunctional. But this is only part of a first step in the journey towards an answer. The next question is even harder: if institutions have such a large effect on economic riches, why do some societies choose, end up with and maintain these dysfunctional institutions?

Modelling institutional differences

As a first step in modelling institutions, let us consider the relationship between three institutional characteristics: (a) economic institutions, (b) political power, and (c) political institutions.

As already mentioned, economic institutions matter for economic growth because they shape the incentives of key economic actors in society; in particular, they influence investments in physical and human capital and technology, and the organization of production. Economic institutions determine not only the aggregate economic growth potential of the economy but also the distribution of resources in the society, and herein lies part of the problem: different institutions will be associated not only with different degrees of efficiency and potential for economic growth, but also with different distributions of the gains across different individuals and social groups.

How are economic institutions determined? Although various factors play a role here, including history and chance, ultimately economic institutions are produced by collective choices of the society. And because of their influence on the distribution of economic gains, not all individuals and groups typically prefer the same set of economic institutions. This leads to a conflict of interest among various groups and individuals over the choice of economic institutions; and the political power of the different groups will be the deciding factor. The distribution of political power in society is also endogenous. To make more progress here, let us distinguish between two components of political power; de jure (formal) and de facto political power (see Acemoglu and Robinson, 2006). De jure political power refers to power that originates from the political institutions in society. Political institutions, similar to economic institutions, determine the constraints on and the incentives of the key actors, but this time in the political sphere. Examples of political institutions include the form of government – for example, democracy versus dictatorship or autocracy – and the extent of constraints on politicians and political elites.
A group of individuals, even if they are not allocated power by political institutions, may possess political power; for example, they can revolt, use arms, hire mercenaries, co-opt the military, or undertake protests in order to impose their wishes on society. This type of de facto political power originates from both the ability of the group in question to solve its collective action problem and from the economic resources available to the group (which determine their capacity to use force against other groups).

This discussion highlights the fact that we can think of political institutions and the distribution of economic resources in society as two state variables, affecting how political power will be distributed and how economic institutions will be chosen. An important notion is that of persistence; the distribution of resources and political institutions are relatively slow-changing and persistent. Since, like economic institutions, political institutions are collective choices, the distribution of political power in society is the key determinant of their evolution. This creates a central mechanism of persistence: political institutions allocate de jure political power, and those who hold political power influence the evolution of political institutions, and they will generally opt to maintain the political institutions that give them political power. A second mechanism of persistence comes from the distribution of resources: when a particular group is rich relative to others, this will increase its de facto political power and enable it to push for economic and political institutions favorable to its interests, reproducing the initial disparity. Despite these tendencies for persistence, the framework also emphasizes the potential for change. In particular, ‘shocks’ to the balance of de facto political power, including changes in technologies and the international environment, have the potential to generate major changes in political institutions, and consequently in economic institutions and economic growth.

Acemoglu, Johnson and Robinson (2005b) summarize this framework in Figure 1.

**Figure 1**

| political institutions, & distribution of resources | de jure political power, & de facto political power | economic institutions, & distribution of resources |

Institutions in action

As a brief example, consider the development of property rights in Europe during the Middle Ages. Lack of property rights for landowners, merchants and proto-industrialists was detrimental to economic growth during this epoch. Since political institutions at the time placed political power in the hands of kings and various types of hereditary monarchies, such rights were largely decided by these monarchs. The monarchs often used their powers to expropriate producers, impose arbitrary taxation, renge on their debts, and allocate the productive resources of society to their allies in return for economic benefits or political support. Consequently, economic institutions during the Middle Ages provided little incentive to invest in land, physical or human capital, or technology, and failed to foster economic growth. These economic institutions also ensured that the monarchs controlled a large fraction of the economic resources in society, solidifying their political power and ensuring the continuation of the political regime.

The 17th century, however, witnessed major changes in the economic and political institutions that paved the way for the development of property rights and limits on monarchs' power, especially in England after the civil war of 1642–6 and the Glorious Revolution of 1688, and in the Netherlands after the Dutch revolt against the Hapsburgs. How did these major institutional changes take place? In England until the 16th century the king also possessed a substantial amount of de facto political power, and, if we leave aside civil wars related to royal succession, no other social group could amass sufficient de facto political power to challenge the king. But changes in the English land market (Tawney, 1941) and the expansion of Atlantic trade in the 16th and 17th centuries (Acemoglu, Johnson and Robinson, 2005a) gradually increased the economic fortunes, and consequently the de facto power, of landowners and merchants opposed to the absolutist tendencies of the Kings.

By the 17th century, the growing prosperity of the merchants and the gentry, based on both internal and overseas (especially Atlantic) trade, enabled them to field military forces capable of defeating the king. This de facto power overcame the Stuart monarchs in the English civil war and Glorious Revolution, and led to a change in political institutions that stripped the king of much of his previous power over policy. These changes in the distribution of political power led to major changes in economic institutions, strengthening the property rights of both landowners and capital owners and spurring a process of financial and commercial expansion. The consequence was rapid economic growth, culminating in the industrial revolution, and a very different distribution of economic resources from that in the Middle Ages.

This discussion poses, and also gives clues about the answers to, two crucial questions. First, why do the groups with conflicting interests not agree on the set of economic institutions that maximize aggregate growth? Second, why do groups with political power want to change political institutions in their favour? In the context of the example above, why did the gentry and merchants use their de facto political power to change political institutions rather than simply implement the policies they wanted? The issue of commitment is at the root of the answers to both questions.

An agreement on the efficient set of institutions is often not forthcoming because of the complementarity between economic and political institutions and because groups with political power cannot commit to not using their power to change the distribution of resources in their favour. For example, economic institutions that increased the security of property rights for landowners and capital owners during the Middle Ages would not have been credible as long as the monarch monopolized political power. He could promise to respect property rights, but then at some point renege on his promise, as exemplified by the numerous financial defaults by medieval kings. Credible secure property rights necessitated a reduction in the political power of the monarch. Although these more secure property rights would foster economic growth, they were not appealing to the monarchs, who would thereby lose their rents from predation and expropriation as well as various other privileges associated with their monopoly of political power. This is why the institutional changes in England as a result of the Glorious Revolution were not simply conceded by the Stuart kings. James II had to be deposed for the changes to take place.

The reason why political power is often used to change political institutions is related. In a dynamic world, individuals care about not only economic outcomes today but also those in the future. In the example above, the gentry and merchants were interested in their profits and therefore in the security of their property rights, not only in the present but also in the future. Therefore, they would have liked to use their (de facto) political power to secure benefits in the future as well as the present. However, commitment to future allocations (or economic institutions) is in general not possible because decisions in the future are made by those who hold political power at the time. If the gentry and merchants had been certain to maintain their de facto political power, this would not have been a problem. However, de facto political power is often transient, for example because the collective action problems that are solved to amass this power are likely to resurface in the future, or other groups, especially those controlling de jure power, can become stronger in the future. Therefore, any change in policies and economic institutions that relies purely on de facto political power is likely to be reversed in the future. In addition, many revolutions are followed by conflict among the revolutionaries. Recognizing this, the English gentry and merchants strove not just to change economic institutions in their favour following their victories against the Stuart monarchy, but also to alter political institutions and the future allocation of de jure power. Using political power to change political institutions then emerges as a useful strategy to make gains more durable. Consequently, political institutions and changes in political institutions are important as ways of manipulating future political power, and thus indirectly shaping future, as well as present, economic institutions and outcomes. Acemoglu and Robinson (2000; 2006) and Acemoglu, Johnson and Robinson (2005b) provide more detailed models and discuss further applications, including the creation and consolidation of electoral democracies in the West and in Latin America.

Growth and international trade

James Rauch
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

International trade is believed to promote growth for countries at the technological frontier by expanding the market over which to exploit new ideas. For countries behind the technological frontier, three views of the relationship between growth and international trade are described and assessed empirically: trade hampers growth for natural resource-abundant countries that specialize in the export of technologically stagnant primary products; trade acts as the ‘handmaiden’ of growth by improving the quality of investment and slowing the tendency of its return to fall; and trade acts as the engine of growth by providing a conduit for technology transfer.

Article

When examining the interaction between international trade and economic growth, it is necessary to distinguish between countries that are at the technological frontier and those that are substantially behind it. The reason is that long-run growth of productivity and ultimately of per capita income is constrained by technological progress in the former group of countries but not in the latter group.

Growth and international trade for countries at the technological frontier

Rivera-Batiz and Romer (1991) argue that a larger economic size of the world promotes worldwide
growth and international trade: The New Palgrave Dictionary of Economics

technological progress, in two ways. First, current research and development (R&D) builds upon the existing stock of ideas or knowledge (standing on the shoulders of giants). Because ideas are non-rival, a larger world implies a larger stock of knowledge that facilitates R&D. International trade is implicated in this effect only to the extent that it promotes exchange or sharing of ideas among countries. Second, a larger economic size of the world raises the rents generated by monopoly holders of patented ideas (or ideas that are too costly to imitate) by providing a larger market for the goods based on the ideas. International trade is needed to exploit this large market and therefore provides greater incentives for innovation, increasing economic growth through this ‘Schumpeterian’ mechanism. Rivera-Batiz and Romer concentrate on these scale effects by modelling integration between similar, developed countries, thereby abstracting from the comparative advantage, resource reallocation effects of trade. This theoretical prediction of a positive effect of international trade on the worldwide rate of technological progress needs to be qualified when international trade occurs between dissimilar countries. For example, trade can be expected to increase the relative price of skilled labour in the most skilled labour-abundant country. This could raise the cost of R&D relative to the cost of goods production enough to offset the positive effects of international trade on R&D for this country. If the most skilled labour-abundant country drives the worldwide rate of technological progress, international trade could reduce world economic growth. For a much fuller discussion of the interactions between international trade, R&D, and economic growth, see Grossman and Helpman (1991).

In so far as technological progress is transmitted equally to all countries at the worldwide technological frontier, there is no room for cross-country variation in the impact of international trade on growth from this source. In other words, the prediction that trade increases the worldwide rate of technological progress (absent strong, offsetting comparative advantage effects), and hence long-run economic growth of countries at the technological frontier, is inherently untestable using cross-sectional data because we have only one world. Since falling transportation and communication costs have tended to make countries more open to international trade over time, this prediction is consistent with time-series evidence that seems to show that the worldwide rate of growth is increasing over the very long run, but this increase is also predicted by the increasing size of the world – standing on the shoulders of more giants.

Growth and international trade for countries behind the technological frontier

The effect of international trade on the economic growth of less developed countries (LDCs) has long been one of the most passionately debated subjects in economics. Here I set out three views that span the range from negative to positive.

Trade as the enemy of growth

The case for trade as the enemy of growth can be made succinctly using the open economy version of the model of Matsuyama (1992). In his model all productivity increase takes place through learning by doing in the manufacturing sector, which is perceived as an external economy by any individual manufacturing firm. (In Matsuyama's model, unlike in the classic infant-industry argument, the potential for learning by doing is never exhausted – the manufacturing sector never catches up to international
best practice. One way this can be justified is by assuming that international best practice is a receding target.) Productivity in agriculture (or, more broadly, in the primary product sector) is constant by assumption. Now consider a country that is well endowed with natural resources relative to labour (and also relative to human and physical capital, if these are assumed to be used more intensively in manufacturing). Comparative advantage will lead this country to export primary products and import manufactures. Exports of primary products draw workers out of manufacturing, both directly and indirectly by generating rents that create demand for services, and thereby reduce productivity growth both in manufacturing and in the aggregate (since there is no productivity growth in primary products). (A variant of this argument is that trade causes ‘lagging’ economies to specialize in goods whose learning potential has been exhausted: Young, 1991.) In this way trade reduces growth in per capita income in countries with abundant natural resources. It is interesting that the sociological literature on ‘dependency’ and ‘world systems’ comes to the same conclusion that development of ‘peripheral’ countries is hindered by their exports of primary products to ‘core’ industrialized countries. For a summary of these arguments and a review of empirical studies see Crowley et al. (1998).

This case for trade as the enemy of growth does not depend on the assumption that productivity in the primary product sector is constant. Obviously learning-by-doing and other forms of productivity increase occur in this sector in the real world. What is crucial is only that this productivity increase tends to be substantially less rapid or less sustainable for a long period than in manufacturing. It is also possible that productivity growth in the primary product exportable sector worsens the terms of trade for the exporting country rather than raising its income, as modelled by Lewis (1969). In this instance the country in question must be large enough in its primary product speciality to influence its world price, or else we must treat the countries to which the argument applies as a bloc rather than individually.

Recently it has become fashionable to introduce inequality and ‘institutions’ into the argument linking trade to slow growth through a comparative advantage in primary products. In this view the problem with exports of primary products, especially minerals and tropical cash crops, is not that they are associated with low productivity growth but rather that they are associated with high inequality between owners of large mines or plantations and their employees. This inequality leads to the adoption of educational and political institutions that tend to exclude and disenfranchise the masses, making these economies less capable of realizing the potential offered by new technologies. This argument has been most thoroughly articulated by Engerman and Sokoloff (2002).

Several studies (for example, Sachs and Warner, 2001) find that the ratio of primary product exports to GDP is strongly negatively associated with per capita income growth. This negative association remains even after many other potential determinants of economic growth are controlled for, such as climate, geography, economic policies, political institutions, and external shocks. Indeed, the ratio of primary product exports to GDP is considered one of the most robust determinants of growth in cross-country growth regressions (Sala-i-Martin, 1997). This cross-country evidence cannot be considered decisive, however. Easterly (2001) points out that the primary product export share for less developed countries has tended to decline since 1960 as resources have been depleted and population has grown, yet per capita income growth rates have not tended to rise.

**Trade as the ‘handmaiden’ of growth**
The phrase ‘trade as handmaiden of growth’ is taken from the title of an article by Kravis (1970). He writes (1970, p. 869),

The term ‘engine of growth’ is not generally descriptive and involves expectations which cannot be fulfilled by trade alone; the term ‘handmaiden of growth’ better conveys the notion of the role that trade can play. One of the most important parts of this handmaiden role for today's developing countries may be to serve as a check on the appropriateness of new industries by keeping the price and cost structures in touch with external prices and costs.

This supportive role can be usefully compared to that of financial development. As discussed in Levine (1997), a well-developed financial system increases the efficiency of investment by helping to channel savings to the most profitable projects. One way that trade can increase the efficiency of investment is by helping to ensure that the most privately profitable projects are also the most socially profitable ones. Foreign competition discourages investors from attempting to establish monopoly positions in small domestic markets and from producing substandard goods. Other ways in which trade can increase the efficiency of investment are enabling producers to realize economies of scale through exporting, and relieving bottlenecks that might reduce the returns to well-conceived downstream investments or divert resources from them. (Openness to international trade can also generate static and dynamic economies of scale – the latter through learning-by-doing spillovers, for example – by promoting specialization. Weinhold and Rauch, 1999, find that productivity growth in the manufacturing sector in less developed countries is higher when production is more specialized.)

Along the same lines, trade can slow or suspend the tendency of the return on investment to fall as physical (or human) capital accumulates. This link between growth and international trade was originally made by Ricardo, who argued that repeal of the Corn Laws in Britain would increase imports of grain, reduce the competition for labour between agricultural landlords and manufacturers, and thereby raise the return to investment in reproducible physical capital. His implicit model was what we now call the Ricardo–Viner model. Here we consider an extension of this model by Deardorff (1984), in which a small open economy produces an agricultural good using land and labour and, potentially, a number of manufactured goods using (reproducible) capital and labour under conditions of constant returns to scale and perfect competition. Let the manufactured goods be ranked unambiguously by capital intensity. Now consider a less developed country with an endowment of capital relative to labour and land that is so small that its manufacturing sector is completely specialized in production of the least capital-intensive manufactured good. As the country accumulates capital its return (marginal product) will fall. However, this reduction in the return to capital allows the country to become internationally competitive in the next least capital-intensive manufactured good, so that its manufacturing sector becomes incompletely specialized. At this point the return to capital (and the wage and, by extension, the rent on land) becomes fixed by international goods prices, as in the standard Heckscher–Ohlin–Samuelson model. Further accumulation of capital then causes both capital and labour resources within the manufacturing sector to be reallocated from the less to the more capital-intensive good (the Rybczynski effect). This forestalls any fall in the return to capital until the manufacturing sector becomes completely specialized in the more capital-intensive good, after which the return to capital falls
until production of the next most capital-intensive good is introduced, and so on. If the view that international trade is the handmaiden of economic growth is correct, the large empirical literature investigating ‘causality’ between trade and growth (for example, Jung and Marshall, 1985) is somewhat beside the point. There should, however, be a strong cross-country correlation between openness to international trade and the rate of growth. Many studies have found such a correlation, but its robustness has been called into question (Rodriguez and Rodrik, 2001). Part of the problem may be that most studies try to include all countries for which there are reliable data, yet we have seen that there is no clearly predicted relationship between openness to trade and economic growth for countries at the technological frontier (the so-called industrialized or rich countries) and that trade may reduce growth for countries whose exports are concentrated in primary products. The positive correlation between openness to trade and growth should be most robust for the intermediate group of countries between least and most developed, a group sometimes labelled the ‘semi-industrialized’ countries. Given the complexity of the handmaiden view, however, it is probably best investigated by theoretically informed case studies like the classic NBER volumes (1974–8) supervised by Jagdish N. Bhagwati and Anne O. Krueger.

Trade as the engine of growth

The view of trade as the engine of growth takes technological progress rather than investment to be the ultimate source of growth, and sees imported ideas as the main determinant of technological progress in less developed countries. In other words, trade with more technologically advanced countries acts as a vehicle for the flow of knowledge from them and thereby drives growth in less advanced countries. Foreign direct investment (FDI) from more to less developed countries plays the same role. (This contemporary view of trade as the engine of growth must be distinguished from the older view, in which growth is driven by expansion of land devoted to production of technologically stagnant primary products to meet the demand of industrialized countries; see, for example, Caves, 1965.) The emphasis on imported ideas is associated with the work of Romer (for example, 1993). His work, however, leaves open the question of the specific mechanisms through which firms in less developed countries absorb knowledge from contact with technologically advanced countries. Economists have typically modelled technology transfer as an arm's-length phenomenon. Firms are not taught the new technology. Rather, they engage in purposive imitative activity on their own (see, for example, Grossman and Helpman, 1991, ch. 11), employ machinery and equipment that embodies foreign knowledge (for example, Coe, Helpman and Hoffmaister, 1997), license the new technology, and so on. In reality, however, it is difficult to learn new technology from a distance. Keller (2004, p. 756) writes, ‘Only the broad outlines of technological knowledge are codified – the remainder remains “tacit”. non-codified knowledge is usually transferred through person-to-person demonstrations and instructions.’ There is a growing body of evidence that, for less developed country firms in particular, a major and perhaps predominant source of technology transfer (and transfer of managerial know-how) is instruction by developed country buyers: producers seeking cheaper suppliers of inputs and distributors seeking cheaper suppliers of final goods.

One example of such evidence is a study by Egan and Mody, who surveyed US buyers operating in LDCs, including ‘manufacturers, retailers, importers, buyers' agents, and joint venture partners’ (1992,
Buyers also render long-term benefits to suppliers in the form of information on production technology. This occurs principally through various forms of in-plant training. The buyer may send international experts to train local workers and supervisors ... Buyers may also arrange short-term worker training in a developed country plant. (1992, p. 328)

Rhee, Ross-Larson and Pursell surveyed Korean exporters of manufactures. Their findings were similar to those of Egan and Mody:

The relations between Korean firms and the foreign buyers went far beyond the negotiation and fulfillment of contracts. Almost half the firms said they had directly benefited from the technical information foreign buyers provided: through visits to their plants by engineers or other technical staff of the foreign buyers, through visits by their engineering staff to the foreign buyers... (1984, p. 61)

This process of learning foreign technology can be thought of as taking place within international production networks or 'global commodity chains' (Gereffi, 1994; 1999). This theoretical framework predicts that, once LDC firms are incorporated into the 'bottoms' of the chains, their learning will continue by movement up the chains. There are two types of chains: 'producer-driven' and 'buyer-driven' (Gereffi, 1994, p. 97). In the former, large manufacturers play the central roles in coordinating the production networks. Producer-driven chains are typical in capital- and technology-intensive industries such as automobiles, aircraft, computers, semiconductors, and heavy machinery. In the latter, large retailers, branded marketers, and branded manufacturers play the coordinating roles. Buyer-driven commodity chains are typical in labour-intensive, consumer goods industries such as garments, footwear, toys, housewares, and consumer electronics. Profitability is highest at the tops of the chains where barriers to entry are greatest: scale and technology in producer-driven chains, design and marketing expertise in buyer-driven chains.

In buyer-driven commodity chains, one mode through which learning is predicted to continue is organizational succession: from assembler to original equipment manufacturer (OEM) to original brand-name manufacturer (OBM), which is from more subordinate, competitive, and low-profit positions to more controlling, oligopolistic, high-profit positions. In the apparel industry, Gereffi (1999) finds that LDC firms that have parts provided to them for assembly learn how to find on their own the parts needed to make the product according to the design specified by the buyer (and may then subcontract the assembly); firms that have reached this level learn how to design and sell their own merchandise, becoming branded manufacturers (and may then subcontract the production, becoming branded marketers). Additional study is needed to determine whether this pattern of learning is common in other consumer goods industries. At the same time, work is needed to reconcile the kind of findings discussed here with econometric analyses (surveyed in Rodrik, 1999, ch. 2) which conclude that more productive firms export, but exporting does not make firms more productive.

In producer-driven commodity chains, one mode of learning is through ‘vertical linkages’ established between foreign subsidiaries of the large manufacturers that coordinate the production networks and host
country suppliers. Saggi (2002, p. 213) writes:

Mexico's experience with FDI is illustrative of how such a process works. In Mexico, extensive backward linkages resulted from FDI in the automobile industry. Within five years of investments by major auto manufacturers there were 300 domestic producers of parts and accessories, of which 110 had annual sales of more than $1 million (Moran, 1998). Foreign producers also transferred industry best practices, zero defect procedures, and production audits to domestic suppliers, thereby improving their productivity and the quality of their products.

Javorcik (2004) finds econometric evidence that in Lithuania upstream suppliers to foreign subsidiaries experienced increases in productivity.

Conclusions

Here I highlight what I feel are the most important challenges facing the exponents of each of the three views of trade and growth described in the previous section. Those who see trade as the enemy of growth for natural resource-abundant countries need to do more than merely assert that the primary product export sector is incapable of rapid productivity growth. This assumption has recently been challenged by Dolan, Harris-Pascal and Humphrey (1999) and others who provide evidence that the fresh vegetable export sector in sub-Saharan Africa can realize the kind of learning benefits and investment opportunities associated with manufacturing by upgrading quality and presentation. Those who see trade as the handmaiden of growth must formulate their views more precisely if they are to be used to guide policy or subjected to rigorous empirical testing. Finally, those who see trade as the engine of growth must resolve the contradictions between case studies and econometric results regarding the benefits from exporting. Are the case studies unrepresentative, or does the statistical estimation suffer from measurement problems (as suggested by Katayama, Lu and Tybout, 2003)? Perhaps the case studies and the surveys that collect the data for econometric analysis need to be coordinated to make sure that the right questions are being asked.

How to cite this article

Learning by doing refers to improvements in productive efficiency arising from the generation of experience obtained by producing a good or service. The formal modelling of learning by doing was initiated in Arrow (1962) and was motivated by two main factors. The first motivating factor was empirical: several studies of wartime production found that input requirements decreased as a result of production experience. For example, Searle (1945) studied productivity changes in the Second World War shipbuilding programmes. During the Second World War, US production of ships increased dramatically, from 26 vessels in 1939 to 1,900 ships in 1943, an almost fiftyfold increase. Searle (1945) noticed that unit labour requirements decreased at a constant rate for a given percentage increase in output. On average, a doubling of output was associated with declines of 16 to 22 per cent in the number of man-hours required to build Liberty ships, Victory ships, tankers and standard cargo vessels. Alchian (1963) studied the relationship between the amount of direct labour required to produce an airframe and the number of airframes produced in the United States during the Second World War. He found that a doubling of production experience decreased labour input by approximately one-third. Other empirical studies of learning by doing include Rapping (1965), Irwin and Klenow (1994) and Thornton and Thompson (2001).

The second motivating factor behind the work of Arrow (1962) was a search for a theory of economic growth which did not rely on exogenous change in productivity as a driving force. In particular, Arrow's contribution and its extensions in Levhari (1966a; 1966b) were to show how economic growth could be sustained in a market with perfect competition. Arrow's original model is quite sophisticated, but the main insight can be derived in a simpler setting, as shown in Sheshinski (1967) and presented here. Consider a one good economy, where the production of the good requires capital and labour input according to the constant returns to scale production function:
In this specification of the production technology, \( A \) represents the efficiency of labour in producing the good. The main idea in the learning by doing literature is that \( A \) is a function of past experience. Arrow assumed that experience can be measured by cumulative investment or, in other words, the capital stock. The form of the relationship between \( A \) and the capital stock is posited to be:

\[
A_t = (K_t)^\alpha, \quad 0 < \alpha < 1
\]

where the assumption that \( 0 < \alpha < 1 \) is motivated by the empirical studies. In order to close the system, assume that the labour force grows exponentially at the rate \( \eta \) and let capital accumulation be driven by a constant saving rate out of incomes, \( s \) where, in the absence of depreciation, this implies

\[
\dot{K} = sY
\]

In this environment, on the assumption that the change in \( A \) is an unintended consequence of production, it can be shown that a balanced growth path exists where per-capita income and per-capita capital grow at the rate

\[
\alpha - \frac{\eta}{1 - \alpha}
\]

The two important aspects to note about the resulting growth rate is that it is positive if \( \eta > 0 \) and it is independent of the saving rate \( s \). The additional property – that the rate of growth of income is tied to a positive rate of population growth – is generally seen as a weakness of this type of model. This property can be partially remedied, as shown in Romer (1986), if one assumes that \( \alpha = 1 \). In this case, even in the absence of labour force growth there exists a balanced growth path where the rate of growth is given by

\[
sF(1, L)
\]
The drawback of this specification ($\alpha = 1$) is that the growth rate now depends on the size of the labour force, which is referred to as a ‘scale effect’. The attractive feature of this specification is that the growth rate can be modified by an economic decision variable such as the savings rate. An alternative way of modifying Arrow's original model is to posit, as in Lucas (1988), that $A$ depends on the per-capita value of the capital stock instead of on the level of the capital stock. This assumption is justified in Lucas (1988) on the grounds that $A$ reflects the knowledge of the average worker with respect to how best to operate the technology. In the case where the relationship is given by $A = \frac{K}{L}$, the steady growth rate of per-capita output is given by $sF(1, 1) - \eta$. This formulation has the attractive property that it is positive even if $\eta = 0$, and it does not exhibit a scale effect. Accordingly it offers a succinct theory of economic growth. Lucas conjectured that the assumption of constant returns to learning (that is, $\alpha = 1$) could be justified in a model where there is bounded learning in any one good but where there is continual entry of new goods over time. This idea is formally studied in Stokey (1988) and Young (1993). There is also a large literature that discusses how learning by doing can interact with international trade and potentially give rise to income divergence across countries; see for example Lucas (1993) and Young (1991).

growth models, multi-sector

W.A. Brock and W.D. Dechert
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Multisector growth models have been increasingly used since the 1980s. The duality between growth models and dynamic general equilibrium models renders the multisector growth model ideal for the analysis of efficient intertemporal resource allocation. This includes renewable and non-renewable natural resources, produced resources such as capital, and land and labour resources. Growth models have been widely used in business cycle theory and in asset pricing theory. They have also been applied to the optimal management of dynamic ecological systems that have an economic component as a part of a complex systems model.

Keywords

asset pricing model; bequest motive; business cycles; central limit theorem; computation; concavity; convergence; decentralization; dynamic macroeconomic theory; equity premium puzzle; equivalence theorem; general equilibrium; indirect utility function; infinite horizons; law of large numbers; multisector growth models; New Keynesian macroeconomics; optimal growth models; optimal planning models; overtaking ordering; rational expectations equilibrium; real business cycles; recursive intertemporal general equilibrium models; representative agent; separating hyperplane theorem; single-sector growth models; turnpike theorems

Article

Multisector growth models are basic building blocks not only for optimal planning models (Majumdar, 1987; McKenzie, 1986) but also for recursive general equilibrium models (McKenzie, 2002; Stokey and Lucas, 1989), and for econometrically tractable models for business cycle research (Cooley, 1995) and general macroeconomics (Sargent, 1987). Majumdar (1987) has already covered some basic theory, some efficiency and decentralization analysis, as well as some optimization concepts. We attempt to fill...
in the space between Majumdar (1987) and the current research frontier as well as to outline applications not treated by Majumdar.

Before we begin, we wish to stress that the style of this article is to point the reader towards surveys of the subject in order to economize on references to the many researchers who have contributed to this rather large area, and to paint, in broad strokes, the overall structure of this research area, especially its impact on empirical work, in order to illuminate directions where the research frontier might go.

Dynamic macroeconomic theory has made much use of the stochastic one-sector growth model (Cooley, 1995; Altug and Labadie, 1994; Sargent, 1987; Stokey and Lucas, 1989), for two primary reasons. First, it is a classical result that optimal growth models can be viewed as general equilibrium models by use of the separating hyperplane theorem in an appropriate space to construct the support prices. See Becker and Boyd (1997) for this general result, which they call the ‘equivalence theorem’. It is closely related to the use of decentralization prices in Majumdar (1987) and the general treatment of decentralization in Majumdar (1992).

The basic idea of the class of the ‘equivalence theorem’ of Becker and Boyd is as follows. Consider an infinite horizon intertemporal general equilibrium model with a representative infinitely lived consumer who faces intertemporal prices as given. Then it is a classical result that the rational expectations equilibrium of such a model is the same as the optimal solution of a planning problem where the planner has the same preferences as the representative consumer. Technical issues arise from the infinite horizon such as the necessity and sufficiency of transversality conditions at infinity (that is, the present discounted mathematical expectation of value of any stocks ‘left over’ at infinity should be zero, much as in a finite horizon case with no bequest motive). But the general ideas behind this type of result are much the same as in the well-known finite dimensional cases. See Becker and Boyd (1997) for the details.

Second, infinite horizon stochastic multisector models are also basic in constructing econometrically tractable models to use in analysing data. Here, especially, is where stochastic versions of the turnpike theorem (explained below) are used. For example, it is used to justify use of laws of large numbers and central limit theorems in econometric time-series applications.

A key property of the one-sector model that promotes its use in real business cycle applications as well as intertemporal general equilibrium asset pricing applications is the stochastic analog of the turnpike theorem. This theorem states that optimal capital stock and optimal consumption converge in a stochastic sense to a unique stochastic limit under standard assumptions of concavity of the payoff function (for example, the planner's preferences) and of the production function and modest assumptions on the structure of the stochastic shocks. It is much more difficult to obtain such results for general multisector stochastic models (Arkin and Evstigneev, 1987; Marimon, 1989) and even for deterministic versions of those models (McKenzie, 1986; 2002).

However, one can show that if the discount rate on the future is small enough there are results available in the literature that locate useful sufficient conditions on payoffs and technology such that stochastic convergence occurs (Marimon, 1989) and deterministic convergence occurs (McKenzie, 1986; 2002). Results for stochastic multisector growth models in both discrete time settings and continuous time settings are also contained in the papers in Dechert (2001).

The basic idea behind these results, called ‘turnpike’ results, is to first observe that, if the discount rate on the future is zero, the dynamic optimization problem will attempt to maximize a long-run ‘static’
objective in order to avoid infinite ‘value loss’ if it failed to do so. Making this intuition mathematically precise requires introduction of a partial ordering called the ‘overtaking ordering’ and making assumptions on the objective function and the dynamics so that avoidance of infinite value loss results in convergence of the optimal quantities to a unique long-run limit (see Arkin and Evstigneev, 1987, and the papers in Dechert, 2001, for stochastic cases and McKenzie, 1986; 2002, for deterministic cases.) Once one has results well in hand for the case of zero discounting on the future, intuition suggests that there should be a notion of ‘continuity’ that would enable one to prove that, if the discount rate is close enough to zero, convergence would still hold. Unfortunately, turning such intuition into precise mathematics turns out to be rather difficult (see McKenzie, 1986; 2002, for deterministic literature and Arkin and Evstigneev, 1987, the papers in Dechert, 2001, and Marimon, 1989, for the stochastic case). We attempt to give the reader a brief idea of how the mathematical arguments work in a sketch of the arguments used to prove turnpike theorems for the deterministic case below. Let preferences of a planner be given by

\[ \max_{\{x_t\}} \sum_{t=0}^{\infty} \beta^t \left[ u(x_t, x_{t-1}) - u(x^*_\beta, x^*_\beta) \right] \]

(1)

where \( u: R^n \rightarrow R \) is a twice continuously differentiable function (typically an indirect utility or payoff function), \( \beta \) is a discount factor, \( 0 < \beta \leq 1 \), and \( x^*_\beta \) is an optimal steady state which solves the first-order necessary conditions of the optimization in (1):

\[ D_i u(x_t, x_{t-1}) + \beta D_j u(x_{t+1}, x_t) = 0 \quad \forall t \geq 1 \]

(2)

\( D_i \) denotes partial derivative with respect to the \( i \)th argument of \( u \), and \( x_0 \) is given. We assume that \( u \) is jointly concave in its arguments and use eq. (2) evaluated at the optimal steady state \( x^*_\beta \) to rewrite the sum in (1). To simplify the notation, we let \( u^*_\beta = u(x^*_\beta, x^*_\beta) \) and \( D_i u^*_\beta = D_i u(x^*_\beta, x^*_\beta) \). Also, define

\[ d_t = - \left[ u(x_t, x_{t-1}) - u^*_\beta - (D_1 u^*_\beta)(x_t - x^*_\beta) - (D_2 u^*_\beta)(x_{t-1} - x^*_\beta) \right] \]
which is positive by the concavity of \( u \). With this notation,

\[
\sum_{t=1}^{T} \beta^t \left[ u(x_t, x_{t-1}) - u^* \right] = \beta^T \left( D_1 u^* \right)(x_T - x^*) + \left( D_2 x^* \right)(x_0 - x^*) - \sum_{t=1}^{T} \beta^t d_t
\]

Equation (3) immediately suggests that a good strategy to construct candidate optimal programs \( \{x_t\} \) is to choose a program \( \{x_t\} \) to solve

\[
\min \sum_{t=1}^{\infty} \beta^t d_t.
\]

This strategy works for all \( \beta \in (0,1] \). Following McKenzie (1986, and his references to David Gale) for \( \beta = 1 \), classify a program \( \{x_t\} \) as good (bad) if the series \( \sum_{t=1}^{T} d_t \) converges (diverges) and note that all programs \( \{x_t\} \) are either good or bad. Solve (4) over good programs to get a top candidate for an optimum. By defining an appropriate partial ordering of programs that is a total ordering on the set of good programs, this top candidate turns out to be optimum. Since the series \( \{d_t\} \) converges to 0 for all good programs, this forces \( \{x_t\} \) to converge to a unique \( x^* \) which is the maximizer of \( u(x, x) \) under the assumption that \( u \) is strictly concave. We call this analytical strategy the ‘value loss’ strategy.

There are basically two analytical strategies used for the case \( \beta \) is less than but close to 1. It is beyond the scope of this article to discuss them here; see McKenzie (1986; 2002) for the details.

All three of these analytical strategies can be generalized to stochastic cases where the indirect utility \( u \) contains stochastic shocks provided that Markovian type conditions are assumed on the stock process; \( \{x_t\} \) is replaced by a sequence of random variables \( \{X_t\} \); and \( x^*_\beta \) is replaced by a certain stationary ergodic stochastic process, \( \mathcal{X}^*_\beta \), that plays the role of the optimal stochastic steady state. This is not simple but we hope that our outline of one of the analytical strategies makes that one, at least, intuitively plausible (see, for example, Arkin and Evstigneev, 1987; Marimon, 1989; and the papers by Brock and Majumdar, 1978, Brock and Mirman, 1972, and Brock and Magill, 1979, reprinted in Dechert, 2001).

Our sketch of the above results has been deliberately brief since excellent survey treatments are readily available in the literature that we have cited. We wish to discuss here applications of multisector models to the following areas of economics: (a) a general vision of how the economy works; (b) asset pricing; (c) coupled ecological/economic dynamical systems.
General vision

It is no exaggeration to say that classical general equilibrium theory is analytically organized around existence of equilibrium, the core and equilibria, the two welfare theorems, as well as the ‘anything goes’ theorem of Sonnenschein, Mantel and Debreu (SMD) as the subject is expounded in McKenzie (2002). The SMD result requires users to place restrictions on the consumers and producers that populate general equilibrium models in order to use the theory for empirical work. In intertemporal economics a most popular way of doing this is to restrict oneself to recursive intertemporal general equilibrium models, and that restriction (via the ‘equivalence theorem’) places us in the domain of multisector growth models (Becker and Boyd, 1997).

Black (1995), stimulated by general equilibrium theory, sketches with broad strokes a vision of the economy that is basically operating close enough to a complete set of markets so that the device of generating equilibria by maximizing a weighted sum of utilities can be applied (McKenzie, 2002). Analytically, this device puts us in the domain of a large multisector model viewed as general equilibrium via a generalization of the ‘equivalence theorem’ in Becker and Boyd (1997). As McKenzie (2002) shows, turnpike theory could be extended to recursive intertemporal general equilibrium models with heterogeneous consumers provided markets are complete. Black (1995) proposes adding various elements to received intertemporal recursive general equilibrium models (that is, multisector growth models) not only to fill in gaps in the existing literature up to the mid-1990s but also to make the models match up better to data.

The book by Altug, Chadha, and Nolan (2003) might be viewed as an example of a realization of Black's vision. It shows the power of variations on uses of single-sector and multisector growth models as building blocks for closed- and open-economy macro models. We give some specific examples below. The examples are chosen because current cutting-edge work is being done in these areas and because the subject is moving fast in the directions of these chosen areas.

Asset pricing

Use of the ‘equivalence theorem’ rapidly lead to development of recursive econometrically tractable intertemporal general equilibrium asset pricing models based upon multisector stochastic optimal growth models (Becker and Boyd, 1997, and the papers in Dechert, 2001). The confrontation with data has not been all positive. Three main directions in which these models failed when confronted with data came to be known as the equity premium family of puzzles. But Weitzman (2004, p. 1) has shown that ‘…the subjective distribution of the future growth rate has its mean and variance calibrated to average past values. This paper shows that using the Bayesian posterior estimates of these parameters can go a very long way toward eliminating simultaneously all three puzzles.’ A major point of Weitzman is that, once the uncertainty inherent in the fact that there is estimation uncertainty in key parameters that the agents living in the model must take into account in addition to the shocks inherent in the model, then the puzzles tend to vanish.

Akdeniz and Dechert (2007) show that a single-sector stochastic asset pricing model with production and with heterogeneous firms can go a long ways toward removing the puzzles without having to
introduce Weitzman's Bayesian modification of the underlying basic model. Work like that of Akdeniz and Dechert is now possible due to advances in computational technology. Jog and Schaller (1994) have shown that a modification of the basic model for liquidity-constrained firms can account for patterns of mean reversion observed in returns data across size classes of firms.

Macroeconomics

We have already mentioned the real business cycle literature (Cooley, 1995; Altug, Chadha and Nolan, 2003) as macroeconomic applications of multisector growth models and their decentralization analysis.

A major recent development in macroeconomics is to replace the representative consumer agent and competitive firms in such models with a representative agent facing a set of differentiated products, each produced by a differentiated products monopolist who faces a stochastic process that gives it realizations of periods when it is allowed to change prices. This strategic modeling device allows one to add an analytically tractable theory of price setting which can be grafted onto the existing analytical apparatus of recursive multisector models to produce a model where a unification of the ‘real side’ and the ‘monetary side’ of macroeconomics can take place. Various devices are used to produce a demand for money balances in the model that include real balance services in the indirect utility function and cash in advance constraints. This modeling strategy has produced a new generation of very fruitful ‘New Keynesian’ macro models which has allowed treatment of key issues of monetary policy as well as better fit to data especially data resulting from interactions between the real side and the monetary side of an economy. See Altug, Chadha and Nolan (2003) and, especially, Woodford's treatise (2003) for this genre.

The real world has distortions such as taxes, inflation and other government activities such as production of public goods which require modifications of the basic structure of intertemporal recursive general equilibrium theory. Fortunately the analytical core can be quite readily modified to include these elements (Turnovsky, 1995).

Much of the literature on multisector optimal growth theory assumes convex technology and concave payoff (that is, concave utility) so that the indirect utility $u(x_t, x_{t-1}, S_t)$ is jointly concave in $(x_t, x_{t-1})$ for each value of the stochastic shock $S_t$. We believe much activity in the future will involve generalizations to models of coupled ecological and economic dynamic systems where such concavity does not hold. Some analytical work in this area has already appeared (Becker and Boyd, 1997; Majumdar, 1992) and as computational technology progresses we expect to see more developments that use a combination of analytics and computation.

growth take-offs

Matthias Doepke
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Following a phase of near-constant living standards lasting from Stone Age until the onset of the Industrial Revolution, a large number of countries have experienced growth takeoffs, in which stagnation gives way to sustained economic growth. What causes some countries to enter a growth takeoff while others remain poor? We discuss three mechanisms that can trigger a growth takeoff in a country previously trapped in poverty: fertility decline, structural change, and accelerating technological progress.

Keywords

child labour; demographic transition; economic growth; fertility; fixed factors; growth takeoffs; human capital; income–population feedback; Industrial Revolution; land; Malthus's theory of population; mortality; nutrition and development; population growth; productivity growth; skill-intensive technology; stagnation; structural change; technological progress; women's work

Article

Viewed on a historical timescale, economic growth in the world economy is characterized by a long phase of stagnation in living standards, followed in many, but not all, countries by a growth take-off, that is, a transition to steady and sustained economic growth.

Figure 1 illustrates the basic facts. Before 1800, GDP per capita was low and near-constant in all world regions, with little cross-country variation in income levels. The first country to experience a growth take-off was Britain with the start of the Industrial Revolution, closely followed by other west European countries and the ‘Western Offshoots’ such as the United States. More recently, a number of Asian and Latin American countries have undergone a transition to rapid economic growth as well. In much of Africa, however, income per capita continues to stagnate. What causes some countries to enter a growth takeoff while others remain poor?

Figure 1

The evolution of income per capita across world regions, years 1500–2001. Note: The ‘Western Offshoots’ are defined as the United States, Canada, Australia, and New Zealand. ‘Asia’ excludes Japan. Source: Maddison (2003, Table 8c).
Explaining stagnation

Before one can account for a growth takeoff after a phase of stagnation, it is essential to understand why economies stagnated in the first place. The explanation suggested by one of the earliest writers on the subject, British economist Thomas Malthus in his *Essay on the Principle of Population* of 1798, is widely accepted to the present day. The Malthusian model relies on two key ingredients: an agricultural production function that uses the fixed factor of land, and an income–population feedback where the population growth rate is an increasing function of income per capita.

Consider an aggregate production function of the form

\[ Y_t = A_t N_t^\alpha Z^{1-\alpha}, \]

(1)
where \( Y_t \) denotes output in period \( t \), \( A_t \) is productivity, \( N_t \) is the size of the population, and \( Z \) is the fixed amount of land. (The results outlined below can be generalized to the case where physical capital also enters production.) In what follows, we use lower-case letters to denote per capita variables \( (Y_t = \frac{Y_t}{N_t} \text{ and so on}) \), and the growth rate of a variable \( x \) is written as \( \gamma(x) \). Output per capita is given by \( \gamma(Y_t) = \gamma(A_t) + (1 - \alpha) \gamma(Z_t) \).

Since land \( Z \) is constant, we have \( \gamma(Z_t) = \gamma(Z) - \gamma(N_t) = -\gamma(N_t) \). Using this relationship, the growth equation can be rewritten as

\[
\gamma(Y_t) = \gamma(A_t) - (1 - \alpha) \gamma(N_t). \tag{2}
\]

Growth in income per capita is thus an increasing function of productivity growth and a decreasing function of population growth. The negative effect of population growth reflects the fact that land is a fixed factor: when the size of the population increases, there is less land for each person to work with, which lowers income per capita.

To turn the growth equation (2) into a theory of stagnation, one needs to specify how productivity \( A_t \) and population \( N_t \) evolve over time. Assume for now that productivity growth is constant, \( \gamma(A_t) = Y_A \). The main assumption underlying the Malthusian theory of stagnation is that population growth is an increasing function of income per capita \( y_t \):

\[
\gamma(N_t) = f(y_t), \tag{3}
\]

where \( f'(y_t) > 0 \). A number of different justifications can be given for this relationship. One possibility is that children enter the utility function of parents as normal goods. A rise in income would then increase the demand for children, leading to higher population growth. Alternatively, the mechanism could also work through mortality. If higher income leads to better nutrition and, as a consequence, lower mortality rates, a positive relationship between income per capita and population growth follows. As an empirical matter, the assumption of a positive relationship appears to fit the experience of most pre-industrial economies rather well.

Using (3), the growth equation (2) reads:

\[
\gamma(Y_t) = Y_A - (1 - \alpha) f(y_t). \tag{4}
\]

According to this equation, the growth rate of income per capita is a decreasing function of its level. If the detrimental effect of population growth is sufficiently strong, this mechanism leads to stagnation as the only possible long-run outcome. In a country where income per capita is initially rising, population growth will accelerate until it fully offsets productivity growth, \( (1 - \alpha) f(y_t) = Y_A \) resulting in stagnation.

The Malthusian model is remarkably successful in terms of explaining economic growth (or the lack thereof) until Industrial Revolution. However, we now know that ultimately many countries managed to escape from the Malthusian trap. In these countries, living standards today are far superior to what almost any human alive before 1800 could have
experienced. How can this drastic change in the economic fate of countries be explained?

**Endogenous population growth**

Given the growth equation (4), one scenario that could lead to a growth takeoff is a reversal of the income–population feedback. If the positive relationship described by the equation \( \gamma(N_t) = f(N_t) \) breaks down, and subsequent population growth is low, growth will ensue. Consider, for example, the case where population growth ceases altogether, \( \gamma(N_t) = 0 \). According to eq. (2), growth in output per capita is then equal to productivity growth. Thus, as long as productivity keeps increasing, income per capita will grow indefinitely. Historically, the Malthusian relationship between income and population growth did indeed break down in every single country that experienced a growth take-off. In a pattern known as the *demographic transition*, the high fertility and mortality rates of the pre-industrial era gave way to a new regime in which fertility, mortality, and population growth are low. In modern data, the relationship between income per capita and population growth is negative (both in a cross section of countries and in the time series for most rich countries), which is the opposite of what the Malthusian model assumes.

Figure 2 illustrates the demographic transition by comparing population growth in western Europe (the first region to experience a take-off) with Asia and Africa (the regions that stagnated the longest). In western Europe, population growth reached a peak at the end of the 19th century and has been declining since, despite rapid growth in income per capita. In Asia and Africa, in contrast, population growth has accelerated since the mid-19th century, and is now much higher than in western Europe.

Figure 2

A number of authors have developed theories that integrate models of economic growth and the demographic transition to explain growth take-offs. In this literature, fertility decline is usually interpreted as a substitution of child ‘quantity’ (a large number of children) by child ‘quality’ (fewer children in which parents invest in terms of education or human capital). As an example of a model capturing this trade-off, consider the decision problem of a parent with preferences

\[ u(c, n, h) = (1 - \beta)\log(c) + \beta [\log(n) + \gamma \log(h)] \]

over consumption \( c \), the number of children \( n \), and the children's human capital \( h \), where \( \beta > 0 \) and \( 0 < \gamma < 1 \). The parent has to spend fraction \( \varphi \) of its time to raise each child, and can choose to spend an additional per-child fraction \( e \) on educating the children. The total child-rearing time is then given by \( (\varphi + e) n \), and the budget constraint for the parent is \( c = (1 - (\varphi + e) n) wH \), where \( H \) is the parent's human capital, \( w \) is the wage per unit of human capital, and the time endowment is normalized to one. A child's human capital depends on the parent's human capital \( H \) and education time \( e \):

\[ h = 1 + \mu He, \]

where \( \mu \) is the productivity of the education technology. Notice that a child receives at least one unit of human capital even if education \( e \) equals zero, which represents basic productive skills (such as physical strength) that do not rely on education. Lastly, the parent also has to observe a subsistence consumption constraint, \( c \geq \bar{c} \), where \( \bar{c} \) is the minimum amount of consumption required for survival.

In this model, the relationship between income and fertility depends on whether the optimal choices for education and consumption are at a corner. Assume that, initially, the wage \( w \) and the education productivity \( \mu \) are so low that the subsistence constraint is binding and the parent chooses zero education \((e = 0)\). The number of children is then constrained by the need to earn at least \( \bar{c} \) units of consumption:

\[ n = \frac{1}{\varphi} \left( 1 - \frac{\bar{c}}{wH} \right). \]

Under this regime, the relationship between income \( wH \) and fertility \( n \) is positive, as assumed by the Malthusian model.

The outcome changes substantially if, through an increase in the wage \( w \) and the education productivity \( \mu \), the economy enters a regime where the subsistence constraint is no longer binding, and education is positive: \( e > 0 \). Under this regime, parents spend a fixed fraction of their time on child rearing. The balance between child quality and quantity depends on parental human capital \( H \). The optimal decision rules are:

\[ n = \frac{\beta}{\varphi + e} \text{ and } (5) \]
Equation (5) captures the trade-off between child quality and quantity: the number of children is a decreasing function of education $e$. Intuitively, investing a lot in each child renders children expensive, which reduces demand. Education $e$, in turn, depends positively on parental human capital $H$. An increase in income per capita (through a rise in $H$) therefore lowers fertility $n$, the opposite of the Malthusian assumption.

Given these results, an escape from the Malthusian trap is possible if some change in the economy generates increased investment in child quality. The literature proposes different candidates for the underlying cause of such an event. In Galor and Weil (2000), the take-off is ultimately a consequence of technological progress. Accelerating productivity growth increases the return to education (the parameter $\mu$ in the model outlined above), which eventually triggers the quantity-quality substitution and the growth take-off. Galor and Moav (2002), in contrast, suggest that evolving parental preferences (through an increase in the parameter $\gamma$) are the driving force behind fertility decline. Yet other authors have emphasized the role of declining mortality rates (Boucekkine, de la Croix and Licandro, 2002; Cervellati and Sunde, 2005; Doepke, 2005; Kalemli-Ozcan, 2002; Lagerlöf, 2003a; Soares, 2005), increasing female labour-force participation (Galor and Weil, 1996; Lagerlöf, 2003b), changes in the provision of old-age security (Boldrin and Jones, 2002), changes in child-labour and education laws (Doepke and Zilibotti, 2005), and the introduction of skill-intensive production technologies that raise the return to education (Doepke, 2004).

### Structural change

Apart from endogenous population growth, the Malthusian model also relies on the presence of the fixed factor of land to generate stagnation. A second potential trigger for a growth take-off is therefore structural change that decreases the role of land. In pre-industrial economies, agriculture was the main mode of production. In contrast, in modern industrial economies the share of agriculture in output is small, and consequently land is less important. Translated into the growth equation (4), structural change amounts to a shift in the parameter $\alpha$. In particular, an increase in $\alpha$ lowers the detrimental effect of population growth on income per capita. In the limit case of $\alpha = 1$, income per capita is independent of the size or growth rate of the population, and is solely driven by productivity growth.

In Hansen and Prescott (2002), a decline of the role of land is generated endogenously in an environment where two competing technologies can be used for production. (Related contributions include Matsuyama, 1992; Laitner, 2000; Kögel and Prskawetz, 2001; Gollin, Parente and Rogerson, 2002; Ngai, 2004). In addition to the production function (1) above, an ‘industrial’, constant-returns technology is also available:

$$Y^I_t = \alpha^I_t N^I_t,$$

where $Y^I_t$ is industrial output, $\alpha^I_t$ is productivity, and $N^I_t$ is the amount of labour employed in the industrial sector. Productivity $\alpha^I_t$ is assumed to grow at a constant rate. The total amount of labour is allocated optimally between the traditional sector and the industrial sector. Given the linear production technology, output per worker in the modern sector is given by $\alpha^I_t$. Early in development, when $\alpha^I_t$ is still low, it is optimal to allocate all workers to the traditional sector. During this phase the economy behaves just like a Malthusian economy where the modern technology does not exist at all.

Ultimately, however, the modern technology becomes sufficiently productive to be introduced. If $w_M$ is the (constant) marginal product of a worker in the Malthusian regime, the technology will be introduced once $\alpha^I_t > w_M$. From this point on, population growth no longer affects output per worker, since land is not used in the industrial sector. Output per worker therefore starts to grow at the rate of technological progress. Viewed through the lens of the Hansen–Prescott model, what initially appears as a structural break in economic history is merely the outcome of an optimal sectoral allocation decision in an otherwise stable economic environment.
Starting once again from the growth equation (4), a third potential trigger for a growth takeoff is a sustained increase in productivity growth that is large enough to ‘outrun’ population growth. Clearly, population growth cannot increase indefinitely, as there are physiological constraints on child bearing. Let $\bar{Y}_N$ be an upper bound for population growth that cannot be exceeded for biological reasons. If now productivity growth satisfies

$$Y_A > (1 - \alpha)\bar{Y}_N,$$

even at maximum population growth the detrimental effect of increasing population density does not suffice to negate productivity improvements, and improving living standards ensue. 

A potential cause for accelerating productivity growth is scale effects in the production of ideas. An increase in world population implies that there are more people who might invent new, productive technologies. An increase in world population should therefore imply an acceleration of productivity growth. Scale effects of this kind underlie the takeoff models of Kremer (1993), Jones (2001), and Tamura (2002).

**Conclusions**

The three potential triggers for a growth take-off presented here should not be regarded as mutually exclusive alternatives, but rather as complementary explanations for a joint phenomenon. From an empirical perspective, there is little doubt that all three explanations are relevant: every country that underwent a growth takeoff also experienced a demographic transition, a sectoral shift from agriculture to industry and services, and an acceleration of productivity growth. Reflecting these observations, many papers in the literature already incorporate more than one of the mechanisms. For example, a number of authors propose models where accelerating endogenous productivity growth triggers a fertility transition. This is true, for example, of the seminal paper of Galor and Weil (2000) and, in a framework driven by human-capital externalities, for de la Croix and Doepke (2003). Similarly, Greenwood and Seshadri (2002) and Doepke (2004) integrate models of structural change with theories of fertility decline.

Building on the different mechanisms behind growth take-offs that have been proposed in recent years, a major challenge for future research is to understand why in many countries these mechanisms fail to work to the present day. Conceivably, a better understanding of the mechanisms that allowed some countries to overcome economic stagnation two centuries ago might help us learn how the same feat could be accomplished in poverty-stricken developing countries today.

Haavelmo, Trygve (1911–1999)

Agnar Sandmo

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

balanced budget multiplier; capital theory; econometrics; Haavelmo, T.; inequality (global); investment theory; neoclassical theory of capital accumulation; probability

Article

Haavelmo was born in Skedsmo, Norway. He graduated from the University of Oslo in 1933 and joined Ragnar Frisch's newly created Institute of Economics as a research assistant. He spent the war years working for the Norwegian government in the United States. After a year's stay at the Cowles Commission at the University of Chicago, he returned to Norway in 1947, becoming professor of economics at the University of Oslo in 1948. He retired from his chair in 1979. In 1989 he was awarded the Nobel Memorial Prize in Economics, the Nobel citation referring to 'his clarification of the probability theory foundations of econometrics and his analyses of simultaneous economic structures'. Haavelmo first made his name by a series of path-breaking contributions to the theory of econometrics, most of which were written during his years in the United States. His 1943 article in *Econometrica* was the first to consider the statistical implications of simultaneity in economic models. This paper was one of the main sources of inspiration for the extensive work carried out in this area over the next decade, particularly at the Cowles Commission. Haavelmo developed his ideas further in the famous 1944 supplement to *Econometrica*; the main general contribution of this work was to base econometrics more firmly on the foundations of probability theory.

After his return to Norway, Haavelmo turned away from econometrics to economic theory as his main field of interest. In his 1957 presidential address to the Econometric Society (published the next year) he emphasized the need for a more solid theoretical foundation for empirical work as well as the need for theory to be inspired by empirical research.

Haavelmo's *Study in the Theory of Economic Evolution* (1954), is a broad exploration of the contributions that analytical economics can make to the understanding of global economic inequality. As an early contribution to growth theory it is less notable for simple models and precise theorems than for its imaginative and experimental attitude towards hypotheses concerning population growth, education,
migration and the international struggle for redistribution. The open-mindedness of the approach is very characteristic of the author.

Similar remarks apply to his 1960 book, *A Study in the Theory of Investment*. Its main objective is to provide a firmer microeconomic foundation for the macroeconomic theory of investment demand. To this end Haavelmo probes deeply into capital theory, emphasizing strongly, however, that a theory of optimum capital use does not in itself provide a theory of investment. This insight, and his clear statement of what has since been known as the neoclassical theory of capital accumulation, has been a major influence on late work in this area, both theoretical and applied.

Of Haavelmo's other contributions to economic theory, special mention should be made of his 1945 analysis of the balanced budget multiplier. The expansionary effect in a Keynesian unemployment situation of a balanced increase of public expenditure and taxes had been pointed out before, but Haavelmo was the first to provide a rigorous theoretical analysis of it.

Haavelmo was also been very active as a teacher. His lecture notes on a wide range of topics in economic theory exerted a formative influence on generations of Norwegian economists.

Habakkuk, John Hrothgar (1915–2002)

Ravi Mirchandani
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Britain, economics in; capital-intensive technology; falling rate of profit; Habakkuk, J. H.; labour supply; technical change; United States, economics in

Article

Born in Wales in 1915, Habakkuk graduated from Cambridge in 1936, where he was a Fellow of Pembroke College from 1938 until 1950. He held the Oxford chair of economic history from 1950 to 1967, when he became Principal of Jesus College, Oxford. He retired in 1984. As a member of the Advisory Council on Public Records (1958–70), the Royal Commission on Historic Manuscripts, and the British Library Organizing Committee, amongst other bodies, he was active in the field of public records; he was knighted in 1974.

His major contribution was to the study of the rates of technological change in Britain and America in the 19th century and the reasons for the much more rapid development and use of manufacturing technology in the United States. In his book, *American and British Technology in the Nineteenth Century* (1962), American industrial development is roughly divided into two important stages, the period before the first wave of immigration in the 1840s, which laid the ground for future development, and the period after 1870 when abundant natural resources and rapid growth of market demand provided the stimulus for growth.

Habakkuk argues that American technological development in the early period, by contrast with Britain, was stimulated by the high cost of labour relative to capital and the relative inelasticity of labour supply. The expanding manufacturer, to avoid a falling marginal rate of profit, was more likely than his British counterpart to look to capital-intensive and labour-saving technology. Though Habakkuk was also keen to stress the importance of social factors, the suspicion of British employers and the hostility of British labour to new techniques, his explanation of the disparity is grounded in economic relationships.

Habakkuk's thesis has come under considerable scrutiny; recent research has tended to suggest that there was considerable diversity, both on a regional basis and between different industries, in development on both sides of the Atlantic. Economic historians have also questioned the timing of significant
development in the States and chosen to put greater stress on non-economic explanations. Habakkuk also made notable contributions to the debates on British population growth in the late 18th century and on the changing pattern of landholding as smaller holdings gave way to larger units in the same period.

Article

Gottfried Haberler was born on 20 July 1900 in Purkersdorf, near Vienna. He studied economics at the University of Vienna under Friedrich von Wieser and Ludwig von Mises, where he received doctorates in law (1923) and economics (1925). After two years in the United States and Britain he returned to Vienna, received his habilitation in 1928, and was appointed lecturer, later professor, of economics, at the University of Vienna, from 1928 to 1936. He was appointed professor at Harvard University in 1936, where he remained until his retirement in 1971, after which he was a resident scholar at the American Enterprise Institute, Washington, DC. He was President of the International Economic Association (1950–1), the National Bureau of Economic Research (1955), and the American Economic Association (1963). In 1980 he was awarded the Antonio Feltrinelli prize.

Haberler's first major work was his habilitation thesis (1927), *The Meaning of Index Numbers*, summarized in Koo (1985, pp. 546–9). This work stimulated a great deal of subsequent research on the theory of the price or cost-of-living index. Haberler defined the ‘true change in the price level’ as ‘the ratio of the money income in the first period to the money income in the second period that would leave the individual indifferent’ (Koo, 1985, p. 547). Haberler's main concern was to find conditions under which this ‘true price index’ would be bounded by the Laspeyres and Paasche price indices. Some of the difficulties with this approach (and with the similar, earlier approach of Konüs, 1924) were discussed by Bortkiewicz (1928), Neisser (1929), Staehle (1935), and Frisch (1936). Frisch remarked (p. 25) that Haberler's definition of the ‘true change of the price level’ involved an implicit assumption of expenditure proportionality (homothetic preferences), and attributed this point (but apparently without
justification) to Bortkiewicz; he also interpreted Haberler (1929) in his reply to Neisser and Bortkiewicz as accepting this point. In terms of contemporary concepts we may say that homothetic preferences characterize indirect utility functions of the form \( \frac{Y}{C(p)} \) where \( Y \) is income and \( C(p) \) is a homogeneous-of-degree-1 function of prices.

Undoubtedly Haberler's most significant contribution was his reformulation of the theory of comparative costs (Haberler, 1930a), which revolutionized the theory of international trade. Prior to this paper, the Ricardian theory still held sway, but had been so amended with ill-defined concepts such as ‘real cost’ and ‘units of productive power’ taking the place of labour allocation that it had lost all its simplicity and elegance. Haberler introduced the production ‘substitution curve’ (now usually known as the production-possibility frontier), allowing for several factors of production, and taken to be concave to the origin as a result of diminishing returns. This laid the foundations for Ohlin's theory, as well as Lerner's and Samuelson's. True, as recently brought to light by Maneschi and Thweatt (1987), a footnote contained in the posthumous edition of Barone's Principi (1936, pp. 170–3), depicting a (non-concave) production-possibility frontier and a community indifference curve, was actually present in the first (1908) edition – but not subsequent ones; hence Barone must be accorded priority. But Haberler's independent discovery – and the use to which he put it – is what transformed the theory of international trade. Haberler also introduced the concept of a ‘specific factor’ – one that is completely immobile among industries – and used this concept with great effect in Haberler (1950) to illustrate the proposition that the gains from trade do not depend on the assumption of factor mobility.

Haberler made numerous other contributions to international economics, including (1) his synthesis and clarification of the Keynes–Ohlin debate on the transfer problem (Haberler, 1930b); (2) his judicious use of purchasing-power-parity calculations to set exchange rates (Haberler, 1945); (3) his introduction of the concept of supply and demand schedules for foreign exchange (1936) and his subsequent use of them (Haberler, 1949) in qualified support of the proposition that a devaluation in a pegged-rate regime could improve a country's balance of payments – but subject to the important proviso (1949, p. 213) that it would, through monetary expansion, likely shift these schedules; (4) his advocacy of free trade as the best policy for developing countries (Haberler, 1959); (5) numerous contributions to past and current history of international economic relations (cf. Koo, 1985).

The third area in which Haberler made major contributions is business-cycle theory (Haberler, 1937; 1942). His classic synthesis, notably in the third edition of Prosperity and Depression (1941), introduced the important ‘real-balance effect’, initially called the ‘Pigou effect’ by Patinkin (1948), although Patinkin in his 1951 revision acknowledged Haberler's priority over Pigou (1943). In the 1970s and 1980s Haberler furnished trenchant analyses of the phenomenon of worldwide inflation and the political economy of stagflation (cf. Koo, 1985), displaying the unique combination of clarity and wisdom that are characteristic of his writings.

Information on Haberler's life and work may be found in Schuster (1979), Chipman (1982), Baldwin (1982), Officer (1982), and Willett (1982). A complete bibliography of his writings is contained in Koo (1985).

habit persistence

Stephanie Schmitt-Grohé and Martin Uribe
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews the concept of habit persistence and its application in macroeconomics and finance. Special attention is given to the role of habit persistence in explaining the equity premium puzzle, observed business-cycle fluctuations and inflation dynamics, and in generating a theory of countercyclical markups of prices over marginal costs.

Keywords

asset pricing; business-cycle fluctuations; currency pegs; deep habits; equity premium puzzle; Euler equation; habit persistence; imperfect competition; inflation dynamics; investment adjustment costs; partial equilibrium; risk aversion; sticky prices; variable capacity utilization

Article

Habit persistence, or ‘habit formation’ in its most common representation, is a preference specification according to which the period utility function depends on a quasi-difference of consumption.

Specifically, if the utility function without habit formation is given by \( \sum_{t=0}^{\infty} \beta^t U(c_t) \), where \( c_t \) denotes consumption in period \( t \), \( U \) denotes the period utility function, and \( \beta \in (0, 1) \) denotes the subjective discount factor, then the utility function with habit persistence is given by \( \sum_{t=0}^{\infty} \alpha \beta^t U(c_t - \alpha c_{t-1}) \). The parameter \( \alpha \in (0, 1) \) denotes the intensity of habit formation and introduces non-separability of preferences over time. Under habit persistence, an increase in current consumption lowers the marginal utility of consumption in the current period and increases it in the next period. Intuitively, the more the consumer eats today, the hungrier he wakes up tomorrow. It is in this sense that this type of preferences captures the notion of habit formation.

In the habit-forming preferences given above, past consumption represents the consumer's stock of habit in period \( t \). More general specifications allow for the stock of habit to be a function of possibly all past
consumptions. In this case, the period utility function is given by $U(c_t - \alpha S_{t-1})$, where $S_{t-1} = S(c_{t-1}, c_{t-2}, \ldots)$ denotes the stock of habit in period $t$. Often, the stock of habit is assumed to follow an autoregressive law of motion of the form $S_t = (1 - \delta)S_{t-1} + \lambda c_t$. The parameter $\delta$ governs the rate of depreciation of the stock of habit, and the parameter $\lambda$ measures the sensitivity of the stock of habit to current consumption.

A common variant of the habit persistence model is to treat habits as external to the consumer. When habits are external, the stock of habit depends on the history of aggregate past consumption as opposed to the consumer's own past consumption. Early formulations of the habit formation model, for example Pollak (1970), were cast in the external form. Since the work of Abel (1990), external habit formation has become known as ‘catching up with the Joneses’. The external form of habit persistence simplifies the optimization problem of the consumer because the evolution of the stock of habit is taken as exogenous by the individual.

Another variation of the habit formation model is relative habit persistence, which features a quasi-ratio of consumption rather than a quasi-difference of consumption, as the argument of the period utility function (Duesenberry, 1949; Abel, 1990).

Habit persistence and the equity premium puzzle

Habit persistence has been proposed in financial economics as a possible solution to the equity premium puzzle first identified in the seminal work of Mehra and Prescott (1985). The equity premium puzzle is that, under the assumption of power utility and no habit persistence, observed excess returns of stocks over less risky assets, such as commercial paper, are too high to be consistent with actual consumption behaviour unless households are assumed to be extremely risk averse. At the heart of the equity premium puzzle lies the low volatility of observed consumption growth. To see this, note that a risky asset commands a high rate of return if it provides poor insurance against consumption fluctuations by paying plenty in periods of high consumption growth and little in periods of low consumption growth. If fluctuations in consumption growth are small (as is observed in the data), then high returns on risky assets can be supported only if one assumes that even minute consumption fluctuations are very painful to consumers. In other words, one must assume that consumers are extraordinarily risk averse. With this intuition in mind, one can readily see why habit persistence has the potential to solve the equity premium puzzle. Habit-forming consumers dislike variations in habit-adjusted consumption, $c_t - \alpha S_{t-1}$, rather than variations in consumption itself, $c_t$. A given percentage change in consumption produces a much larger percentage change in habit-adjusted consumption than in consumption itself. In this way, small fluctuations in consumption growth can generate large variations in habit-adjusted consumption growth and hence explain sizable excess returns on risky assets even for moderate values of the degree of risk aversion. Early studies of the ability of habit persistence to resolve the equity premium puzzle include Sundaresan (1989), Abel (1990), and Constantinides (1990). Subsequent work has refined the habit-formation model to account for additional asset-pricing puzzles, such as the risk-free-rate puzzle and the forecastability of excess returns (see, for example, Campbell and Cochrane, 1999).

Habit persistence and the business cycle
In the asset-pricing literature, most applications of habit persistence are conducted within the context of partial equilibrium settings, in which private consumption is assumed to be exogenous. This assumption is not inconsequential. Indeed, it has been shown that, once a general equilibrium approach is adopted, in which consumption decisions are endogenous, the ability of habit persistence to reconcile the behaviour of asset prices and consumption is diminished. This is because habit formation induces excess smoothness in consumption expenditure (Lettau and Uhlig, 2000). Boldrin, Christiano and Fisher (2001) show that habit formation can help explain salient aspects of asset prices and business cycles only in combination with severe inflexibilities in factor markets.

Habit persistence features prominently in the literature devoted to the estimation of medium-scale macroeconomic models (for example, Christiano, Eichenbaum and Evans 2005; Smets and Wouters, 2004). The goal of this literature is to build dynamic general equilibrium models capable of explaining the observed behaviour at business-cycle frequency of a large number of macroeconomic variables. To this end, this literature has brought together in a single model most of the theoretical advances in business-cycle theory since the mid-1980s. Thus, these models include not only habit persistence but also other rigidities such as investment adjustment costs, variable capacity utilization, sticky product and factor prices, money demand by households and firms, and imperfect competition in product and factor markets. In the data, the response of consumption to expansionary shocks of various natures is hump-shaped, with the peak response occurring several quarters after the innovation. Such a response is hard to replicate in the absence of habit formation. For in this case consumption has a tendency to peak immediately after the shock and then to decline to its long-run level.

In the applications of habit formation discussed thus far, it matters little whether habits are of the internal or external type. The distinction is of importance in situations in which the consumer expects a regime shift of some nature in the future. A case in point is the consumption dynamics associated with temporary exchange-rate-based inflation stabilization programmes. Exchange-rate-based stabilization programmes, or currency pegs, constitute the most commonly used policy to control high inflation in emerging-market countries. It is well documented that, in response to the announcement of a currency peg, consumption rises initially, reaches a peak and then declines. Importantly, the observed eventual decline in consumption typically takes place before the currency peg is abandoned. Habit formation, be it of the internal or external type, can explain the observed gradual increase in consumption after the implementation of the stabilization plan (Uribe, 2002). However, Uribe shows that the observed contraction in consumption that begins well before the collapse of the stabilization programme can be rationalized with internal habit formation but not with the external form of habits. In effect, maintaining a high consumption habit after the collapse of the stabilization programme is expensive because high inflation acts as a tax on consumption expenditures. When consumers internalize the habitual nature of consumption they start reducing their stock of habit – by cutting back consumption – before the price of consumption increases to mitigate the transition to a lower stock of habit. By contrast, when consumers do not internalize the habitual nature of their consumption, they continue to take advantage of the temporarily low price of consumption until the last day of the stabilization programme.

Deep habits
All of the models of habit persistence discussed thus far in this article assume that habits are formed at the level of a single aggregate consumption good. An important consequence of this assumption is that the introduction of habit formation alters the propagation of macroeconomic shocks only in so far as it modifies the consumption Euler equation and possibly the household's labour supply schedule. Ravn, Schmitt-Grohé and Uribe (2006), hereafter RSU, propose a general equilibrium model of habit formation on a good-by-good basis. They refer to this type of habit formation as ‘deep habits’. They have in mind environments in which consumers can form habits separately over narrowly defined categories of goods, such as clothing, vacation destinations, music, and cars.

The assumption that agents can form habits on a good-by-good basis has two important implications for macroeconomic dynamics. First, the demand side of the macroeconomy – in particular the consumption Euler equation – is indistinguishable from that pertaining to an environment in which agents form habits over a single aggregate good. Second, and more significantly, the assumption of deep habit formation alters the supply side of the economy in fundamental ways. Specifically, when habits are formed at the level of individual goods, firms take into account the fact that the demand they will face in the future depends on their current sales. This is because higher consumption of a particular good in the current period makes consumers, all other things equal, more willing to buy that good in the future through the force of habit. Thus, when habits are deeply rooted, the optimal pricing problem of the firm becomes dynamic.

RSU embed the deep-habit-formation assumption in an economy with imperfectly competitive product markets. This combination results in a model of endogenous, time-varying markups of prices over marginal cost. A central result of RSU's work is that in the deep habit model markups behave counter-cyclically in equilibrium. In particular, expansions in output driven by demand shocks are accompanied by declines in markups. This implication of the deep-habit model is in line with the existing empirical literature. In addition, RSU show that, because of the strong counter-cyclical movements of markups, the deep-habit theory is capable of explaining increases in wages and consumption in response to a positive demand shock as is observed in the data. This latter empirical regularity has proved difficult to explain with standard models of the transmission of demand shocks.

In the deep-habit model it is of great consequence whether habits are internal or external. RSU show that the firm's pricing problem is time consistent under external habit persistence but time inconsistent under internal habit persistence.

Hadley, Arthur Twining (1856–1930)
Robert B. Ekelund, Jr.
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
American Economic Association; cartels; economic evolution; exhaustible resources; Hadley, A. T.; Monopoly; period analysis; price discrimination; profit maximization; property rights; state capture; transport markets

Article
American economist, educator and public servant, Hadley was educated at Yale and at the University of Berlin, where he studied under German historicists. In a remarkable career, Hadley was, in turn, a freelance writer and lecturer on railway economics, a professor of political economy at Yale (1891–9), president of the American Economic Association, president of Yale University (1899–1921), chairman of the Railroad Securities Commission providing the Hadley Report on Railway finances in 1911, and was widely sought after as a political candidate for high political office in the United States. An inveterate traveller, Hadley died aboard ship in Kobe harbour in 1930.

Hadley was an extremely prolific and eclectic writer, but the bulk of his important work in economics was completed before the turn of the 20th century. His reputation rests essentially on two works, Railway Transportation (1885) and a basic text, Economics: An Account of the Relations between Private Property and Public Welfare (1896), which received high praise from his friend and colleague, Irving Fisher.

In Railway Transportation Hadley revealed himself as the most creative railway economist of the day through an integration of sophisticated (certainly for the time) economic analysis with the problems of railway organization. Among other theoretical insights Hadley formalized a theory of monopoly and price discrimination; developed, in the mathematical terms of Cournot, a marginal rule for profit maximization; and anticipated the period analysis of Marshall's Principles. More importantly, perhaps, he developed a modern and complete theory of cartels, showing that, in the presence of open competition, such unsanctioned behaviour on the part of railroads, would lead to the benefits of competition without the attendant disadvantages. In another perspicacious insight Hadley correctly characterized railway regulation as resulting from the capture, by the industry, of legal sanctions to
obtain rate stability. In the main, Hadley viewed regulation as representing a low-cost cartel enforcement device. In *Economics* Hadley went further than Marshall by explicitly developing the interrelations between property rights, economic evolution and economic efficiency. Hadley utilized the real world examples of the fisheries and mining to demonstrate the impact of ill-defined property rights on depletable resources, emphasizing the necessity of altered systems to obtain optimal resource use and allocation. This contribution, along with his prophetic analyses of transport market structure, establishes Hadley as one of the most inventive pre-20th-century American economists.

Hagen, Everett Einar (1906–1993) - The New Palgrave Dictionary of Economics Online

Hagen, Everett Einar (1906–1993)

Robert R. Nathan

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

economic development; Keynesianism; New Deal; population growth; technical change; unemployment

Article

Hagen was born in Holloway, Minnesota. He graduated from St Olaf College (BA, 1927) and the University of Wisconsin (MA, 1932; Ph.D., 1941). After a short period at the University of Illinois (1948–51) he became professor of economics at the Massachusetts Institute of Technology (1953–72); from 1970 to 1972 he was Director of the Center for International Studies at MIT.

Since the Second World War, developing nations have received unprecedented attention from economists and large financial resources from the industrialized world. Dr Hagen was an important contributor to analysing key problems and processes of economic development.

Before concentrating on economic development, Hagen served in the Bureau of the Budget as a close associate of Gerhard Colm in the application of Keynesian principles to US fiscal policies. His firm commitment to Keynes's concepts was a factor in his transfer to the MIT from the University of Illinois, where more traditionalist faculty and top officialdom were hostile to the views of Keynes and of the New Deal.

In his book *On the Theory of Social Change* (1962), Hagen correctly concluded that economics alone could not provide the theoretical or policy directions for economic development. He studied deeply the role of human behaviour based on studies of anthropologists, sociologists and political scientists.

Hagen's multidisciplinary approach provided invaluable insights for formulating development plans and policies.

In his fourth edition of *The Economics of Development* (1986), Hagen continued to elaborate on theoretical aspects as well as policies and implementation processes essential for development progress. Hagen updates the most promising lessons from successful nations replicable in the lagging nations.

Hagen disputes the common view that high population growth rates are a major deterrent to development. He also documents the thesis that protectionism is helpful to the developing world. He sets forth a strong case for attributing considerable unemployment to technological change. These somewhat
unorthodox views are persuasively articulated and documented. Of major importance are Hagen's conceptual formulations, his analyses based on personal experiences, and his challenges to economists and members of other disciplines to work jointly to overcome the persistent barriers to significant progress in the lagging nations.

Hamilton, Alexander (1755–1804)

Henry W. Spiegel

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

credit; Hamilton, A.; implied powers; Jefferson, T.; Protection; public credit; public debt; subsidies

Article

One of the founding fathers of the United States and Secretary of the Treasury in President Washington's cabinet, in which Thomas Jefferson served as Secretary of State. The two great men differed widely in their views about the destiny of the young nation. Jefferson wanted to preserve the position of the states and assign to the national government not much more than authority over foreign affairs. Hamilton favoured a strong and active central government. Jefferson was eager to preserve the rural economy in which he had grown up in Virginia. Hamilton proposed to promote economic development, especially manufacture, and vest in the national government the function of actively fostering such development. Jefferson took a dim view of public debts, paper money and financial institutions. Hamilton favoured them all. Jefferson was more of an egalitarian and had greater faith in the common man than Hamilton, who placed his trust in an alliance of government and the aristocracy of wealth: neither could flourish without the support of the other. Hamilton died in a duel with a political adversary during Jefferson's presidency, but his ideas were strong enough to survive him. The exigencies of the time caused Jefferson himself to adopt a number of Hamiltonian policies.

Thus Hamilton became the architect of what in *The Federalist* (1787, No. XI) he had called 'the great American system', later to be buttressed by such economic writers as the Careys, Daniel Raymond and Frederick List, and by Henry Clay in politics. He set forth his economic ideas in a series of state papers, published under his name when serving as Secretary to the Treasury. These papers are the first and second *Report on the Public Credit* (1790a; 1795), the *Report on a National Bank* (1790b), and the *Report on Manufactures* (1791). The state papers are justly famous, not as repositories of economic analysis, but as a masterly presentation of a case of which Hamilton, who had been trained in the law, was an eloquent advocate.

The apotheosis of credit found in Hamilton's reports refers to public and private credit as well. According to Hamilton, credit is a substitute of capital almost as useful as gold and silver. It has, and
Hamilton has no doubt about this, a tendency to lower the interest rate. If the public credit is in a bad state, it can only have deleterious effects on private credit. The preservation of a healthy credit system is thus an important task. Foreign creditors should enjoy the same protection as domestic ones. Domestic holders of the public debt should be protected against the imposition of taxes on the public funds, as foreign creditors should be protected from repudiation or expropriation.

With the help of the public debt it will be possible to promote the economic development of the country. Scrupulous attention must be paid to the rights of the creditors, both for the sake of public expediency and as a moral obligation. The public debt of the United States should be funded, that is, arrangements should be made for the service of the debt by putting aside funds for the payment of interest and principal. A funded debt has great benefits. It will facilitate the use of instruments of debt as money and bring about lower interest rates, and will result in an increase in land values, which have declined in consequence of the scarcity of money.

Hamilton also proposed that the Union assume responsibility for the debts of the states, and that the funding of the debt should be financed in part from new duties on imported spirits and taxes on domestic ones and on stills. These proposals met considerable opposition because of the windfall gains that would accrue to speculators who had purchased instruments of the debt at low prices. To obtain Jefferson's support for this measure, Hamilton had to agree that the future capital of the nation would be located in the South, that is, in what is now Washington, DC.

The national bank, which Hamilton proposed to establish, was designed to aid in the expansion of the money supply, thereby facilitating the payment of taxes, the reduction of interest rates, the fulfilment of public functions, and the development of the national economy. The bank was to be under private rather than public direction, with the government playing the role of a minor shareholder. When the question was raised whether the Constitution granted the federal government the authority to establish a bank, Hamilton resolved it by referring to ‘implied powers’, that is, the power to employ suitable means to pursue constitutional ends. This solution was to have far-reaching consequences for the future development of constitutional law.

The Report on Manufactures goes into considerable detail examining the relative merits of agriculture and industry. Hamilton underlines the merits of both and the benefits which each derives from the other. He stresses that both are productive, a point that had to be made, and made forcefully, in view of the teachings of the Physiocrats. Hamilton demonstrates great ingenuity in enumerating the factors that are responsible for favourable effects of industrial development on the national income. Among these factors he mentions the division of labour, the more extensive use of machinery, the utilization of manpower that is not suited for agricultural pursuits, the promotion of immigration, the widening of opportunities for the exercise of entrepreneurial talent, and the strengthening of demand for agricultural products.

As far as international trade is concerned, Hamilton holds that the benefits from free trade are more imaginary than real because of the obstacles which foreign countries place in the way of United States exports. Moreover, foreign governments support domestic industries in various ways, and the United States should adopt similar policies by imposing protective and prohibitive duties, granting subsidies to domestic industries, and promoting internal improvements that facilitate the flow of commerce. Subsidies are liable to be abused, but their advantages outweigh the disadvantages. Lastly, Hamilton proposes that a board be established to promote economic development by bringing in skilled workers from abroad, rewarding useful improvements and inventions, paying premiums to importers of
machinery, and similar means.

Hamiltonians

Karl Shell
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Hamiltonian dynamics arises not only in economic optimization problems but also in descriptive economic models in which there is perfect foresight about asset prices. Hamiltonian dynamics applies in discrete time as well as in continuous time. In discrete time, the system of differential equations is replaced by a closely related system of difference equations. The theory accommodates differential correspondences or difference correspondences, which naturally arise in economics. The Hamiltonian approach through the Hamiltonian function has proved remarkably successful in establishing sufficient conditions for the saddle-point property and related stability questions in a class of optimal economic growth models.

Keywords

continuous and discrete time models; duality; Hamilton, W. R.; Hamiltonian dynamical system; Hamiltonian function; Hamiltonians; Lyapunov functions; optimal-growth theory; overlapping generations models; Poincaré, J. H.; Pontryagin's maximum principle; saddle-point property; transversality conditions

Article

The laws of motion for a perfect-foresight economy, whether centrally planned or competitive, can be described by a Hamiltonian dynamical system or by a simple perturbation thereof. The Hamiltonian dynamical system and the Hamiltonian function which generates it are named for their inventor, the great Irish mathematician William Rowan Hamilton (1805–1865). Hamilton's differential equations serve as the basic mathematical tool of classical particle mechanics (including celestial mechanics). Let $x(t) = (x_1(t), \ldots, x_j(t), \ldots, x_m(t))$ and $\gamma(t) = (\gamma_1(t), \ldots, \gamma_j(t), \gamma_m(t))$ be $m$-vectors dependent on time $t$. Let $H$ be a continuous, differentiable function of $x, y,$ and $t, H: \mathbb{R}^m \times \mathbb{R}^m \times \mathbb{R} \rightarrow \mathbb{R}$. Think of $H$ as the Hamilton's function (HF) which
generates Hamilton's differential equations,

\[ \frac{dx_i(t)}{dt} = \frac{\partial H(x(t), y(t), t)}{\partial y_i(t)} \]

and

\[ \frac{dy_i(t)}{dt} = \frac{\partial H(x(t), y(t), t)}{\partial x_i(t)} \]

for \( i = 1, \ldots, m \). If the Hamiltonian function \( H \) depends on time only through the variables \( x(t) \) and \( y(t) \), i.e., \( \partial H / \partial t \equiv 0 \), then the corresponding Hamiltonian dynamical system (HDS) is said to be *autonomous*. These differential equations are frequently interpreted in physics as solutions to some extremization problem. In mechanics for example, HDS is implied by the principle of least action. Since economic planning and many other economic problems involve maximization or minimization over time, it is unsurprising that the Hamiltonian formalism has substantial application in economics. Its appeal to economists goes much further than this. There is a duality (conjugacy, in the language of mechanics) between \( x_i(t) \) and \( y_i(t) \) which allows us to interpret one as a (primal) economic flow and the other as a (dual) economic price. Given this point of view, the Hamiltonian function (HF) itself has important economic interpretations. Hamiltonian dynamics not only arises in economic optimization problems but it also arises in descriptive economic models in which there is perfect foresight about asset prices.

Hamiltonian dynamics applies in discrete time as well as in continuous time. In discrete time, the system of differential equations is replaced by a closely related system of difference equations. The right side of the equations describing Hamilton's law of motion need not be single-valued. The theory accommodates differential correspondences or difference correspondences, which naturally arise in economics.

Consider first the application of Hamiltonian approach to the theory of economic growth; see, for example, the Cass–Shell (1976a) volume. A large class of economic growth models can be described by simple laws of motion based on the instantaneous production set \( T \), with feasible production satisfying,

\[(c, z, -k, -l) \in T \subset \{(c, z, -k, -l) | (c, k, l) \geq 0\},\]

where \( c \) denotes the vector of consumption-goods outputs, \( z \) the vector of net investment-goods outputs, \( k \) the vector of capital-goods inputs, and \( l \) the vector of primary-goods inputs. There is an equivalent representation of static technological opportunities that is better suited to dynamic analysis: the representation of the static technology by its Hamiltonian function \( H \).

Let \( p \) be the vector of consumption-goods prices and \( q \) be the vector of investment-goods prices. Define
the Hamiltonian function $H(p, q, k, l)$ by

$$H(p, q, k, l) = \max_{(\epsilon', z')} \left\{ \rho \epsilon' + qz' | (\epsilon', z', -k, -l) \in T \right\},$$

$H$ is defined on the non-negative orthant and can be interpreted as the maximized value of net national product at the output prices $(p, q)$ given input endowments $(k, l)$. Obviously, if we know the set $T$, then we know precisely the function $H$. If $T$ is closed, convex, and permits free disposal, then $H$ is continuous, convex and homogeneous of degree one in the output prices $(p, q)$, and concave in the input stocks $(k, l)$. If $H$ is a function of $(p, q, k, l)$ which is continuous, convex and homogeneous of degree one in $(p, q)$, and concave in $(k, l)$, then $H$ corresponds to a unique $T$ among closed, convex technologies permitting free disposal. In many dynamic applications, it is only the $H$ representation which matters. Relax, for example, the free-disposal assumptions on $T$. For a given function $H$, the set $T$ might be unique, but the dynamics would be independent of the particular set $T$ which generated the function $H$. Relax, as another example, the assumption that $T$ is convex. Given an $H$ which is convex in $(p, q)$, and concave in $(k, l)$, the set $T$ will not be unique, but the continuous dynamics (HDS) will not be altered in an essential way.

Representation of the static technology by the Hamiltonian function permits one to describe the economic laws of motion as a Hamiltonian dynamical system. In continuous time, the motion is described by

$$\dot{k}(t) \in \partial H(p(t), q(t), k(t), l(t)) / \partial q(t)$$

(HDS)

$$\dot{q}(t) \in - \partial H(p(t), q(t), k(t), l(t)) / \partial k(t)$$

where $\dot{k}(t)$ and $\dot{q}(t)$ are vectors of time derivatives and $(\partial H/\partial q)$ and $(\partial H/\partial k)$ are gradients (derivatives when $H$ is differentiable). The first line of (HDS) is immediate from the definition of net investment since it reduces to $\dot{k}(t) = z(t)$, where $z(t)$ is the vector of net investment. The second line is an equal-asset-return condition which reduces to $\dot{q}(t) + r(t) = 0$, where $r(t)$ is the dual vector of shadow rental rates.

For discrete time, the Hamiltonian dynamical system is
\[ k_{t+1} = k_t + z_t \]
\[ q_{t+1} = q_t - r_t + 1 = 0, \]
where \( z_t \) is the time \( r(t) \) gross investment vector and \( r_{t+1} \) is the dual vector of shadow capital-goods rental rates in period \((t+1)\).

For openers, let us analyse the case where \( H \) is autonomous. This occurs if \( p(t) = \bar{p} \) and \( l(t) = \bar{l} \) for (HDS) or \( p_t = \bar{p} \) and \( l_t = \bar{l} \) for (HDS)' . Let \((q^*, k^*)\) be a rest point to (HDS) or (HDS)'. Hence, we have

\[ 0 \in \partial H(\bar{p}, q^*, k^*, \bar{l}) / \partial q, 0 \in \partial H(\bar{p}, q^*, k^*, \bar{l}) / \partial k. \]

Consider the linear approximations about \((q^*, k^*)\) of (HDS) and (HDS)' (taken, for example, as if \( H \) were quadratic). Study the characteristic roots to the linearized systems. A simple but remarkable theorem due to Poincaré tells us that if \( \lambda \) is a root for the linearized, autonomous version of (HDS) then so is \(-\lambda\). For the linearized, autonomous version of (HDS)', we have if \( \lambda \) is a root, then so also is \( 1/\lambda \). If for (HDS), we could rule out pure imaginaries (Re \( \lambda \neq 0 \)), then we would have: The dimension of the manifold in \((q, k)\) – space of solutions tending to \((q^*, k^*)\) as \( t \rightarrow \infty \) is equal to the dimension of the manifold of solutions tending to \((q^*, k^*)\) as \( t \rightarrow -\infty \). This is the saddle-point property, where the manifold of forward solutions and the manifold of backward solutions each have dimension equal to half the total dimension of the space. Similarly, we would have the saddle-point property for (HDS)', if the modulus \(|\lambda|\) is unequal to unity.

Poincaré’s result nearly gives us the saddle-point property. In the autonomous cases, the saddle-point property can be assured if the geometry of the Hamilton function is correct. We need to add very little to the convexity–concavity assumption (see Cass and Shell, 1976b, and Rockafellar, 1976). Strict convexity in \( q \) and strict concavity in \( k \) will do the trick. So will a weaker uniform Hamiltonian steepness condition, which reduces to a value-loss condition; see, for example, McKenzie (1968), and Cass–Shell (1976b).

What about non-autonomous systems, such as optimal economic growth with the constant, positive...
discount rate $\rho$? Here $c(t)$ or $c_t$, is a scalar called felicity and usually denoted in optimal-growth problems by $u(t)$ or $u_t$. In this case, present prices must satisfy

$$-\frac{\dot{p}(t)}{p(t)} = \rho$$

or

$$-\frac{p_t - p_{t-1}}{p_t} = \rho.$$  

For simplicity, allow only for a single fixed factor and adopt the convention $l(t) = 1$, or $l_t = 1$. It is natural then to re-express the systems (HDS) and (HDS)' in terms of current prices $Q \equiv q / p$, rather than in terms of present prices $q$. We then have

$$\dot{k} \in \mathcal{H}(Q, k) / \partial Q$$

(PhDS)

$$\dot{Q} \in -\mathcal{H}(Q, k) / \partial k + \rho Q$$

and

$$k_{t+1} \in k_t + \mathcal{H}(Q_t, k_t) / \partial Q_t$$

(PhDS)'

$$Q_{t+1} \in Q_t - \mathcal{H}(Q_{t+1}, k_{t+1}) \partial k_{t+1} + \rho Q_t.$$
The systems (PHDS) and (PHDS)′ are perturbed Hamiltonian dynamical systems. We no longer have Poincaré’s root-splitting theorems in pure form: the roots split but not about 0 for (HDS) nor 1 for (HDS)′. The trick here is to strengthen the geometry of $H$ to give a saddle-point property or something like it.

This is the basics of the approach taken by Cass and Shell (1976b), Rockafellar (1976) and Brock and Scheinkman (1976). Conditions are found on $H$ which assure that either (PHDS) or (PHDS)′ along with transversality conditions defines a globally stable system. It suffices to strengthen the convexity–concavity of $H$ by an amount dependent on $p$ or (weaker) to strengthen the steepness of $H$ by an amount dependent on $p$. (The Lyapunov function which does the trick is $V = (Q - Q^*)(k - k^*)$ in the continuous-time model.)

The Hamiltonian approach through the Hamiltonian function has proved remarkably successful in establishing sufficient conditions for the saddle-point property and related stability questions in a class of optimal economic growth models. The parallel programme of using the Hamiltonian formalism in optimal-growth theory to yield sufficient conditions for cycling or other dynamic configurations has not yet been pursued in a systematic fashion but should prove equally successful when applied. The success of the Hamiltonian approach in decentralized and descriptive growth theory has so far been very limited; see Cass and Shell (1976b, Section 4). This has been disappointing. I still hope to see the Hamiltonian approach playing a pivotal technical role in, say, the dynamical analysis of overlapping-generations models, but there has not been much tangible encouragement for this hope.

Many of us first met Hamiltonian dynamical systems as necessary conditions for intertemporal maximization in the form of Pontryagin's maximum principle; see Pontryagin et al. (1962). See Shell (1967) for applications to economics and references. Samuelson and Solow (1956) were probably the first in economics to mention the Hamiltonian formalism. For some of the history of Hamiltonian dynamics, in economic, mathematics, and physics, and for some of the classical references, see Magill (1970).

Hannan, Edward J. (1921–1994)

P.M. Robinson

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We review the research of the late Edward J. Hannan. Hannan contributed deeply and influentially to the development of econometric time series analysis, both in the elegance and incisiveness of his technical work and in his invention of new methodology.

Keywords

ARMA models; ARMAX models; band-spectrum regression; econometrics; errors in variables; Hannan, E.; Hannan-efficient estimation; heteroscedasticity; maximum likelihood; semi-parametric estimation; statistics and economics; time series analysis; Whittle estimation

Article

Ted Hannan, who died in 1994 at the age of 72, made contributions to statistical time series analysis of considerable depth and originality. His research by no means focused entirely on problems with econometric motivation, and he stopped publishing in econometric journals in the 1970s. However, Hannan introduced important econometric methodology and theory, and some of his ideas anticipated themes that later became important in econometrics. I focus on his most econometric-related contributions rather than attempt to survey the breadth of his research (of which an account can be found in Robinson, 1994, on which we draw upon here).

Hannan in fact started out as an economic researcher at the Reserve Bank of Australia, in Sydney, following an undergraduate commerce degree. While visiting the Australian National University (ANU), Canberra, in 1953 he was ‘discovered’ by the then Professor of Statistics P. A. P. Moran, who encouraged him to undertake doctoral research in statistics. Hannan quickly completed a Ph.D. and within a few years achieved professorial status at the ANU, retiring in 1986 but continuing to be very productive in research up to his death. Altogether he published over 130 articles and five books (all of which are definitely in the research monograph category).
Hannan's intellectual development was unusual in that his mathematical abilities and taste for abstraction increased throughout his career, suggesting that a different early training might well have led to a career in pure mathematics. This partly explains why it is the earlier part of his career in which he did most of his econometric-related work.

In the early 1950s testing for zero autocorrelation was a major theme of time series research. Two of Hannan's first papers, published in 1955 in *Biometrika*, concerned exact tests for autocorrelation. However he quickly realized the limitations of finite-sample theory, and began the research on asymptotic theory which he developed with such originality and power during the rest of his years. His first published contribution to asymptotics, in 1956, concerned Pitman efficiencies.

Soon thereafter he wrote an early, and widely uncredited, contribution to a topic that has, since the mid-1980s, been actively pursued in econometrics, so-called ‘heteroscedasticity-and-autocorrelation consistent variance estimation’. It had already been noticed by Grenander and Rosenblatt that the variance of the sample mean of a weakly dependent time series is approximately proportional to the spectral density at zero frequency. On the other hand, Parzen and others had recently developed consistent smoothed estimation of nonparametric spectral densities. Hannan put these ideas together in a 1957 paper in the *Journal of the Royal Statistical Society*. The awareness he displayed here of the importance of bandwidth choice was notable for the time. Other early contributions included bias-correction in spectrum estimation for detrended data.

One major innovation for which Hannan does receive credit is what econometricians know as ‘Hannan-efficient estimation’. The problem is one of efficiently estimating regression coefficients when the disturbances have nonparametric autocorrelation, that is, to do as well asymptotically as if one correctly assumed the disturbance followed a particular parametric model, such as an autoregression (as Cochrane and Orcutt had assumed). Based on the property of unitary transformation of a stationary time series to a heteroscedastic, approximately uncorrelated, one, Hannan, in a paper published in the 1963 Brown Symposium proceedings, proposed a frequency-domain generalized least squares procedure involving inverse weighting by the disturbance spectral density. Moreover, he established its asymptotic normality and efficiency. This was perhaps the first instance of justifying smoothed nonparametric estimation in a semi-parametric model. The technical difficulties here, of establishing parametric convergence rates despite a slowly converging nonparametric nuisance function, are now familiar, but Hannan was perhaps the first to solve them. He and others subsequently developed the approach in more general models, but it is most notable that his 1963 paper preceded by over 20 years work in the analogous problem of adapting to heteroscedasticity of nonparametric form, and by over ten years work in adapting to distribution of unknown form in location and regression models, though papers on these topics rarely mention his work. A related paper, also published in 1963, in *Biometrika*, is also insufficiently cited. There, Hannan introduced what subsequently became known as ‘band-spectrum regression’, omitting from a frequency-domain formulation of the least squares estimate non-degenerate bands of frequencies, with the aim of reducing errors-in-variables bias.

Around the same time Hannan introduced new ideas in the seasonal analysis of time series, using operators in estimating seasonality in the presence of trend and stationary noise, and modelling the seasonal component by a cosinusoid whose coefficients form stationary processes. He developed this model in a 1967 *Journal of Applied Probability* paper, allowing the coefficients to have roots on the unit circle, years before unit roots became the focus of so much econometric interest. Indeed, Hannan's model resembles the random component models that subsequently became popular. One non-time series

contribution to econometrics was his work on the relation between canonical correlation and simultaneous equations estimation, which led to a 1967 *Econometrica* paper. Hannan had published a short but influential 1960 monograph on time series analysis, and in 1970 he developed this into the major work *Multiple Time Series*. This constituted a detailed and rigorous account of time series, mainly in a multivariate setting, and covering continuous-time as well as discrete-time processes. It has been an invaluable reference for researchers, stimulating new research on a number of aspects.

Like the earlier book, *Multiple Time Series* put considerable stress on the frequency domain, but not exclusively and certainly not focusing particularly on nonparametric spectral methods. The frequency domain is sometimes misguidedly identified with nonparametric spectral estimation, but, just as nonparametric time series analysis can be considered in the time domain, so frequency-domain inference on parametric models is possible, and indeed the frequency domain is basic in much theoretical discussion of time series. Hannan's work showed how combining time- and frequency-domain assumptions can lead to an incisive theory, and also demonstrated immense resourcefulness in using techniques from Fourier analysis and other areas of mathematics in his proofs.

These qualities stand out in Hannan's work on linear time series models, which were the focus of much of his effort from around 1970 on. The publication of Box and Jenkins’ 1970 book had greatly increased interest, especially among econometricians, in autoregressive moving average (ARMA) modelling. Hannan had already become interested in the topic, as *Multiple Time Series* shows. There, and in 1969 and 1971 papers, he addressed the difficult problem of identification in multivariate ARMA models, which he built on in several subsequent pieces of work.

In a 1973 *Journal of Applied Probability* paper, Hannan gave a rather definitive treatment of the asymptotic theory of various forms of Whittle estimation of scalar ARMA processes. This paper is notable for several aspects, which typify much of his work. First, while ARMA models are the linear time series models of leading practical importance, he showed that models with much stronger autocorrelation can be handled. Indeed, his proof of (strong) consistency actually covered long-range dependent processes, though these had not really been identified as a class at that time. Moreover, he showed that second moments suffice not only for consistency but for asymptotic normality (for parameters describing only autocorrelation). Another feature was his use of martingale difference rather than independence assumptions on innovations. From a methodological viewpoint, Hannan proposed a discrete-frequency version of Whittle estimation, which has computational advantages over Gaussian maximum likelihood or continuous-frequency Whittle, in that it makes nice use of the neat, explicit form of the spectral density for ARMA and some other models, and makes direct use of the fast Fourier transform algorithm. Later, in a 1976 paper with Dunsmuir, Hannan extended the 1973 paper to multivariate ARMA models, and in a 1980 paper with Deistler and Dunsmuir, to models with lagged explanatory variables (‘ARMAX’ models). From 1979 onwards, Hannan made several major contributions to the practically important problem of order determination in ARMA and ARMAX models. His 1988 book with Deistler, *The Statistical Theory of Linear Systems* collects much of his work on linear time series models.

Ted Hannan is mainly thought of as an outstanding technician, with the ability to elegantly solve highly challenging problems under conditions that are at the same time incisive and comprehensible, but he also repeatedly demonstrated a keen practical sense, inventing new methodology, involving interesting tricks, and well understanding computational issues. His influence in econometrics has been profound.
and lasting, but had he chosen to devote much more of his brilliance and energy to econometric problems it would be difficult to overstate the further benefits to the econometric profession that could have accrued.

Article
Alvin Hansen grew up in Viborg, South Dakota, a small rural community with a one-room school house and traditional values. Preferring academic pursuits to farm work, he proceeded to Sioux Falls for his high school education and then to Yankton College for his BA degree. Several years of high school teaching followed, with rapid advancement to principal and superintendent. The financial basis for his graduate work thus laid, Hansen entered the University of Wisconsin in 1914, where John R. Commons and R.T. Ely were to impress him with the importance of data and their institutional setting. In 1919 he moved to Brown University as assistant professor. There he completed his dissertation, later published as *Cycles of Prosperity and Depression* (1921). He then accepted a position at the University of Minnesota, where he remained for nearly 20 years. His major works during the 1920s included a solid *Principles* text, co-authored with F.B. Garver (1928), and an historical study of *Business Cycle Theory* (1927). Ranging from Malthus to Spiethoff and Hawtrey, stress was on structural shifts in investment rather than on monetary factors, and special attention was given to the interaction of short cycles with longer waves of economic development.

A Guggenheim fellowship in 1928 permitted extensive travel abroad, an experience that he continued to cherish and renew in later years. The early 1930s also brought a growing policy involvement outside the campus, activities that in subsequent years were to claim an increasing share of his time. Such early activities included that of Director of Research for the Committee of Inquiry on International Economic Relations (1933–34) and service as adviser on trade agreements to Secretary Cordell Hull.

In 1936 Harvard University had received a grant to establish the Littauer School of Public Administration, and Hansen was appointed as its first Lucius S. Littauer Professor of Political Economy.
As fortune had it, his arrival at Harvard in the fall of 1937 closely followed the appearance of Keynes's *General Theory*. Hansen, distressed by the wastes of the Great Depression, soon (though with some initial hesitation) adopted the Keynesian approach. With Harvard's Fiscal Policy Seminar as his base, Hansen became the leading analyst and expositor of Keynesian economics in the United States. Driven by his enthusiasm for new ideas, his determination to find policy solutions, and his eagerness to learn as well as to teach, the seminar left a deep impact on the course of macroeconomics. The still obscure components of the Keynesian system had to be sorted out and new tools, such as the concept of governmental net contribution, the multiplier-accelerator model and the balanced budget theorem, were forged. With the application of these new tools to the setting of the US economy as its challenge, the seminar thus became the training ground for a generation of US policy economists.

The output of these years may be traced in Hansen's writings, beginning with the two key volumes of *Full Recovery and Stagnation* (1938) and *Fiscal Policy and Business Cycles* (1941). Other volumes followed, including *Business Cycles and National Income* (1951) and his widely used *A Guide to Keynes* (1953). The persistent theme was that of unemployment, caused by a failure of private investment to match the level of saving at a full employment income. With the effectiveness of monetary policy reduced by inelastic investment and high liquidity preference in a sluggish economy, the required level of aggregate demand would have to be provided by fiscal expansion responded to in the private sector by a multiplier-accelerator process. The need for expansionary fiscal policy, however, would not be one of pump-priming only. Linking back to his earlier interest in the long waves of the cycle, the weakness of the economy was seen as the downward phase of a long wave, with the declining population growth the most depressing factor. The stagnation thesis, offered in Hansen's presidential address before the American Economic Association (1937), placed the Keynesian model in a historical perspective and once more emphasized the strategic role of expansionary budget policy. Events, to be sure, proved different. The Second World War generated massive budgetary expansion and a strengthened post-war economy called for a correction, combining the traditional role of monetary policy with that of fiscal controls. Hansen the pragmatist welcomed the neoclassical synthesis of the mid-1960s.

While macro policy and stabilization remained his major concern, his activities during the Harvard years covered a much wider range. As a member of the Advisory Council on Social Security in 1937–38, he helped to shape the Social Security System. During 1941–43 he served as Chairman of the US–Canadian Joint Economic Commission, and from 1940 to 1945 he acted as Economic Advisor to the Federal Reserve Board. At the close of the war he participated in the monetary reconstruction of Bretton Woods and the birth of IMF. At the same time, he played a strategic role in the creation of the Full Employment Act of 1946 and the Council of Economic Advisers. After retiring from Harvard in 1956, Hansen remained in Belmont, Massachusetts, until 1972, when he joined his daughter in Virginia. He died there in 1975.

Throughout Hansen's work, the goal of full employment was central, as was the need for fiscal action to achieve it. His social philosophy was expressed ‘in the democratic ideal of providing for all individuals a reasonable approach to equality of opportunity’. Beyond this, he was pragmatic and non-ideological in approach. For him, economics – as James Tobin put it when presenting him with the Walker Medal at his 80th birthday – was a science for the service of mankind.

The economics of happiness assesses welfare by combining economists’ and psychologists’ techniques, and relies on more expansive notions of utility than does conventional economics. The research highlights factors other than income that affect well-being. It is well suited to informing questions in areas where revealed preferences provide limited information – for example, the welfare effects of inequality and of inflation and unemployment. Despite the potential contributions for policy, a note of caution is necessary because of the potential biases in survey data and the difficulties in controlling for unobservable personality traits.

Article

The economics of happiness is an approach to assessing welfare which combines the techniques typically used by economists with those more commonly used by psychologists. While psychologists have long used surveys of reported well-being to study happiness, economists only recently ventured into this arena. Early economists and philosophers, ranging from Aristotle to Bentham, Mill, and Smith, incorporated the pursuit of happiness in their work. Yet, as economics grew more rigorous and quantitative, more parsimonious definitions of welfare took hold. Utility was taken to depend only on income as mediated by individual choices or preferences within a rational individual's monetary budget constraint.

Even within a more orthodox framework, focusing purely on income can miss key elements of welfare. People have different preferences for material and non-material goods. They may choose a lower-paying but more personally rewarding job, for example. They are nonetheless acting to maximize utility in a classically Walrasian sense.

The study of happiness or subjective well-being is part of a more general move in economics that challenges these narrow assumptions. The introduction of bounded rationality and the establishment of behavioural economics, for example, have opened new lines of research. Happiness economics – which represents one new direction – relies on more expansive notions of utility and welfare, including interdependent utility functions, procedural utility, and the interaction between rational and non-rational influences in determining economic behaviour.

Richard Easterlin was the first modern economist to revisit the concept of happiness, beginning in the early 1970s. More generalized interest took hold in the late 1990s (see, among others, Easterlin, 1974; 2003; Blanchflower and Oswald, 2004; Clark and Oswald, 1994; Frey and Stutzer, 2002a; Graham and Pettinato, 2002; Layard, 2005).

The approach

The economics of happiness does not purport to replace income-based measures of welfare but instead to complement them with broader measures of well-being. These measures are
based on the results of large-scale surveys, across countries and over time, of hundreds of thousands of individuals who are asked to assess their own welfare. The surveys provide information about the importance of a range of factors which affect well-being, including income but also others such as health, marital and employment status, and civic trust. The approach, which relies on expressed preferences rather than on revealed choices, is particularly well suited to answering questions in areas where a revealed preferences approach provides limited information. Indeed, it often uncovers discrepancies between expressed and revealed preferences. Revealed preferences cannot fully gauge the welfare effects of particular policies or institutional arrangements which individuals are powerless to change. Examples of these include the welfare effects of inequality, environmental degradation, and macroeconomic policies such as inflation and unemployment. Sen's capabilities-based approach to poverty, for example, highlights the lack of capacity of the poor to make choices or to take certain actions. In many of his writings, Sen (1995) criticizes economists’ excessive focus on choice as a sole indicator of human behaviour. Another area where a choice approach is limited and happiness surveys can shed light is the welfare effects of addictive behaviours such as smoking and drug abuse.

Happiness surveys are based on questions in which the individual is asked, ‘Generally speaking, how happy are you with your life?’ or ‘How satisfied are you with your life’, with possible answers on a four-to-seven point scale. Psychologists have a preference for life satisfaction questions. Yet answers to happiness and life satisfaction questions correlate quite closely. The correlation coefficient between the two – based on research on British data for 1975–92, which includes both questions, and Latin American data for 2000–1, in which alternative phrasing was used in different years – ranges between .56 and .50 (Blanchflower and Oswald, 2004; Graham and Pettinato, 2002).

This approach presents several methodological challenges (for a fuller description of these, see Bertrand and Mullainathan, 2001; Frey and Stutzer, 2002b). To minimize order bias, happiness questions must be placed at the beginning of surveys. As with all economic measurements, the answer of any specific individual may be biased by idiosyncratic, unobserved events. Bias in answers to happiness surveys can also result from unobserved personality traits and correlated measurement errors (which can be corrected via individual fixed effects if and when panel data are available). Other concerns about correlated unobserved variables are common to all economic disciplines. Despite the potential pitfalls, cross-sections of large samples across countries and over time find remarkably consistent patterns in the determinants of happiness. Many errors are uncorrelated with the observed variables, and do not systematically bias the results. Psychologists, meanwhile, find validation in the way that people answer these surveys based in physiological measures of happiness, such as the frontal movements in the brain and in the number of ‘genuine’ – Duchenne – smiles (Diener and Seligman, 2004). Micro-econometric happiness equations have the standard form: \[ W_{it} = x + \beta X_{it} + \epsilon_{it}, \] where \( W \) is the reported well-being of individual \( i \) at time \( t \), and \( X \) is a vector of known variables including socio-demographic and socioeconomic characteristics. Unobserved characteristics and measurement errors are captured in the error term. Because the answers to happiness surveys are ordinal rather than cardinal, they are best analysed via ordered logit or probit equations. These regressions typically yield lower R-squares than economists are used to, reflecting the extent to which emotions and other components of true well-being are driving the results, as opposed to the variables that we are able to measure, such as income, education, and marital and employment status. (Cross-section work also typically yields low R-squares.) The availability of panel data in some instances, as well as advances in econometric techniques, are increasingly allowing for sounder analysis (Van Praag and Ferrer-i-Carbonell, 2004). The coefficients produced from ordered probit or logistic regressions are remarkably similar to those from OLS regressions based on the same equations. While it is impossible to measure the precise effects of independent variables on true well-being, happiness researchers have used the OLS coefficients as a basis for assigning relative weights to them. They can estimate how much income a typical individual in the United States or Britain would need to produce the same change in stated happiness that comes from the well-being loss resulting from, for example, divorce ($100,000) or job loss ($60,000) (Blanchflower and Oswald, 2004).

**The Easterlin paradox**

In his original study, Easterlin revealed a paradox that sparked interest in the topic but is as yet unresolved. While most happiness studies find that within countries wealthier people are, on average, happier than poor ones, studies across countries and over time find very little, if any, relationship between increases in per capita income and average happiness levels. On average, wealthier countries (as a group) are happier than poor ones (as a group); happiness seems to rise with income up to a point, but not beyond it. Yet even among the less happy, poorer countries, there is not a clear relationship between average income and average happiness levels, suggesting that many other factors – including cultural traits – are at play (see Figure 1).

**Figure 1**

Happiness and income per capita, selected countries, 1990s
Within countries, income matters to happiness (Oswald, 1997; Diener et al., 2003, among others). Deprivation and abject poverty in particular are very bad for happiness. Yet after basic needs are met other factors such as rising aspirations, relative income differences, and the security of gains become increasingly important, in addition to income. Long before the economics of happiness was established, James Duesenberry (1949) noted the impact of changing aspirations on income satisfaction and its potential effects on consumption and savings rates. Any number of happiness studies have since confirmed the effects of rising aspirations, and have also noted their potential role in driving excessive consumption and other perverse economic behaviours (Frank, 1999).

Thus, a common interpretation of the Easterlin paradox is that humans are on a ‘hedonic treadmill’: aspirations increase along with income and, after basic needs are met, relative rather than absolute levels of income matter to well-being. Another interpretation of the paradox is the psychologists’ ‘set point’ theory of happiness, in which every individual is presumed to have a happiness level that he or she goes back to over time, even after major events such as winning the lottery or getting divorced (Easterlin, 2003). The implication of
this theory for policy is that nothing much can be done to increase happiness. Individuals are remarkably adaptable, no doubt, and in the end can get used to most things, and in particular to income gains. The behavioural economics literature, for example, shows that individuals value losses more than gains (see Kahneman, Diener and Schwarz, 1999, among others). Easterlin argues that individuals adapt more in the pecuniary arena than in the non-pecuniary arena, while life changing events, such as bereavement, have lasting effects on happiness. Yet, because most policy is based on pecuniary measures of well-being, it overemphasizes the importance of income gains to well-being and underestimates that of other factors, such as health, family, and stable employment. There is no consensus about which interpretation is most accurate. Yet numerous studies which demonstrate that happiness levels can change significantly in response to a variety of factors suggest that the research can yield insights into human well-being which provide important, if complementary, information for policymakers. Even under the rubric of set point theory, happiness levels can fall significantly in the aftermath of events like illness or unemployment. Even if levels eventually adapt upwards to a longer-term equilibrium, mitigating or preventing the unhappiness and disruption that individuals experience for months, or even years, in the interim certainly seems a worthwhile objective for policy.

Selected applications of happiness economics

Happiness research has been applied to a range of issues. Since a comprehensive review cannot be undertaken here, a selection of some of the issues the surveys can inform is provided. These include the relationship between income and happiness, inequality and poverty, the effects of macro-policies on individual welfare, and the effects of public policies aimed at controlling addictive substances. Some studies have attempted to separate the effects of income from those of other endogenous factors, such as satisfaction in the workplace. Studies of unexpected lottery gains find that these isolated gains have positive effects on happiness, although it is not clear that they are of a lasting nature (Gardner and Oswald, 2001). Other studies have explored the reverse direction of causality, and find that people with higher happiness levels tend to perform better in the labour market and to earn more income in the future (Diener et al., 2003; Graham, Eggers and Sukhtankar, 2004).

A related question, and one which is still debated in economics, is how income inequality affects individual welfare. Interestingly, the results differ between developed and developing economies. Most studies of the United States and Europe find that inequality has modest or insignificant effects on happiness. The mixed results may reflect the fact that inequality can be a signal of future opportunity and mobility as much as it can be a sign of injustice (Alesina, Di Tella and MacCulloch, 2004). In contrast, recent research on Latin America finds that inequality is negative for the well-being of the poor and positive for the rich. In a region where inequality is much higher and where public institutions and labour markets are notoriously inefficient, inequality signals persistent disadvantage or advantage rather than opportunity and mobility (Graham and Felton, 2006).

Happiness surveys also facilitate the measurement of the effects of broader, non-income components of inequality, such as race, gender, and status, all of which seem to be highly significant (Graham and Felton, 2006). These results find support in work in the health arena, which finds that relative social standing has significant effects on health outcomes (Marmot, 2004).

Happiness research can deepen our understanding of poverty. The set point theory suggests that a destitute peasant can be very happy. While this contradicts a standard finding in the literature – namely, that poor people are less happy than wealthier people within countries – it is suggestive of the role that low expectations play in explaining persistent poverty in some cases. The procedural utilities and capabilities approaches, meanwhile, emphasize the constraints on the choices of the poor.

What is perceived to be poverty in one context may not be in another. People who are high up the income ladder can identify themselves as poor, while many of those who are below the objective poverty line do not, because of different expectations (Rojas, 2004). In addition, the well-being of those who have escaped poverty is often undermined by insecurity and the risk of falling back into poverty. Income data does not reveal the vulnerability of these individuals, yet happiness data shows that it has strong negative effects on their welfare. Indeed, their reported well-being is often lower than that of the poor (Graham and Pettinato, 2002).

Happiness surveys can be used to examine the effects of different macro-policy arrangements on well-being. Most studies find that inflation and unemployment have negative effects on happiness. The effects of unemployment are stronger than those of inflation, and hold above and beyond those of forgone income (Di Tella, MacCulloch and Oswald, 2001). The standard ‘misery index’, which assigns equal weight to inflation and unemployment, may be underestimating the effects of the latter on well-being (Frey and Stutzer, 2002b). Political arrangements also matter. Much of the literature finds that both trust and freedom have positive effects on happiness (Helliwell, 2004; Layard, 2005). Research based on variance in voting rights across cantons in Switzerland finds that there are positive effects from participating in direct democracy (Frey and Stutzer, 2002b). Research in Latin America finds a strong positive correlation between happiness and preference for democracy (Graham and Sukhtankar, 2004).

Happiness surveys can also be utilized to gauge the welfare effects of various public policies. How does a tax on addictive substances, such as tobacco and alcohol, for example, affect well-being? A recent study on cigarette taxes suggests that the negative financial effects may be outweighed by positive self-control effects (Gruber and Mullainathan, 2005).
Richard Layard (2005) makes a bold statement about the potential of happiness research to improve people's lives directly via changes in public policy. He highlights the extent to which people's happiness is affected by status – resulting in a rat race approach to work and to income gains, which in the end reduces well-being. He also notes the strong positive role of security in the workplace and in the home, and of the quality of social relationships and trust. He identifies direct implications for fiscal and labour market policy – in the form of taxation on excessive income gains and via re-evaluating the merits of performance-based pay.

While many economists would not agree with Layard's specific recommendations, there is nascent consensus that happiness surveys can serve as an important complementary tool for public policy. Scholars such as Diener and Seligman (2004) and Kahneman et al. (2004) advocate the creation of national well-being accounts to complement national income accounts. The nation of Bhutan, meanwhile, has introduced the concept of 'gross national happiness' to replace gross national product as a measure of national progress.

Despite the potential contributions that happiness research can make to policy, a sound note of caution is necessary in directly applying the findings, both because of the potential biases in survey data and because of the difficulties associated with analysing this kind of data in the absence of controls for unobservable personality traits. In addition, happiness surveys at times yield anomalous results which provide novel insights into human psychology – such as adaptation and coping during economic crises – but do not translate into viable policy recommendations.

One example is the finding that unemployed respondents are happier (or less unhappy) in contexts with higher unemployment rates. The positive effect that reduced stigma has on the well-being of the unemployed seems to outweigh the negative effects of a lower probability of future employment (Clark and Oswald, 1994; Stutzer and Lalive, 2004; and Eggers, Gaddy and Graham, 2006). (Indeed, in Russia even employed respondents prefer higher regional unemployment rates. Given the dramatic nature of the late 1990s crisis, respondents may adapt their expectations downwards and are less critical of their own situation when others around them are unemployed.) One interpretation of these results for policy – raising unemployment rates – would obviously be a mistake. At the same time, the research suggests a new focus on the effects of stigma on the welfare of the unemployed.

Happiness economics also opens a field of research questions which still need to be addressed. These include the implications of well-being findings for national indicators and economic growth patterns; the effects of happiness on behaviour such as work effort, consumption, and investment; and the effects on political behaviour. In the case of the latter, surveys of unhappiness or frustration may be useful for gauging the potential for social unrest in various contexts.

In order to answer many of these questions, researchers need more and better quality well-being data, particularly panel data, which allows for the correction of unobserved personality traits and correlated measurement errors, as well as for better determining the direction of causality (for example, from contextual variables like income or health to happiness versus the other way around). These are major challenges in most happiness studies. Hopefully, the combination of better data and increased sophistication in econometric techniques will allow economists to better address these questions in the future.

Harris, Seymour Edwin (1897–1975)

John Kenneth Galbraith

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Federal Reserve System; Harris, S. E.; Keynesianism; New Deal

Article

Harris was born in Brooklyn, New York, and graduated from Harvard University, where he also took his doctorate. His career, apart from the Second World War period and a few post-retirement years at the University of California at La Jolla, was spent at Harvard. In the Second World War, he was in charge of the pricing of exported and imported products and various liaison tasks for the Office of Price Administration. Throughout his life he undertook numerous regional and developmental assignments in New England and was one of the founders of the highly successful Massachusetts community college system.

Harris's early academic work, including a major history of the Federal Reserve System, was competent, orthodox and, as he would later view it, uninspired. Upward progress in his academic career at Harvard was also gradual and unspectacular, a circumstance related at the time to his Jewish origins. In later years he emerged as one of the most highly regarded members of the Cambridge (USA) economic and university community. He became a highly respected chairman of the Harvard economics department, and was the editor of the *Review of Economics and Statistics* and of numerous essay collections by fellow economists. He did not entirely escape criticism from his more relaxed colleagues for his prodigious work and publication schedule. President John F. Kennedy, shortly before he was killed, told of his intention of making Harris his next appointment to the Board of Governors of the Federal Reserve System.

From his earlier orthodox, even conservative, tendencies Harris was released by Keynes and the New Deal. His work came to reflect a strong commitment to Keynesian economics and policy and to the broad welfare measures of the Roosevelt, Kennedy and Johnson years. He was not a compelling writer; in his books, however, this was more than compensated for by the solid competence of his research and preparation, his strongly compassionate views on welfare issues and his very evident desire to extend knowledge on a great range of subject matter. On the economics of health care, education, social
security, international monetary policy, central-bank policy, monetary history and literally a dozen other topics, he provided the basic source material from which legislators learned what could be done, what should be done and how it might be done. A full listing of his works would be among the longest in this Dictionary. Among the prominent later examples are those listed below.

Harris–Todaro hypothesis

M. Ali Khan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Harris–Todaro hypothesis replaces the equality of wages by the equality of ‘expected’ wages as the basic equilibrium condition in a segmented, but homogeneous, labour market, and in so doing generates an equilibrium level of urban unemployment when a mechanism for the determination of urban wages is specified. This article reviews work in which the Harris–Todaro hypothesis is embedded in canonical models of trade theory in order to investigate a variety of issues in development economics. These include the desirability (or the lack thereof) of foreign investment, the complications of an informal sector and the presence of clearly identifiable ethnic groups.

Keywords

Article

The replacement of the equality of wages by the equality of ‘expected’ wages as the basic equilibrium condition in a segmented, but homogeneous, labour market has proved to be an idea of seminal importance in development economics. Attributed originally to Todaro (1968; 1969) and Harris and Todaro (1970), and commonly referred to as the Harris–Todaro hypothesis, the idea was very much in the air around the late 1960s, as can be seen from the contemporaneous writings of Akerlof and Stiglitz (1969), Blaug, Layard and Woodhall (1969) and Harberger (1971), among others.

The motivation for the Harris–Todaro hypothesis lies in an attempt to explain the persistence of rural to urban migration in the presence of widespread urban unemployment, a pervasive phenomenon in many,
so-called less-developed, countries (but also see Suits, 1985; Partridge and Rickman, 1997). It is natural to ask why such unemployment does not act as a deterrent to further migration. According to the Harris–Todaro hypothesis, the answer lies in the migrant leaving a secure rural wage $w_r$ for a higher expected urban wage $w^e_u$ even though the latter carries with it a non-zero probability of urban unemployment. The expected wage is computed by using the rate of urban employment as an index for the probability of finding a job. Thus

$$w^e_u = w_u \frac{L_u}{L_u + U} + 0 \frac{U}{L_u + U} = w_u \frac{1}{1 + \lambda},$$

(1)

where $w_u$ is the urban wage, $L_u$ is the number of urban employed, $U$ the number of urban unemployed and $\lambda = (U / L_u)$ the rate of urban unemployment. Thus, the Harris–Todaro hypothesis is precisely formulated by the equilibrium condition

$$w_r = w^e_u \Leftrightarrow w_u = w_r (1 + \lambda).$$

(2)

Since the Harris–Todaro hypothesis introduces a further unknown, namely, the rate of unemployment, a model in which the hypothesis is embedded must be buttressed by a theory of urban wage determination. The simplest setting is the one originally adopted by Harris–Todaro and subsequently by Bhagwati and Srinivasan (1971; 1973; 1974). This setting assumes the urban wage to be an exogenously given constant and typically rationalizes it as a consequence of government fiat.

In the 1970s, however, several theories of endogenous urban wage determination were simultaneously proposed. Foremost among these is the work of Stiglitz, who provides a microfoundation for the urban wage in terms of labour turnover (Stiglitz, 1974), or in terms of biological efficiency considerations (Stiglitz, 1976). One may also mention in this context the work of Calvo (1978), who sees the equilibrium urban wage as an outcome of trade union behaviour (also Quibria, 1988; Chau and Khan, 2001; and Calvo and Wellisz, 1978, who see a higher urban wage as a consequence of costly supervision). At this stage of the development of the literature, each theory of urban wage determination led to a particular version of the Harris–Todaro model, and the common structural similarities were obscured.

In Khan (1980a), the elementary observation is made that all these variants of the Harris–Todaro model could be studied under one rubric if the Harris–Todaro hypothesis is embedded in the Heckscher–Ohlin–Samuelson (HOS) two-sector, so-called general equilibrium model (see Jones, 1965; Johnson, 1971), and the determination of urban wages is seen in a somewhat more abstract way, that is,
where $R$ is the rental on capital and $\tau$ a shift parameter. This led to a model whose importance lay, not so much in synthesizing the several variants of urban wage determination, but in emphasizing its points of contact with the trade theory literature. In particular, when (3) collapses to

$$w_u = w_r,$$

(4)

that is, when the elasticity of the omega function $\Omega(\cdot)$ with respect to $w_r$ is unity, and those with respect to $R$ and $\lambda$ are zero, we obtain the HOS model.

This point deserves further articulation. Let a stylized economy consist solely of an urban and a rural sector, indexed by $u$ and $r$ respectively, and be endowed with positive amounts of labour $L$ and capital $K$.

Let the $i^{th}$ sector produce a commodity $i$ in amount $X_i$ in accordance with a production function

$$X_i = F_i(L_i, K_i), \ i = u, r,$$

(5)

which is assumed to exhibit constant returns to scale and is twice continuously differentiable and concave. The allocation of labour and capital, $L_i$ and $K_i$, is determined through marginal productivity pricing. Thus, we have

$$p_r F_r^K = R = p_u F_u^K, \ p_r F_r^L = w_r \text{ and } p_u F_u^L = w_u,$$

(6)

where $F_i^j$ is the derivative of $F_i(i = u, r)$ with respect to $j(j = L_i, K_i)$.

The economy is considered too small to influence the positive international prices of the two commodities, $p_u$ and $p_r$. On rewriting the equilibrium condition (2) in the slightly more general form,
Harris–Todaro hypothesis: The New Palgrave Dictionary of Economics

\[ w_u = \rho w_r (1 + \lambda); \quad \rho \text{ a shift parameter,} \]

(7)

(3), (5), (6) and (7), along with the material balance equations below, complete the specification of the model.

\[ K_r + K_u = K \quad \text{and} \quad L_r + L_u (1 + \lambda) = L. \]

(8)

The first point to be noticed about this model is a decomposability property whereby the factor prices, \( w_u, w_r, R \) and the unemployment rate \( \lambda \) are all independent of the endowments of labour and capital and depend solely on \( p_u, p_r \) and the shift parameters \( \tau \) and \( \rho \). This can be seen most easily if we subsume the marginal productivity conditions (6) into price-equal-unit-cost equations

\[ p_i = C_i (w_i, R), \quad i = u, r. \]

(9)

This allows one to decompose the model into a subsystem comprising eqs. (7) and (3) along with (9).

This basic observation leads to several interesting characteristics of the equilibria of the model. First, the market rural wage and market rental correctly measure the social opportunity cost of labour and capital if we use the international value of GNP as the relevant measure of social welfare. Second, despite the presence of a distorted labour market, there is no possibility of immiserizing growth. Third, an increase in capital (labour) increases the output of the capital- (labour-) intensive commodity provided the intensities are measured in employment adjusted terms, that is

\[ \frac{K_u}{1 + \lambda} = \frac{K_u}{L_u (1 + \lambda)} > (or < ) \frac{K_r}{L_r} = k_r. \]

(10)

This third property is an analogue of the Rybczynski property of the HOS model. Not surprisingly, we
also obtain an analogue of the Stolper–Samuelson property whereby the effect of changes in international prices on factor returns depends on factor intensities, provided these are now measured in elasticity adjusted terms. The urban sector is said to be capital intensive in elasticity adjusted terms if

\[ \theta \tau \mu L(\theta \mu K(1 - e) + \theta \mu L e_R) - \theta \mu L \theta \tau K(e_W - e) > (or <) 0, \]

(11)

where \( \theta \mu \) is the share of the \( j \)th factor \( j = K, L \) in the \( i \)th sector \( i = \mu, \tau \), and \( e_i \) is the elasticity of the \( \Omega (\cdot) \) function with respect to the relevant variable. In the setting where \( e_W \) equals unity and \( e_R \) and \( e_\lambda \) are all zero, (10) and (11) collapse to the conventional physical and value intensities of Magee (1976) and Jones (1971) for the HOS model with proportional wage differentials. Under the further specialization that \( \rho \) in (7) equals unity, there is no difference between these two kinds of intensities and a perfect correspondence between the Rybczynski and Stolper–Samuelson theorems.

This reappearance of the divergence of the physical and value intensities of the wage-differential model leads us to inquire into the possibility of downward-sloping supply curves of \( X_\tau \) and \( X_\mu \). This is indeed a possibility, and a sharp generalization is available in the result that there are perverse price–output responses in the model if and only if the employment-adjusted factor intensities do not conflict with the elasticity-adjusted intensities; see Khan (1980b) for details. Another direct consequence of the decomposability property of the model is a generalization of the Bhagwati (1968), Johnson (1971), Brecher–Alejandro (1977) paradox. This states that capital inflow in the presence of a tariff and with full repatriation of its earnings is immiserizing if and only if the imported commodity is capital intensive in employment-adjusted terms. This result is independent of the various mechanisms for the determination of urban wages; see Khan (1982a) for details, and also subsequent work by Beladi-Naqvi (1988), Grinols (1991), Chao and Yu (1994; 1995c), Chaudhuri and Mukhopadhyay (2002), Chaudhuri (2001) and Sen, Ghosh and Barman (1997). Both of these results have a trade-theoretic flavour, and one question that has remained in the forefront of analytical work on the Harris–Todaro hypothesis relates to the effect of urban wage subsidies on urban unemployment and urban output. (As emphasized above, this question could indeed be seen as the \textit{raison d’être} for the introduction of the hypothesis.) A seminal result here is the Corden–Findlay (1975) paradox, which draws attention to the fact that urban employment and urban output could rise if the urban wage is increased. This question has been readdressed by Neary (1981) and completely resolved in the context of endogenous urban wage determination by Khan (1980b).

So far we have focused on the comparative-static properties of the Harris–Todaro equilibrium. It is also worth emphasizing that the actual existence of the Harris–Todaro equilibrium cannot be taken for granted and must be proved. In the original Harris–Todaro model with an exogenously given rigid wage, equilibrium exists if and only if the rural sector is more capital intensive in employment-adjusted terms; see Khan (1980a) and Basu (1991) for an application of the geometric technique. Furthermore, once the ‘isomorphism’ with the HOS model is established and understood, one can follow Neary's (1978) lead...
and ask for ‘reasonable’ adjustment processes under which the Harris–Todaro equilibrium is locally asymptotically stable. It can be shown that an adjustment process of the Marshallian type leads to a stable equilibrium if and only if the employment-adjusted factor intensities do not conflict with the elasticity-adjusted intensities; see Khan (1980b) for details. Since the elasticity-adjusted intensities of (11) collapse to $\theta_r \theta_L \theta_u K$ in the Harris–Todaro model with a rigid wage, we have the satisfying result that the criteria for the existence of equilibrium and its stability coincide; also see Neary (1981) for this special case.

The entry on this subject in the first (1987) edition of *The New Palgrave: A Dictionary of Economics* was furnished under the title Harris–Todaro hypothesis, and the model presented above referred to as the ‘generalized Harris–Todaro’ (GHT) model. This is somewhat misleading in that any model in which the Harris–Todaro hypothesis is embedded has a justifiable claim to the title of a Harris–Todaro model. Indeed, unlike the case of the HOS model where capital is intersectorally mobile, the hypothesis can be embedded in the Ricardo–Viner model, a setting with three factors, or under an alternative interpretation, one where capital can be viewed as non-shiftable (for details on this and other basic constructions of classical trade theory, see, for example, Caves and Jones, 1985). In many ways, this case of a two-sector model with sector-specific capital is more difficult and also more interesting; see Khan (1982a; 1982b) and Bhatia (2002) for details. And there is at least one example in the literature where a particular Harris–Todaro model has been exported to international trade theory rather than imported from it: Jones and Marjit (1992) investigate a multi-sectoral setting of Khan (1991) by stripping it of the Harris–Todaro hypothesis.

This updated entry would be seriously incomplete if it did not note a criticism of the Harris–Todaro hypothesis centering on the urban unemployed living on a zero wage, and a corresponding generalization of the hypothesis. This criticism also dovetails into an issue that has received increasing attention from sociologists and development economists since the early 1990s: the existence of a dynamic informal urban sector, and the possibility of the urban unemployed being incorporated in it; see Portes et al. (1989) and Fields (1975; 2005b) and their references. This has led to a reformulation of (1) and (2) to

\[
\begin{align*}
    \frac{w_u^e}{L_u + U} + \frac{w_i}{L_u + U} & = \frac{w_u + \lambda w_i}{1 + \lambda} = \Rightarrow w_r = w_u^e \iff w_u + \lambda w_i = w_r(1 + \lambda),
\end{align*}
\]

where $w_i$ is the wage in the informal sector. Again, as in the original Harris–Todaro hypothesis, this generalized hypothesis can be embedded in alternative production structures to yield a variety of models tailored to the purpose the investigator has in mind; see Chandra (1991) and Chandra and Khan (1993) for a more detailed elaboration of this point of view. The subject continues to receive attention; see Stiglitz (1982), Fields (1990; 1997), Rauch (1991), Gupta (1993; 1997a; 1997b), Bandyopadhyay and Gupta (1995), Kar and Marjit (2001), Yabuuchi and Beladi (2001), Yabuuchi, Beladi and Wei (2005); and Chaudhuri (2003).
We conclude this article with a partial list of some other issues in trade and development that have been discussed in the context of urban–rural migration: gains from trade, now depending on the asymmetric nature of the model and on whether the rural or the urban commodity is being exported, as in Khan and Lin (1982), Chao and Yu (1993; 1997; 1999) and Choi and Yu (2006); underemployment or educated unemployment as in Bhagwati and Srinivasan (1977) or in Chaudhuri and Khan (1984) and Chaudhuri and Mukhopadhyay (2003); public inputs as in Chao, Lafargue and Yu (2006); variable returns to scale as in Panagariya and Succar (1986), Beladi (1988) and Choi (1999); growth and technical progress as in Bourguignon (1990), Chau and Yu (1995a) and Chow and Zeng (2001); foreign enclaves as in Gupta-Gupta (1998); capital markets, distorted or otherwise, as in Khan and Naqvi (1983) and Chao and Yu (1992); interaction of ethnic groups as in Khan (1979; 1991) and Khan and Chaudhuri (1985); risk and uncertainty as in Beladi and Ingene (1994); environmental issues, as in Chao, Kerkviliet and Yu (2000) and Chao and Yu (2003); cost–benefit analyses as in Srinivasan and Bhagwati (1975), Stiglitz (1977; 1982), Gupta (1988) and Chao and Yu (1995b); poverty and income inequality as in Moene (1992) and Rauch (1993). In summary then, the Harris–Todaro hypothesis is a versatile and useful analytic instrument for investigating a variety of questions arising in international and development economics where urban unemployment is a prominent issue.

Article

Roy Harrod was born in February 1900 and died in 1978. His father, Henry Dawes Harrod, was a businessman and author of two historical monographs. His mother, Frances (née Forbes-Robertson) was a novelist, and sister of the notable Shakespearean actor-manager, Sir Johnson Forbes-Robertson. Henry Harrod's business failed in 1907, but Roy won a scholarship to St Paul's School in 1911 and a King's Scholarship to Westminster in 1913. He became Head of his House, and in 1918 won a scholarship in history to New College, Oxford, his father's college. He enlisted in September 1918 and was commissioned in the Royal Field Artillery, but the war ended before his training was completed.

He went up to Oxford in early 1919 and first read Literae Humaniores (Classical Literature, Ancient History and Philosophy). He might well have devoted his career to academic philosophy, and he valued his publications in that subject more highly than his seminal contributions to economics. He has remarked that significant economic problems have only attracted the attention of profound thinkers for about 200 years, and interest in them might well disappear in another 200. In contrast, deep thought has been devoted to the great philosophical problems (such as the validity of inductive methods of thought) for more than 2,000 years and new contributions will be read for so long as civilized life remains. But his philosophy tutor at New College, H.W.B. Joseph, deterred him from devoting his life to that subject, by reacting extremely negatively to his essays. Harrod has left an account of a seminar on Einstein's theory of relativity in Oxford in 1922 where Joseph drew attention to a few terminological problems and believed this had undermined the theory. Einstein's theory of relativity survived, but Harrod was persuaded not to pursue a career in academic philosophy. In later years he published in the distinguished
philosophical journal, *Mind*, and his *Foundations of Inductive Logic* (1956a) has received serious critical attention from philosophers as distinguished as A.J. Ayer (1970), but his main scholarly work was not to be in philosophy.

He followed his first class honours in Literae Humaniores in 1922 with a first class in modern history just one year later, and in 1923 Christ Church, Oxford, elected him to a Tutorial Fellowship (confusingly described as a studentship in that college) to teach the novel subject, economics, which was to be part of Oxford's new Honour School of Politics, Philosophy and Economics.

Harrod was allowed two terms away from Oxford so that he could learn enough economics to teach it, and it was suggested that he might spend this time in Europe, but he first went to Cambridge where he attended a wide range of lectures and wrote weekly essays on money and international trade for John Maynard Keynes. He was equally fortunate when he returned to Oxford, for while he was critically discussing the economics essays of Christ Church's undergraduates he was himself writing weekly microeconomic essays for the Drummond Professor of Political Economy, Francis Ysidro Edgeworth. In addition to his new academic work Harrod took a notable part in the administration of his college (where he was Senior Censor in 1929–31, the most responsible office a student of Christ Church can be called upon to discharge), and also the university where he was elected to Oxford's governing body (the Hebdomadal Council) in 1929 before he was 30. In the university and in Christ Church, he fought powerful campaigns on behalf of Professor Lindemann (subsequently Lord Cherwell) who held Oxford's Chair of Experimental Philosophy (Physics), and became principal scientific adviser to Winston Churchill's wartime government and a member of his post-war cabinet.

By 1930 his economics had developed to the point where he was able to publish his first important and original contribution, ‘Notes on Supply’, in which he was the first 20th-century economist to derive the marginal revenue curve. This should have appeared in 1928 to produce a claim for international priority, but Keynes, the editor of the *Economic Journal*, sent the article to Frank Ramsey, who first believed there were difficulties with the argument. He subsequently appreciated that his objections rested on a misunderstanding, but Harrod's new contribution was less startling in 1930 than it would have been in 1928. He followed this initial contribution to the imperfect competition literature with an important article, ‘Doctrines of Imperfect Competition’ (1934), in which he summarized the essential elements of the new theories of Edward Chamberlin and Joan Robinson.

During the 1930s Harrod frequently stayed with Keynes and he was increasingly drawn into the group of brilliant young economists which included Richard Kahn and Joan Robinson, who were helping him develop the new theories which culminated in *The General Theory of Employment, Interest and Money*. Harrod had written a number of important and influential articles in the press advocating new reflationary policies in the early 1930s, and these together with his extension of Kahn's employment multiplier to international trade in his *International Economics* (1933b) prompted Joseph A. Schumpeter to write in 1946 in his obituary article on Keynes, ‘Mr Harrod may have been moving independently toward a goal not far from that of Keynes, though he unselfishly joined the latter's standard after it had been raised’.

Shortly after the *General Theory* appeared, Harrod published *The Trade Cycle* (1936a) in which he developed some of the dynamic implications of the new theory of effective demand. The conditions where output would grow were a central theme in Adam Smith's *The Nature and Causes of the Wealth of Nations*, and it had been much analysed in the great 19th-century contributions of Malthus, Ricardo, Mill and Marx, but the long-term dynamic implications of immediate changes to particular economic
variables received virtually no attention in the neoclassical work that followed the marginal revolution. In the *General Theory* Keynes mostly went no further than to work through completely the immediate effects on a formerly stationary economy of a variety of disturbances such as an excess of the saving which would occur at full employment over the investment businessmen considered it prudent to undertake. Harrod went a vital step further and showed what could be expected to occur if saving was permanently high in relation to the long-term opportunity to invest. In 1939 he followed *The Trade Cycle* with ‘An Essay in Dynamic Theory’ (1939c), and after the war he developed his growth theory further in the book, *Towards a Dynamic Economics* (1948a). Important articles followed including a ‘Second Essay in Dynamic Theory’ (1960a), and ‘Are Monetary and Fiscal Policies Enough?’ (1964a).

It is almost certainly because of Harrod's rediscovery of growth theory in the 1930s and his notable contributions to it that Assar Lindbeck, the Chairman of the Nobel Prize Committee, chose to state that he was among those who would have been awarded a Nobel Prize in economics if he had lived a little longer. The nature of Harrod's original contribution and the gradual evolution of his theory from 1939 to 1964 are set out in the second part of this article. The detailed technical characteristics of Harrod's growth model are the subject of Eltis (1987).

In the Second World War Harrod's friendship with Lindemann and his increasing distinction as an economist led to an invitation to join the Statistical Department of the Admiralty (S Branch) which Churchill set up when he again became First Lord in 1939. This moved to Downing Street when Churchill became Prime Minister in 1940, but Harrod did not have a particular talent for detailed statistical work and he developed an increasing interest in the international financial institutions, the International Monetary Fund and the World Bank, which would need to be set up as soon as the war was won, and from 1942 onwards he pursued this work in Christ Church. In the immediate post-war years he took a strong interest in national politics, and stood for Parliament unsuccessfully as a Liberal in the general election of 1945 and for a time he was a member of that party's Shadow Cabinet. He had served on Labour Party committees before the war, and in the 1950s with Churchill's support he unsuccessfully sought adoption as a Conservative parliamentary candidate: his economic advice was warmly welcomed by Harold Macmillan, Conservative Prime Minister in 1957–63. Harrod received the honour of knighthood in 1959 in recognition of his public standing and his notable academic achievements in the pre-war and post-war decades.

He had succeeded Keynes as editor of the *Economic Journal* in 1945, and in partnership with Austin Robinson (who looked after the book reviews) he sustained its reputation and quality until his retirement from the editorship in 1966. His own post-war academic work included important contributions in three areas. In addition to the continuing development and refinement of his pre-war work on dynamic theory, he published extensively on the theory of the firm and on international monetary theory which had been his particular concern during the war.

The Oxford Economists' Research Group had begun to meet prominent British industrialists before the war. A group of Oxford economists which generally included Harrod invited individual industrialists to dine in Oxford, and after dinner they were questioned extensively on the considerations which actually influenced their decisions. This led to the publication of a number of much cited articles and the book, *Oxford Studies in the Price Mechanism* (Wilson and Andrews, 1951) to which Harrod himself did not contribute. Propositions which emanated from these dinners included the notion that businessmen took little account of the rate of interest in their investment decisions, and that they did not seek to profit
maximize, but priced instead by adding a margin they considered satisfactory to their average or ‘full’ costs of production. In his important articles, ‘Price and Cost in Entrepreneurs’ Policy’ (1939b) and ‘Theories of Imperfect Competition Revised’ (1952a), Harrod set out a theoretical account of how firms price in which industrialists follow something like these procedures. Their object is especially to achieve a high market share, and by setting prices low enough to deter new entry they actually succeed in maximizing their long-run profits and avoid the excess capacity that Chamberlin and Joan Robinson had considered an inevitable consequence of monopolistic or imperfect competition. This attempt to reconcile the ‘rules of thumb’ that the businessmen revealed with the propositions of traditional theory was more highly regarded outside Oxford than some of the books and articles in the new tradition.

His work on the world's international monetary problems occupied a good deal of his time and attention in the post-war decades. Keynes himself had considered the breakdown in international monetary relations a crucial element in the collapse of effective demand in so many countries in the 1930s, and he devoted much of the last years of his life to the creation of new institutions which would avoid a repetition of these disasters. Harrod believed he was continuing this vital work when he devoted much thought and energy to these questions. He arrived at the conclusion that there was bound to be some inflation in a world which was successfully pursuing Keynesian policies, and that the liquidity base of the world's financial system was bound to become inadequate if the price of gold failed to rise with other prices. He believed that underlying world liquidity which rested on gold in the last resort must be allowed to rise in line with the international demand for money. He therefore came to focus on the price of gold, and in his book, Reforming the World’s Money (1965), he proposed that a substantial increase in the price of gold would be needed if subsequent international monetary crises were to be avoided. Harry Johnson (1970) has summarized his contribution to this debate.

Harrod took a great interest in actual developments in the United Kingdom economy, and published seven books and collections of articles in the first two post-war decades which were directly concerned with the policies Britain should follow. There was in addition an immense range of articles in the academic journals, the bank reviews and the press on these questions, not to mention monthly stockbrokers’ letters for Phillips and Drew. Harrod argued strongly and powerfully that nothing was to be gained by running the economy below full employment, which meant an unemployment rate of less than two per cent in the 1950s and the 1960s. In the late 1950s he was deeply concerned that the removal of import controls would render it increasingly difficult for Britain to pursue such Keynesian policies, and he was a vigorous opponent of European Common Market entry. He attached more significance than some distinguished Keynesians to holding down inflation but he published statistics in Towards a New Economic Policy (1967a) to show that in Britain this had tended to be faster when the economy was in recession than when output was allowed to expand. He argued therefore that deflationary policies could play no useful role in policies to control the rate of cost inflation, which he considered the essential element in inflation in Britain. Policy swung sharply away from this Keynesian tradition in the last years of his life, and he wrote a final letter to The Times on 21 July 1976 in which he praised the economics of Tony Benn and Peter Shore for their opposition to the Labour government’s public expenditure cuts, for, ‘To cut public spending when there is an undesirably high rate of unemployment is crazy’. His advocacy of import controls and his adverse reaction to deflationary policies at all times might suggest that he was an economist of the Left, but his willingness to support each of the British political parties at various times underlines how his approach to economic and social problems cannot be
typecast. The lines of policy he supported always followed directly from his understanding of the significance of the major interrelationships, and it was his belief that Keynesian theory (which he had so notably helped to refine and develop) provided the appropriate tools for the analysis of Britain's economic problems that led him towards the expansionist policies he so consistently advocated. But further theoretical and empirical relationships which he believed were equally well founded led him to advocate a series of social policies to which very right-wing labels can be attached.

Just before the 1959 election his article, ‘Why I Shall Vote Conservative’, in *The Sunday Times*, put forward the startlingly unfashionable argument that only the Conservatives would allow more money to go to the better off who had most to contribute to the future of Britain. Harrod's strong belief in the importance of the *quality* of the country's population stock (which, he held, mattered no less than the physical capital stock) lay behind this article. Harrod thought the quality of the population would be bound to deteriorate if the middle classes continued to have fewer children than the poor. He was a strong believer in the inheritance of every kind of ability, and a provocative conversational conclusion he drew was that in an ideal world one-third of Christ Church's much sought-after undergraduate places should be sold to the rich. Their children often had insufficient academic ability to perform well in examinations, but they had inherited abilities of other kinds which would take them to the highest positions, so they should go to Oxford first. Harrod's reasoning on the inheritance of ability and its implications is set out in detail in the Memorandum he submitted to the Royal Commission on Population in 1944. There he suggested that a difficulty in finding servants was one reason why the middle classes had fewer children. Among his suggestions to remedy this state of affairs was that Diplomas in Domestic Service should be established, and that it should become common practice for servants to have latch-keys and the same rights as their mistresses to enjoy social lives with no questions asked. His Memorandum reads strangely nowadays when it is widely regarded as unacceptable that any practical conclusions may be drawn from the proposition that human abilities are inherited. Harrod never hesitated to carry his arguments to their limits, and he always went where his reasoning took him, irrespective of the predictable reactions of others.

The unselfconsciousness of both his academic and his public writing comes out especially in his two biographical volumes, the official life of Keynes (commissioned by the executors) which he published in 1951 and *The Prof* (1959a), his personal sketch of Lord Cherwell. As well as providing magnificent accounts of their subjects from the standpoint of one who had known them intimately (and who profoundly understood the economic problems Keynes wrestled with), these books contain extensive autobiographical passages which will enable later generations to know more of Harrod than any biographer can begin to convey.

He ceased to lecture in Oxford in 1967 upon reaching the statutory retirement age of 67, but as a Visiting Professor he continued to teach in several distinguished North American Universities. He died in his Norfolk home in 1978 eleven years after his Oxford work came to an end.

**Harrod's revival of growth theory and his contribution to Keynesian macroeconomics**

Harrod was intimately involved in the origins and development of Keynesian economics. As the galley proofs of the *General Theory* emerged from the printers from June 1935 onwards, copies were sent to Harrod, to Kahn and to Joan Robinson and with their assistance, Keynes rewrote extensively for final publication. Harrod helped to clarify the relationship between Keynes's new theory of the rate of interest...
and the then ruling neoclassical theory where this depended upon the intersection of \textit{ex ante} saving and investment schedules. In the course of their correspondence, Harrod showed Keynes how well he understood the essence of the \textit{General Theory} by setting out its novelty and its principal elements in ten lines on 30 August 1935:

Your view, as I understand it is broadly this:

\begin{align*}
\text{Volume of investment determined by} & \quad \begin{cases}
\text{marginal efficiency of} \\
\text{capital schedule} \\
\text{rate of interest} \\
\text{liquidity preference} \\
\text{schedule} \\
\text{quantity of money}
\end{cases} \\
\text{Rate of investment determined by} & \quad \begin{cases}
\text{volume of investment} \\
\text{multiplier}
\end{cases} \\
\text{Value of multiplier determined by} & \quad \begin{cases}
\text{propensity to save}
\end{cases}
\end{align*}

Keynes responded, ‘I absolve you completely of misunderstanding my theory. It could not be stated better than on the first page of your letter.’

Almost immediately after the appearance of the \textit{General Theory}, Harrod published \textit{The Trade Cycle} (1936a) which contained for the first time in the Keynesian literature the concept of an economy growing at a steady rate. Keynes wrote of it to Joan Robinson on 25 March 1937, ‘I think he has got hold of some good and important ideas. But, if I am right, there is one fatal mistake’, and to Harrod himself on March 31, ‘I think that your theory in the form in which you finally enunciate it is not correct, being fatally affected by a logical slip in the argument.’ Harrod replied devastatingly on April 6th, ‘There is no slip … The fact is that you in your criticism are still thinking of once over changes and that is what I regard as a static problem. My technique relates to steady growth.’ Harrod's slip was in fact the first step towards the reinstatement of growth theory into mainstream economic analysis.

Harrod convinced Keynes, who on 12 April congratulated him for ‘having invented so interesting a theory’, but with the reservation, ‘I should doubt whether any reader who has not talked or corresponded with you could be aware that the whole of the last half of the book was intended to be in relation to a moving base of steady progress.’ Keynes added that it was vital that Harrod carry his ideas further and restate them more comprehensibly.

Harrod made important progress in the next 15 months, and on 3 August 1938 he sent Keynes a preliminary draft of the article, ‘An Essay in Dynamic Theory’, and wrote in his accompanying letter,

\begin{quote}
my re-statement of the dynamic theory … is, I think, a great improvement on my book … I have been throwing out hints in a number of places of the possibility of formulating a simple law of growth and I want to substantiate the claim. It is largely based on the ideas
\end{quote}
of the general theory of employment; but I think it gets us a step forward.

A lengthy correspondence then developed between Harrod and Keynes in which the two most original elements in Harrod's contribution which later excited much interest and controversy in the economics profession were extensively discussed. Harrod's principal innovation was the invention of a *moving equilibrium growth path* for the economy, and he described this as the ‘warranted’ line of growth. Harrod had perceived before he wrote *The Trade Cycle* that there was a fundamental contradiction between the assumptions prevalent in the microeconomic theory of the firm and industry, to which he had made notable contributions, and the new Keynesian macroeconomics. In the theory of the firm, long-term investment was zero, for firms had no motivation to undertake further investment once they were in long-period equilibrium. But the new Keynesian macroeconomics required that there be net investment by firms or the government whenever there was any net saving in the macroeconomy. A theory compatible with both macro and microeconomic equilibrium therefore required that firms invest all the time, so that they can continually absorb total net saving. Harrod's formulation of the warranted rate of growth, his novel discovery, was an attempt to set out this necessary equilibrium growth path that industrial and commercial investment decisions must all the time follow in order to achieve a complete economic equilibrium.

Harrod's moving equilibrium or warranted growth path required that saving (of $s$ per cent of the national income) be continually absorbed into investment, so he asked the question: at what rate of growth will firms all the time choose to invest the $s$ per cent of the national income, which equilibrium growth requires? To answer this question, he made use of the acceleration principle or ‘the relation’, as he called it, that firms need say $C_r$ units of additional capital to produce an extra unit of output. It follows from these premises that the warranted rate of growth of output will be $s/C_r$ per cent per annum. Since each rise in output by 1 unit entails that $C_r$ extra units be invested, a rise in output by $s/C_r$ per cent of the national income will call for an equilibrium investment of $C_r$ times this, which is precisely $s$ per cent of the national income, the ratio of *ex ante* saving in the national income. In Harrod's examples at this time, he suggested a typical $s$ of 10 per cent of the national income and a $C_r$ of 4, to produce a warranted rate of growth of 2.5 per cent.

This idea that if there is continual saving, then equilibrium entails a continual geometric growth in production came as a considerable surprise to Keynes and the other members of the ‘circus’. As Harrod had already explained in April 1937,

> The static system provides an analysis of what happens where there is no increase [in output] which entails (as in Joan Robinson's long-period analysis) that saving=0. Now I was on the lookout for a steady rate of advance, in which the rates of increase would be mutually consistent.

But Harrod's second discovery had equally radical implications. Suppose the actual growth of output is marginally above the equilibrium or warranted rate of growth. In Harrod's numerical example with $s$ 10 per cent and $C_r$ 4, it can be supposed that output actually grows 0.1 per cent faster than the warranted rate, that is by 2.6 per cent instead of 2.5 per cent. Then with 2.6 per cent output growth, the acceleration principle or relation will entail that 4 times 2.6 per cent be added to the capital stock, so that *ex ante*
investment is 10.4 per cent of the national income. With *ex ante* saving limited to 10.0 per cent, the 0.1 per cent excess of actual growth over warranted growth then produces an excess in *ex ante* investment over *ex ante* saving of 0.4 per cent of the national income. Any excess in *ex ante* investment over *ex ante* saving will be associated with extra expansion of the national income according to the economics of the *General Theory*. Thus, if the actual rate of growth exceeds the warranted rate of \( s/C_r \) per cent, the tendency will be for actual growth to rise and rise, for as soon as actual growth rises from 2.6 to say 3 per cent, required investment will rise further to 4 times 3 per cent which equals 12 per cent and so exceed the 10 per cent savings ratio by a still greater margin. Conversely, when actual growth comes out at a rate just short of the warranted 2.5 per cent, *ex ante* investment will be below the 10 per cent savings ratio, which will cause the rate of growth to decline. This second discovery, which became known as Harrod's knife-edge, was therefore that any rate of growth in excess of the equilibrium or warranted path he had discovered would set off a continual acceleration of growth, while any shortfall would set off deceleration. He wrote to Keynes of this discovery on 7 September 1938:

If in static theory producers produce too little, they will be well satisfied with the price they get and feel happy; but this is not taken to be the *right* amount of output; they will be stimulated to produce more. The equilibrium output is taken to be that which *just* satisfies them and induces them to go on as before. Similarly the warranted rate [of growth] is that which *just* satisfies them and leaves them going on as before. The difference between the warranted rate and the old equilibrium (i.e. the difference between dynamic and static theory) is, in my view, that if they produce above the warranted rate, they will be more than satisfied and be stimulated, and conversely, while in the case of equilibrium in static conditions the opposite happens. The ‘field’ round the [static] equilibrium contains centripetal, that round the warranted centrifugal forces.

It took Keynes time to absorb Harrod's startling discovery. On 19 September he proposed a counter-example in which \( C_r \) was merely one-tenth, while \( s \) was also one-tenth. With this counter-example, a deviation of output by a small amount from the warranted path, say by \( \delta x \), which would raise planned investment above the level at which it would otherwise be by \( C_r \delta x \) would merely raise this by 0.10 \( \delta x \), which would equal the rise in planned saving of \( s \delta x \), which would also come to 0.10 \( \delta x \), so there would be no tendency towards an explosive growth in effective demand. This would grow explosively if \( C_r \) was one-ninth (in which case planned investment would rise by 0.11 \( \delta x \) and saving by only 0.10 \( \delta x \)) but the further growth of output would be damped if \( C_r \) was merely one-eleventh, so, Keynes insisted, ‘neutral, stable or unstable equilibrium’ are equally likely.

Harrod protested on 22 September, ‘it is absurd to suppose extra capital required \([C_r]\) only \( \frac{1}{10} \) of annual output, when the capital required in association with the pre-existent level of incomes in England today is 4 or 5 times annual output’. The probability that \( C_r \) would exceed \( s \) so that *ex ante* investment would rise by more than *ex ante* saving in order to produce instability was therefore overwhelming. But several qualifications emerged. In comparing the increase in *ex ante* investment to the increase in *ex ante* saving following a small deviation of output from the warranted rate:
1. The relevant marginal capital coefficient \( (C_r) \) which determines how much planned investment will rise is the net new requirement of induced investment. In so far as investment decisions are autonomous of short-term fluctuations in output, the relevant \( C_r \) will be lower than the economy's overall capital output ratio.

2. The relevant coefficient which determines the increase in planned saving is the marginal and not the average propensity to save. Planned saving will rise more where output deviates upward from the warranted rate, the greater is the marginal propensity to save in relation to the average propensity.

The circumstances that could produce a stable upward deviation of growth from the warranted rate and the avoidance of Harrod's knife-edge are therefore a very high marginal propensity to save in combination with a situation where most investment is autonomous so that the induced investment coefficient, \( C_r \), is considerably less than 1. In ‘An Essay in Dynamic Theory’, Harrod covered this possibility with the caveat, ‘when long-range capital outlay is taken into account … the attainment of a neutral or stable equilibrium of advance may not be altogether improbable in certain phases of the cycle’. The possibility he had in mind here is that in the early stages of a cyclical recovery there may be so much excess industrial capacity that \( C_r \) will be quite low for a time, and therefore quite possibly lower than the marginal propensity to save. But in general any deviation of growth from the warranted line of advance would raise \textit{ex ante} investment by a greater margin than \textit{ex ante} saving with the result that the rate of growth would deviate further.

In addition to establishing the existence of the warranted line of advance and its instability, Harrod had to define the equilibrium investment behaviour by businesses which would actually lead to expansion at the requisite rate. In his 1939 article he omitted to offer any behavioural rule but simply asserted that the warranted rate was ‘that rate of growth which, if it occurs, will leave all parties satisfied that they have produced neither more nor less than the right amount’. That is no more than a description of equilibrium growth, and much the same can be said of his definition of the warranted rate in \textit{Towards a Dynamic Economics} (1948a) as ‘that over-all rate of advance which, if executed, will leave entrepreneurs in a state of mind in which they are prepared to carry on a similar advance’. It was only in the article ‘Supplement on Dynamic Theory’ (1952b) that Harrod arrived at a behavioural assumption that matched his algebraic formulation of the warranted rate:

Let the representative entrepreneur on each occasion of giving an order repeat the amount contained in his order for the last equivalent period, adding thereto an order for an amount by which he judges his existing stock to be deficient, if he judges it to be deficient, or subtracting therefrom the amount by which he judges his stock to be redundant, if he does so judge it.

With that assumption an economy which once achieves growth at the warranted rate will sustain it, while any upward or downward deviations will lead to still greater deviations wherever \( C_r \) exceeds the marginal propensity to save.

But it emerged by 1964, when Harrod published ‘Are Monetary and Fiscal Policies Enough?’, that even that assumption fails to define growth at the warranted rate, for it must also be assumed that the
A representative entrepreneur will expand at a rate of precisely $s/C_r$ when he judges his capital to be neither deficient nor redundant. This requires an expectation by the representative entrepreneur that his market will grow at a rate of precisely $s/C_r$. Hence the full requirement for growth along Harrod's warranted equilibrium path is that entrepreneurs expect growth at this rate and expand and continue to expand at that rate so long as their capital stock continues to grow in line with their market so that it is neither deficient nor redundant. They will of course increase their rate of expansion if their capital should prove deficient, and curtail it if part of their stock becomes redundant.

The warranted rate of growth and its instability were Harrod's great innovations. From 1939 onwards he contrasted this equilibrium rate with the natural rate of growth, ‘the rate of advance which the increase of population and technological improvements allow’, which was entirely independent of the warranted rate. Harrod defined the rate of technical progress more precisely in 1948 as the increase in labour productivity ‘which, at a constant rate of interest, does not disturb the value of the capital coefficient’. This then entered the language of economics as Harrod-neutral technical progress, which, together with growth in the labour force, determines the natural rate of growth, that is, the rate at which output can actually be increased in the long run. This raised few theoretical problems in 1939, and there was nothing novel in the proposition that long-term growth must depend on the rate of increase of the labour force and technical progress. Keynes himself had said as much several years earlier in ‘Economic Possibilities for our Grandchildren’ (1930). But the contrast between this natural rate and Harrod's innovatory warranted rate offered entirely new insights.

If the warranted rate exceeds the feasible natural rate, the achievement of equilibrium growth must be impractical because the economy cannot continue to grow faster than the natural rate. It must deviate downwards from the warranted rate towards the natural rate far more than it deviates upwards with the result that ‘we must expect the economy to be prevailingly depressed’. If the natural rate is greater, output will tend to deviate upwards towards the natural rate with the result that the economy should enjoy ‘a recurrent tendency towards boom conditions’.

Keynes's own reaction to the dichotomy between the warranted and natural rates was characteristically (his letter to Harrod on 26 September 1938) that the warranted rate always exceeded the natural: 

In actual conditions … I suspect the difficulty is, not that a rate in excess of the warranted is unstable, but that the warranted rate itself is so high that with private risk-taking no one dares to attain it …

I doubt if, in fact, the warranted rate – let alone an unstable excess beyond the warranted – has ever been reached in USA and UK since the war, except perhaps in 1920 in UK and 1928 in USA. With a stationary population, peace and unequal incomes, the warranted rate sets a pace which a private risk-taking economy cannot normally reach and can never maintain.

That is characteristic Keynes, but Harrod had persuaded him to express his familiar analysis in the language of his new theory of growth. In the immediate post-war decades when full employment and creeping inflation prevailed, it was widely argued that the natural rate had come to exceed the warranted. The richness of Harrod's model is demonstrated by its ability to illuminate both kinds of situation. Evsey Domar's growth model which has a good deal in common with Harrod's was published seven
years after ‘An Essay in Dynamic Theory’, and a considerable literature emerged in the next 15 years on the stability conditions and other important features of what came to be known as the Harrod–Domar growth model. This is elegantly summarized by Frank Hahn and Robin Matthews in their celebrated 1964 survey article.

The development of neoclassical growth theory in the 1950s led to an increasing realization that the warranted and natural growth rates could be equated by an appropriate rate of interest. If the warranted rate was excessive so that over-saving led to slump conditions, a lower interest rate which raised \( C_r \) sufficiently would bring it down to the natural rate. Conversely the inflationary pressures that resulted from an insufficient warranted rate would be eliminated if higher interest rates reduced \( C_r \) sufficiently. If the real rate of interest and \( C_r \) responded in this helpful way, \( s/C_r \), the warranted rate could always be brought into equality with the natural rate.

Harrod's response included his ‘Second Essay in Dynamic Theory’ (1960a), a title which underlines its significance. He proposed that there was an optimum real rate of interest \( r_n \) which would maximize utility, with a value of \( G_p/e \), \( G_p \) being the economy's long-term rate of growth of labour productivity and \( e \) the elasticity of the total utility derived from real per capita incomes with respect to increases in these. If a one per cent increase in real per capita incomes raises per capita utility 0.5 per cent, \( e \) will be 0.5, and \( r_n \) the optimum rate of interest which maximizes utility will be \( G_p/0.5 \), viz. twice the rate of growth of labour productivity. If the marginal utility of income does not fall at all as real per capita incomes rise, per capita utility will grow one per cent when incomes rise one per cent so that \( e \) is unity, and \( r_n \) equals \( G_p \). The more steeply the marginal utility of incomes fall, the more \( e \) will fall below unity, and the more the optimum real rate of interest, \( G_p/e \), will exceed the rate of growth of labour productivity.

If a society actually seeks to establish the optimum rate of interest determined in this kind of way, the value of \( C_r \) will depend upon this optimum rate of interest, so it will not also be possible to use the rate of interest to equate the natural and warranted rates of growth in the manner the neoclassical growth models of, for instance, Robert Solow (1956) and Trevor Swan (1956) propose. There will therefore still be difficulties because the warranted rate of growth with real interest rates at their optimum level will not in general be equal to the natural rate. Therefore, as Harrod suggested in the final articles he published in 1960 and 1964, governments will have to run persistent budget deficits or surpluses if they are to avoid the difficulties inherent in discrepancies between the natural and the warranted rates of growth.

So Harrod remained a convinced Keynesian who continued to believe that a long-term imbalance between saving, the main determinant of the warranted rate, and investment opportunity would call for persistent government intervention. When that approach to economic policy again becomes fashionable, economists may learn a good deal from Harrod's later articles which have not yet received the same attention from the economics profession as his seminal work in the 1930s and the 1940s.

Harsanyi, John C. (1920–2000)

Roger B. Myerson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

John Harsanyi worked to extend the general theoretical framework of economic analysis. He established the modern basis for utilitarian ethics. He developed a general bargaining solution to that included the Nash bargaining solution and the Shapley value as special cases. He became a leading advocate of non-cooperative game theory as the general framework for analysis of social interactions among rational individuals. He developed the tracing procedure to select among multiple equilibria of games. He showed how to interpret mixed-strategy equilibria in game theory. His general model of Bayesian games with incomplete information became a cornerstone of information economics.

Keywords

Article

John Harsanyi extended the theoretical framework of economic analysis with major contributions to game theory and welfare economics. His general approach to social theory was based on a fundamental assumption that people are rational decision-makers who share a basic understanding of the things that they value in the world. His personal experiences made him profoundly sceptical of theories that try to justify social systems from other assumptions, without respecting the values, the rationality, and the intelligence of all individuals in society. He understood that social institutions and policies should be evaluated by carefully analysing their impact on individuals’ welfare. From his training in philosophy he appreciated the basic importance of general unified frameworks in social theory. He recognized the
foundations of such a framework in Bayesian decision theory, with its compelling axiomatic characterizations. So he devoted his career to the development of a general framework for economic analysis based on these principles. His best-known contribution is the general model of Bayesian games with incomplete information, which became a cornerstone of information economics.

Harsanyi grew up in Budapest, Hungary, where his distinction as a student was marked in 1937 by his winning the first prize in Hungary's national mathematics competition. But at the university he chose to study pharmacy so that he could share his father's business, as other options were then clouded by the threat of war. He was forced into hiding by Nazi racial policies during the last months of the German occupation. After the war, he studied philosophy and earned a doctorate from the University of Budapest in 1947, but his intellectual independence led to political difficulties with the Communist regime, which forced him out of the university. In 1950 he fled Hungary and found refuge in Australia.

He began studying economics at Sydney University, earning an MA in 1953. He then held a lectureship at the University of Queensland, where he began to read game theory. In 1956, when he already had published articles on welfare economics, he enrolled as a student at Stanford University, earning his second doctorate in 1959. He then held faculty positions at the Australian National University, Wayne State University, and, from 1965, in the School of Business Administration at the University of California, Berkeley.

In his early contributions to welfare economics, Harsanyi established the modern basis for utilitarian ethics. Von Neumann and Morgenstern (1947) had shown axiomatically that a rational individual should choose among risky alternatives by maximizing the expected value of a cardinal utility function, but some economists doubted whether this cardinal utility, defined for individual risk analysis, had any relevance for social welfare analysis. Harsanyi (1953) argued that, in ethical decision-making, to avoid any dependence on our particular roles in society, we must imagine ourselves in an initial position before social roles have been assigned, when we could only anticipate getting the role of someone drawn at random from the whole population. Thus, ethical decision-making involves an essential element of risk, and we naturally get a social welfare function equal to the average utility of all members of society. This average requires interpersonally comparable utility scales, assessed by sympathetically comparing the prospect of being in one person's position or another's. Harsanyi argued, as his ‘similarity postulate’, that such comparable utilities for all individuals can be generated by a common utility function, based on shared human values, once the factors that cause apparent differences among individuals’ tastes are included as parameters of the function. Harsanyi (1955) showed that, even without this similarity postulate, the Neumann–Morgenstern utility axioms (applied to individual and social decision-making) and the Pareto welfare axiom (that social preferences should be consistent with any unanimity of individual preferences) together imply that social utility can be defined only as some linear function of individual utility values.

In his later work on welfare economics, Harsanyi (1977a, ch. 4; 1977b; 1977c), argued that ethical analysis should be used to evaluate general social rules or institutions rather than specific acts. That is, we may consider ethical rules that prescribe people's behaviour in a wide range of situations, recognizing that behaviour in other situations could be determined by self-interest according to some Nash equilibrium. Then, as rule utilitarians, we should advocate rules that yield the highest average of expected utilities for all individuals.

Harsanyi began working on cooperative game theory in the mid-1950s, when many different cooperative solution theories were being studied. But most of these theories could yield multiple solutions or no
solutions for a game, or could not even be defined without some special structures like transferable utility. Harsanyi’s view of the field was clarified by his insistence that a good solution concept should yield one well-defined solution to any game. At that time, there were only two cooperative solution concepts that yielded unique solutions to broad classes of games: the Shapley (1953) value for games with transferable utility, and the Nash (1950) bargaining solution for two-person games without transferable utility. Harsanyi (1956) showed that the Nash bargaining solution could be derived from an earlier theory of Zeuthen (1930). Then Harsanyi (1963) developed a general bargaining solution that included the Nash bargaining solution and the Shapley value as special cases.

In the mid-1960s, Harsanyi shifted from cooperative to non-cooperative game theory. The basic definition of non-cooperative equilibrium had been introduced by Nash (1951). But there was little further development of non-cooperative theory until Schelling (1960) analysed bargaining processes as games with multiple equilibria, where any cultural or environmental factor that focuses the players’ attention on one equilibrium can become a self-fulfilling prophecy. Harsanyi (1961) argued that the distribution of power that is measured by a cooperative solution could be the focal factor that selects among the many non-cooperative equilibria of a bargaining game. But then Harsanyi began to recognize the force of Nash’s early arguments for the greater generality of the non-cooperative approach, which is based on a precise specification of each player’s individual decision problem, which is lacking in cooperative models. Thus Harsanyi became a leading advocate of non-cooperative game theory.

Harsanyi understood that the non-cooperative approach could not become a standard methodology for applied economic analysis without some refinements of Nash’s equilibrium concept, because it can yield very large sets of equilibria for many games. So he began a search for theoretical criteria to select among multiple equilibria, which culminated in his book with Selten (1988). Their selection theory is based on Harsanyi’s (1975) tracing procedure, which can select a unique equilibrium from a given initial hypothesis about the players’ strategic behaviour. For each number \( t \) between 0 and 1, we define a \( t \)-auxiliary game that differs from the original game in that each player thinks that the other players have probability \( 1 - t \) of behaving according to the initial hypothesis; otherwise, with probability \( t \), they choose their strategies rationally. The tracing procedure finds a continuous path of equilibria for these auxiliary games, starting from the trivial 0-auxiliary game and ending at a unique equilibrium of the original game when \( t = 1 \).

Harsanyi’s work on incomplete information in games began (1962) with the problems of extending Nash’s bargaining solution to situations where players do not know each others’ payoffs. In this work, he began to recognize the problems of modelling players’ beliefs about each others’ beliefs in a game. Harsanyi (1967–8) confronted these modelling problems at the most general and fundamental level, showing how the basic definition of normal-form games should be modified to analyse situations where individuals have different information.

The early development of game theory was based on von Neumann’s (1928) argument that any dynamic game in extensive form can be represented by a conceptually simpler one-stage game in normal form. In this normal-form game, each player chooses a strategy that is a complete contingent plan of action, specifying what the player would do at each stage of the dynamic game as a function depending on any information that the player might learn during the game. In normal-form analysis, we assume that the players choose their strategies simultaneously and independently at the start of the game, before anyone gets any private information, and thereafter their behaviour in the dynamic game can be determined...
mechanically by their strategies. Thus, questions about the players’ private information are suppressed in normal-form analysis.

Harsanyi (1967–8) showed how to correct this deficiency by developing a more general game model that allows players to have different initial information, without losing the analytical simplicity of the normal form. Each player’s private information at the start of the game is represented by a random variable that is called the player’s type. Harsanyi defined a Bayesian game to be a mathematical model that specifies (a) the set of players, (b) the set of feasible actions for each player, (c) the set of possible types for each player, (d) each player’s expected payoff for every possible combination of all players’ actions and types, and (e), for each possible type of each player, a probability distribution over the other players’ possible types, which describes what each type of each player would believe about the others’ types. The beliefs in a Bayesian game are said to be consistent if the players’ type-contingent beliefs can all be derived by Bayes’s rule from some common prior distribution over types. Although not analytically essential, this assumption of consistent beliefs has been regularly used in applied economic analysis, because it allows that differences in players’ beliefs may be explained by different previous experiences.

To represent dynamic extensive-form games by games in Bayesian form, each player’s action in a Bayesian game may be interpreted as a plan that describes what the player would do in any situation after the beginning of the game, as a function of what the player may learn during the game. A player’s strategy, in von Neumann’s original sense, would then be a function that specifies a feasible action for each of the player’s possible types. But each player is assumed to know his type already when the game begins, and so Harsanyi worked to avoid the fiction of strategic decision-making by players who have not yet learned their types. It would be better, he argued, to imagine that a player’s different possible types correspond to different agents, one of whom will be randomly selected to be active in the game.

The point is that each player’s optimal decisions will maximize his conditional expected payoff given his actual type, and there is no significance to any expected value that is not conditioned on such type information.

Harsanyi emphasized that games must be analysed from the perspective of someone who only knows the information common to all players, which is summarized in the Bayesian game model. Game-theoretic analysis requires us to deny ourselves any knowledge of any player’s actual type, so that we can appreciate the uncertainty of the other players who do not know it. The actual type of each player, being private information, must be treated as an unknown quantity or random variable in our analysis. So an equilibrium of a Bayesian game specifies a feasible action for every possible type of every player, such that the specified action for each type of each player maximizes his conditional expected payoff, given his type, given his beliefs about the others’ types, and given the type-contingent actions of the other players according to this equilibrium.

Applications of Bayesian games developed quickly. Harsanyi and Selten (1972) defined a generalization of Nash’s bargaining solution for Bayesian games, where players have incomplete information about each other. By embedding normal-form games in the larger space of Bayesian games, Harsanyi (1973) showed how to interpret mixed-strategy equilibria in non-cooperative game theory. Such equilibria had seemed to imply paradoxically that rational players should base their decisions on randomizing devices like roulette wheels, but this apparent paradox was a consequence of the normal-form assumption that players choose strategies before they get any private information. By letting each player have some minor private information that changes payoffs only slightly, Harsanyi could transform any mixed-strategy equilibrium into a Bayesian equilibrium where each type chooses an optimal action without
randomization.
Harsanyi's Bayesian games have become the standard economic model for analysing transactions among individuals who have different information. Before 1967, the lack of a general framework for informational problems had inhibited economic inquiry about markets where people do not share the same information. The unity and scope of modern information economics were found in Harsanyi's framework.

decision theory; expectations; Hart, A. G.; uncertainty

Article

Born in Oak Park, Illinois, Hart received his BA from Harvard in 1930 and his Ph.D. from the University of Chicago in 1936. Most of his career – from 1946 until his retirement in 1979 – was spent as Professor of Economics at Columbia University. Much of his noteworthy work concerned the implications of uncertainty for policymakers, but he should also be remembered as having worked with Kaldor and Tinbergen (1964) to produce an ingenious proposal for a commodity reserve currency: this would serve to improve international liquidity simultaneously with providing a means of protecting incomes of primary producers against shrinkage in times of depression.

Hart's work on uncertainty included a monograph (1940), one notable feature of which was an attempt to analyze how decision makers can judge their success or failure, and thence reformulate their expectations, in the light of partial knowledge of performance distributions. From 1936 onwards, he emphasized the rationality, in situations of uncertainty, of choosing flexible production technologies which, though they might not be perfectly adapted to any specific output rate, would not be disastrously expensive to run over a range of outputs. This idea, which was also promoted by his Chicago contemporary Stigler (1939), led Hart to be critical of much writing on decision theory. He felt it misleading to theorize as if firms assign probabilities to rival hypothetical outputs, aggregate these weighted values and then build their plans around the weighted average of probable output rates (1942). Hart was also irritated by Keynes's tendency to speak of expectations in terms of certainty equivalents, and he warned that, ‘generally speaking, the business policy appropriate to a complex of uncertain anticipations is different in kind from that appropriate for any set of certain expectations’ (1947, p. 422).

Hart carried this theme into work critical of deterministic macroeconomic model-building and fiscal policy formulation (1945), and into a distinctive approach to monetary theory (1948, especially part II). In the latter, he introduced the ‘margin of safety’ motive for holding liquid assets, arguing that the structure of economic affairs is such that risks are usually linked: a single disappointment is prone to
cause many other things to go wrong in consequence. Hart's concern with surprise, flexibility, and structural linkages in many ways foreshadows themes that emerged in the 1980s in the business policy literature on scenario planning and strategic choices. However, he is not usually credited as the pioneer of this kind of thinking: having been largely ignored by mainstream writers, his ideas were sufficiently poorly known to end up being reinvented.

Hawkins–Simon conditions

Hukukane Nikaido
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

In a Leontief system of interindustrial input–output relationships consisting of $n$ sectors of industry, each of which produces a single good, without joint products, under constant returns to scale, and using $n$ goods as input in fixed proportions, the balance of demand for and supply of goods is represented by a system of linear equations

\[ x_i = \sum_{j=1}^{n} a_{ij} x_j + c_i \quad (i = 1, 2, \ldots, n), \]

where $a_{ij}$ are non-negative input coefficients of the $j$th sector, $x_j$ is the level of output of the $j$th sector and $c_i$ is the level of final demand for the $i$th good ($i, j = 1, \ldots, n$).

With the input coefficient matrix $A$ having $a_{ij}$ in the $i$th row and the $j$th column, the output vector $x$ having $x_j$ in the $j$th component, and the final demand vector $c$ having $c_i$ in the $i$th component the system is represented in matrix form by the equation

\[ x = Ax + c. \]

The system is productive enough to give positive net output over input, if $x_j$ non-negative units of output of the $j$th sector ($j = 1, \ldots, n$) are produced to meet a bill of positive final demand $c_i$ ($i = 1, \ldots, n$).

The productivity of the system, which is equivalent to the condition that the $n$-dimensional square matrix $I - A$, where $I$ is the identity matrix, have an inverse matrix $(I - A)^{-1}$ having all the elements non-
negative, hinges on and is completely determined by the magnitudes of the input coefficients. A necessary and sufficient condition for such productivity, stated in terms of inequalities constraining the magnitudes of the input coefficients and referred to as the Hawkins-Simon conditions, after the names of its discoverers (Hawkins and Simon, 1949), is that all the principal minor determinants of the matrix \( I - A \) be positive. This is equivalent to the seemingly weaker conditions that the \( n \) principal minor determinants located in the ascending order on the upper left corner of the matrix \( I - A \) be positive.

\[
\Delta_k = \begin{vmatrix}
1 - a_{11} & -a_{12} & \ldots & -a_{1k} \\
-a_{21} & 1 - a_{22} & \ldots & -a_{2k} \\
\ldots & \ldots & \ldots & \ldots \\
-a_{k1} & -a_{k2} & \ldots & 1 - a_{kk}
\end{vmatrix} > 0, \ (k = 1, \ldots, n).
\]

As a mathematical result the equivalence of the Hawkins–Simon conditions to productivity is very easy to prove, as can readily be shown by transforming the equation \((I - A)x = c\) through Gaussian elimination to a triangular form:

\[
b_{11}x_1 + b_{12}x_2 + \ldots + b_{1n}x_n = d_1 \\
b_{21}x_1 + b_{22}x_2 + \ldots + b_{2n}x_n = d_2 \\
\vdots \\
b_{nn}x_n = d_n
\]

where

\[
b_{ij} \leq 0 \ (i < j), \quad d_i \geq 0 \ (i = 1, \ldots, n)
\]

and

\[
\Delta_k = b_{11}b_{22}\ldots b_{kk} (k = 1, \ldots, n).
\]

Since the Hawkins-Simon conditions ensure the productivity of the system, they are a primary prerequisite for the Leontief system, and enlarged systems involving it as a built-in subsystem, to be well-behaved. They also make the Leontief system dynamically well-behaved. In the multiplier process over discrete time,
the solution converges to the equilibrium output levels supplying net output equal to the final demand \( c_i \) \((i=1, \ldots, n)\), if and only if the Hawkins–Simon conditions are satisfied. This stability is equivalent to the convergence of the matrix geometric progression

\[ I + A + A^2 + \ldots + A^t + \ldots \]

to the inverse matrix \((I - A)^{-1}\). In the multiplier process over continuous time,

\[ \frac{dx_i}{dt} = \alpha_i \left( \sum_{j=1}^{n} a_{ij} x_j + c_i - x_i \right), \quad (i = 1, \ldots, n) \]

the Hawkins–Simon conditions are necessary and sufficient as well for the convergence of the solution to the same equilibrium output levels, which is equivalent to the condition that the real parts of all the eigenvalues of the matrix \( A-I \) be negative.

Hawley, Frederick Barnard (1843–1929)

Mauro Boianovsky

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Frederick Barnard Hawley (1843–1929) advanced the ‘risk theory of profit’: profit is the reward entrepreneurs get to relieve the other productive factors from risk in competitive conditions. The normal rate of profit is determined by the expectation of profit that just covers the marginal entrepreneur's subjective valuation of risk. The current rate of profit will converge to its normal value because of the operation of the ‘readjustment period’, when income contraction brings about a fall in aggregate supply larger than the reduction in aggregate demand. This is explained by Hawley's concept of the consumption function.

Article

Frederick Barnard Hawley was born on 5 February 1843 in Albany (New York State), and died on 31 May 1929 in New York City. After spending his freshman year at Harvard University, he went to Williams College (Massachusetts) in 1861, where he graduated three years later. Returning to Albany, he took up the study of law, but gave it up after a year to go into the family's lumber business. In 1876 he became a cotton broker and merchant in New York City, a position he held until his retirement in 1926.

A couple of years after his move to New York Hawley published his first articles, advancing an approach to aggregate economic fluctuations based on his new conception of the saving–investment process. Those articles were expanded in 1882 into his book *Capital and Population*. In the 1890s and early 1900s Hawley published several articles in the *Quarterly Journal of Economics*, where he put
forward his ‘risk theory of profit’. Hawley's contributions to economics are contained in his 1907 book
*Enterprise and the Productive Process*, in which he put together and elaborated ideas he had developed
since the late 1870s. Feeling that his proposed new framework, based on the key role of the
entrepreneur, had not been widely discussed, Hawley wrote 20 years later an article in the *American
Economic Review* summing up his theoretical system. He was a member of the American Economic
Association from 1888 to his death, and served as its treasurer (1892–95) and vice-president (1909).
Hawley was one of the main protagonists in the long and intense controversy about the theory of profit
that took place in American economics from the end of the 19th century to the beginning of the 20th
century and culminated with the publication of Frank Knight's classic 1921 volume. Hawley enunciated
the fundamental principle that there would be no profits in a competitive market in which the course of
future events was entirely foreseen, since all factor services would be paid at rates fixed in advance, with
changes in their productivity during the period of contract taken into consideration. Prices and costs
would converge; there would be no ‘residue’. In actual economies, subject to future unforeseen
influences, the function of the entrepreneur is to relieve others of risk. The entrepreneur bargains with
the workers, capitalists and landlords for the use of their services, paying them not with any share of the
product itself but with stipulated amounts of purchasing power. The actual product is owned by the
entrepreneur, who must assume the responsibility of the enterprise and convert the output into
purchasing power at the market price (cf. J. M. Keynes's 1933 similar distinction between a cooperative
economy and an entrepreneur economy). According to Hawley, the entrepreneur is the dominant active
element in the productive process, combining the three subsidiary passive productive factors. Since the
incomes of individuals are necessarily composite, factors must be associated with functions, not with
individuals. The entrepreneur's profit is a residual, non-contractual income whose amount is determined
only after the output is sold. Hawley assumes that, in order to be relieved of a risk, agents are willing to
pay more than the risk, calculated according to the laws of probability, is worth, since they ‘prefer a
certainty to an uncertainty’. Entrepreneurs perform a service worth more to its recipients than the price
they have to pay, and yet worth less to themselves than they get for it. Hence, the assumption of risk by
the entrepreneur creates value by rendering a service in transferring risks from those to whom their
subjective value is great to those to whom their subjective value is less, a mutually advantageous
exchange of ‘certain goods’ for ‘uncertain goods’. Profit is the reward entrepreneurs get for performing
that service in competitive conditions, and, by that, a component of the prices of commodities in general.
Entrepreneurs are deemed less risk averse than other economic agents, except for ‘gamblers’ and
‘speculators’, who are not risk averse but do not take part in the productive process. The entrepreneurs’
subjective value of risk – the ‘irksomeness of being exposed to risk’ – is higher than its actuarial value,
which means that industrial risks will not be assumed without the expectation of compensation in excess
of their actuarial value. Since, under Hawley's assumption, entrepreneurs are on average and in the long
run correct in their estimates, they pay productive factors less than the product will probably sell for, and
absorb as profits a considerable portion of the annual flow of purchasing power. The ‘normal rate of
profit’ is defined as the expectation of profit that just covers the marginal entrepreneur's subjective
valuation of risks.
Hawley's theory of profit was taken up by Knight, who, however, criticized Hawley for ignoring the
distinction between (known) risk and (unknown) uncertainty and overlooking the fact that the former is
insurable. Although it is true that Hawley used the words ‘risk’ and ‘uncertainty’ interchangeably, it
should be noted that he did pay careful attention to the implications of insurance for his argument.
first place, the act of insurance does not imply that the risk or its reward are extinguished, but only that
the entrepreneur transfers to the insurer a corresponding part of its expected profits. Moreover, the risks
of ownership – the most substantial part of risk – cannot be shifted by insurance, but only by a sale.
Entrepreneurs can, to some extent, protect themselves from risks arising from price fluctuations by
entering into hedging operations with speculators, as Hawley was aware from his experience as a cotton
merchant. Although forward markets cannot completely eliminate the risks influencing selling prices, to
the extent in which entrepreneurs hedge themselves they will be forced by competition to forgo their
reward for risk bearing and lower their prices accordingly.
Whereas Hawley's theory of profit attracted some attention at the time, his contributions to
macroeconomics went largely unnoticed by the profession, probably because their import became clear
only after the Keynesian revolution. Fluctuations in aggregate economic activity are explained,
according to Hawley, by changes in the saving–investment relation throughout the business cycle.
Investment, described by the act of subjecting capital to the uncertainties inherent in actual ownership of
capital goods, is naturally connected with entrepreneurs, not with capitalists or savers. The demand for
new capital goods depends essentially on the entrepreneurs’ profit expectations, which are subject to
violent changes due to ‘unforeseeable and incalculable causes’ that affect the subjective valuation of
risks. The treatment of savers’ behaviour is based on Hawley's path-breaking concept of consumption as
a function of income. He argued that expenditure changes less than income at all levels of income, since
consumers keep close to the standard of living they have once adopted. More specifically, consumption
plans are determined by expected income, measured by the average income of a series of years (that is,
the mathematical expectation). This implies that a sudden increase of income will yield a larger
percentage for saving than a gradual one of equal extent and, furthermore, that the proportion of saving
out of profits is higher because it is more variable and uncertain than other sources of income.
Hawley used his new hypothesis about the consumption function to investigate the dynamics of the
economy when the current rate of profit differs from its normal value. Periods of depression are
characterized by a rate of profit lower than normal, associated to excess saving in the goods market.
‘What can enterprisers do, by varying the character of supply, to protect themselves against this attack of
the saving class upon their chances of profit?’ asked Hawley (1907a, p. 224). The answer is the
‘readjustment period’, Hawley's main contribution to macroeconomic theory, which set him apart from
the rest of the pre-Keynesian business cycle literature: a decline of output caused by excess aggregate
supply will reduce supply more than demand (because of the consumption function) and bring the
economy to equilibrium at less than full employment. The equilibrating effect of the contraction in
aggregate income, identified by Don Patinkin (1982) as the core of the Keynesian principle of effective
demand, can be found already in Hawley's writings. Some corollaries of the idea of ‘readjustment
period’ were also pointed out by Hawley, such as the notion that an increase of the saving flow for a
given investment level will bring about a contraction of income and a return of saving to its initial
amount, so that in the end ‘national parsimony defeats itself’ – an early formulation of the ‘paradox of
thrift’ usually associated with J. M. Keynes.
Whether he had any influence on Keynes is a moot point in the history of macroeconomics. Despite the
fact that the English economist never referred to Hawley, that possibility cannot be disregarded,
especially in view of the similarity of the wording of some key passages.

Hawtrey was born in Slough, near London, and went up to Trinity College, Cambridge, from Eton in 1898. Three years later he graduated 19th Wrangler in the Mathematical Tripos. Hawtrey remained at Cambridge for a further period to read for the civil service examinations, as was quite common at that time. This latter study included some economics with lectures largely by G.P. Moriarty and J.H. Clapham. In 1903 he entered the Admiralty, but in 1904 he transferred to the Treasury, where he was to remain until retirement in 1947 (his official retirement at 65 was in 1944). Hawtrey's only academic appointments in economics were in 1928–9, when he was given special leave from the Treasury to lecture at Harvard (as a visiting professor) and after his retirement, when he was elected Price Professor of International Economics at the Royal Institute of International Affairs (1947–52). Hawtrey served as President of the Royal Economic Society between 1946 and 1948.

Hawtrey was not, therefore, directly a part of the ‘Cambridge School’ of economics. Marshall took no immediate part in Hawtrey's economic education which was, for the most part, acquired in the Treasury. Nonetheless he had close contacts with the Cambridge economists. Away from economics he was involved with both the Apostles and with Bloomsbury, whilst within the subject he was a visitor to Keynes's Political Economy Club at Cambridge and his major work, *Currency and Credit* (1919a) became a standard work in Cambridge in the 1920s. Furthermore, although there were differences in approach between Hawtrey and the Cambridge School in some areas, Keynes himself noted in reviewing *Currency and Credit* the similarities between Hawtrey's approach to the theory of money and that of the Cambridge School – though Keynes remarked that Hawtrey had reached his results independently (Keynes, 1920).
Hawtrey was primarily a monetary economist; his major contributions related to the quantity theory and the trade cycle. He was one of the first English economists to stress the primacy of credit-money rather than metallic legal tender. Furthermore his income-based approach, like that of the Cambridge School, led to a closer integration of the theories of money and output. For Hawtrey, money income determines expenditure, expenditure determines demand and demand determines prices.

Hawtrey summarized his aims in monetary theory in the preface to *Currency and Credit*:

> Scientific treatment of the subject of currency is impossible without some form of the quantity theory...but the quantity theory by itself is inadequate, and it leads up to the method of treatment based on what I have called the consumers’ income and the consumers’ outlay – that is to say, simply the aggregates of individual incomes and individual expenditures. (1919, p. v)

Investment (the result of saving) is included in consumers’ outlays, since it is spent on fixed capital. Consumers’ balances are then the difference between outlays and income and thus consist only of accumulated cash balances (including money held in bank accounts). In addition there is a similar demand for money balances by traders related to their turnover. Of course individual agents may hold both consumers’ and traders’ balances – Hawtrey notes that the true income of traders is the profits of the business and that this is included in consumers’ income.

The ‘unspent margin’, or total money balances, consists of the consumers’ and traders’ balances taken together. From this Hawtrey derives a form of the quantity theory. Hawtrey argues that traders’ balances are relatively stable, and thus the operational relationships are concerned with the supply of money (in a wide sense taken to include credit) and consumers’ income and outlay. It is worth noting that compared to the Cambridge income-based approach Hawtrey’s places greater emphasis on the demand for nominal balances rather than real balances. It is also interesting to note that Keynes used a similar balances approach to the quantity theory in the period after 1925 leading up to the theory presented in the *Treatise on Money* (1930), where he distinguishes first between investment and cash deposits and later between income, business and savings deposits.

The demand for money is also analysed in terms of motives. Hawtrey identifies a transaction demand, a precautionary demand, and a residual demand which reflects a gradual accumulation of savings balances or what Joan Robinson has called short-hoards (Robinson, 1938). Hawtrey envisages agents as saving gradually but investing only larger sums periodically. In the meantime these short-hoards act as a buffer stock. The main costs of holding money balances is the interest forgone, and thus Hawtrey points to a balancing process between costs and advantages in determining desired balances. The introduction of a banking system into the model allows agents to substitute borrowing power for money balances (Hawtrey, 1919a, pp. 36–7).

II. Hawtrey also introduces a concept of effective demand:

> The total effective demand for commodities in the market is limited to the number of units of money of account that dealers are prepared to offer, and the number they are prepared to offer over any period of time is limited according to the number they hope to receive. (1919a, p. 3)
Later, in *Trade and Credit* (1928) Hawtrey points to a flaw in the theory of an elastic supply of labour based on marginal utilities (or disutilities) of product and effort. He argues that whilst a difference between the marginal utility of the product and the disutility of effort may prompt an additional supply of labour ‘in the simple case of a man working on his own account’ (1928, p. 148), this is not the general case since: ‘the decision as to the output to be undertaken is in the hands of a limited number of employers, and the workmen in the industry are passively employed by them for the customary hours at the prevailing rates of wages’ (1928, p. 149). In this case output decisions are based not on the gross proceeds, but on the net profit margin.

The factor of expectations is also present in Hawtrey’s analysis of fluctuations. Hawtrey suggests that during a downturn in activity money balances will be reduced more quickly than they are replenished in an upswing. This is because as income drops initially consumers will draw on their balances to maintain their outlay.

There is then a further level of adjustment as changes in consumers’ outlays impacts on traders. Consider an upswing: the increase in consumers’ outlays will increase the nominal receipts of traders and reduce their physical stocks. Traders, finding their balances have increased can either order more stock from manufacturers or reduce their bank indebtedness. Prices will tend to rise as traders find they are unable to replenish their stocks fast enough. For Hawtrey quantity adjustments occur before price adjustments, indeed often the price movements result from the quantity movements. Thus ‘the rise of prices, when it occurs, is caused by the activity; it is a sign that production cannot keep pace with demand’ (1928, p. 156). The role of stocks in Hawtrey’s theory is pivotal, in general it is quantity signals rather than price signals which are the more effective. The existence of traders’ stocks means that it is nearly always possible to meet the demand for increased consumption in the short term, which implies that at least in the short term a naive proportionality between increases in the money supply and prices does not hold. Furthermore the model opens the possibility of short-run quantity adjustments in disequilibrium. Thus, argues Hawtrey:

> It is only in times of equilibrium, when the quantity of credit and money in circulation is neither increasing nor decreasing, that the relation of prices and money values to that quantity of credit and money is determined by the individual's considered choice of the balance of purchasing power appropriate to his income. … In practice it seldom, perhaps never, happens that a state of equilibrium is actually reached. (1919a, p. 46)

Nonetheless Hawtrey's theory of the trade cycle is money-driven. It is the fluctuations in money and credit which stimulate and support the price and quantity movements. Hawtrey argued that the periodic nature of the trade cycle was solely due to monetary factors. Traders stocks are viewed as being highly interest elastic since they are held on borrowed funds, investment in fixed capital is also interest elastic (based on a marginal efficiency of capital analysis).

Thus an increase in the rate of interest will tend to reduce the demand for credit due to a lower demand for stocks and a reduced level of new investment. If the increased rate of interest is itself the result of a decreased supply of credit then there may also be some quantitative restrictions of borrowing. To reduce their stocks traders will stop giving new orders to manufacturers, leading to a drop in the level of output which will further diminish the demand for credit, as well as the level of income and demand. Traders
may reduce prices to stimulate sales to accelerate the destocking process. There is thus a tendency to a cumulative decline in output, credit and prices until the banks find themselves with excess reserves and believe it to be profitable to reduce the interest rate and expand credit. For Hawtrey, macroeconomic disequilibrium was defined in terms of monetary disequilibrium.

The solution was also therefore monetary, and in particular the short-term rate of interest (the long-term rate of interest was seen as relatively ineffective as a means of control because of its relatively slow impact on investment). Hawtrey viewed the psychological factors in the trade cycle as secondary, arguing that no amount of good news or bad could seriously affect the cycle if monetary factors were not accommodating. He also opposed the public works solution to a slump in output along similar lines – and in this respect is associated with the ‘Treasury View’ (see Hawtrey, 1925). In later life Hawtrey did acknowledge that public works could play a role in severe depressions, but as Haberler (1939, p. 23) points out Hawtrey viewed those occasions when cheap money would fail to stimulate a revival as generally very rare – although he accepts that this was the case in the 1930s.

III. For Hawtrey, investment decisions were made on a Marshallian marginal productivity of capital basis. In a perfectly competitive market, the marginal return on capital employed would be equalized across every industry. In these circumstances Hawtrey identifies the ‘ratio of labour saved per annum to the labour expended on first cost’ as ‘a physical property of the capital in use’ (1913, p. 66) and as a ‘natural rate’ of interest. Under stable monetary conditions and in the absence of a banking system this natural rate is equal to the market rate of interest or the profit rate, as in the standard marginal efficiency of capital analysis. But changes in monetary conditions will generate changes in prices and thus profits; hence the market rate will diverge from the natural rate in the same direction as the movement in prices.

With the addition of a banking system, the actual rate of interest will depend on the behaviour of the banks, and in particular their reserve position. Thus the interest rate will diverge from the profit rate. There is a three-way equilibrium condition, relating the physical return on capital, the profit rate and the balance position of banks, that is, \( N = p = r \) where \( N \) is the natural rate, \( p \) is the profit rate and \( r \) is the interest rate. An increase in the supply of money will cause a rise in prices and the availability of credit; thus \( N > p \) at the same time the banks will find themselves with excess reserves and thus interest rates will tend to be lower than otherwise to stimulate borrowing, that is, \( p > r \). This will be generally expansive, demand, investment and output will all tend to rise—but the seeds of the eventual slump are already present. The rising prices and relatively low rate of interest will encourage firms to over-invest, expecting returns greater than those actually accruing. On the downward cycle \( N > p \) and \( p < r \).

It is worth briefly considering the relationship between Hawtrey's natural rate and that associated with Wicksell. In his early work Wicksell took the natural rate as that prevailing if loan transactions were made in kind, but he later revised this to equate the natural rate with the rate of profits received in the form of money (see Lindahl, 1939, p. 261; Lindahl also discusses a physical return on capital ‘natural rate’ similar to Hawtrey's'). Thus Wicksell's natural rate can be seen as closer to Hawtrey's profit rate. Wicksell, like Hawtrey, also associates the natural rate with an equilibrium between savings and investment and stability in the price level.

Hawtrey does not place great stress on this natural rate analysis, concentrating more on the relationship of the profit rate and the interest rate. There are also considerable practical problems in determining Hawtrey's natural rate, particularly in imperfect capital markets (see the discussion in Lindahl, 1939, and Haberler, 1939).

IV. Hawtrey, like most of the inter-war Cambridge economists, had a fundamental belief in the self-
adjusting nature of the economic system, even though much of the analysis of the period would suggest otherwise. Hawtrey believed that the system was continually approaching or seeking an equilibrium, though in practice the next shock would come before the adjustment process was complete. However, Hawtrey's theoretical approach was to concentrate on the processes of adjustment to monetary disequilibrium.

The income/inventories approach to the trade cycle is mirrored in Hawtrey's analysis of savings and investment. For Hawtrey, savings were directed into investment opportunities by securities dealers who acted like traders, holding stocks of securities financed by bank borrowing, intermediating between the savers and investors. In the early 1930s Hawtrey developed this analysis into a model where an imbalance between savings and investment results in an unanticipated change in physical stocks of goods as a result of changes in consumers’ incomes (and outlays).

Savings are the excess of consumers’ income over desired consumption and are represented by investment; an increase in money balances; or purchases of goods. Net investment is defined as the total of securities sold less those bought by securities dealers. Clearly the price of securities (and by implication the long-term rate of interest) will move to achieve an equilibrium between the net amount of investment and capital raised, but planned savings can exceed the resources seeking investment, in which case the excess must flow into additional money balances or additional consumption – or vice versa. In either case an expansion or contraction of demand is set in motion. Both Saulnier (1938) and Haberler (1939) note the similarity of this analysis with that of D.H. Robertson. This aspect of Hawtrey's theory is also reviewed by Davis (1981).

Hawtrey's disequilibrium analysis where unintended changes in stocks bring about an equality of actual savings and investment, but a further chain of adjustment if intended savings and investment are not equal, is remarkably close to the modern textbook presentation of the Keynesian equilibrium adjustment process. It is interesting therefore to briefly examine the discussions between Keynes and Hawtrey leading up to the General Theory. Indeed in Hawtrey's comments on the drafts of the Treatise he is often more 'Keynesian' than Keynes himself! (see Keynes, 1973, pp. 138–69). At this stage Keynes envisages:

1. (1) A decline in fixed investment relatively to saving.
2. (2) A fall of prices …
3. (3) A fall of output, as a result of the effect of falling prices and accumulating stocks on the minds of entrepreneurs (Letter to R.G. Hawtrey, 28 November 1930; Keynes, 1973, p. 143).

The fall in output leads to a disinvestment in working capital, and eventually to a situation where total investment and prices fall too far. Once output stops declining this leads to a slight rise in prices, and, given the low level of stocks at this point, so starts the upturn. Hawtrey, on the other hand, sees a direct effect on output from the contraction in demand at unchanged prices, and criticizes Keynes for only taking account of the reduction in prices relative to costs in his fundamental equations (Keynes, 1973, pp. 151–2). Hawtrey argues that ‘the change in prices when it does occur is not by itself an adequate measure of the departure from equilibrium’ (Keynes, 1973, p. 151). And later comments that: ‘A manufacturer restricts output, not because he believes that prices are about to fall, but because he cannot secure sufficient sales at the existing price’ (Letter from R.G. Hawtrey, 6 December 1930; Keynes,
Prices are reduced only gradually in an attempt to boost orders, but Hawtrey also points out that it is the level of retail prices which will determine the ultimate level of sales – and this will depend on how quickly retailers pass on the manufacturers’ reductions. Both Hawtrey and Keynes realize that the decline in output will rebound on savings, but do not appear to treat this as the main equilibrating factor (as in the later Keynesian theory).

V. The high point of Hawtrey's official career came with the Genoa International Financial Conference in 1922. The conference was concerned with the problems relating to a general return to the international gold standard after the First World War. In particular there was concern that the quantity of gold might be insufficient for a return to the system at the old pre-war parities, other concerns centred on problems relating to fluctuations in demand for monetary gold. The result was greater interest in a joint Sterling–gold standard along the lines of the gold exchange standard operated earlier by India and other countries. Hawtrey's main suggestions adopted by the Genoa conference related to greater cooperation between central banks to manage the demand for monetary gold and to regulate credit so as to stabilize the purchasing power of gold. However, the Genoa Resolutions were never acted on, largely as a result of US scepticism, and the failure of other central banks to participate in the planned follow-up conference (see Davis, 1981).

At the Treasury Hawtrey had argued that there were two primary considerations for monetary policy: the stabilization of internal prices and the stabilization of the foreign exchanges. Given the UK’s status as a financial centre he argued that exchange instability was particularly damaging and would make the covering of trade finance offered through London increasingly difficult. This predisposed him towards the gold standard as the de facto most practical means of achieving exchange stability.

Though Hawtrey was aware of possible deflationary problems associated with the return to gold, he appears to have believed that the exchange rate would return to par naturally, and that the necessary adjustments would come from American inflation rather than UK deflation (see the discussion in Moggridge, 1972, pp. 71–2, 91).

VI. Despite a long and active life, Hawtrey's main theoretical contributions to economics came largely in the interwar period. His first book, Good and Bad Trade, was published in 1913 and sets out a view of the trade cycle which received a more rigorous theoretical treatment in Currency and Credit (1919a), but which remained little changed thereafter, although the debates surrounding Keynes's Treatise prompted some refinements and revisions, as did the experience of the 1930s depression. The last major contemporary studies of his work were Saulnier (1938), which also reviewed the theories of D.H. Robertson, F.A. von Hayek and J.M. Keynes, and Haberler (1937; 1939). Interest in Hawtrey revived in the later 1970s following his death (for example, Davis, 1977; 1981; 1983; see also Deutscher, 1990). Particular attention has been given to Hawtrey's role in the development of multiplier analysis; see Dimand (1997).

In the 1920s innovative monetary theory in England was largely associated with the Cambridge School and in particular D.H. Robertson and Keynes. Hawtrey with his close Cambridge contacts contributed to this work, as the correspondence with Keynes now reprinted in the Collected Works shows. The three were often working along similar lines in this period and their work reflects (to varying degrees) an increasing failure of conventional theory to match the problems of the age.

How to cite this article

This article reviews the major intellectual contributions of the Austrian-born Nobel laureate Friedrich Hayek. Within economics, Hayek made contributions to many areas, among them monetary theory, trade cycle theory, and capital theory. His ‘knowledge-based’ critique of socialism and subsequent work on ‘the knowledge problem’ are widely viewed as seminal contributions to economics. Hayek also did substantial work in such fields as political theory, the methodology of the social sciences, psychology and intellectual history. Finally, his writings on spontaneous orders and his ‘theory of complex phenomena’ anticipated later developments in such areas as complexity theory and agent-based modelling.

Article

Born on 8 May 1899, the polymath economist and social theorist Friedrich August von Hayek had the good fortune to be repeatedly in the right place at the right time, crossing paths with some of the century's most brilliant economists and thinkers. He grew up in fin de siècle Vienna, a place and time of extraordinary intellectual vitality. Through his maternal grandfather, Franz von Juraschek, a professor of
civil law and civil servant, he gained an introduction to the academic world in Vienna, and through his father, August, a medical doctor and devoted botanist, a love of biology and the sciences as well as an acquaintance with another extended community of scholars. As a student at the University of Vienna his major professor was Friedrich von Wieser, and among his classmates were Oskar Morgenstern, Gottfried Haberler, and Fritz Machlup. After finishing his studies Hayek spent 15 months in the United States where, armed with letters of introduction from Joseph Schumpeter, he encountered most of the major American economists, both those contributing to the Marginalist School as well as the leading institutionalist and business cycle analyst Wesley Clair Mitchell. When he returned he joined the Miseskreis, Ludwig von Mises's study circle.

In the later 1920s he published an article in German that was read by Lionel Robbins, a newly appointed professor at the London School of Economics (LSE). This led to an invitation to present some lectures, and ultimately, in 1932, to Hayek being appointed to the Tooke Chair of Economic Science and Statistics. While at the LSE Hayek would engage in debates in the leading issues in economics with some of the discipline’s most important members: John Maynard Keynes and Piero Sraffa over monetary theory, Frank Knight and Nicholas Kaldor over capital theory, Oskar Lange and Evan Durbin over socialism. He was also instrumental in bringing the philosopher of science Karl Popper to the LSE. Hayek remained at the LSE until 1950, when he moved to the Committee on Social Thought at the University of Chicago. There he counted among his colleagues Milton Friedman, Aaron Director, and George Stigler. Retiring in 1962, Hayek had successive appointments at the University of Freiburg and the University of Salzburg, returning again to Freiburg in 1977. In 1974 he was awarded, with Gunnar Myrdal, the Bank of Sweden Nobel Prize in Economic Sciences, and in 1991 the Presidential Medal of Freedom. Hayek died in Freiburg on 23 March 1992.

If Hayek was in the right place at the right time, it was usually with the wrong ideas, at least from the perspective of most of his contemporaries. He was a sharp critic of Keynes well before the onset of the Keynesian Revolution. Though he helped introduce English-speaking economists to general equilibrium theory, he claimed that a preoccupation with static equilibrium analysis would mislead economists about the true nature of a dynamic market process. He attacked socialism when most members of the intelligentsia viewed it as a preferred middle way between an apparently failed capitalist system and totalitarianisms of the communist and fascist varieties; for Hayek such thinking was ‘the muddle of the middle’. When most Western democracies were embracing some form of the welfare state, he criticized the concept of social justice that provided its philosophical foundations. While most of the social sciences were moving towards more and more specialized studies, his work was increasingly integrative and multidisciplinary. The views Hayek embraced over most of his career were almost systematically out of step.

From the perspective of the early 21st century, history would judge Hayek's legacy more kindly than did many of his contemporaries. He lived to witness the collapse of the Soviet bloc, which many took as vindication of his and Ludwig von Mises's early critique of central planning. His view that a competitive market system with freely adjusting prices is an essential mechanism for coordinating social action in a world of dispersed knowledge is taken by economists as a fundamental insight. His insistence that markets be embedded in a host of other social and political institutions for their proper functioning provides a jumping off point for such diverse movements within economics as experimental investigations of market institutions, public choice and constitutional analysis, and the new institutional economics. Philosophers of mind, evolutionary biologists, and neuroscientists have been attracted to his
‘connectionist’ approach for understanding the development and functioning of the brain. His theory of complex phenomena and work on spontaneous orders has clear analogues in complexity theory and agent-based computational modelling (Caldwell, 2004, ch. 14). If Hayek remains a controversial figure in some quarters, even his critics acknowledge the breadth and depth of his contributions. One pundit, writing in the New Yorker in 2000, even went so far as to call the 20th century ‘the Hayek century’ (Cassidy, 2000, p. 45). Considering that this was only about two decades after the British Labour politician Michael Foot had referred to him as a ‘mad professor’, the reputational turnabout has been substantial.

Early work

Hayek's first trip to the United States took place in 1923–24. While there he studied new work on monetary policy and the control of the business cycle; he also witnessed the policy experiments being undertaken under the auspices of the then only recently established Federal Reserve System. Hayek subsequently wrote a paper on US monetary policy in which he criticized the goal of stabilizing the general price level (Hayek, 1926). According to the Austrian theory of the cycle, relative price movements play an essential role in the unfolding of the cycle, so that any policy prescription that focused solely on aggregates was judged deficient for ignoring such movements. Hayek spelled out the Austrian approach in more detail in his first book, published in 1929, an English translation of which appeared in 1933 as Monetary Theory and the Trade Cycle. There he argued for a monetary approach to the origins of the cycle. Hayek claimed, first, and contra both the American institutionalists and German historical economists, that any adequate explanation of the cycle must be theoretical, and, further, that it must be consistent with, and presuppose the validity of, the standard equilibrium theory of the day. This poses a problem, however, for if one accepts the results of standard equilibrium theory, where prices adjust to clear markets, a question immediately arises: how can a disproportionality between the production of capital goods and consumer goods that occurs during the boom phase of the cycle occur? For Hayek, money provided the answer. Though the use of money confers substantial benefits, most evidently to facilitate trade, and thereby to encourage specialization and growth, it is also a ‘loose joint’ in the system of exchange: ‘Money being a commodity which, unlike all others, is incapable of finally satisfying demand, its introduction does away with the rigid interdependence and self-sufficiency of the ‘closed’ system of equilibrium’ (Hayek, 1933, p. 44).

Another significant piece in this period was Hayek's paper 'Intertemporal Price Equilibrium and Movements in the Value of Money' (Hayek, 1928), which is widely acknowledged as an early important contribution to the theory of intertemporal equilibrium.

Hayek comes to the LSE

Hayek's lectures in early 1931 at the LSE were published as Prices and Production, a book in which he completed the task begun in Monetary Theory and the Trade Cycle by tracing out the effects of monetary disturbances on the economy. Using a framework developed by Knut Wicksell (1906) and further adapted by Ludwig von Mises (1924), Hayek posited a natural rate of interest that, in the absence of monetary factors, would just equalize the demand for capital and the supply of savings.
When households save, they forgo present for future consumption. The funds are borrowed by firms for investment in more ‘roundabout’ methods of production which allow firms to produce more goods in the future, thereby satisfying the desires of consumers. The natural rate of interest, then, is a relative price that coordinates a community's preferences regarding present and future consumption with the production processes that create the goods.

However, in the crisis stage of the cycle, an excess of capital goods (relative to consumers’ preferences) are created. This occurs because of a divergence between the natural and the market rate of interest, caused by bank lending activity. Specifically, a lowering of the market rate of interest below the natural rate leads firms to move to more roundabout methods of production, just as they would have done had there been a reduction in the natural rate. However, in this case, because there has been no change in consumers’ preferences, the lengthening of production processes is not sustainable. At some point before the completion of the transition, prices for consumer goods begin to rise, which signals to firms that they have made errors. As they begin to abandon the more roundabout methods, a cyclical downturn is initiated.

Hayek's theory carried the unfortunate policy implication that there was little that policymakers could do once an economy was in a recession. Recessions were avoidable only if one could make money ‘neutral’ by keeping the natural rate equal to the market rate of interest. Unfortunately, no one knows what the natural rate is; only the market rate is observable. The downturn, painful as it is, is actually the system returning to equilibrium, correcting for past errors. As such, policies that attempt to address a recession by injecting money only further encourage firms to persist in their mistaken behaviours, making the ultimate downturn even more severe.

Hayek's book had a tumultuous reception. In late 1930 John Maynard Keynes published his own analysis of the problems of a monetary economy, *A Treatise on Money* (Keynes, 1930), in which he also used the Wicksellian framework. Hayek's critical review of Keynes's book drew a heated response from Keynes, who also took Hayek's *Prices and Production* to task, noting famously that ‘It is an extraordinary example of how, starting with a mistake, a remorseless logician can end up in bedlam’ (Keynes, 1931, p. 154). For a while, as John Hicks later recounted, the burning question of the day for economists was, ‘Which was right, Keynes or Hayek?’ (Hicks, 1967, p. 203).

Others entered the fray, and the weight of the combined criticisms ultimately led both Keynes and Hayek to revise their theories. Keynes finished first, publishing *The General Theory of Employment, Interest and Money* in 1936. Hayek's initial plan was to construct a dynamic theory of a capital-using monetary economy. He worked on the book in starts and stops for the rest of the decade, finally publishing it as *The Pure Theory of Capital* in 1941. There Hayek abandoned the simplifying Böhm-Bawerkian notion of an ‘average period of production’, and in its place systematically explored a variety of possible relations between inputs (both those available at a given point in time and over a continuous period) and outputs (whose availability might likewise vary over time). He examined the effects of substitutability and complementarity, of the introduction of new ‘inventions’, both in cases in which they are foreseen and when they are not, and of whether decisions are made by a single individual or within a competitive system. A key theme of the book is that the capital structure is constantly evolving as the market continually provides new information. In that evolution, capital is rarely either so malleable as to be instantaneously transformable, or so permanent as to be incapable of being applied in a different production process.

Hayek's book made important advances in capital theory, but he never was able to accomplish his larger
goal. After seven years of labour he could only provide in the closing three chapters of the book a sketch of how to integrate his capital theory into a monetary framework. As he later once put it, once you get beyond Böhm-Bawerk's simplifying assumption of an average period of production, 'things become so damn complicated it's almost impossible to follow it' (Hayek, 1994, p. 141). Meanwhile Keynes's victory in the area of macroeconomics quickly became complete.

Socialist calculation and the knowledge problem

In the 1920s, the British economy went through wrenching structural adjustments, and with the depression of the 1930s many among the intelligentsia came to view socialist planning as the only acceptable alternative system. Economists, some of them colleagues of Hayek's at the LSE, began issuing proposals for how to organize such a system. In 1935, Hayek entered the discussion with the publication of Collectivist Economic Planning, a collection of translations of essays from an earlier debate that had been initiated by Ludwig von Mises. Hayek included his mentor's essay, in which Mises argued that rational planning was 'impossible' under socialism. His point was that a monetary economy with freely adjusting market prices reveals relative scarcities among factors of production. When the means of production are state-owned, there are no prices for factors of production, and hence no signals to help socialist managers allocate resources rationally (Mises, 1920).

Some socialists (for example, Dickinson, 1933) responded by invoking Paretian general equilibrium theory, which they argued disproved Mises's thesis. They noted that any economic system could be represented by a system of equations, so that the only difference between a planned and a free market system lay in who was responsible for 'solving' the equations, socialist managers or private entrepreneurs. If some of the prices that the socialist managers chose were wrong, gluts or shortages would appear, signalling them to adjust the prices up or down, just as in a free market. Through such a trial and error procedure, a socialist economy could mimic the efficiency of a competitive free market system, while avoiding its many problems: wasteful competition, the market failures that attend monopoly and externalities, and an unjust income distribution (Lange, 1938).

Hayek challenged this vision in a series of contributions (Hayek, 1937; 1945; 1968) to what has since come to be called 'the knowledge problem'. In 'Economics and Knowledge' (1937) he pointed out that the standard equilibrium theory of his day assumed that all agents have full and correct information. In the real world, however, different individuals have different bits of knowledge, and furthermore, some of what they believe is wrong. In that world, the key question is how it comes about that the actions of individuals ever get coordinated, a question that equilibrium analysis with its full information assumption brushes aside.

Hayek posited the market as a key coordinating institution. He described the market process as operating in a world of constant change, in which freely adjusting prices are formed as the result of decisions, typically forward-looking, of literally millions of market participants. Their decisions are based in part on the vast array of prices that they confront in the market, prices that give them information about relative scarcities. But in addition, agents act on the basis of localized knowledge, knowledge of particular circumstances of time and place, some of which is tacit – that is, they cannot say why they are acting on it. Their market activity also reflects this localized knowledge, and by acting their knowledge becomes embedded in the array of market prices. In short, market activity is both price-determined (prices shape what people do) and price-determining (what people do, based on local knowledge,
determines what prices are). Market prices coordinate the specific knowledge of time and place possessed by millions of market agents. Socialist schemes that involve price fixing, as many of the proposals did, would keep the communication system from working. Hayek also doubted that trial and error price adjustment methods could ever mimic the speed of adjustment produced by markets, where errors to be corrected are simultaneously profit opportunities for alert entrepreneurs. Finally, Hayek criticized the profession's focus on standard equilibrium analysis which, by concentrating on equilibrium states, obscures the competitive process by which knowledge about relative scarcities becomes known: that theory ‘starts from the assumption of a “given” supply of scarce goods. But which goods are scarce goods, or which things are goods, and how scarce or valuable they are – these are precisely the things that competition has to discover’ (Hayek, 1968, p. 181). In short, market competition provides a discovery procedure. Hayek developed these ideas in a series of papers, the most famous of which, ‘The Use of Knowledge in Society’, is still widely cited by traditional general equilibrium theorists as well as economists working in the economics of information (Hayek, 1945).

The abuse of reason project and the road to serfdom

Though Hayek felt he had launched a telling attack against socialism, few in the late 1930s were persuaded by his economic reasoning. Hayek began to realize that the attractiveness of socialism went far beyond economics. Socialists promised a society that was not only more efficient than capitalism, but also one that was more just, where individuals have more self-determination and greater political freedom, and in which scientific reasoning would be used to improve upon a host of outdated social institutions. If he were successfully to challenge these utopian visions, economic arguments were not enough. He would need to develop political, historical and ethical arguments against them as well. During the Second World War Hayek began doing just that, in a massive piece of work that he called the ‘Abuse of Reason’ project. His overarching goal was to show how a number of then-popular doctrines and beliefs, doctrines with which he disagreed, had a common origin in some fundamental misconceptions about the proper methods for studying social phenomena. Central to his argument was the critique of scientism, which he defined as the ‘slavish imitation’ of the methods of the natural sciences in the study of social phenomena (Hayek, 1942–44, p. 24). He criticized the objectivism, historicism and collectivism of the ‘scientistic prejudice’, and contrasted these with his own preferred approach, one that was subjectivist, theoretical, and individualist. In the essay ‘Scientism and the Study of Society’ (Hayek, 1942–44) he also articulated a fundamental thesis about the limitations of our knowledge in the social sciences: that rather than make precise predictions often the best we can do is to make a pattern prediction, or alternatively to provide an explanation of the principle by which some social phenomenon came into being.

Hayek never completed the Abuse of Reason project, although sections of it were published separately during and after the war. One of these became his most famous book, The Road to Serfdom. As noted above, many advocates of socialism had promised that socialism would bring greater political freedom. In The Road to Serfdom Hayek countered that planning of the economy would soon lead to increasing political control as well. One of the virtues of a market economy is that it allows people with very different tastes to express them, and (for those with the means) to get them satisfied, through the market. In a planned economy, socialist managers must decide which goods, and in what quantities, get produced. Invariably some people will not like the decisions they make, and will protest. A change in
the mix will cause others to protest. If any progress is to be made, even democratically elected socialist regimes will at some point be forced simply to make the decisions for the people. This is much easier to do if political dissension is suppressed. Hayek’s claim was that, to run a fully socialized planned economy successfully, its socialist managers ultimately must secure control of the political process as well.

Hayek's book was only one of many at the time to address the issues of planning versus markets and other issues related to the shape of the post-war economic and political order. Its fame, and in some quarters notoriety, was due to its being condensed in the pages of Reader's Digest in April 1945, appearing just as the war in Europe was coming to an end. Reader's Digest then had a circulation of almost nine million, and in addition, a Book of the Month Club reprint was made available that added another million readers. As a result, Hayek's little book, and the even smaller condensed version, gained widespread attention and iconic status among both its supporters and critics.

Besides fame, the publication of the book brought with it other unintended consequences. On a publicity trip to the United States, Hayek made a number of contacts, people who shared his views regarding the merits of a liberal democratic market order. In 1947 he organized the first meeting of the Mont Pèlerin Society, which brought together like-minded people from America and Europe to discuss and debate questions concerning the appropriate economic, political, legal and social institutional framework for a free society. Participants included Milton Friedman, Aaron Director and George Stigler, who would over the course of the next decade form the Chicago School of economics.

**The sensory order**

From 1945 until he joined the faculty at Chicago, Hayek took on yet another wholly different subject, theoretical psychology. Building on a student paper he had completed in 1920, he titled the resulting book *The Sensory Order* (Hayek, 1952a).

This book is probably best viewed as an outgrowth of his earlier attack on scientism. Two ‘objectivist’ doctrines that he criticized in the ‘scientism’ essay were physicalism, a view espoused by the logical positivist philosopher Otto Neurath, and behaviourist psychology. The doctrines were related: physicalism insists that all truly scientific statements make reference only to observables, and behaviourist psychology likewise insists that scientific psychology should eschew all reference to mental states and deal only with observable behaviour. By eliminating all reference to subjective states and interpretations, the objectivity of science is guaranteed.

Hayek posited two orders, the sensory order that we experience, and the underlying natural order that natural science has revealed: atoms, molecules, electromagnetic waves and the like. The question arises: why are these two orders different? Hayek's answer was that the sensory order is in fact a product of our brain. He characterized the brain as a highly complex but self-ordering, hierarchical classification system, a huge network of connections. A given stimulus triggers an extensive set of neuronal firings that gives rise to our experience of a sensation. The richness of our sensory experience is due to the sheer vastness and hierarchical nature of the classifier system. As he once noted, ‘During a few minutes of intense cortical activity the number of interneuronic connections actually made (counting also those that are actuated more than once in different associational patterns) may well be as great as the total number of atoms in the solar system (that is, 10^56)’ (Hayek, 1964, p. 25).

If Hayek's description was right it posed problems for behaviourists, who did not even recognize the
existence of the two orders, taking the sensory order as fundamental. Furthermore, the supposedly uninterpreted sensory experience so vital to the behaviouralist was itself simply a product of our minds; it was itself an interpretation. Hayek's book went virtually unnoticed when published, but subsequent neuroscientific research broadly supports his principal claims.

**Political theory**

J.M. Keynes read Hayek's *The Road to Serfdom* on a boat going to the Bretton Woods conference, later writing to Hayek that ‘morally and philosophically I find myself in agreement with virtually the whole of it; and not only in agreement with it, but in a deeply moved agreement’ (Keynes, 1944, p. 385). Keynes went on to say, though, that

> You admit here and there that it is a question of knowing where to draw the line. You agree that the line has to be drawn somewhere, and that the logical extreme is not possible. But you give us no guidance whatever as to where to draw it. (1944, p. 386)

Hayek evidently took the criticism to heart, for in the coming years he would make two further important contributions to political philosophy that would refine and extend the arguments made in *The Road to Serfdom*.

In *The Constitution of Liberty* Hayek defined liberty as a condition ‘in which coercion of some by others is reduced as much as possible in society’ (Hayek, 1960, p. 11). This poses a dilemma, because the best way to avoid coercion is to set up a coercive power that is strong enough to suppress it. Liberal constitutionalism attempts to solve the problem by defining a private sphere of acceptable individual activity, granting the state a monopoly on coercive powers, then constitutionally limiting the power of the state to those instances where it is required to prevent coercion. The state's coercive actions are limited by the rule of law: its laws made in protection of the private sphere must be prospective, known, certain, and equally enforced (Hayek, 1960, pp. 205–10). He contrasted these with laws that seek particular outcomes within the private sphere, for example, price-fixing to help certain groups, or social legislation whose intent is to create or preserve a particular pattern of redistribution. Hayek linked his discussion with his perennial concern for problems caused by dispersed knowledge by noting how liberty enables individuals to make the best use of local knowledge:

> The rationale of securing to each individual a known range within which he can decide on his actions is to enable him to make the fullest use of his knowledge, especially of his concrete and often unique knowledge of the particular circumstances of time and place. The law tells him what facts he may count on and thereby extends the range within which he can predict the consequences of his action. (Hayek, 1960, pp. 156–7)

In the last third of the book Hayek outlined the specific sorts of government policies that are consistent with constitutional liberalism. Soon after completing this book he felt the need to readdress some of the same questions, ultimately producing the trilogy *Law, Legislation and Liberty* (1973–79). There Hayek lamented how Western
democracies were increasingly circumventing the constitutional constraints outlined in his earlier book. Because the ideals of constitutionalism had failed to take root, the rule of law was weakening. Governments were increasingly passing coercive legislation, typically under the guise of achieving social justice, that in reality typically served well-organized coalitions of special interests. Coercive legislation was gradually replacing the rule of law.

Hayek began by contrasting spontaneous, self-generating orders (what the Greeks called a *kosmos*) with organizations that are constructed, created orders (what the Greeks referred to as a *taxis*). Agents in organizations aim at accomplishing specific goals, and do so by following explicit commands. Grown orders tend to be much more complex. They do not aim at specifiable outcomes, and agents interact in them by following abstract rules. Hayek applied these ideas to the development of the law, or *nomos*, in which rules of just conduct eventually become codified into law. He contrasted this common law heritage with legislation, the rules for organizing government, also known as *thesis*. Under the influence of various rationalist constructivist doctrines (Hayek identifies utilitarianism and legal positivism as particularly noxious), legislation to achieve particular ends began to replace the grown law, which itself does not aim at specific outcomes but instead provides a stable ordered environment in which individuals are able to employ their knowledge to make decisions.

In developing these contrasts, Hayek argued that though the concept of justice provides the foundation for notions of just conduct and ultimately of the law itself, the idea of *social justice* only has meaning within the context of a *taxis*. Only human conduct by individuals or organizations, not states of affairs or outcomes, can be called just or unjust. One must be able to hold someone responsible to apply the term. Rationalist constructivists make a fundamental error, a category mistake, to argue that it can also be applied to the outcomes of a spontaneous process, which has no specific purpose other than to allow millions of agents to pursue their own purposes. Hayek ended his trilogy with the pessimistic view that majoritarian democratic governments operating under the errors of constructivism and the guise of achieving greater social justice were increasingly replacing grown law with legislation, most of which served powerful special interests, with dire consequences for the persistence of the grown order. In the final chapter he proposed a unique political reform that aimed at increasing the independence of legislators from the influence of special interests, thereby strengthening the ideal of liberal constitutionalism. Interestingly, about the same time Hayek (1978a) also proposed an equally provocative scheme for the competing currencies that he dubbed the denationalization of money.

His final major contribution was *The Fatal Conceit* (Hayek, 1988), the conceit being socialism – for Hayek the ultimate form of rationalist constructivism. The book had its origins in the late 1970s, when he tried to arrange a debate between socialists and advocates of markets on the merits of their respective systems. Though the debate never came off, the project led him to begin work on a final wide-ranging critique of socialism and constructivism. Hayek worked on the book during the early 1980s, but when his health began to fail in 1985 the philosopher W.W. Bartley III (who was also the general editor of *The Collected Works of F.A. Hayek*) stepped in to assist him. Questions have been raised about how much of the book should be attributed to Bartley and how much to Hayek, but one fundamental Hayekian claim is that the moral rules, norms, ethical precepts and practices that have led to the development of the extended market order have emerged through a process of cultural evolution. Many of these rules go against the ‘natural morality’ that allowed earlier humans to function successfully in small hunter-gather groups. Furthermore, because they were seldom consciously adopted and their effects are often difficult to identify, they tend to chafe against human reason, as well. Many of our moral beliefs, then, lie
between, and fit uneasily with, both our instinct and our reason. This is why humans instinctively rebel against the market order, and seek to use their reason to construct an alternative. A theme that runs throughout Hayek's work is an emphasis on the limits of our reason, and the role of rule-following in allowing us to deal successfully in a world in which knowledge is dispersed. In field after field Hayek identified spontaneous complex orders that form as the result of agents following rules. The price system represents one such an order, and, as his work on capital theory showed, if one extends the system in time it can also serve as a mechanism for the intertemporal coordination of human action. The brain is another example of a self-organizing complex order: vast networks of neuronal firings give rise to the larger phenomenon of consciousness. Within political theory, the common law tradition (as opposed to legislation) and the requirement that we follow the rule of law and obey constitutional rules are yet another manifestation of our discovering procedures that allow us to deal more successfully with the limits of our reason. It is unfortunate that Hayek remains in some quarters a controversial figure, but it is also probably inevitable, given that so many of his key insights were formed within a context of intense political debate, and that it is difficult to separate them from that context. Even so, one hopes that his contributions on knowledge and its limits, on the role of grown institutions in helping us to overcome our ignorance, and on the workings of hierarchical networks and spontaneous self-organizing complex orders, will continue to stimulate future research.

hazardous waste, economics of

Hilary Sigman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Public policies for hazardous waste address both current waste management and the clean-up of a legacy of contamination. Policies for current waste management should provide incentives for waste generators that are sensitive to the varying hazards posed by waste. Although conventional regulations have difficulty accomplishing this variation, alternative incentive-based policies show promise empirically. Policies for clean-up of contamination often fail to strike an appropriate balance between hazards posed by the contamination and costs of clean-up. In addition, relying on legal liability to fund these clean-ups has consequences for the costs of clean-up and possibly for the redevelopment of contaminated land.

Article

Hazardous waste has become a major focus of environmental regulation. In the United States, spending on hazardous waste rose from only about two per cent of the compliance cost of all federal environmental regulations in 1985 to a projected 17 per cent in 2000 (U.S. EPA, 1990); its share of environmental expenses in Europe may have been comparable in 2000 (European Commission, 2000). The costs arise from the management of waste from current activities and from the clean-up of a legacy of contamination. This article addresses, first, current hazardous waste management and, second, clean-up of past contamination.

Hazardous waste management
A wide range of industrial processes create hazardous wastes; they are also generated by commercial activities (for example, used oil and batteries from automobile repair shops) and by households (for example, used electronics). Once generated, wastes are managed in one of three ways: disposal, which usually involves placing wastes in landfills or injecting liquid wastes into underground wells; treatment (for example, incineration or stabilization), which renders the wastes less hazardous, but rarely eliminates the need to dispose some hazardous residuals; and recycling or reuse. Most hazardous waste is managed on-site by the small number of plants that generate vast quantities of waste; however, most generators create smaller quantities and use off-site commercial waste management.

The risk posed by a waste depends not only on the nature of the hazardous chemicals but also on their concentration and mobility and on the way the waste is managed. Waste generators control these variables through their output decisions, production processes, and handling of wastes, so the challenge for public policy is to create optimal incentives in all these dimensions. An efficient policy would correct many different environmental externalities, such as air pollution from incineration and groundwater and surface water contamination from land disposal. Such a policy might use taxes on environmental releases or, where feasible, impose legal liability for harms. With a competitive waste management market, these policies would not only affect waste management but also send the correct signals to waste generators to choose how much and which sorts of waste to generate.

Actual public policy for hazardous waste in developed countries tends to regulate waste management, with relatively few direct rules about the quantities or nature of wastes generated. Regulations use a traditional command-and-control approach, often requiring specific technologies (for example, specifying the thickness of liners required for hazardous waste landfills). These approaches do not provide much flexibility in tailoring the management methods to the characteristics and risks of the waste in question. For example, the United States requires that wastes be treated (often incinerated) before land disposal. These ‘land disposal restrictions’ probably account for most of the cost of hazardous waste regulations, yet economic assessments by the U.S. Environmental Protection Agency (EPA) strongly suggest that their costs greatly exceed their benefits (Sigman, 2000). The land-disposal restrictions founder on their absolute nature; although the restrictions would pass a cost–benefit test for some wastes, they also apply to many wastes that are not easily treated or pose low hazards.

Some jurisdictions also impose taxes on hazardous waste. Sometimes called ‘waste-end’ taxes, these taxes vary with the quantity of waste and may depend on how waste is managed. Sigman (1996) reports empirical evidence that generators respond to waste-end taxes by reducing waste and altering their management methods. Levinson (1999) shows that the waste-end taxes levied by the United States have altered the geography of waste management. Although this evidence demonstrates the potential of incentive-based environmental policies to motivate private decisions, current taxes in the United States do not seem efficient. Indeed, Levinson (2003) argues that states practise destructive competition, specifically an inefficient ‘race to the top’, through these taxes.

Enforcement of both command-and-control waste regulation and waste-end taxes is difficult. Unlike air and water pollutants, hazardous waste is easily transported away from its source, giving rise to the possibility of illegal disposal (known as ‘midnight dumping’ in the United States and ‘fly tipping’ in the UK). Sigman (1998a) finds that rules requiring recycling or reuse of waste raise the frequency of illegal dumping. If the elasticity of illegal disposal to legal waste management costs is high enough, public policies may be counterproductive because the environmental harm from illegal disposal can be much
greater than that from legal disposal. A response to this enforcement problem is to use a deposit-refund or similar tax–subsidy combination (Fullerton and Kinnaman, 1995). The policy would tax inputs or products that give rise to waste and give a refund for legal waste management that may vary with the external costs of the waste management method. For example, it might refund a modest portion of the initial tax for land disposal and a larger share for incineration. Such a system could mimic waste-end taxes without the incentives for illegal disposal. The effective tax for illegal disposal is the forfeit of the deposit; for all other activities, the effective tax is the difference between the deposit and appropriate refund. Deposit-refunds (with the refund equal to the deposit) are common internationally for products such as used batteries, electronics, and lubricating oil (OECD/EEA, 2006).

The location of facilities that manage waste also raises issues. Local communities often reject these facilities because of their perceived hazards. Economists have sought to design policies that create optimal incentives in siting facilities through compensation for host communities (for example, Minehart and Neeman, 2002). In assessing ‘environmental equity’, numerous studies examine whether poor people and members of minority groups disproportionately live near hazardous waste facilities, with mixed conclusions for developed countries (Hamilton, 2005). Concern about the incidence of waste management costs may also be behind the Basel Convention of 1989, which restricts international shipment of hazardous wastes between developed and developing countries.

Clean-up of contaminated sites

Land disposal of hazardous wastes and other activities, such as storage of toxic substances for industrial processes, have created a legacy of contaminated sites that may cause damage and require clean-up. The U.S. federal policy for clean-up of abandoned contaminated sites is the Comprehensive Emergency Response Compensation and Liability Act (CERCLA), commonly known as Superfund. Superfund clean-up is mostly funded by legal liability imposed on the generators and transporters of waste and past and present owners of contaminated land. Liable parties must either undertake clean-up themselves or reimburse the government for clean-up by paying into a dedicated trust fund, which also received some tax financing in earlier years. European countries have similar programmes; a 2004 EU Environmental Liability Directive imposed additional requirements.

The appropriate level of clean-up (or ‘how clean is clean?’) has been the subject of a long-running debate. In the early years, public policies called for sites to be rendered completely clean; however, as costs have grown, greater (or at least more explicit) balancing of benefits and costs has become common. Still, decisions often fall well short of the economist’s ideal. For example, the Superfund programme sets goals that reflect biases in risk perception and political objectives as well as costs and risks to the exposed population (Hamilton and Viscusi, 1999).

Quantifying the benefits of clean-up can be difficult. A substantial literature uses hedonic property value methods to evaluate the welfare effects of proximity to contaminated sites and finds large effects. In a literature survey by the U.S. EPA (2005), the studies on average find that house prices are seven per cent (or more) lower near contaminated sites. Studies also find that discovery of a site lowers local house prices. Although these results suggest that households perceive harm from contaminated sites, the much smaller literature that looks at whether clean-ups improve prices finds disappointing results; for
example, Greenstone and Gallagher (2005) conclude that Superfund clean-up had minimal effect on house prices.

Another debate concerns the desirability of funding clean-up through legal liability. This funding source has advantages and disadvantages relative to use of general government revenues or a dedicated tax. Liability may create desirable incentives for current waste management, reducing the need for *ex ante* regulation of land disposal, such as the command-and-control regulation discussed above. However, unless the required clean-up spending is optimal, these incentives may not be efficient. In addition, much liability is retroactive (applying to contamination from before the clean-up law) and thus does not directly affect active waste management.

Liability also helps privatize clean-ups because liable parties may dispatch their responsibility by undertaking government-approved clean-ups. Relative to the government, private parties may have stronger incentives to control costs, better knowledge of the contamination, and greater ability to limit disruption to current economic activity at the site. However, in an effort to lower their costs, private parties may drag their feet and use political and other means to make the government choose less extensive clean-up remedies (Sigman, 1998b; 2001).

Many policymakers fear that environmental liability deters redevelopment of ‘brownfields’, sites with potential contamination from their past use. Brownfields are a concern because they are a source of urban blight and because firms may develop relatively pristine land as a substitute for old industrial land. A buyer of a contaminated site may find itself partially or fully liable for clean-up costs; in the United States, CERCLA lists current landowners as among the potentially responsible parties. The government may choose to pursue a new owner, for example, if it has deeper pockets than the previous owner or is a private rather than a public entity. However, it is unclear that such liability deters redevelopment because it may be capitalized into land prices, as empirical research suggests (McGrath, 2002).

A number of distortions may make price adjustments insufficient to restore efficient incentives for redevelopment of brownfields. Segerson (1993) argues that a distortion can arise when sellers are judgment-proof (sheltered from liability by the option of declaring bankruptcy), so a sale may increase collective private clean-up costs by exposing a buyer’s deeper pockets to the government. Other studies point to adverse selection, imperfect enforcement of liability, and the effects of joint and several liability as sources of a disincentive for redevelopment of brownfields (Boyd, Harrington and Macauley, 1996; Chang and Sigman, 2005). Empirical research does suggest higher vacancy rates for urban industrial land where expected liability is higher (Sigman, 2006). Numerous public policies address brownfields, for example, by providing liability protections and direct subsidies to new owners of land.

Finally, liability incurs substantial legal costs, as the government sues liable parties and liable parties sue each other and their insurance carriers. Based on surveys of liable parties, Dixon (1995) estimates that as much as 30 per cent of private spending on Superfund will be transaction costs. However, these costs may be similar to the transaction costs of tort liability generally and the excess burden of the taxes that might replace liability as a funding source.

The specific form of environmental liability has also been controversial. In the European Union (EU), a debate on strict liability preceded the adoption of the 2004 Environmental Liability Directive. Under strict liability, parties are liable for any harm whereas under an ‘at fault’ or negligence rule parties are liable only when they fail to exercise appropriate care. The EU settled on a mixed regime in which certain hazardous activities are subject to strict liability. An extensive literature in law and economics...
Hazardous waste, economics of: The New Palgrave Dictionary of Economics compares these liability regimes. For hazardous waste, empirical studies have suggested that strict liability reduces accidental toxic spills and violations of hazardous waste laws (Alberini and Austin, 2002; Stafford, 2003).

Rules for apportioning liability with multiple defendants have been even more controversial. In the United States, courts have interpreted Superfund to impose ‘joint and several’ liability, meaning that the government may sue any liable party for the entire cost of clean-up at the site, regardless of that party’s contribution to the contamination; the party initially held liable may then recover cost shares from other defendants. Most European countries also rely on joint and several environmental liability, but some have begun restricting its use. Joint and several liability strengthens the government's hand and increases its ability to collect ‘orphan shares’, the share of costs attributable to parties that are bankrupt or substantially judgment-proof. It also affects incentives for parties to settle rather than litigate, which may be favourable depending on empirical conditions (Kornhauser and Revesz, 1994; Chang and Sigman, 2000), and incentives for ex ante precaution in managing hazardous substances (Tietenberg, 1989). Although some of its effects may be desirable, joint and several liability is often decried as unfair.

**How to cite this article**

Health care expenditures form an ever-increasing burden in most developed countries, especially the United States, where they accounted for 16.0 per cent of GDP in 2004, up from 5.1 per cent of GDP in 1960. These cost increases alone suggest that health economics is a dynamic field of economic research, but the importance and the interest of the field are driven by broader considerations. This article delineates important market failures and research issues in health and health care, the relationship between income and health, methodological issues in the measurement of health, and quality issues in the measurement of health care.

Article

Health care expenditures form an ever-increasing burden in most developed countries. Between 1960 and 2002, expenditures as a percentage of GDP rose from 3.8 to 9.7 per cent in France, from 5.4 to 9.6 per cent in Canada, and from 4.9 to 11.2 per cent in Switzerland. (Cross-country comparisons are hindered to some extent by the differential inclusion of components of health care and social services in different countries.) In the United States, health care expenditures are far greater; they accounted for 16.0 per cent of GDP in 2004 (a per capita expenditure of $6,280), up from 5.1 per cent of GDP in 1960. By themselves these increases, projected to rise to 20 per cent or more of GDP by 2015, suggest that
health economics is a dynamic field of economic research, but the importance of the field is driven by far more than the costs of care.

In many ways, health economics mimics the broader field of classical economics in its areas of research specialization – there are theoretical studies, micro and macro studies, industrial organization studies, public economic studies, and labour studies, among others. But health economics has a unique quality, identified in one of the earliest papers in the field, by Kenneth Arrow (1963). That is the large role played by *market failures*, which make it likely that resources will be allocated inefficiently if market outcomes alone prevail.

**Market failures**

Market failures take several forms.

**Failures related to information**

Individuals tend to be poor judges of the care they need and the quality of care they obtain. This ignorance works both *ex ante* and *ex post*. Consumers do not know whether they might benefit from medical care. They tend to lack information about the appropriate type, amount, quality, and price of care. They also lack information about the counterfactual. would alternative care, or even no care at all, be equally or more or less beneficial and cost-effective? The rapid introduction of new technology and the need to make decisions under stress tend to result in ineffective information searches.

**Failures related to the role of supplier agents**

Providers acting for the patient are rarely perfect agents. they do not fully understand individual patient preferences, their own earnings are influenced by their advice (conflict of interest), and their training tends to impel them to do all that is technologically possible (that is, provide care until expected marginal benefits equal zero). The usual remedy for this kind of failure is public sector interventions in the health care market. These include licensing of providers to assure a minimum level of competence; licensing of facilities and new technologies (including pharmaceuticals) to assure quality; reimbursement schemes to minimize conflicts of interest; subsidies for certain types of care (for example, those with external benefits, such as vaccinations); and subsidies for the purchase of insurance.

**Failures related to uncertainty**

The combination of uncertain need for care and the high expense associated with a major health problem leads naturally to a demand for pooling risk and insurance. But, as in most types of insurance, willingness to pay for coverage based on individual assessments of one's own (differing) risks may lead to adverse selection (see below) and incomplete coverage. For those insured, the reduction in the price of care may lead to increased demand for care, less attention to the price of care, and less attention to avoiding the need for care (‘moral hazard’), making it very difficult to estimate optimal amounts of care. Insured individuals may demand care beyond the point where the marginal expected benefit is equal to
the true cost of the resource, or substitute care for other health-preserving options such as exercise or diet. When insurance is combined with reimbursement schemes that pay providers for each service (‘fee for service’), the likely result is demand and provision of care in excess of expected benefits. (The idea of providers recommending care to the patient, knowing that the expected benefit to the patient is less than the cost, has been termed ‘physician-induced demand’. Though numerous articles have been written on the topic, proof of such behaviour remains elusive.) But reimbursement schemes that pay providers a fixed or capitated amount for all services may lead to too little care, based on a comparison of marginal cost to marginal benefits. Much recent work has focused on designing reimbursement schemes that mitigate overuse or underuse.

The demand for health

Michael Grossman (1972) was the first to emphasize that the outcome of interest in health economics is health, not medical care. The demand for medical care, in other words, is derived from the demand for good health. Grossman's model and all the work that derives from it are essentially extensions of the household production literature. In brief, Grossman argues that health capital is a form of human capital which changes over time because of depreciation and investment. His model begins with a utility function where health is an argument in addition to utility gained from the consumption of goods and services. Health investments include time (exercise and sleep) and medical care, subject to health endowments such as genetic traits or environmental factors that are known to the individual or family. Without investment in health, health deteriorates. Net investment in health equals gross investment minus depreciation, the rate of which is assumed to be exogenous and to increase with age, so that it becomes more and more expensive to obtain good health. There is also an education efficiency parameter. Higher health stock increases healthy time, leading to higher income (increased productivity and time to work), making income endogenous in the model. All individual choices are subject to both a time and money budget constraint. The time constraint requires that the total amount of time available in any period must be exhausted by all possible uses, which include time spent working, producing health, lost to illness, and spent in leisure activities. The income constraint explicitly includes expenditures on medical care.

Empirical estimates have used both reduced form and structural versions of this model to answer questions such as how much a tax on cigarettes will reduce low birthweight (reduced form), or how much a change in maternal smoking might influence birthweight (structural estimates of the marginal product). The models underlie some studies of unhealthy behaviours (such as alcohol abuse) and have extensive applications in environmental economics. Although there are always issues of endogeneity (for example, income, medical care) and hence of identification in empirical applications of this model, the model's improved focus on the nature of the demand for medical care and the important role of time allocation have had a major impact on the field. (Gerdtham et al., 1999, conducted one of the best empirical tests of the Grossman model using Swedish individual data.)

Income and health. estimating the relationship

Consistent with the empirical evidence, the Grossman model suggests that income is positively
associated with health, but the direction of causation is not clear. Those with better health earn more and hence have higher incomes, whereas those with higher incomes can invest more in better health, suggesting that the observed income–health gradient may best be modelled as a simultaneous system.

The idea that income is associated with health goes back a long way in the health economics literature, and a number of hypotheses have been advanced to explain the relationship. Samuel Preston (1975) observed that the impact of additional income on health (as measured by mortality) is greater for those with lower income than for those with higher income. This observation of diminishing marginal productivity is called the ‘absolute income’ hypothesis. In its simplest form, it argues that, if income is all that matters to individual health, a community with more equal income will tend to have better average health than a community with more inequality, even if the two communities have the same average income. In an international context, Angus Deaton (2002) points out that, according to the absolute income hypothesis, redistribution can improve health even if average income is not increased, and that redistribution from rich to poor countries would in principle improve worldwide average health.

A related concept is the ‘absolute deprivation’ or poverty hypothesis, which suggests that those with the lowest incomes face poorer health and a greater risk of mortality owing to inadequate nutrition, poor-quality health care, exposure to physical hazards, and heightened stress. According to this hypothesis, a dollar redistributed from rich to poor would improve the health of the poor and improve the average health of the entire population.

The ‘relative income’ hypothesis focuses on an individual's income relative to others in his or her group. If the incomes of all members but one in a group increase, that one person's health is expected to deteriorate. A related, ‘relative position’ hypothesis holds that one's rank (occupation or education) in society is tied to health outcomes. Research in the United States and the United Kingdom has demonstrated an association between socio-economic position and health (Mullahy, Robert and Wolfe, 2004, review the evidence for this). Referred to as a ‘gradient effect’, this hypothesis implies that psycho-social and other factors that remain unevenly distributed all the way up the income scale perpetuate income inequalities in health. Perceptions of being relatively deprived (‘keeping up with the Joneses’), stress, and other non-material factors may play a role in perpetuating income inequalities in health at the upper income levels. The distinction between absolute and relative income effects has important policy implications; if the income of everyone were to increase or decrease, no change in health would be expected under a relative income model, but change would be expected under an absolute income model.

The hypothesis that focuses most directly on the tie between inequality in both health and income has two versions, one ‘strong’ and one ‘weak’. According to the strong version of the income inequality hypothesis, if the average income of the society is held constant, societies with greater inequality produce worse health among their citizens. Those in the most unequal communities may fear for their lives and property whether they are poor or wealthy, or the stress of keeping up with the Joneses may reduce time allocated to producing health. The weaker version argues that those with incomes below the mean will be negatively influenced by greater income inequality, perhaps through higher residential density and the associated increases in crime and contagious disease. A related issue for research is the extent to which these observed ties between income and health can be ascribed to race or ethnicity, through the systematically differing average incomes of racial and ethnic groups in a country like the United States. But if groups also differ in diet and genetics, health may be causally linked to these other factors rather than to the observed income gradient.
In general, there have been two empirical approaches to examining the hypotheses described above. Research into the absolute deprivation, relative income, and relative position hypotheses has usually relied upon individual-level data on income and health or mortality to examine the existence and shape of the income–health relationship among individuals; research on race and ethnicity follows a similar approach. In contrast, research examining the income inequality hypothesis has employed aggregate data exclusively, at least in measuring income inequality.

Insurance

As noted above, uncertainty in the need for medical care and the potentially very large costs of care lead to a demand for health insurance. (Nyman, 1999, has suggested an additional motivation for demanding health insurance. having insurance permits consumers to consume very expensive care that would otherwise be beyond their budget constraints.) But costs of operation, inability of the insurer to accurately discern risks (information asymmetry), and the potential for increased expenditures on the insured mean that insurance may not be supplied at a price reflecting an individual's actuarially fair cost. A traditional market failure may occur, in which only those with high expected medical expenditures are willing to buy coverage (adverse selection). Or there may be complete failure of the insurance market because no (risk-neutral) supplier is willing to offer coverage at a price that any individual would willingly pay. This has led to publicly provided coverage in many countries and subsidies towards the purchase of insurance in others, such as the United States. It has also led to incomplete insurance, in which deductibles, co-payments, and co-insurance attempt to reduce moral hazard. (A deductible requires that some initial level of expenditures is covered directly by the consumer; a co-payment is usually a fixed dollar payment per specified unit of service; and co-insurance is a fixed percentage payment. In general, although co-payments are quite common – for example, in pharmaceutical coverage – they have poorer incentive effects than coinsurance.)

The insurance market raises several interesting issues.

1. **The role of secondary insurance.** Secondary insurance may reduce the cost of public coverage if privately financed care is sufficiently substituted for publicly financed care, or may raise the cost of public coverage if it primarily pays for the cost-sharing components of publicly financed care. In the United States, for example, ‘Medigap’ insurance covers deductibles and co-payments required under Medicare, the system covering those aged 65 or more and the significantly disabled; it thereby increases demand for those services primarily paid for by Medicare.

2. **The efficiency and equity of subsidizing the purchase of insurance through the tax system.** The US system provides the highest subsidies to those with the highest marginal tax rates (those with high incomes) and offers little or no subsidy to those with low incomes.

3. **The incentive effects of income-conditioned eligibility for public insurance.** To be eligible for the Medicaid programme in the United States, persons have to meet state-specified eligibility requirements linked to income, assets and family structure. There is an all-or-nothing eligibility requirement, such that a person with income or assets a dollar above the cut-off is ineligible for Medicaid. Three potential consequences are less work effort (reduced earnings) by individuals who wish to become or remain eligible, increased numbers without private insurance among the near-eligible who are in effect ‘insured’ for costly care since they could become eligible if they...
needed such care, and reduced savings among those eligible and near-eligible.

4. The welfare loss from public subsidies for private insurance or public provision of medical care. This is potentially higher the more services that are covered, for example, covering all new technology rather than only that which passes some benefit–cost analysis, covering all pharmaceuticals compared with only the least costly drug within a category, or covering all types of counselling rather than that tied to a diagnosis of severe mental illness.

5. Issues tied to optimal breadth of coverage. Such issues include, for example, whether universally provided or mandated insurance increases welfare and the optimal depth of that coverage, life-threatening emergency care but not cosmetic surgery, semi-private hospital rooms but not private rooms, treatment for cancer but not dementia.

6. The labour market implications of using a payroll tax to subsidize or directly provide health insurance coverage. This policy potentially increases the costs to employers of hiring additional workers, especially older workers or those who have a chronically ill family member. Most modern economies struggle with how best to design employer-based taxation to fund health care insurance.

7. How to minimize crowd-out in countries with both public and private health insurance systems. In the United States the issue is designing public insurance coverage to minimize incentives to turn down private coverage (see issue 3 above). In the Netherlands the issue is balancing payroll taxes against private insurance premiums so that younger and healthier earners will not find ways to join the private system in lieu of the public system.

8. Designing policies to increase take-up of insurance among eligible populations within the constraints of equity and efficiency, thus avoiding unnecessary subsidies for those already enrolled.

9. How to effectively cover the treatment of mental illnesses. A particular variant of this in the United States is the role and design of mental health parity laws.

The demand for medical care

Much research has focused on empirically estimating the elasticity of demand for medical care. This question gets renewed attention whenever there are proposed changes to insurance coverage, since the cost of such policy changes lies in the elasticity of demand. (An additional or second-order cost of any expansion of insurance via public policy is the magnitude of the social welfare loss – deadweight loss – associated with the moral hazard effect. The most-cited original contribution on this is Mark Pauly, 1968.) The simplest empirically estimated models (most of which use number of visits or units of care as the dependent variable) include the price of care, income, simple demographic factors, and the price of alternative goods and services. But accurately measuring the marginal cost of care is not a simple proposition for individuals with insurance coverage that includes deductibles, co-payments or co-insurance, maximums per episode, and otherwise incomplete coverage. More satisfactory models include the value of time (including time spent in care, time spent in transit, and time spent waiting). Most empirical research differentiates the demand for hospital stays from physician services. A number of studies narrow the question still further, to the level of the market for hospital or physician services or for individual physicians. As expected, demand elasticities for individual physicians are quite high in large markets (suggesting a competitive market), whereas elasticities for physicians as a whole or for
hospitals tend to be far lower, suggesting their considerable market power. All non-experimental estimates of the demand for care using US populations suffer from the endogeneity of the marginal price of care because the demand for insurance is endogenous to the demand for medical care; that is, individuals or families with the highest expected medical expenses will seek out relatively generous coverage. In a large-scale experiment, the RAND Health Insurance Experiment (see Newhouse, 1994), individuals were randomly assigned to various plans ranging from full coverage (free care) to care with a 95 per cent coinsurance and a maximum dollar contribution. The design of the experiment was such that researchers could more accurately assess elasticities of demand and the marginal price of care. Participants were observed for 3–5 years. The study had shortcomings (some by design). It excluded those with the highest demand (the elderly and disabled), experienced attrition especially among those with the least generous plans, and made the decision to pay participants a lump sum to be sure all families were made no worse off by participation in the experiment. The experiment convincingly established that individuals do respond to price, even for hospital care. (The experiment found that 86.7 per cent of those with full coverage used care in a given year compared with 68 per cent of those with 95 per cent coverage. Medical expenditures for the year, in 1984 dollars, were $777, or 32.8 per cent, versus $534, or 27.4 per cent, respectively.)

Substantial econometric issues in estimating demand elasticities remain and have spawned much methodological research in health economics. Four main issues are. (a) the highly skewed nature of utilization and expenditure distributions in populations of interest (a multipart – usually two-or four-part – model in which first the probability of any use, or particular use such as outpatient care, and then the level of use conditional on any use has been frequently used in the literature. These models may not be readily identifiable, however; Duan et al., 1983.); (b) the episodic nature of care; (c) whether to use quantity of care as the outcome of interest (and, if so, how to include dimensions of the duration, extent, and quality of care) or to use expenditures (and, if so, how to measure actual expenditures rather than billed amounts); and (d) how to capture the nature of demand, much of which is based on ill health, which is difficult to measure accurately.

Measuring health outcomes

Given the prominence of market failure in health economics, accurate measures of health to capture the effectiveness of medical care are crucial. (Defining health is a major problem that lies largely outside the domain of the health economist. Perhaps the most often used concept is that promoted by the World Health Organization – a complete state of well-being. This is not very useful for the measurement of health.) Mortality is the ‘health’ measure most commonly discussed – and arguably most precisely measured – in this literature, but the relationship of mortality to care may be quite distant in time as well as ‘coarse’ or ‘noisy’. Other measures of health, which may have more proximate temporal relationships to medical care, are necessary. Such non-mortality measures of health (‘biological well-being’) may be of many types. Cellular or molecular (such as measles antibodies or titres); clinical (for example, body mass index); functional (for example, indices such as Activities of Daily Living scores); self-rated (for example, on a scale from excellent to poor); medical providers’ diagnosis of particular physical or mental health diseases, or tied to activities (such as days of school missed). Many measures are straightforward while others attempt to capture ‘utility’ by asking individuals to compare a state of illness to days or years of total healthiness to create indices such as quality adjusted life years (QALYs).
The measures selected must be appropriate for the purpose. For instance, some measures of health may be largely determined by genetic factors (such as risk for schizophrenia), others closely related to opportunity costs (for example, days of school missed because of parental work schedules). A measure appropriate for the analysis of labour force participation (for example, poor or fair health versus good or better health) may not be suitable for evaluating a targeted intervention. And, as with other empirical work, measures should detect changes (vary), measure what they intend to measure (be valid), and be free from error (be reliable).

Measurement issues in evaluating policy

Although the RAND Experiment established that consumers are responsive to the price of care, their results did not establish the value or effectiveness of care in influencing health. Nor did they determine how we might socially evaluate the benefits from a change in policy (such as an increase in the proportion of people eligible for public coverage) or the safety and efficacy trade-offs involved in designing regulation of new technologies. A large ‘industry’ exists to try to determine whether individual well-being improves, deteriorates, or remains largely unchanged after some change in policy or intervention. Critical issues include how to measure and value health changes and how to account for individual differences.

These issues tie health economics to core questions in public finance centring on the evaluation of policy changes using cost–benefit analysis, cost-effectiveness analysis, and multi-attribute utility analysis. Health economics has a further question, however. Is only the social perspective relevant, or is the perspective of a more narrowly defined group (payers, patients, providers) relevant also? And which population or individuals should be included in the analysis – only those currently alive, the next generation, or those who might survive only because of the intervention? The perspective adopted may determine whether to provide an intervention or invest in a new technology. Measuring costs is also very complex; calculation is rendered difficult by skewed cost distributions, interdependent costs, and economies. In many countries the pricing of new technologies and drugs is an additional and growing concern in policy design. (A related issue is the rate of change of technology, including pharmaceuticals. Decisions made on adoption and pricing modify the incentives for private investment in developing new drugs and equipment. Challenging issues include. Who should take the risk, particularly at early stages of development? How to encourage investment in new technology for diseases that have limited markets? How to share the benefits of new technology with those with limited incomes (including those in poor countries)?

Quality issues in evaluating care

Research concerning health care providers ranges from the role of licensing and malpractice to the use of quality indexes both broad (for example, hospital report cards) and narrow (for example, risk-adjusted mortality indices for interventions such as coronary artery bypass grafts or high-risk deliveries). The concept of ‘pay for performance’ is gaining credibility among both private and public payers, but the implications for quality and distribution of care and for overall expenditures need further research. Preliminary studies suggest that both practices – quality indicators and pay for performance – pose a real
danger of cream skimming; the ability to obtain high-quality care may diminish for those with the most to gain from such care. The medical malpractice system aims to signal the appropriate amount and quality of care, but to work properly it requires that all who suffer significant injury through medical care bring a legal action, that rewards or settlements reflect true utility-based losses, and that rewards are not paid where the cost of prevention exceeds the full loss. Economists continue to debate whether the system leads to defensive medicine (too much care) and to evaluate the implications of tort reform for quality of care.

Supply side issues

Providers

Do we have enough medical providers? Restrictions on entry into the profession make this an interesting question. In order to practise medicine one must be licensed, and in order to be licensed one must have a medical degree from an accredited institution. The supply of medical schools and student enrolment are regulated in nearly all countries. As Eli Ginzberg (1989, p. 88) noted, ‘Neither the restrictive policies of the first four decades of [the 20th] century, nor the expansionary policies of the postwar era were formulated and implemented on the basis of demand and supply of physician services’. Rate of return calculations indicate, in general, that rates are high for specialists and lower for primary care doctors, but, because entry into specialties is limited by available residencies, such analysis cannot fully answer the question of supply. Current research on the adequacy of supply extends beyond numbers per capita to include primary versus specialty care, geographic distribution, design of public subsidy, and repayment schemes. The substitutability of other health professionals including nurses, nurse practitioners, and social workers for medical doctors (or psychologists for psychiatrists) is tied to two main issues. whether we have sufficient medical providers and whether competition and lower reimbursement may increase the efficiency of some types of medical care, many of them routine and predictable. A sufficient supply of nurses is from time to time a particularly acute issue. Issues of interest in the market for nurses include the monopsony power of hospitals, working conditions including work hours and locations, and childcare during working hours, which tend to fall outside the standard 8 a.m. to 5 p.m. workday.

Hospitals

Much earlier work in health economics focused on hospitals, memorably described by Baumol and Bowen (1966, p. 497, referring to non-profit organizations in general) as ‘bottomless receptacles into which limitless funds can be poured’. Various alternative reimbursement schemes have been designed to limit these expenditures, but all have difficulties. Hospitals paid on the basis of fee-for-service have an incentive to provide care wherever marginal benefits are positive (especially if patients are fully insured.) From an efficiency perspective, this leads to too much care, because costs are not considered. Hospitals paid according to a fee schedule have an incentive to over-provide services for which the fee is greater than or equal to the marginal cost but to skimp on other services. Hospitals paid a per diem have an incentive to extend patient stays, especially since marginal costs tend to be far lower later in a stay.
Hospitals paid by diagnosis (such as in Medicare's diagnosis-related groups or DRGs) have the incentive to serve the healthiest of those who seek care (cream skimming), avoiding those for whom expected costs are greater than expected payments (dumping). Finally, hospitals paid on the basis of capitation, or that are part of a fully owned health maintenance organization (HMO) with a capitation-based income, face incentives to provide cost-effective care, but perhaps not all care with positive net benefits. Understanding hospital behaviour is important for designing policies that influence their behaviour. Many, but far from all, hospitals are non-profit, and use their non-profit status to convey the message to patients that quality is not compromised by the desire for profits. They thus aim to generate trust that reduces the need for complicated contracts between the hospital and the consumer. (Hospitals are increasingly adding for-profit components to their array of services, thus masking the difference between for-profit and non-profit institutions.) The non-profit nature of most hospitals has led to a variety of models of hospital behaviour. One model views hospitals as two organizations in one. There is first the hospital staff, which provides resources to the physicians for the care of their patients. The physician staff want sufficient resources to treat their patients without delays and prefer some excess capacity; they want the latest technology, however expensive. Hospitals provide such technology in order to compete for physicians and their patients. The result is duplication and rapid diffusion of the newest technology. A second model is a utility maximization model of hospitals, in which hospital managers get utility from the increased quantity (size or number of beds) and quality of care provided. They can expand in both dimensions more easily within non-profits and with fewer binding constraints than within for-profit hospitals. Again the result is duplication. (A related version of this is a quantity maximization model.)

Two other models of hospitals suggest (a) that physicians control hospitals, behaving in ways that maximize their own incomes, or (b) that hospitals can be thought of as physician cooperatives that act to maximize their own well-being but are inefficient if the hospital grows too large. Some research on forms of ownership and hospital behaviour suggests that competition matters far more than form of ownership where price is concerned.

Managed competition

First put forward by Alain Enthoven (1978), this approach changed the incentives facing providers to improve efficiency and quality. The plan called for multi-specialty group practices that would provide a specified, comprehensive set of medical care services in exchange for a per capita prospective payment covering a defined period of time. Individuals could choose an HMO plan (usually a closed panel or a limited set of providers) or traditional fee-for-service; all bidders would be required to offer a plan that covered the specified set of services. Employers would offer a broad set of plans but would pay only a fixed dollar amount towards the premium; consumers would pay the full difference between that contribution and the actual premium. The lower cost and more comprehensive benefits of the prepaid plans would lead consumers to choose those plans. Information on the quality of care under these plans would be systematically collected and shared with consumers, who would have an annual open enrolment period.

Empirical evidence on the effectiveness of managed competition suggests that it generates one-time savings but that the forces driving toward new technology, the desire among consumers for point-of-service choice, and adverse selection have limited its role. Reform, analysis and experimentation with
variants of managed competition continue. The issue of how to reduce the rate of increase in the cost of medical care continues to be important in all developed countries. Managed competition is but one approach. Others include, limiting the number of providers who can practise in a jurisdiction (Canada and the United Kingdom, for example); increasing the co-payments required of consumers; modifying reimbursement of providers; using waiting lists to reduce access; providing free telephone advice to improve efficiency of demand (Australia and parts of the United Kingdom); regulating insurance coverage; setting a budget for a fixed period of time; and rationing care on the basis of age. Designing these approaches and evaluating their success is a continuing challenge.

The economics of disability

In this area, health economists have been concerned with the proper design of public policy, in particular the efficiency of disability-based benefits, including their work and health insurance incentives. Measurement (in this case, of disability) is again a major impediment to the quality of the research. Health economists are attempting to better understand the determinants of chronic health problems, including those such as obesity, asthma, and diabetes, which are on the increase. Models from other fields of economics (such as intergenerational mobility, time use, and consumer demand models) are being applied to understand the determinants of the increase and to identify interventions to stem the trend. This short overview suggests that problems for exploration and opportunities to influence the design of policies from prevention, through insurance design, to reimbursement and regulation are likely to expand as the costs of health care continue to rise. Health economics approaches range from theory through empirical analysis to policy reform. They can include the development of new models or improved policy analysis and design. They can be country-specific or comparative; sector-specific (hospital care) or more comprehensive; and tied to labour, public, micro theory, or international studies.

**Abstract**

Health care finance has been dominated by moral hazard, potential rents and the deadweight loss from financing them, and adverse selection. Public health services and insurance tend to be universal, solving the selection problem. Private health insurance markets and public schemes that offer a choice of insurance plans generally exhibit selection. Research has found strong evidence of responsiveness of demand to insurance coverage. In health insurance markets information is asymmetric among patients, providers, and insurers, and principal–agent relationships abound. Actual health insurance and health care financing institutions have adapted to these features.

**Article**

As the capabilities and the associated expense of medicine advanced during the 20th century, the demand for financial protection against the risk of large medical spending grew. The result of the increased demand has been widespread health insurance or direct public provision of medical care, or both, in every developed country.

Both health insurance and the public provision of medical care heavily subsidize that care at the point of service, meaning that the user bears only a fraction (usually a small one) of the cost. As a result, insurance induces moral hazard and potentially rents in factor prices as well, which in turn induces deadweight loss through the taxes needed to finance any public insurance. Both private and public insurers, however, may combat moral hazard and rents through the nature of their contracts with
In addition to moral hazard and potential rents, a voluntary health insurance market exhibits adverse selection. To combat selection, voluntary insurance contracts may contain provisions for medical underwriting (exclusion of an individual from a small group insurance plan), exclusions of pre-existing conditions from coverage, or exclusion of certain services from coverage altogether. Such features may prevent willing buyers and sellers from contracting, as well as hamper the efficiency of labour markets with employment-based insurance, as employees may not leave jobs because of the inability to obtain comparable insurance (Gruber, 2000).

These three features – moral hazard, potential rents and the deadweight loss from financing them, and adverse selection – have influenced countries’ health care financing institutions, as first suggested in the seminal paper by Kenneth Arrow (1963). To combat selection, some countries, for example the United Kingdom and southern Europe, deliver health services through a public health service. In this case health insurance markets are supplemental to the public health service. Other countries, such as Canada and many northern European countries, combat selection by offering public or quasi-public insurance with no choice of insurance plan; private health insurance markets are again supplemental. Because public health services and public health insurance tend to be universal (though in some countries the affluent can opt out), the selection problem is solved, potentially at the expense of a poorly performing monopoly.

By contrast, private health insurance markets and public schemes that offer a choice of insurance plans generally do exhibit selection. Among developed countries the United States relies most on private health insurance markets, although because of selection American private health insurance is primarily organized through employment rather than through an individual insurance market. Again in part because of selection, many Americans without an employment connection, most notably the elderly, are insured through public insurance. But not all American employers offer insurance, not all those employees offered insurance purchase it, and not all those without a labour market connection are eligible for public insurance. As a result, the United States has a much higher proportion of its population with no health insurance than other developed countries. This group tends to receive care through subsidized direct delivery systems.

In this article I first discuss selection and the demand for insurance. Then I discuss moral hazard and the demand for medical care conditional on insurance. Finally, I discuss the nature of the contract between the insurer and the provider, such as the physician or hospital, and its relation to the provider's supply of services. The material covered in this entry is treated more extensively in Cutler and Zeckhauser (2000).

Selection

Health insurance was used as an example of selection by two of the classic papers on asymmetric information (Akerlof, 1970; Rothschild and Stiglitz, 1976). The models in those papers showed that an equilibrium may not exist in competitive insurance markets if insurers could not identify high risks (for example hypochondriacs and possibly the chronically ill). If a competitive market pooled high and low risks (that is both risk types buying the same policy), insurers would offer products that differentially appealed to low risks, thus breaking the pooling equilibrium. Under certain conditions a separating equilibrium (that is each risk type buying a different policy) might also be impossible.
Later papers showed that under different assumptions an equilibrium might exist (Dubey and Geanakoplos, 2002; Newhouse, 1996; Wilson, 1977), but selection behaviour seems pervasive in individual health insurance markets, and even a separating equilibrium is a form of market failure given the almost universal nature of annual contracts in private insurance markets. That is because a low risk this year has the risk of becoming a high risk next year, for example by contracting a chronic disease. But the higher premium facing a high risk is uninsurable with annual premiums. Notice that in a family insurance context this risk includes having a high-risk child born into the family, and, when the child becomes an adult, extends also to the child (typically the child can no longer be covered under a parent's policy after a certain age).

Cochrane (1995) pointed out that lifetime contracts would solve this problem, but lifetime contracts are not observed in the private market, for several reasons. First, the rapid rate of technological change in medicine and the associated cost increase (Cutler, 2004; Newhouse, 1992) is a non-diversifiable risk for a given cohort. Second, there are large economies to group insurance, in part because of lower marketing costs. To avert selection, however, groups must be formed primarily for reasons other than obtaining health insurance, which is why health insurance in many countries forms around the place of employment. But even here selection can be a problem, most obviously for the self-employed, who are effectively in an individual market, but also for small employers.

Empirical work has confirmed the importance of selection. I show three examples. The first is the variation in insurance premiums by generosity of the insurance. Table 1 orders insurance policies by generosity, where a higher percentile indicates more complete coverage. The column labelled ‘Premium’ is the premium charged for the policy; the column labelled ‘Actuarial value’ is the estimated spending among a standardized population for each policy, reflecting the increase in demand for services when the insurer covers a greater portion of any medical spending. (One might ask how actuarial values are known. They can come from similar policies from groups where selection is minimal, such as employees of large firms with no choice of insurance plan, or from other evidence on how the demand for care varies with insurance generosity; one form of such evidence is discussed below in conjunction with moral hazard.)

*Source: Cutler (1994, Table 2).*

Whereas premiums between the 90th and 10th percentile plans differ by a factor of about 2.7, the actuarial value of the two plans differs only by a factor of 1.4. The difference between these values indicates that high risks are disproportionately choosing the 90th percentile plan, and low risks are
disproportionately choosing the 10th percentile plan.

A second form of evidence comes from the US Medicare programme, the near-universal insurance programme for individuals over the age of 65. Medicare gives its beneficiaries choice between a traditional indemnity insurance plan that allows free choice of physician, and a prepaid plan, which can restrict choice of physician but in return charges a smaller premium or covers certain additional services. Through 2005 individuals have been allowed to change between these two types of plans monthly (under current law this is to change in 2006).

The data suggest the traditional indemnity plan has been more appealing to high-risk individuals. Although spending and use data have not been available for those in prepaid plans, one can compare use among those in the traditional plan who subsequently enrol in a prepaid plan with that of those who do not. Adjusted for age and sex and a few other covariates, spending among those switching from the traditional plan to a prepaid plan in the 12 months before they switched was 23 per cent less than among those who remained in the traditional plan (Medicare Payment Advisory Commission, 2000). Because the individuals had the same insurance plan when this difference was observed, the group opting to change to the prepaid plan appeared to be in considerably better health. Similarly, adjusted for age and sex, mortality rates among those enrolled in prepaid plans were 15 per cent less than among those in the traditional plan, a difference much too large to be plausibly related to any difference in benefits or care. Consistent with selection, the mortality rate difference was largest, 21 per cent, among those who had switched to the prepaid plan within the previous 12 months, and then steadily narrowed as individuals remained in the prepaid plan, a form of regression to the mean.

Finally, selection can give rise to so-called premium death spirals. Cutler and Reber (1998) studied a natural experiment among Harvard University employees that gave rise to one such spiral. Harvard allowed its employees to choose among insurance plans of varying generosity. Initially it subsidized a constant percentage of the premium (between 75 and 85 per cent, depending on the employee's earnings), but it subsequently changed the subsidy to a lump sum. (I note in passing that the rationale for an employer subsidy is to combat selection. In effect, such a subsidy makes it attractive for low risks to pool with high risks within the employment group.)

With a percentage-of-premium subsidy, the employee bore only 15–25 per cent of the premium difference among plans, but with a lump sum subsidy the employee bore the full incremental cost of more generous plans. For the employee who only marginally favoured a more generous plan with a percentage-of-premium subsidy (that is, the better risk within the group choosing the more generous plan), it became attractive with a lump sum to choose a less generous plan (the relative price to the employee of more generous plans rose by a factor of four or more). But, as the better risks within the more generous plans opted out, the premium necessary to cover the medical cost of those remaining rose. This in turn set off another round of plan changing, which raised the premium in the more generous plans still more. At that point the most generous plan was withdrawn from the market.

Moral hazard

Insurance creates a trade-off between risk aversion and moral hazard, or the failure to take actions that would lessen the probability of or the severity of or damage from an adverse event (Zeckhauser, 1970). In the context of health insurance, the focus has been on the costliness of the event rather than on the
likelihood of the event. That is because there are enough unpleasant uninsured consequences around illness and injury, such as pain and discomfort, that the extent of insurance for medical care probably changes the incentive to avoid illness or injury rather little. In fact, individuals when randomly assigned to better insurance do not change their lifestyle habits (Newhouse and Group, 1993).

The RAND Health Insurance Experiment randomized 2000 American families to health insurance plans that varied the portion of medical bills they had to pay, from nothing (all services were free to the family) to approximately a large family deductible of $1,000 in late 1970s dollars (Manning et al., 1987; Newhouse and Group, 1993). The deductible was scaled down for low-income families. The families were followed for either three or five years (the period was randomly assigned), and both their medical care use and health outcomes were observed. Over the course of the experiment families assigned to the large deductible plan used around 30 per cent fewer services than those assigned to the plan in which services were free. They made about two fewer visits to physicians during the year, and they were admitted to the hospital about 20 per cent less.

The average family's health was little changed by the additional medical services consumed when care was free to them, although those who were both sick and poor had better outcomes, primarily because of better control of hypertension (high blood pressure). There was thus ample confirmation of moral hazard. For a review of studies of moral hazard see Zweifel and Manning (2000).

The supply of medical care

Insurers or health care services either contract with or employ health care providers, most notably physicians, to deliver medical services. The need for this is most apparent if the insurance policy covers all of the patient's medical costs in full; because the patient has no incentive to search for a lower-cost provider, if the insurer passively reimbursed medical bills providers could in theory bill an infinite amount. The same incentives apply if patients bear a modest fixed charge for each, say, physician visit. The terms of the insurer's contracts with medical providers can have important effects on the services delivered. I discuss here two features of such contracts: provider networks and so called supply-side cost sharing. (For further discussion of these issues see Chalkley and Malcolmson, 2000; McGuire, 2000; Newhouse, 2002; and Pauly, 2000.)

Before the 1980s the usual model of American health insurance allowed ‘free’ choice of provider, meaning that to a first approximation the patient's out-of-pocket payment was unaffected by the physician(s) he or she sought care from. Many non-American models still allow this. These arrangements began to change in the 1980s with the advent of managed care insurance plans, which sought to establish networks of preferred physicians and hospitals. In-network physicians contracted with the insurer; at a minimum the contract specified a discount off a usual fee. In return, patients were given financial incentives to use in-network physicians. By increasing the elasticity of demand facing a physician, networks began to reduce rents in physician fees (Cutler, McClellan and Newhouse, 2000).

Many insurance plans went further than simply asking for fee discounts, and gave physicians financial incentives to reduce utilization. For example, instead of being paid a fee for each narrowly defined service (such as a visit or a laboratory test), a primary care physician might receive a capitation payment for each insured who selected that physician as a personal physician. In this case, the proximate marginal revenue the physician earned from delivering any additional services was zero, although there
might have been an indirect effect of reducing services on patient retention. A less high-powered incentive than pure capitation was a ‘risk corridor’ around a target utilization rate. For example, the physician and the insurer might share deviations from the target rate fifty-fifty up to a certain size deviation, and above or below that amount all risk was on the insurer.

Such arrangements, also used in the British National Health Service and in Denmark, were termed ‘supply-side cost sharing’, in contrast to the demand-side cost sharing described above that was paid by the patient. Supply-side cost sharing created two incentives. First, and most obviously, it created an incentive for the physician to treat less intensively than with pure fee-for-service reimbursement, thereby potentially addressing moral hazard (Chalkley and Malcolmson, 1998; 2000; Ellis and McGuire, 1986). Second, if the capitation were only for the primary care physician's own services, the most common arrangement, it created an incentive for that physician to refer the patient to another physician, a form of unbundling. In the American context the insurer would simply pay for the services of the other physician; in the British context the patient would be referred to a salaried physician at a hospital that might have a lengthy queue.

Several pieces of evidence support the view that physicians respond to the type of contract they face. A near-universal finding of American managed care plans is that they reduce the use of services relative to traditional indemnity plans, which passively paid a fee-for-service; that is, they indemnified the patient against any incurred medical bills (Glied, 2000). As described above, however, a characteristic of managed care plans is that they did not passively reimburse whatever service a physician chose to deliver.

Other data show the effects of particular contracts. A natural experiment in Denmark showed that physicians whose services were only partly at risk delivered more services than those who were fully at risk, although the increase was not sustained (Krasnik et al., 1990). A small-scale experiment in the United States randomized pediatricians to be paid by either a fee-for-service system or a salary; the salaried pediatricians earned no additional income for treating more intensively (Hickson, Altmeier and Perrin, 1987). The physicians paid with a fee-for-service method delivered more than 20 per cent more services, with the difference almost entirely in well-child visits (preventive care). Most likely, mothers brought sick children in, but brought well children in only with some effort from the pediatrician.

Finally, numerous studies have shown that physicians respond to the level of payment (McGuire, 2000; Newhouse, 2002). This is particularly relevant to insurers that administratively set prices on a take-it-or-leave-it basis and to insurers that negotiate fees for all physicians in an area.

In sum, health insurance markets violate numerous assumptions of the introductory textbook model of perfectly competitive markets with full or at least symmetric information. In particular, information is asymmetric among patients, providers, and insurers, and principal–agent relationships abound. Actual health insurance and health care financing institutions have adapted to these features.

health outcomes (economic determinants)

Christopher J. Ruhm
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article summarizes the conclusions of research examining how health is affected by income inequality and temporary changes in macroeconomic conditions. In both cases, recent analyses have raised serious doubt about the ‘conventional wisdom’ derived from earlier studies using less adequate analytical methods. Specifically, the latest studies question the hypothesis that inequality has a large independent effect on population health, and suggest that economic downturns improve rather than worsen physical well-being.

Keywords

absolute income hypothesis; counter-cyclical; fixed effects; health outcomes; income inequality hypothesis; inequality of income; life expectancy; macroeconomic conditions; morbidity; mortality; pro-cyclical; relative income hypothesis; unemployment

Article

The health of individuals and populations is affected by a variety of economic factors. Other dictionary entries (health economics; population health, economic implications of) consider how health is related to income, education, infrastructural investments, prices and insurance. This article focuses on the roles of income inequality and of temporary changes in macroeconomic conditions in wealthy industrialized countries, which have been the subjects of considerable debate and empirical analysis. In both cases, the recent use of more sophisticated analytical approaches has raised serious doubt about the ‘conventional wisdom’ derived from earlier research using techniques less able to account for possible sources of bias. Income and health are positively correlated. Although there are questions about the extent to which higher incomes cause better health (Smith, 1999), most analysts believe that there is some causal effect and the discussion below presumes this is so. Similarly, permanent economic progress is assumed to improve most aspects of health.
Income inequality and health

Conceptual issues

There is a widespread belief that average health would improve if inequality could be reduced by redistributing income from richer to poorer households, without changing its average level. This is supported by the predictions of theory and empirical evidence, since at least Preston (1975), indicating that the health benefits of income exhibit diminishing returns. A direct consequence is that the health reductions resulting from lowering incomes of the well-off are more than offset by gains to the less advantaged, improving average health. Wagstaff and van Doorslaer (2000) call this the *absolute income hypothesis* (AIH). One important implication of AIH is that income inequality will be negatively related to average health in the cross section, but that this correlation will disappear if individual incomes are controlled for.

Far more controversial is the proposition that inequality has negative effects on health, with individual (or household) income held constant. This is the *income inequality hypothesis* (IIH). Under IIH, an individual living in a country with high inequality will be in worse health than a counterpart with the same income but residing in a nation with a more equal distribution. The main mechanism for this is hypothesized to be that relative income (or position) matters – this is the *relative income hypothesis* (RIH). For instance, being higher in the income distribution might allow access to goods that promote health and provide individuals with more control over their lives; conversely, low status might raise stress and reduce social trust or cohesion (Wilkinson, 1997).

The existence of RIH is not a sufficient condition for the income inequality hypothesis. An additional requirement is that the negative health effects of low rank exceed the gains (if any) accruing to high relative position. On the other hand, since some deleterious effects of increasing inequality (for example, loss of social capital) have adverse effects throughout the distribution, heightened inequality could worsen health of the wealthy as well as the poor. Direct tests of the relative income hypothesis are rare, partly due to the difficulty in defining an appropriate reference group. Advocates therefore often cite animal studies indicating that low-status primates have greater stress levels than their higher-status counterparts. Recently, however, some research provides direct evidence on the role of relative status. For instance, Eibner and Evans (2005) show high rates of mortality, morbidity, and body mass index, and poor self-reported health for persons whose incomes are low relative to a reference group defined by location, race, education and age.

Empirical evidence

Much interest in the income inequality hypothesis stems from Wilkinson's (1992) influential study. His most important finding was that more equal incomes were strongly positively correlated with life expectancy in nine industrialized countries, while average incomes had little effect. Subsequent research initially focused on cross-national comparisons but, starting in mid-1990s, was increasingly conducted for geographic regions within countries, particularly the United States.

The early studies were criticized on both technical and methodological grounds. For instance, Judge,
Mulligan and Benzeval (1998) discuss problems with the data used by Wilkinson (1992), and provide evidence that the results are sensitive to the choice of inequality measures. Moreover, as mentioned, ‘ecological studies’ using aggregate data will generally reveal a negative correlation between inequality and health (with average incomes controlled for) if income has diminishing benefits, and so cannot distinguish between the absolute income and income inequality hypotheses (Gravelle, 1998).

A potential solution is to use micro-data, since IIH predicts that the inequality relationship will persist after individual income is controlled for. Such research has proliferated in recent years, beginning with Fiscella and Franks (1997). These investigations do not, however, fully address the concern that cross-sectional inequality–health relationships may be confounded by omitted factors. Particularly significant, in this regard, is evidence that the association disappears or diminishes greatly when covariates are included for education, census region or per cent black (Mellor and Milyo, 2002; Deaton and Lubotsky, 2003). Other researchers (for example, Subramanian and Kawachi, 2003) argue that one or more of these variables may be caused by inequality and so are not appropriate to control for, or present evidence that a (diminished) correlation persists after including them. Nevertheless, the sensitivity of results suggests the vexing difficulty in accounting for all relevant causal factors when using cross-sectional data.

Whereas early studies provided strong evidence favouring IIH, the conclusions of more recent research, generally using better data and more sophisticated techniques, are far more mixed. An indication of this can be obtained from the comprehensive literature review by Lynch et al. (2004). They classified 98 peer-reviewed studies according to whether they supported IIH, had mixed findings, or obtained no associations or positive estimated effects of inequality on health. Overall, 40 studies contained strongly favourable evidence, 25 had mixed findings, and 33 were not supportive. However, 24 of the 37 studies published after 2001 failed to obtain results consistent with IIH, and just five were strongly favourable. The evidence is also generally less supportive when individual rather than aggregate data are used, particularly for recent analyses. For instance, of the 18 such studies published after 2001 and reviewed by Lynch et al., 12 obtained negative findings, two had mixed results, and only four strongly supported IIH.

After carefully reviewing the literature, Angus Deaton states, ‘The stories about income inequality affecting health are stronger than the evidence’ (Deaton, 2003, p. 150). This conclusion seems reasonable. There may be some causal effect but it is almost certainly weaker than that suggested by the early research, and is probably confined to a limited set of health outcomes (such as homicides).

Macroeconomic conditions and health

Conceptual issues

Health is conventionally believed to improve during economic expansions and deteriorate during downturns. Psycho-social determinants are usually focused upon, with recessions postulated to harm physical and mental health by increasing stress and risk taking (Brenner and Mooney, 1983). However, economic factors could also matter if, for example, incomes fall or medical care becomes more expensive because health insurance becomes less available or comprehensive. However, there are at least four reasons why health instead might improve in bad times. First, the
opportunity cost of time declines, making it less expensive to undertake time-intensive health investments such as exercise and consumption of a healthy diet. Second, health is an input into the production of goods and services, implying that hazardous working conditions, job-related stress and some environmental risks (like pollution) may decrease. Third, some external sources of death may fall. For instance, traffic fatalities are likely to decrease due to reductions in driving. Fourth, migration may fall if individuals have fewer opportunities to move into areas with robust economic conditions. This could reduce social isolation, with especially beneficial effects on the young and old (Eyer, 1977).

The health effects of temporary and permanent changes in economic conditions may be quite different. An important distinction is that transitory growth is usually produced through more intensive use of existing inputs, whereas lasting improvements require some combination of technical innovation or increases in productive capital that have the potential to raise all types of consumption, including good health.

**Time-series evidence**

Most empirical research, until recently, analysed aggregate time-series data for a single geographic area. Particularly influential were a series of investigations by M. Harvey Brenner providing evidence that recessions (and other sources of macroeconomic instability) raise overall mortality, specific sources of death, and other health problems. For instance, using data from England and Wales for 1936–76, Brenner (1979) found that unemployment rates (growth in per capita income) were positively (negatively) related to total and age-specific mortality. However, researchers (such as Wagstaff, 1985) have pointed out serious technical flaws in Brenner’s methods, and studies correcting the problems (for example, McAvinchey, 1988) failed to replicate his findings.

A key issue is that any lengthy time series may contain omitted variables that are spuriously correlated with economic conditions and have a causal effect on health. Potential confounders include changes in lifestyles, the public health infrastructure or medical technologies. Given this fundamental shortcoming, it is no surprise that the results of aggregate time-series analyses are sensitive to the countries, time periods, and proxies for health examined. After reviewing 16 such studies, Ruhm concludes: ‘with the exception of Brenner’s analyses, the majority of the time series evidence suggests that the contemporaneous effect of economic downturns is to improve health or reduce mortality’ (Ruhm, 2006, p. 5). Interestingly, such ‘counterintuitive’ findings are not new. Research undertaken as early as the 1920s identifies a positive association between macroeconomic activity and mortality (Ogburn and Thomas, 1922).

**Estimates using pooled data**

A potential solution to the aforementioned shortcoming is to conduct ‘a more refined ecological analysis … taking advantage of local and regional variations in the business cycle as well as in disease rates’ (Kasl, 1979, p. 787). Research using such strategies has become increasingly common beginning with Ruhm’s (2000) analysis of state-specific mortality rates for 1972–91. The key advantage of using multiple geographic areas and periods is that time effects can be included to account for potential time-varying confounders that have common impacts across locations, and location ‘fixed effects’ can be
added to control for unobserved factors that differ across geographic areas but remain constant within them. Researchers also often include area-specific time trends, which hold constant some other time-varying omitted determinants. Although most analyses have utilized aggregate data, the techniques can easily be adapted for use with individual data, and some research has begun to do so.

Mortality rates are the most commonly studied health outcome, and area unemployment rates are the typical proxy for macroeconomic conditions. Although data from the United States was first examined, analysis has recently been conducted for several European nations (for example, Neumayer, 2004; Tapia Granados, 2005), as well as using international data on multiple countries. Ruhm (2006) reviews seven such studies published between 2000 and 2004, and concludes that there is strong evidence of a procyclical variation in total mortality, infant deaths and fatalities from traffic accidents, cardiovascular disease and influenza or pneumonia. The results are mixed for other types of mortality, and it is noteworthy that some studies uncover a counter-cyclical variation in suicides. This raises the possibility that people become ‘healthier but not happier’ when economic conditions deteriorate. Data restrictions have severely limited analyses of morbidities, although the majority of evidence from the few studies available (for example, Ruhm, 2003) indicates a counter-cyclical variation in health.

Lifestyle changes appear to explain some of the health improvements observed during economic downturns. Most available research suggests that alcohol use and problem drinking, smoking, severe obesity and physical inactivity all decline when the economy weakens. However, direct evidence on the role of work hours is mixed and disparate results are sometimes obtained for specific population groups or countries other than the United States. Also, the improvements in physical health appear to occur despite reductions in incomes and decreased use of medical care.

Hearn, William Edward (1826–1888)

M. White

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

competition; Hearn, William Edward; income distribution; prices

Article

Hearn was born in County Cavan, Ireland and died in Melbourne, Australia. Educated at Trinity College Dublin, he was appointed professor of political economy and other subjects at the University of Melbourne in 1854. Subsequently a member of the Legislative Council of the State of Victoria and contributor to the local press, Hearn is known to economists principally for his *Plutology* (1863). *Plutology* explains increasing wealth as a result of the competitive exchange of services. The analysis owes a good deal to Herbert Spencer and Frederic Bastiat. Competition is held to have three general results. It is: beneficent, since prices reflect the minimum cost of procuring a service; just, because recompense is in proportion to merit; and equalizing, since no recompense permanently reflects the effects of chance. As an ‘unfailing rule’, the pursuit of self-interest means services are produced in ‘order of their social importance’. Competition results in a natural social order, ordained by Providence, in which the principles of Darwin's natural selection are applied to industry (ch. 19).

The price of any service, determined by the extent of demand and supply, oscillates towards the minimum cost of production. The upper price limit is set where the purchaser equates desire for a service with the sacrifice necessary to either directly produce or obtain it from another source. The minimum price must cover any outlays and provide the ‘average’ reward for the vendor's type of service (ch. 14). The discussion of price formation is not conducted in marginalist terms and owes a good deal, via J.S. Mill, to de Quincey.

The distribution of income is explained according to the general principles of exchange. The manager of an enterprise, for example, contracts with the vendors of labour and ‘capital’ for their services at a fixed price. Discounting all costs and gross returns, the manager then has full title to the output, assuming responsibility for losses and receiving net gains. If capital is supplied in ‘commodity’ form (machinery, buildings), rent is paid; if it is supplied in money form (loans, insurance), interest accrues. Directly following Bastiat's *Harmonies*, Hearn argues that ground rent cannot be a gratuitous gift of nature as
land has a price only if labour is bestowed on it (ch. 18).
The role of a central government in an ‘advanced’ nation is thus basically a nightwatchman, although it may undertake some limited regulation. It is acknowledged, however, that the accumulation path will be impeded to some extent. The most serious problems result from enterprises mistaking market demand and engaging in speculative ventures. Still, fluctuations in output and investment have relatively little importance. ‘Failures, poverty, suffering and privation’ are not part of the ‘ordinary course of events’, any ‘ravages’ are soon repaired and objects destroyed in commercial fluctuations would have mainly been consumed rather than invested. Any ‘disturbances’ are thus ‘incidental’ to the natural laws of economic organization (ch. 24).
Marshall and Edgeworth bestowed high praise on Plutology, while Jevons considered its arguments were ‘nearly identical’ to those in his Theory. Subsequent commentary has noted Hearn's dogmatism and plagiarism, especially from John Rae and Bastiat.

heavy-tailed densities

Rustam Ibragimov
From The New Palgrave Dictionary of Economics Online, 2009
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews several frameworks commonly used in modelling heavy-tailed densities and distributions in economics, finance, risk management, econometrics and statistics. The results and conclusions discussed in the article indicate that the presence of heavy tails can either reinforce or reverse the implications of a number of models in these fields, depending on the degree of heavy-tailedness.

Keywords

heavy-tailed densities; heavy-tailed distributions; power laws; stable distributions; mean; variance; moments; semi-heavy tails; diversification; portfolio choice; value at risk; linear estimators; sample mean; efficiency; regression; robustness; dependence; $\alpha$-symmetric distributions; models with common shocks

Article

Several notions and classes of heavy-tailed densities and distributions are available in the economic, financial, statistical and probability literature. A unifying property common to such densities and distributions is that their tails are heavier than in the Gaussian case, either in the sense of faster decay to zero or in the sense of comparisons of heavy-tailedness measures, such as kurtosis.

1 Heavy-tailed models

In models involving a heavy-tailed random variable (rv) $X$ it is usually assumed that the distribution of $X$ has power tails, so that
heavy-tailed densities: The New Palgrave Dictionary of Economics Online

\[ P(|X| > x) \propto \frac{C}{x^\alpha}, \quad x > 0, \quad C > 0, \quad as \quad x \to +\infty \]

(1)

(here and throughout the article, \( f(x) \cdot g(x) \) as \( x \to +\infty \) means that \( \lim_{x \to +\infty} \frac{f(x)}{g(x)} = 1 \)). The parameter \( \alpha \) in (1) is referred to as the tail index, or the tail exponent, of the distribution of \( X \). An important property of rvs \( X \) satisfying (1) is that the absolute moments of \( X \) are finite if and only if their order is less than the tail index \( \alpha : E|X|^p < \infty \) if \( p < \alpha \) and \( E|X|^p = \infty \) if \( p \geq \alpha \).

Examples satisfying (1) include Pareto distributions with densities \( f(x) = \alpha x_0^\alpha / x^{\alpha + 1} \) for \( x > x_0 > 0 \); \( f(x) = 0 \) for \( x \leq x_0 \). In addition, (1) is satisfied for Student's \( t \) - distributions with densities

\[ f(x) = \frac{\Gamma((\alpha + 1)/2)}{\sqrt{\alpha \pi} \Gamma(\alpha/2)} (1 + x^2 / \alpha)^{-(\alpha + 1)/2}, \quad x \in \mathbb{R}, \quad \text{where} \quad \Gamma(z) = \int_0^\infty t^{z-1} e^{-t} dt, \quad t > 0, \]

denotes the Gamma function. Relation (1) also holds for the important class of stable distributions that are closed under portfolio formation.

In addition to distributions that follow power laws (1), several other frameworks for modelling heavy-tailed phenomena have been proposed in the literature, including distributions with finite moments of any order and semi-heavy tails. Such tails are thinner than in the case of any power law (1) but much heavier than those of normal distributions. Semi-heavy tails in this sense are exhibited, for instance, by normal inverse Gaussian and, more generally, generalized hyperbolic distributions (see section 3.2 in McNeil, Frey and Embrechts, 2005, and references therein), as well as by the important case of log-normal distributions.

2 Empirical results

Numerous studies in economics, finance, risk management and insurance have indicated that distributions of many variables of interest in these fields exhibit deviations from Gaussianity, including those in the form of heavy tails (1) (see, among others, the discussion and reviews in Embrechts, Klüppelberg and Mikosch, 1997; Rachev, Menn and Fabozzi, 2005). This stream of literature goes back to Mandelbrot (1963) (see also Fama, 1965, and the papers in Mandelbrot, 1997), who pioneered the study of heavy-tailed distributions in economics and finance.

The following is a sample of estimates of the tail index \( \alpha \) in distributions satisfying (1) for returns on various stocks and stock indices: \( 3 < \alpha < 5 \) (Jansen and de Vries, 1991), \( 2 < \alpha < 4 \) (Loretan and Phillips, 1994), \( 1.5 < \alpha < 2 \) (McCulloch, 1997), \( 0.9 < \alpha < 2 \) (Rachev and Mittnik, 2000), \( \alpha \approx 3 \) (Gabaix et al., 2003). Power laws (1) with \( \alpha \approx 1 \) (Zipf laws) have been found to hold for firm sizes and city sizes (see Gabaix, 1999a, 1999b; Axtell, 2001). As discussed by Nešlehova, Embrechts and Chavez-Demoulin (2006), tail indices less than 1 are observed for empirical loss distributions of a number of operational risks. Silverberg and Verspagen (2007) report the tail indices \( \alpha \) to be significantly less than 1 for
financial returns from technological innovations. The analysis in Ibragimov, Jaffee and Walden (2008) indicates that the tail indices may be considerably less than 1 for economic losses from earthquakes and other natural disasters. Anderson (2006) discusses the heavy-tailedness paradigm in many modern economic and financial markets transformed by the Internet and the development of technology.

3 Stable distributions

Canonical examples of power laws (1) are given by stable distributions. For \(0<\alpha \leq 2\) and \(\sigma >0\), the symmetric stable distribution \(S_{\alpha}(\sigma)\) is the distribution of an rv \(X\) with the characteristic function (cf) \(E(e^{ixX})=\exp\{-\sigma \alpha |x|^\alpha \}, i^2=-1, x \in \mathbb{R}\). Throughout the article, we write \(X \sim S_{\alpha}(\sigma)\), if the rv \(X\) has the distribution \(S_{\alpha}(\sigma)\). Given two rvs \(X\) and \(Y\), the notation \(X=dY\) means that the distributions of \(X\) and \(Y\) are the same.

The parameters \(\alpha\) and \(\sigma\) are referred to as the characteristic exponent (index of stability) and the scale parameter of the symmetric stable distribution \(S_{\alpha}(\sigma)\). In general, stable distributions also depend on the skewness parameter \(\beta\) and the location parameter \(\mu\). Symmetric stable distributions \(S_{\alpha}(\sigma)\) correspond to the case \(\mu=\beta=0\).

A closed form expression for the density \(f(x)\) of a stable distribution is available only in the following cases: normal densities that correspond to the case \(\alpha=2\); Cauchy densities \(f(x)=\sigma/(\pi(\sigma^2+(x-\mu)^2)), x \in \mathbb{R}, \alpha=1\); and the densities \(f(x)=(\sigma/(2\pi))^{1/2}\exp(-\sigma/(2x))x^{-3/2}, x>0; f(x)=0, x \leq 0\), of Lévy distributions with \(\alpha=1/2\) and their shifted and reflected versions. While normal and Cauchy distributions are symmetric about the location parameter \(\mu\), Lévy distributions are concentrated on the positive semi-axis \((0, \infty)\).

The index of stability \(\alpha\) characterizes heaviness of tails of the distribution \(S_{\alpha}(\sigma)\). If \(X \sim S_{\alpha}(\sigma)\), then \(X\) satisfies power law (1). Thus, the absolute moments \(E|X|^p\) of an rv \(X \sim S_{\alpha}(\sigma)\), \(\alpha \in (0,2)\) are finite if \(p<\alpha\) and are infinite otherwise. The same conclusions hold for skewed stable distributions. In particular, second and higher moments are infinite for all non-Gaussian stable distributions with \(\alpha<2\). Cauchy distributions with \(\alpha=1\) have infinite first and higher absolute moments. If the rv \(X\) has a Lévy distribution with \(\alpha=1/2\), then \(E|X|^p=\infty\) for all \(p \geq 1/2\).

The distributions of stable rvs \(X\) with \(\alpha>1\) are moderately heavy-tailed in the sense that they have finite first absolute moments: \(E|X|<\infty\). In contrast, the distributions of stable rvs \(X\) with \(\alpha<1\) are extremely heavy-tailed in the sense that their first absolute moments are infinite: \(E|X|=\infty\).

The scale parameter \(\sigma\) is a generalization of the standard deviation; it coincides with the standard deviation for normal distributions with \(\alpha=2\). For \(\alpha>1\), the location parameter \(\mu\) of a stable distribution coincides with its mean: in particular, \(EX=0\) for symmetric stable rvs \(X \sim S_{\alpha}(\sigma)\) with \(\alpha \in (1,2]\).

Stable distributions are closed under portfolio formation. In particular, if \(X_i \sim S_{\alpha}(\sigma)\), \(\alpha \in (0,2]\), are iid symmetric stable risks, then, for all portfolio weights \(w_i \geq 0, i=1,\ldots,n\),
\[ \sum_{i=1}^{n} w_i x_i = d \left( \sum_{i=1}^{n} w_i^\alpha \right)^{1/\alpha} x_1, \]

or, equivalently, \[ \sum_{i=1}^{n} w_i x_i \sim S_\alpha(\tilde{\sigma}), \]
where \[ \tilde{\sigma} = \sigma \left( \sum_{i=1}^{n} w_i^\alpha \right)^{1/\alpha} \] (see Zolotarev, 1986; Embrechts et al., 1997; Rachev and Mittnik, 2000, for a review of properties of stable distributions).

Multivariate extensions of the stable family such as \( \alpha \)-symmetric distributions allow one to model frameworks with a wide range of heavy-tailedness in marginals and dependence among them (see Fang, Kotz and Ng, 1990 and the discussion in Ibragimov, 2007, and Ibragimov and Walden, 2007). The class of \( \alpha \)-symmetric distributions contains models with common shocks affecting all heavy-tailed risks as well as spherical distributions. Spherical distributions, in turn, include such examples as Kotz type, multinormal, logistic and multivariate \( \alpha \)-stable distributions. In addition, they include a subclass of mixtures of normal distributions as well as multivariate \( t \)-distributions that were used in the literature to model heavy-tailedness phenomena with dependence and finite moments up to a certain order.

4 Robustness of economic models

Heavy-tailedness has important implications for robustness of many economic models, leading, in a number of settings, to reversals of conclusions of these models to the opposite ones.

This may be illustrated, for instance, by the properties of value at risk (VaR) models and the analysis of diversification and portfolio choice in VaR frameworks under heavy-tailedness (see Embrechts, McNeil and Straumann, 2002; ch. 12 in Bouchard and Potters, 2004; Ibragimov, 2005a, 2005b, and references therein).

Given a loss probability \( q \in (0,1) \) and an rv (risk) \( X \) we denote by \( VaR_q(X) \) the VaR of \( X \) at level \( q \), that is, its \((1-q)\)–quantile: \( VaR_q(X)=\inf \{ z \in R: P(X>z) \leq q \} \) (in what follows, we interpret the positive values of \( X \) as a risk holder's losses).

Throughout the article, \( \mathcal{F}_n = \{ w = (w_1, ..., w_n) : w_i \geq 0, i = 1, ..., n, \sum_{i=1}^{n} w_i = 1 \} \). For \( w = (w_1, ..., w_n) \in \mathcal{F}_n \), denote by \( Z_w \) the return on the portfolio of risks \( X_1, ..., X_n \) with weights \( w \).

Denote \( \mathcal{W} = (1/n, 1/n, ..., 1/n) \in \mathcal{F}_n \) and \( \tilde{w} = (1, 0, ..., 0) \in \mathcal{F}_n \). The expressions \( VaR_q(Z_\mathcal{W}) \) and \( VaR_q(Z_{\tilde{w}}) \) are thus the VaRs of the portfolio with equal weights and of the portfolio consisting of only one return (risk). It is natural to think about the portfolio with weights \( \mathcal{W} \) as the most diversified and about the portfolio with weights \( \tilde{w} \) as the least diversified among all the portfolios with weights \( w \in \mathcal{F}_n \). A simple example where diversification is preferable is provided by the standard case with normal risks.

Let \( n \geq 2, q \in (0,1/2) \), and let \( X_1, ..., X_n \sim S_2(\sigma) \) be iid symmetric normal rvs. For the portfolio of \( X_i \)'s with the equal weights \( \mathcal{W} = (1/n, 1/n, ..., 1/n) \) we have \( Z_\mathcal{W} = (1/n) \sum_{i=1}^{n} X_i = d(1/\sqrt{n})X_1 \). Consequently, by positive homogeneity of the VaR,
Thus, the VaR of the most diversified portfolio with equal weights $\bar{w}$ is less than that of the least diversified portfolio with weights $\bar{w}$ consisting of only one risk $Z_1$.

Using (2), one can also show (see Ibragimov, 2005a, 2005b) that diversification is preferable in the VaR framework for all iid moderately heavy-tailed risks $X_i \sim S_\alpha (\sigma)$ with $\alpha \in (1,2]$ in the sense that $VaR_q(Z_{\bar{w}}) \leq VaR_q(Z_{\bar{w}}) \leq VaR_q(Z_{\bar{w}})$ for all $q \in (0,1/2)$ and all weights $w \in g_n$.

The settings where diversification is suboptimal in the VaR framework may be illustrated as follows. Let $q \in (0,1)$ and let $X_1, \ldots, X_n$ be iid positive risks with a Lévy distribution with the tail index $\alpha = 1/2$ and the density $f(x) = (\sigma/(2\pi))^{1/2} \exp(-\sigma/(2x))x^{-3/2}$. Similar to symmetric stable distributions, the portfolios of the risks $X_i$ satisfy (2) with $\alpha = 1/2$. Using (2) for equal weights $w_i = 1/n$, we get

Thus, the VaR of the least diversified portfolios with weights $\bar{w}$ that consists of only one risk is less than the VaR of the most diversified portfolio with equal weights $\bar{w}$.

Relation (2) further implies (see Ibragimov, 2005a, 2005b) that the results on diversification suboptimality in the VaR framework continue to hold for all iid extremely heavy-tailed risks $X_i \sim S_\alpha (\sigma)$ with $\alpha \in (0,1)$. Namely, for such risks, $VaR_q(Z_{\bar{w}}) \leq VaR_q(Z_{\bar{w}}) \leq VaR_q(Z_{\bar{w}})$ for all $q \in (0,1/2)$ and all weights $w \in g_n$.

The results in Ibragimov (2005b) provide portfolio VaR comparisons for convolutions of stable distributions with different tail indices and their extensions to dependence, skewness and heterogeneity, including convolutions of $\alpha$ – symmetric distributions and models with common shocks. Ibragimov and Walden (2007) and Ibragimov, Jaffee and Walden (2008) show that the (non-)diversification results in heavy-tailed value at risk models continue to hold for bounded risks. Ibragimov et al. (2008) further use these conclusions to develop a simple model for markets for catastrophic risk in which nondiversification traps may arise.

5 Implications for statistical and econometric methods

Similar to the portfolio VaR analysis, heavy-tailedness presents a challenge for applications of standard statistical and econometric methods. In particular, as pointed out by Granger and Orr (1972) and in a number of more recent studies (see, among others, ch. 7 in Embrechts et al., 1997, and references therein), many classical approaches to inference based on variances and (auto)correlations such as regression and spectral analysis, least squares methods and autoregressive models may not apply directly in the case of heavy-tailed observations with infinite second or higher moments.

An important simple illustration is provided by the failure of the law of large numbers (LLN) for observations with infinite first moments and variances. When more information about the structure of heavy-tailedness is available, one can obtain more refined results that point out to crucial differences between moderately heavy-tailed and extremely heavy-tailed populations.

Consider the problem of estimating the parameter $\mu$ in the simple model
where $\eta_i$ are iid errors with an absolutely continuous symmetric distribution. Given a random sample $X_1, \ldots, X_n$ that follows (3), denote by $\hat{\theta}_n(w)$ the linear estimator $\hat{\theta}_n(w) = \sum_{i=1}^{n} w_i X_i$.

It is well known that, if $E\eta_i^2 < \infty$, then the sample mean $\bar{X}_n = (1/n) \sum_{i=1}^{n} X_i$ is the best linear unbiased estimator (BLUE) of the population mean $\mu = E X_i$. That is, $\bar{X}_n$ is the most efficient estimator of $\mu$ among all unbiased linear estimators in the sense of variance comparisons: $\text{Var}[\bar{X}_n] \leq \text{Var}[\hat{\theta}_n(w)]$ for all $w \in \mathcal{F}_n$.

The definition of efficiency based on variance breaks down in the case of heavy-tailed populations with infinite second moments. A natural approach to comparison of performance of estimators under heavy-tailedness is to order them by likelihood of observing their large deviations from the true population parameter. This approach relies on the concept of peakedness of rvs and leads to the following definition.

Let $\hat{\theta}(v)$ and $\hat{\theta}(w)$ be two linear estimators of the parameter $\mu$ in model (3). The estimator $\hat{\theta}(v)$ is said to be more efficient than $\hat{\theta}(w)$ in the sense of peakedness (P-more efficient than $\hat{\theta}(w)$ for short) if $P(|\hat{\theta}(v) - \mu| > \varepsilon) \leq P(|\hat{\theta}(w) - \mu| > \varepsilon)$ for all $\varepsilon \geq 0$, with strict inequality whenever the two probabilities are not both 0 or both 1.

The results in Ibragimov (2007) for general dependent settings such as convolutions of $\alpha$-symmetric distributions and models with common shocks imply that the sample mean $\bar{X}_n$ is the best linear unbiased estimator of the population mean $\mu$ in the sense of P-efficiency for moderately heavy-tailed errors $\eta_i \sim S_\alpha(\sigma)$ with $\alpha > 1$. However, if the errors $\eta_i \sim S_\alpha(\sigma)$ are extremely heavy-tailed with $\alpha < 1$, then P-efficiency of the sample mean is smallest among all linear estimators $\hat{\theta}(w)$ of the population centre $\mu$ with weights $w \in \mathcal{F}_n$.

The conclusions in Ibragimov (2005a) show that, similar to the portfolio VaR analysis and the efficiency properties of linear estimators, many models in economics and related fields are robust to heavy-tailedness assumptions provided the distributions entering these assumptions are moderately heavy-tailed. However, the implications of these models are reversed for distributions with sufficiently heavy-tailed densities.

6 Conclusion

The results reviewed in this article and those obtained in the recent literature imply that the presence of heavy-tailedness can either reinforce or reverse the implications of many models in economics, finance, econometrics, statistics and risk management, depending on the degree of heavy-tailedness. Typically, the standard implications of the models continue to hold for moderately heavy-tailed distributions. However, these implications may become the opposite ones under sufficient heavy-tailedness. Therefore, the models should be applied with care in heavy-tailed settings, especially in the case of the
tail indices close to the value $\alpha = 1$, which in many cases provides the critical robustness boundary.

Heckman, James (born 1944)

Richard Blundell, Lars Peter Hansen and Derek Neal
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

James Heckman has made fundamental contributions to the development of methods that allow economists to estimate models of economic behaviour using data on individual decisions. He has also produced numerous important empirical results that advanced understanding of how government policies that regulate labour markets and influence educational opportunity affect economic inequality among individuals and groups.

Keywords

Article

1 Labour supply and selection

In Heckman's early work on labour supply we see at least three related contributions. First, he integrated consumer theory and the theory of labour supply. Second, he developed an empirical life-cycle setting for labour supply. Third, he provided an economically coherent framework for the statistical analysis of participation, labour supply and market wages. Heckman's work on labour supply, which originated in
the early to mid-1970s, set the scene for the development of his research on selection, on labour market dynamics and on programme evaluation. They are all empirically oriented but with a keen eye on the identification and estimation of structural economic parameters from micro data. Heckman's initial aim was to estimate the parameters of indifference curves for leisure and consumption. Given these, one could measure the welfare cost of some tax or welfare intervention and also simulate the impact of new policies. There were at least three key unresolved issues in the literature at that time: the econometric problem of non-participation in the presence of childcare costs; the need for a reasonably flexible functional form that could capture variation in hours worked among participants; and the lack of information concerning wage offers among those who do not participate. Heckman successfully addressed all of these issues in two remarkable papers (1974a; 1974b). He recognized that a simple least squares analysis of hours of work, wages and participation would not, by itself, identify preference parameters and that the standard Tobit model alone was also insufficient to deal with the problem. As an alternative, Heckman developed an estimation procedure that allowed the work decision to be based on interrelated choices over hours of work and the use of formal childcare, each with its own separate source of stochastic variation. This approach is the forerunner of many microeconometric developments in this area and continues to set the standard by which models are judged. Indeed, Heckman's development of a likelihood that captures the sampling information on participation and wages can be seen as the beginning of the analysis of endogenously selected samples. Yet the contributions of this work go beyond the insights concerning selection. His marginal rate of substitution specification for preferences turned out to be a highly innovative way of dealing with non-participation while allowing flexible but heterogeneous preferences, and the endogenous choice of formal and informal childcare jointly with hours of work and participation provided a basis for the analysis of multiple regime models. In this ‘static’ labour supply analysis, we find repeated references to the potential importance of a more dynamic setting. In fact, Heckman conducted this work alongside his development of a life-cycle framework for labour supply. The origins of this work are in the first essay of his 1971 Princeton University doctoral thesis. Heckman began by noting that both income and consumption appear to follow a similar hump-shaped path over the life cycle that is out of line with the most basic consumption-smoothing model. Heckman (1974c) provides a beautifully simple, yet complete, integration of intertemporal consumption and labour supply theory and shows that a model with labour supply and uncertainty can easily explain these empirical phenomena. Heckman extended this life-cycle analysis in two different directions. In Heckman (1976), he incorporated human capital investment and showed how earnings functions that ignored life-cycle labour supply tended to overestimate rates of depreciation. In other work, he developed an empirically implementable form of the intertemporal substitution model for labour supply. Here, he pointed out that given standard neoclassical assumptions the marginal utility of wealth is constant over time for an individual but differs across individuals and is clearly correlated with wages. Since labour supply choices could be written in terms of current wages and the marginal utility of wealth, Heckman's observation pointed to a perfect application of a fixed effects estimator for panel data, and in Heckman and MaCurdy (1980) he applied such an estimator to the panel data analysis of female labour supply. Heckman's model could also be adjusted to account for uncertainty and so became the prototypical intertemporal model of labour supply. It directly recovered the intertemporal substitution elasticity for labour supply and showed immediately the relationship of this intertemporal elasticity with the standard
Heckman's empirical investigations of individual labour supply behaviour stimulated further analysis of their statistical implications, and at least two major innovations in econometrics came out of this work. This work yielded new methods for analysing selected samples and also for estimating simultaneous multivariate choice models in which outcomes are a mixture of discrete and continuous decision variables. It is easy to see how important work on labour supply led to progress in these areas. Labour market participation is a choice based, in part, on wage offers that are observed only among those who participate, and household choices concerning participation, hours, and childcare present a mixture of both discrete and continuous decision variables. While the links to labour supply analysis are clear, the applicability of these two developments grew far beyond the study of labour supply.

Heckman's (1979) selection model is one of the most renowned econometric models since the mid-20th century. This work laid the foundation for the subsequent work on returns to training, the study of union wage differentials and to many other microeconometric problems. His approach was innovative but also simple. Starting with an additive regression model, Heckman noted that for normal distributions the conditional mean for a selected sample involves a single additional term that is itself a function of the selection probability. This term or 'control function' may be estimated in a first step from the choice probability model, and thus a computationally convenient two-step estimator is available for the analysis of selected samples.

Future work demonstrated that the selection model and the two-step estimator are more generally applicable in cases where the normality assumption fails. Heckman (1990) and others developed semiparametric extensions for the additively separable model. Heckman and Honoré (1990) derived the general nonparametric identification of the Roy model – a two-regime generalization of the additively separable selection model. Both Heckman and Sedlaceck (1985) and Heckman and Scheinkman (1987) provide empirical analyses of aggregate and sectoral wage distributions when individuals self-select into the labour market and into sectors of the economy.

If actions are a mixture of discrete and continuous decision variables that are simultaneously determined, then there will be a further condition on the econometric model to guarantee it provides a coherent statistical relationship between inputs and response. Heckman labelled this condition the ‘principle assumption’, and in Heckman (1978) he derives the conditions required for a coherent econometric framework. This work has influenced econometric work in industrial organization. Heckman's condition concerning a jump parameter in the mean of the latent variable underlying a discrete choice is easily mapped into analyses of entry decisions when fixed costs are present.

2 Panel data and state transitions

During the 1970s and 1980s economists gained much greater access to panel data-sets, and this development greatly shaped the research agenda in labour economics and other applied fields. Economists began to focus their attention on the sequence of decisions that firms and individuals make over time and attempted to model and understand the patterns of correlation over time in these decisions. The current choices of individuals may be correlated with their past choices because of persistent unobserved individual differences (heterogeneity) or because current preferences or opportunities depend on past actions (state dependence). Thus, heterogeneity and state dependence can easily be
Heckman, James (born 1944) : The New Palgrave Dictionary of Economics

confounded. Heckman (1981a; 1981b) formally characterizes this identification problem, discusses pitfalls with simple or naive attempts at measuring one or the other effects, and shows how panel data can be used constructively to sort out competing explanations.

Heckman and Singer (1984) confront formally the statistical aspects of unobserved heterogeneity in the context of duration models. Duration models are used in studying job search, mortality, labour supply, marriage and other phenomena. Fully parametric models of duration include precise parameterizations of the unobservable (to an econometrician) attributes of individuals that influence the optimal duration of spells. Heckman and Singer show that these parameterizations can contaminate estimates of the economic parameters that pin down the structural relationship between spell duration and the rate of spell completions. As an alternative they propose, formally justify and implement a maximum likelihood estimator where the unobserved heterogeneity is modelled nonparametrically. Interestingly, in their application to data on unemployment spells, their nonparametric estimator chooses a small number of support points (individual types), and their Monte Carlo results in the same paper show that their estimates of the distribution of unobserved types are never close to the truth. However, their nonparametric treatment of unobserved heterogeneity allows them to choose points of support in a flexible way that avoids contaminating the estimated parameters of interest. The empirical results presented by Heckman and Singer strongly suggest that many of the somewhat puzzling results in the previous literature on the determinants of unemployment spells were the result of researchers trying to simultaneously estimate models with parametric assumptions concerning both the true underlying model of duration times and the distribution of unobserved individual heterogeneity.

The competing risks model has been used in many disciplines. In this model, observed outcomes reflect the minimum realized transition time over a discrete set of possible state transitions. Heckman and Flinn (1982) develop a structural interpretation of the competing risks model in the context of labour markets and apply it to study employment spells. They investigate the identification of the underlying economic parameters of interest as restrictions are removed from the auxiliary statistical specification. In a related paper, Heckman and Honoré (1989) explore identification of the competing risks model of failure times, and they show how introducing regressors into the competing risks model overturns previously established non-identification results. In the previous section, we mentioned Heckman and Honoré's (1990) work on requirements for identification is a generalized Roy model. Here, too, they demonstrated precisely how identification could be achieved through either restrictions on the shape of underlying skill distributions or sufficient variation in prices or exogenous regressors.

3 Estimation of treatment effects

In Section 1 we described how Heckman's early work on labour supply led to developments in the analysis of selected samples. Over the years, Heckman began to demonstrate that numerous problems other than labour supply are actually problems where missing data are the key challenge for empirical investigators. The work on identification in general versions of the Roy model is part of this research agenda. In the 1990s Heckman produced a series of related empirical and methodological papers that grew out of sustained research on methods of programme evaluation (see Heckman, Ichimura and Todd, 1997; see also Ichimura, Heckman, Smith and Todd, 1998, and Clements, Heckman, and Smith, 1997). Heckman emphasized that the key impediment to measuring the return to any investment in training or education is the inability to see what those who receive treatment would have experienced in the absence
of training.

Heckman's work in this area helped clarify several important points. First, Heckman produced much evidence consistent with the proposition that the treatment effects associated with various training and education programmes vary greatly among participants, even among those who are similar with respect to observed demographic characteristics. Second, outcomes from experiments involving random assignment to treatment and control status do permit straightforward estimates of the average gain from treatment in a given sample, but more structure is required in order to draw inferences concerning the distribution of gains and losses from treatment. Third, the performance of non-experimental methods such as matching or control function models can be greatly improved when researchers take care to balance treated and non-treated samples with respect to the probability of treatment. Careful attention to the support of this probability in each sample as well as its density can greatly improve the performance of non-experimental estimators. For example, Ichimura, Heckman, and Todd (1997) demonstrate clearly that the performance of matching estimators improves when samples are re-weighted so that the density of the probability of treatment is the same among the treated and the untreated. Finally, difference-in-difference estimators may be an attractive strategy in situations where researchers have before and after data on treated and non-treated samples, but only in cases where there is evidence that the selection bias associated with treatment takes the form of a subject fixed effect that is constant over time.

Heckman has continued working in this area while devoting special attention to the mapping between various estimators in the literature and the precise set of counterfactual questions that they can address under various assumptions concerning how the data are generated. Heckman and Vytlacil (2005) present results that reflect the culmination of much of this research. In this paper, they explain how numerous estimators employed in the estimation of treatment effects may all be written as weighted averages of the marginal treatment effects (MTE) in the population. The marginal treatment effect is defined as the expected gain from treatment with the observed and unobserved determinants of participation held constant at particular values. Heckman and Vytlacil not only demonstrate how other estimators, such as instrumental variables, can be expressed in terms of the distribution of MTE, but they also demonstrate how MTE can be used as a building block in the construction of estimators that capture the expected treatment effects of specific policies on particular populations. This paper also clarifies an asymmetry in the way that heterogeneity enters models of selection and treatment. Agents may exhibit heterogeneity in terms of what they gain from treatment, but changes in their environment must affect each individual's likelihood of receiving treatment in a similar manner. Heckman goes on to spell out the challenges that researchers face if they wish to estimate models in which selection equations involve random coefficients.

4 Empirical work on inequality

To this point, we have focused almost exclusively on contributions that involve the development and implementation of new methods that seek to overcome some problem involving missing data. However, Heckman has also made noteworthy contributions that involve no methodological innovation but rather the use of simple methods to establish important facts about the sources of economic inequality and their relationship to government policy. His work in the areas of black–white inequality and the economics of education are ripe with examples of this type of work.

During the 1970s economists in the United States devoted considerable attention to the question of
whether or not the Civil Rights Act had actually improved the economic well-being of blacks. Butler and Heckman (1978) made an important early contribution to this literature by pointing out that declining labour-force participation rates among less skilled blacks during the post-Civil Rights era could create the impression of economic progress among blacks even if none existed. To measure changes in the distribution of potential real wages facing blacks, researchers needed to address the fact that an increasing fraction of less skilled workers did not report market work and thus did not report wages in most surveys.

Butler and Heckman (1978) greatly influenced future work on black–white economic progress, but Heckman's most important contributions to this literature are summarized in a 1991 *Journal of Economic Literature* piece with John Donohue that cataloged evidence supporting the hypothesis that the Civil Rights Act of 1964 did serve as a catalyst for a discrete episode of black economic progress that was not simply a continuation of existing trends.

Donohue and Heckman (1991) acknowledge that long-term improvements in access to schools and school quality contributed to secular progress for blacks in the labour market in decades before and after the Civil Rights Act. However, they also show that federal government intervention served as an important catalyst for black progress during the civil rights era. They demonstrate that black relative earnings rose during the 1960s primarily because of gains in the South, where civil rights laws were imposed on local communities by the federal government. Further, they cite previous work by Heckman and his co-authors that demonstrates how the Civil Rights Act broke down de facto and de jure occupational segregation in the South (see Heckman and Payner, 1989, and Butler, Payner, and Heckman, 1989. Donohue, Heckman, and Todd, 2002, show how private philanthropy and legal activism served as catalysts for improvements in black educational opportunity that pre-date the civil rights era).

Finally, they note a drastic decrease in the rate of net migration among blacks from the South to the North around 1965, a development that strongly suggests the Civil Rights Act did expand opportunity for blacks in the South.

Around the same time, Cameron and Heckman (1993) documented another set of important results concerning outcomes associated with a government programme. Cameron and Heckman demonstrated that persons who receive a high-school diploma by taking the General Educational Development (GED) test do not enjoy employment and earnings outcomes as adults that are in any way equivalent to those observed among high-school graduates. In fact, male GED recipients look quite similar to high-school dropouts with respect to many labour market outcomes.

Since the mid-1990s a growing literature has examined the cost and implied benefits of obtaining a GED for various types of individuals. Heckman and Rubinstein (2001) have taken this literature in a new direction by demonstrating that the difference between GED recipients and persons who finish high school takes the form of differences in non-cognitive skills related to self-esteem, work habits, and other personal traits. This discovery provides a natural explanation for the facts documented by Cameron and Heckman (1993). While the GED does certify that a young person has certain basic skills that are valued by employers, the combination of these skills and the failure to finish high school is a signal to employers that these youth are deficient in other areas.

**Conclusion**
Taken as a whole, the breadth and depth of Heckman's contributions to economics are stunning. His work on selection models, transition dynamics, and the estimation and identification of treatment effects has changed the way that economists analyse micro-data. At the same time, his empirical work in the economics of education and inequality produced numerous results that shape our understanding of modern labour markets and future research agendas for theorists and empiricists. He has also shaped the profession as a teacher and advisor of students. During his career, Heckman has served as primary thesis adviser for scores of graduate students, and a significant number of his students have earned tenure in top economics departments, served as editors of journals, and helped produce yet another generation of scholars who take seriously the task of using economics to guide empirical investigations of important questions.

Article

Born into a Jewish family in Stockholm, Heckscher studied history under Hjärne and economics under Davidson at Uppsala University from 1897. In 1907 he became a docent at Stockholm University College of Commerce, and from 1909 to 1929 he was professor of economics and statistics. Then, because of his great research productivity, the college authorities changed his position to research professor, lightened his teaching duties and made him director of the newly established Institute of Economic History. Heckscher continued in this position until he retired in 1945. He succeeded in establishing economic history as a subject of graduate study in Sweden's universities. In 1950, the Ekonomisk-historiska Institutet, Stockholm, through Bonniers Co., published the Eli F. Heckscher bibliografi 1897–1979 (123 pp.). It contains 1148 entries for his 36 books, 174 articles in professional journals, his chapters in government reports, and the more than 700 short articles he wrote for the weekend issues of Stockholm's leading newspapers. Only a few of his books and articles have been translated and will be referred to by their English titles; other works will be mentioned only by the English translation of their original titles and identified by their numbers as entries in the Heckscher bibliography.

By 1929, when he was able to specialize in economic history, Heckscher had already written a dozen books on such diverse subjects as Economic Principles (1910, No. 158), The Continental System (1918, No. 443, later republished, Oxford, 1922) and Economics and History (1922, No. 478). As a result of his teaching, his contributions to economics are a blend of innovations in economic theory and a new methodology for economic history research, an approach to quantitative research very different from that used by leaders in his field such as Schmoller, Cunningham and Sombart.

Heckscher's most significant contributions to economic theory may be found in two articles. ‘Effects of Foreign Trade on Distribution of Income’ (1919) is the origin of the modern Heckscher–Ohlin factor.
proportions theory of international trade, developed further in Ohlin (1933).

‘Intermittently Free Goods’ (1924) presents a theory of imperfect competition nine years ahead of that by Joan Robinson and Edward Chamberlin, and a discussion of collective goods not priced by the market. Heckscher observed that significant new products are introduced by firms with investment in plants that have a capacity which far exceeds initial demand for their products. The latter are sold at prices which barely cover unit variable costs, and so, for a time, the services of the fixed investment are provided as ‘free goods’. Then, as weaker firms are eliminated, demand shifts to the remaining larger firms who use up their production capacity. By and by these firms expand, enjoy economies of scale, differentiate their products and become prosperous oligopolies dividing a mass market into more or less definite shares.

A situation of the opposite kind arises when the smallest feasible production facility has a production capacity which suffices for a growing and indefinitely large demand without affecting the costs and service life of the production unit. This is the case with many so called ‘pure’ public or collective goods. Heckscher used street illumination as an example of a collective good, which can be used simultaneously by few or many persons, a service that cannot be priced per unit of individual use. The costs of providing this service, then, are usually met by an increase in local government taxes. In that case, and in contrast to that of intermittently free goods, the citizens pay the full-cost price of the service from the outset in their current taxes. Then, as activities in and use of lighted streets increase over time, the citizens derive increased utility per tax dollar spent for street lighting.

At the Institute of Economic History Heckscher's first work, one of his major and most widely known treatises, was *Mercantilism* (1931). His other major work, the fruit of many years of pioneering research devoted to his own country, was *Sweden's Economic History from the Reign of Gustav Vasa* (vols 1 and 2, 1935–6, No. 878; vols 3 and 4, 1950, No. 1146). He also wrote a popular version of this work, *Life and Work in Sweden from Medieval Times to the Present* (1941), No. 1014, republished as *An Economic History of Sweden* (1954). Among his other books of particular interest are *Materialist and Other Interpretations of History* (1944, No. 1052), *Industrialism, Its Development from 1750 to 1914* (1946, No. 1123) and *Studies of Economic History* (1936, No. 918). It was in this work he presented a new methodology he proposed for economic history research in his essay ‘The Aspects of Economic History’, pp. 9–69. This was reinforced in his articles, ‘A Plea for Theory in Economic History’ (1929) and ‘Quantitative Measures in Economic History’ (1939).

For the analysis of any epoch of economic history – as distinct from factual description of a chronologically arranged body of heterogeneous source materials – Heckscher proposed consideration of a succession of its ‘economic aspects’, to introduce order and inject economic theory into the interpretation of that epoch. Unlike ‘periods’, ‘aspects’ are not necessarily time dependent. They are theoretical and imply hypotheses that are, within limits, testable against the given data. A series of aspects, for instance of (a) the exchange processes; (b) natural resources and technologies; (c) labour force and capital; (d) forms of enterprise organization; and (e) extent and composition of demand, form an economic model of the epoch. This done, the function of the economic historian is to provide a synthetic overview and explanation of the relations between the aspects of the model.

Thus Heckscher bridged the gap between economic history and theory by addressing broad questions or hypotheses to the source materials for intensive and critical study. He always preferred to present his finding supported by statistical data. That done, he was not satisfied until he had explained and illuminated these by economic analysis, that is, by applying cognate principles of economic theory to
their interpretation.

Heckscher–Ohlin trade theory

Ronald W. Jones
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Heckscher–Ohlin trade theory consists of four principal theorems, viz. the Heckscher–Ohlin trade theorem whereby relatively capital-abundant countries export relatively capital-intensive commodities, the factor-price equalization theorem whereby trade in goods may serve to equalize wage rates between countries, the Stolper–Samuelson theorem whereby an increase in the price of the relatively labour-intensive commodity unambiguously improves the real wage rate, and the Rybczynski theorem stating that an increase in capital endowment by itself must cause some output to fall if prices are held constant. The article discusses the nature and fate of these theorems.

Article

Eli Heckscher (1919) and Bertil Ohlin (1933) laid the groundwork for substantial developments in the theory of international trade by focusing on the relationships between the composition of countries’ factor endowments and commodity trade patterns as well as the consequences of free trade for the functional distribution of income within countries. From the outset general equilibrium forms of analysis were utilized in these developments, which gradually came to be sorted out into four ‘core propositions’ (Ethier, 1974) in the pure theory of international trade.

The four theorems
Although all four of the propositions to be discussed are an outgrowth of the seminal work of Heckscher and Ohlin, only one of these propositions bears their name explicitly. The *Heckscher–Ohlin theorem* states that countries export those commodities which require, for their production, relatively intensive use of those productive factors found locally in relative abundance. The twin concepts of relative factor intensity and relative factor abundance are most easily defined in the small dimensional context in which the basic theory is usually developed. Two countries are engaged in free trade with each producing the same pair of commodities in a purely competitive setting, supported by constant returns to scale technology that is shared by both countries. Each commodity is produced separately with inputs of two factors of production that, in each country, are supplied perfectly inelastically. (For a thorough analysis of having endowments respond endogenously, see Findlay, 1995). Following the Ricardian distinction, commodities are freely traded but productive factors are internationally immobile.

Although one country may possess a larger endowment of each factor than another, the presumed absence of returns to scale guarantees that only relative factor endowments are important. The home country is said to be relatively labour abundant if the ratio of its endowment of labour to that (say) of capital exceeds the corresponding proportion abroad. This is known as the physical version of relative factor abundance. An alternative involves a comparison of autarky relative factor prices in the two countries: the home country can be defined to be relatively labour-abundant if its wage rate (compared with capital rentals) is lower before trade than is the foreign wage (relative to foreign capital rentals).

Since autarky factor prices are determined by demand as well as supply conditions, these two versions need not correspond. In particular, if the home country is, in the physical sense, relatively labour abundant it might nonetheless have its autarky wage rate relatively high if taste patterns at home are strongly biased towards the labour-intensive commodity compared with tastes abroad. In such a case the trade pattern reflects the autarky factor–price comparison: the home country exports the physically capital-intensive commodity. As discussed below, the link between commodity price ratios (the proximate determinant of trade flows) and factor price ratios is more direct than that between commodity price ratios and physical factor endowments. Thus the Heckscher–Ohlin theorem is more likely to hold if relative factor abundance is defined in terms of relative factor prices prevailing before trade. The procedure typically followed in the literature is to assume that both countries share identical and homothetic taste patterns. Such an assumption, in conjunction with the presumed identity of technology at home and abroad (with an even stronger version of homotheticity–linear homogeneity) helps to isolate the separate influence of physical factor supplies and makes the validity of the Heckscher–Ohlin theorem with the physical definition of factor abundance as likely as with the autarky factor price definition.

These assumptions are less than sufficient to guarantee the Heckscher–Ohlin theorem, even in the simple context of two-country, two-factor, two-commodity trade. The potential stumbling block is the fact that even though countries share the same technology, the commodity that is produced by relatively labour-intensive techniques at home may be produced by relatively capital-intensive techniques abroad. This is the phenomenon of factor-intensity reversal. If production processes are independent of each other, there is nothing (other than bald assumption) to rule out its appearance. The bald assumption would assert that regardless of factor endowments one industry always employs a relatively higher ratio of labour to capital than does the other industry, where techniques are chosen with reference to the wage/rental ratio common to both industries. If this is not the case, and if the commodity that is relatively labour-intensive
at home is produced by relatively capital-intensive techniques abroad, the phrasing of the Heckscher–Ohlin theorem that explicitly states ‘each country exports the commodity that is produced in that country making relatively intensive use of the factor found in relative abundance in that country’ is fatally flawed. The reason? If the relatively labour-abundant country exports its labour-intensive commodity, it must do so in exchange for the commodity that, in the relatively capital-abundant foreign country, is produced by labour-intensive techniques. Thus if one country satisfies the theorem, the other country cannot (Jones, 1956).

In the event of factor-intensity reversal, it must be the case that, whatever the commodity exported by the labour-abundant home country, the ratio of labour to capital employed in its production must exceed the labour/capital intensity adopted in foreign exports. However, this observation is of little value if one wishes to infer from an intensity comparison between exportables and import-competing goods within a given country whether that country is more labour abundant than some foreign country. Such an inference lay behind the celebrated study of Leontief (1953) on United States trade patterns. This research, the conclusions of which came to be known as the Leontief paradox (American exportables are produced by more labour-intensive techniques than are import-competing goods) provided the major stimulus to developing and defining the meaning and conditions supporting the Heckscher–Ohlin theorem.

Earlier work in Heckscher–Ohlin trade models was focused on the pricing relationships embodied in Heckscher–Ohlin theory. Ohlin (1933) stressed the effect which free trade would tend to have on the distribution of income within countries, viz. relative factor prices would move in the direction of equality between trading countries which share the same technology. Ohlin's mentor, Heckscher, went even further in his pioneering 1919 article. Absolute factor-price equalization was purported to be ‘an inescapable consequence of trade’. (For recent appraisals of each of these economists see Jones, 2002; 2006a). Nonetheless, Ohlin's view of partial equalization seems to have dominated, with the exception of Lerner's unpublished 1933 manuscript (which surfaced after Samuelson's articles), until the statement of the factor-price equalization theorem in articles by Samuelson in 1948 and 1949. Rejecting his earlier tacit acceptance of the Ohlin thesis of partial equalization (in the Stolper–Samuelson article, which appeared in 1941), Samuelson proved that within the traditional confines of the 2×2×2 model (with no factor-intensity reversals and each country incompletely specialized), free trade would drive wage rates to absolute equality in the two countries (and, as well, would equate returns to capital) despite the assumption that labour (and capital) are assumed to be immobile between countries.

The logic of the argument for the simple 2×2 case can be stated briefly. In a competitive equilibrium unit cost equals price if the commodity is produced. Thus let $A$ represent the matrix of input–output coefficients, $a_{ij}$, $w$ the vector (pair) of factor prices, and $p$ the vector (pair) of commodity prices. Techniques need not be constant; in general they depend upon prevailing factor prices so that $A=A(w)$. Therefore the competitive profit conditions if both goods are actually produced dictate that:

$$A(w) \cdot w = p.$$  

(1)
If we assume no factor-intensity reversals, $A(w)$ is non-singular. Therefore if countries share the same technology and face the same pair of free-trade commodity prices, they must face exactly the same set of factor prices if each country produces both goods.

This approach may suggest that the crucial issue in the factor-price equalization argument is the unique dependence of factor price vector $w$ on commodity price vector $p$, and an extensive literature has developed which focuses on this issue. In the $2 \times 2$ case uniqueness is a simple question – it depends on factor intensities differing between sectors and not reversing. But from the outset Samuelson pointed out that this was not the only issue. The question of uniqueness involves properties of technology alone, whereas under appropriate circumstances two countries in free trade will have factor prices equalized only if factor endowments are reasonably similar. For, if factor endowments are too dissimilar, it will be impossible for both countries to produce both commodities, in which case the equalities in (1) cannot universally hold.

These ideas can be made more precise by considering a concept due to McKenzie (1955), which Chipman (1966) called the ‘cone of diversification’. For any factor price vector, $w$, there is determined a pair of techniques (labour/capital ratios) for the two commodities. Both factors can be fully employed only if the country's endowment vector is contained within the cone spanned by these techniques. Suppose two countries face a common free-trade commodity price vector, $p$, and that the commonly shared technology associates a unique factor price $w$ corresponding to this $p$. Then if the endowment vectors of both countries lie within the cone of diversification, their factor prices must be equalized (McKenzie, 1955).

Some seven years prior to Samuelson's first factor-price equalization essay there appeared the article by Stolper and Samuelson (1941), which must be ranked a classic not only for its discussion of what became known as the *Stolper–Samuelson theorem*, but because it is one of the first concrete developments of the ideas of Heckscher and Ohlin in the explicit format of a two-factor, two-commodity, general equilibrium model. (This theorem became so widely cited that on the golden anniversary of its appearance a conference was held at Stolper's university, the University of Michigan. See Alan Deardorff and Robert Stern, 1994.) Their argument supposedly concerns the effect of protection on real wages, and in the course of the argument they assume that a tariff does not change the terms of trade so that locally import prices rise. Subsequently, in what has become known as the ‘Metzler tariff paradox’, Metzler (1949) showed that with sufficiently inelastic demand a tariff might so improve a country's terms of trade that the relative domestic price of imports falls. If so, the Stolper–Samuelson contention that a tariff yields an increase in the real return to a country's relatively scarce factor would be reversed. However, it is now commonly agreed that the Stolper–Samuelson theorem refers to the general phenomenon whereby an increase in the relative domestic price of a commodity (whether brought about by a tariff increase, decrease, or some other reason) must unambiguously raise the real return to the factor of production used relatively intensively in the production of that commodity. Introducing the production-box diagram technique (for a single country), Stolper and Samuelson illustrate how an increase in the relative price of labour-intensive watches attracts resources from capital-intensive wheat. To clear factor markets, both sectors must then use labour more sparingly. That is, the ratio of capital to labour utilized in each sector rises, which implies an unambiguous increase in labour's marginal productivity measured either in watches or in wheat. Thus regardless of workers’ taste pattern, protection has increased the real wage.
The logic of the Stolper–Samuelson argument rests heavily upon the presumed absence of joint production. It takes labour and capital to produce watches, and, in a separate activity, a higher capital/labour ratio is used to produce wheat. In competitive settings any change in a commodity's price must reflect an average of factor price changes so that unit costs change as much as do prices. Therefore one factor price must rise relatively more than either commodity price. Which factor gains depends only upon the factor-intensity ranking. If the price of watches rises, and that of wheat does not, the wage rate must increase by relatively more. And this result follows even if techniques are frozen so that no resources can be transferred between sectors (as they can be in the Stolper–Samuelson discussion) and marginal products are not well defined (Jones, 1965).

To round out the quartet of theorems, the Rybczynski theorem (1955) deals with the same model but focuses on the relationship between factor endowments and commodity outputs. Suppose commodity prices are kept fixed in the 2×2 setting and an economy is incompletely specialized. Then by the factor-price equalization theorem, factor prices are determined and fixed as well, which implies also that techniques of production remain constant. If the economy's endowment of one factor increases, while its endowment of the other factor remains constant, the economy must in some sense grow (the transformation schedule shifts out). However, this growth is strongly asymmetric: one output actually falls. The factor-intensity ranking selects the loser – the commodity that uses intensively the factor that is fixed in overall supply must decline. The reasoning is simple. As one factor expands, it must be absorbed in producing the commodity using it intensively. But with techniques frozen (since prices are assumed fixed), the expanding sector must be supplied with doses of the non-expanding factor as well. The only source for this factor is the other industry that must, perforce, contract.

**Relationships among the theorems**

All four propositions are based on the same ‘mini-Walrasian’ general equilibrium model of trade and there are some interesting relationships and distinctions among them. Perhaps most importantly, both the Heckscher–Ohlin theorem and the factor-price equalization theorem refer explicitly to a comparison between (two) countries, whereas the Stolper–Samuelson and Rybczynski propositions are involved with relationships within a single country. This distinction implies that the assumption that countries share an identical technology is not necessary for the latter two propositions. Thus, for example, a country could protect the factor used intensively in its import-competing sector in real terms (according to Stolper and Samuelson) regardless of the level or type of technology adopted by other countries. The factor-price equalization theorem is a razor's-edge type of result. Should the technology available to two countries differ only slightly, any presumption of exact factor-price equalization in the absence of explicit international factor markets disappears. The Heckscher–Ohlin theorem is a little more robust in this regard. In general, trade patterns depend on all those variables that influence prices: tastes, technology, and factor endowments (not to mention taxes or other distortions). If tastes are identical (and homothetic) but factor endowments are not, the latter difference will tend to dominate the trading pattern even if technologies differ as long as this difference is ‘less important’. At issue is a weighing of endowment differences with the Ricardian emphasis on technology differences. A particular variation of the factor-price equalization theorem is more general, and does not need to assume that technologies are identical between countries. It concerns the dependence of factor prices only upon commodity prices. It follows as long as the country produces both commodities.
Two versions of the Heckscher–Ohlin theorem have been cited, depending on which definition of relative factor abundance is selected. If the physical factor intensity ranking is chosen as the criterion, the basis for the Heckscher–Ohlin theorem resides in the kind of link between endowment patterns and outputs for a single economy exemplified by the Rybczynski theorem. An extension of this theorem allows a comparison of the transformation schedules for two economies with similar technologies. The relatively labour abundant (physical definition) country will produce relatively more of the labour-intensive commodity at common commodity prices (Jones, 1956). Therefore, unless taste differences are sufficiently biased to counter this effect, the labour-intensive good will, in autarky, be cheaper in the labour-abundant country and, with trade, will be exported. The Stolper–Samuelson theorem is closely linked to the alternative form of the Heckscher–Ohlin theorem. Suppose there are no factor-intensity reversals. Then if both goods are produced there is a monotonic relationship between the wage/rent ratio and the relative price of the labour-intensive good such that a rise in the latter is associated with a greater than proportionate increase in the former. Thus the relatively low wage country must, in autarky, have been the relatively cheap producer of the labour-intensive commodity. As mentioned earlier, no caveat must be added about tastes, since these are already incorporated in the autarky factor-price comparison. Although a comparison of factor endowments between countries is crucial in considering both the Heckscher–Ohlin theorem and the factor-price equalization theorem, such a comparison works in opposite directions for these two propositions. Thus if factor endowment proportions are sufficiently 

dissimilar, trade patterns suggested by the Heckscher–Ohlin theorem must hold (aside from the possibility of factor-intensity reversals) whereas free trade cannot bring about factor-price equalization. Sufficiently different factor endowments entail one country's transformation schedule being everywhere flatter than the other country's. At least one country must be specialized with trade. By contrast, the factor-price equalization result holds if factor endowments are similar enough so that international differences in the composition of outputs are capable of absorbing these endowment differences at the same set of techniques (and factor prices). If endowments are this close, it would always be possible for demand differences to be so biased that the physically labour-abundant country exports the capital-intensive commodity. Indeed, if such a demand reversal of the Heckscher–Ohlin theorem takes place, free trade must result in factor-price equalization (Minabe, 1966).

Samuelson's name occurs so frequently in the literature on Heckscher–Ohlin trade theory that it is often appended to the other two names. One of his results not cited heretofore is the reciprocity relationship (Samuelson, 1953). This states that in any general equilibrium model the effect of an increase in a commodity price (say \( p_j \)) on a factor return (say \( w_i \)) is the same as the effect of an increase in the corresponding factor endowment (\( V_i \)) on the output of commodity \( j \). Of course, in each case some other set of variables is being held constant. Thus:

\[
\frac{\partial w_i}{\partial p_j} = \frac{\partial x_j}{\partial V_i}
\]  

(2)
with all other commodity prices and all endowments held constant in the left-hand derivative and all other endowments and all commodity prices held constant in the right-hand derivative. This relationship is easy to prove (see, for example, Jones and Jose Scheinkman, 1977). It also reveals the dual nature of the Stolper–Samuelson and Rybczynski theorems. If an increase in the price of watches lowers capital returns, then an increase in the endowment of capital (at constant prices) would lower the output of watches. In each case it is the presumed labour-intensity of watches that is operative.

In the 2x2 setting both the Stolper–Samuelson and Rybczynski theorems reflect the ‘magnification effects’ (Jones, 1965) that stem directly from the assumed lack of joint production. With a ‘^’ over a variable designating relative changes, if watches are labour intensive and wheat capital intensive and if the relative price of watches rises,

\[ \hat{w} > \hat{p}_{wa} > \hat{p}_{wh} > \hat{r}. \] (3)

In addition, should an economy grow, but with labour (L) growing more rapidly than capital (K),

\[ \hat{x}_{wa} > \hat{L} > \hat{K} > \hat{x}_{wh}. \] (4)

Inequality ranking (3) shows commodity price changes trapped between factor-price changes (since two factors are required to make a single good), while inequality (4) shows that in order to absorb endowment changes, the composition of outputs (each of which uses both factors) must change more drastically. Stolper and Samuelson stressed the first inequality in (3), while Rybczynski focused on the last inequality in (4), assuming \( \hat{K} \) equals zero.

**Higher dimensions**

International trade theory generally, and Heckscher–Ohlin trade theory in particular, has frequently been criticized for its restriction to the low dimensionality represented by two commodities, two factors, and two countries. In fairness to both Heckscher and Ohlin it should be stressed that their discussions typically were not so confined. But neither were their conclusions as precise as those subsequently developed by Samuelson and others in the 2x2x2 versions of the four core propositions. And in the years following Samuelson’s pioneering work on factor-price equalization, scores of articles have indeed appeared dedicated to the question of robustness of these results in higher-dimensional contexts. A highly detailed discussion of the issue of dimensionality is provided in Ethier (1984), and an earlier critique of the limitations imposed by small numbers of goods and factors is found in Ethier (1974) and
Part of the difficulty embedded in the move to higher dimensions lies in the ambiguity involved in what the propositions should state for cases beyond $2 \times 2$. The one proposition for which this is not the case is the factor-price equalization theorem. Consider the case of equal numbers of factors and produced commodities, with all goods traded and factors immobile internationally. The uniqueness of a factor price vector, $w$, corresponding to a given commodity price vector, $p$, is not guaranteed even in the $2 \times 2$ case; a factor-intensity reversal could lead to two (or more) values of $w$ consistent with a given $p$. For the $n \times n$ case Gale and Nikaido (1965) provided conditions sufficient to guarantee global univalence of the factor price–commodity price relationship: the $A(w)$ matrix of input–output coefficients should be a ‘P-matrix’, that is a matrix with all positive principal minors. These conditions have been slightly weakened by Andreu Mas-Colell (1979), and earlier a fundamental interpretation of the conditions was supplied by Yasuo Uekawa (1971). It remains the case, however, that this condition on technology alone is somewhat remote from the issue of factor-price equalization. Just as in the $2 \times 2$ case, two countries sharing a common technology and each capable of producing the same set of $n$ commodities (at the same traded-goods prices) with $n$ productive factors, will, if techniques of production are the same, have their factor prices driven to equality if their factor endowments are sufficiently close. The concept of the ‘cone of diversification’ within which both endowment vectors must lie for factor-price equalization is as meaningful and relevant in $n$ dimensions as it is in two.

Although the factor-price equalization theorem has an unambiguous meaning in higher dimensions, it is a theorem that cannot be expected to hold if the number of productive factors exceeds the number of freely traded commodities. The reasoning is basic, and can be linked to eq. (1). These competitive profit conditions supply $n$ links between factor prices and traded commodity prices, where $n$ is the number of traded commodities. If $r$, the number of factors, should exceed $n$, the relationships in eq. (1) are insufficient in number to provide a solution for the vector $w$ for given $p$. Other conditions are required, and these are provided by the full employment conditions, one for each productive factor. Thus a nation's endowment bundle, $V$, becomes a determining variable affecting factor prices that is additional to the commodity price vector, $p$. For example, in the simple three-factor, two-commodity ‘specific-factor’ model (Jones, 1971; Samuelson, 1971), suppose a country faces a given world price vector, $p$, and experiences a slight increase in its endowment of a factor ‘specific’ in its use in the first industry. The intensity with which factors are utilized depends upon factor prices, and if these do not change, there is no way in which outputs can adjust to clear all factor markets. The return to the factor specific to the first industry must fall so as to encourage the further use of that factor. Two countries of this type with different endowments will generally have different sets of factor prices with trade, even if they share a common technology. It may be interesting to note that Heckscher's (1919) discussion of the necessity of factor-price equalization is focused on a three-factor, two-commodity numerical illustration (Jones, 2006a). As just suggested, such a $3 \times 2$ setting in general does not lead to factor-price equalization.

The Heckscher–Ohlin model with two factors but many commodities available in world markets provides a useful scenario in which to re-examine the Heckscher–Ohlin theorem concerning the pattern of trade. The strong influence of factor endowments on production and trading patterns is revealed by considering two countries sharing the same technology but with different endowment ratios. Suppose commodity prices for traded goods are determined in a world market composed of a number of different countries with potentially a wide variation in technologies. Given world prices, any pair of countries
with the same technologies shares a Hicksian composite unit-value isoquant for all traded goods (Jones, 1974), made up of strictly bowed-in sections (where only one commodity is produced) alternating with flats (where a pair of commodities is produced). Regardless of the number of commodities, each country engaged in trade need produce only one or two (in the two-factor case), and these commodities will be the ones requiring factors in proportions close to that country's endowment ratio. (Not explicitly considered here is that the activity of exporting a commodity may require factor proportions different from those required in production; see Jones, Beladi and Marjit, 1999.) In this setting the spirit of the Heckscher–Ohlin theorem is that each country concentrates its resources on a small range of commodities whose factor requirements mirror closely that country's endowment base; the country exports some or all commodities in this set and imports commodities that are more labour-intensive than these goods as well as those that are more capital-intensive. Two countries whose endowments are fairly similar may produce the same pair of goods and thus achieve factor-price equalization with trade. Countries further apart in endowment composition will have disparate sets of factor prices and may produce completely different bundles of commodities (see also Krueger, 1977).

With many factors and many commodities a different approach can be taken. The ability of autarky commodity price comparisons to predict trade patterns item by item is severely questioned, so that little hope remains of linking endowment differences to the detailed composition of trade. But statements about aggregates or ‘correlations’ between trade patterns and autarky prices can be made (Deardorff, 1980; Dixit and Norman, 1980). A nation's net imports, \( M \), are positively correlated with the comparison of its autarky commodity price vector, \( p^A \), and the vector of free-trade commodity prices, \( p^T \). Thus:

\[
( p^A - p^T ) M \geq 0 
\]  

(5)

(see Ethier, 1984, p. 139). This idea can be extended to the further relationship between autarky commodity prices and the vector of autarky factor prices (as in (1)) to establish that countries possess a comparative advantage, on average, in commodities using intensively factors that are relatively cheap in autarky. (See Deardorff, 1982, and Ethier, 1984, for more details.)

The reciprocity relationship expressed in (2) is quite general in terms of dimensionality and thus serves to link the Rybczynski theorem in a dual relationship to the Stolper–Samuelson theorem. However, when the number of factors exceeds the number of produced commodities, differences between the two types of theorems do appear. This basic asymmetry is linked to the failure of the factor-price equalization theorem when factors exceed commodities in number.

Major efforts have been made to generalize the Stolper-Samuelson and Rybczynski theorems from the 2×2 settings to the \( n \times n \) setting, and a pair of earlier efforts met with only limited success. Murray Kemp and Leon Wegge (1969) searched for conditions on the original activity matrix, \( A \), or distributive share matrix, \( \theta \), that would be sufficient to ensure what is known as the strong form of the Stolper–Samuelson theorem: Each factor is associated with a unique commodity such that if that commodity price (alone) increases, the return to the associated factor increases by a relatively greater extent and all
other factor returns fall. The conditions they tried are stated by the inequalities in (6):

\[
\frac{\theta_{ti}}{\theta_{ki}} > \frac{\theta_{tj}}{\theta_{kj}} \quad \text{for all } i, j \neq i, \text{ and } k \neq i.
\]  
(6)

For each factor, \(i\), the ratio of its distributive share in the industry positively associated with that factor \((i)\) to that of any other factor's share in industry \(i\), exceeds the corresponding ratio of these two factors in any other industry. These strong conditions do indeed lead to the desired strong result on factor returns (that is the inverse of the distributive share matrix has positive diagonal terms, greater than unity, and negative off-diagonal elements) for the 3×3 case. However, the authors provided a counter-example for the 4×4 case and that was that. Even stronger conditions for sufficiency are required, and these were supplied by Jones, Marjit, and Mitra (1993). These conditions are, in a sense, suggested by the statement of the theorem that for any price change all factor returns except one must fall. That is, they must have a relatively similar fate, suggesting fairly similar intensity use. The inequality that suffices is shown in (7):

\[
\frac{\theta_{ti}}{\theta_{ki}} - \frac{\theta_{tj}}{\theta_{kj}} > \sum_{s \neq k, i, j} \left| \frac{\theta_{si}}{\theta_{ki}} - \frac{\theta_{sj}}{\theta_{kj}} \right| \quad \text{for all } i, j, k \neq i.
\]  
(7)

That is, condition (6) is not strong enough; the difference between the two terms in (6) must exceed the absolute value of similar differences in all the unintensive factors (whose returns all must fall). As occasionally happens, an article by John Chipman (1969) in the same issue of the same journal provided a condition sufficient for a weaker result, namely that the elements along the diagonal all be positive and exceed unity, regardless of signs off the diagonal. His condition met the same fate – sufficient for the 3×3 case but not higher. Mitra and Jones (1999) provided a sufficient condition for the \(n \times n\) case.

It is possible to argue that these conditions are so strong as to suggest the Stolper–Samuelson and Rybczynski theorems really do not generalize. However, there is a form of the Stolper–Samuelson theorem that does generalize to higher dimensions with relatively little structure and, arguably, captures the essence of the original 1941 result. Stolper and Samuelson addressed the question of a particular government policy on real wages – the imposition of a tariff. But consider a more general question. Suppose an arbitrary factor of production seeks government aid sufficient to have its real return improved in a non-transparent fashion, that is, without a direct payment (out of tariff or any other source of government revenue). It is to be done by changes in taxation or government demand that would affect commodity prices. What would be required? Very little, as shown in Jones (1985; 2006b). Suppose there is little or no joint production (to be discussed below), and that there is a sufficient number of commodities (at least equal to the number of factors). These conditions suffice to ensure that there exists a subset of commodities that, if their prices are raised by the same relative amount with no other
commodity price changes, the real return to the particular factor is guaranteed to increase. This result should have pride of place in the field of political economy and represents a significant generalization of the original Stolper–Samuelson result. The kind of detailed requirements shown by (6) and (7) is not necessary as long as a single commodity is not by itself required to do the job and as long as (along with Chipman, 1969) it is not required that all other factors lose. Indeed, the favoured factor might well appreciate not standing nakedly as the only winner.

There are a few special cases of the \( n \times n \) Heckscher–Ohlin setting that deserve mention. The most important might be the contribution of Roy Ruffin (1988). Ruffin redefines the Ricardian setting in which each country has a distinct labour force whose productivities in producing a number of goods differ from those in other countries. Instead of having each type of labour restricted to a single country, Ruffin suggests letting each country be populated by a wide variety of labour types, with the relative supplies of each type differing from country to country. This shifts the focus to relative endowment differences among countries, with the same technologies (a single type of labour is the same no matter where located). The key feature of such a model is that there is not only no joint production of outputs, there is no need for any single factor to have to work jointly with any others to produce commodities. As a consequence, factor prices are always equalized by free trade in commodities. Furthermore, each country's transformation surface looks just like that of a world transformation surface in the Ricardian model. In the two-commodity case this is a broken, bowed out, join of the two linear schedules for each country. In higher dimensions there are various dimensional ‘facets’ down to those of zero-dimension, that is, points at which each type of labour is fully employed in a different commodity. Except for the relative size of these facets, each country's transformation curve looks like that of any other country. At given commodity prices the common ‘price plane’ is ‘tangent’ to each surface such that each labour type is assigned to the same commodities in any country. At free-trade prices the relative production pattern in any country exactly mirrors the relative labour supplies and productivity of labour in that country.

Another special version, one that does give the Kemp–Wegge strong results, is the ‘produced mobile factor’ structure introduced by Jones and Marjit (1985; 1991). Imagine an \( \{(n + 1) \times n\} \) specific-factors structure, with \( n \) specific factors and a single factor mobile between sectors. This is often taken to be labour, but instead, suppose it is a mobile input that is produced by all the specific factors. (That is, each ‘specific’ factor produces a particular commodity and, in addition, joins with other factors to produce the mobile factor.) This reduces to an \( n \times n \) model with strong Stolper–Samuelson properties.

Fred Gruen and Max Corden (1970) introduced a simple model in discussing the possibility that a country such as Australia might, in levying a tariff, worsen its terms of trade. There are two sectors in the economy, manufacturing and agriculture. The manufacturing sector consists of a single commodity produced by labour and capital. Agriculture has two commodities, wheat and wool, each using labour and land. Thus, this is a special form of 3×3 model. As developed by Jones and Marjit (1992), it is possible to consider the \( n \times n \) version of the Gruen–Corden model in which \( (n - 2) \) sectors of the economy each use mobile labour and a type of capital specific to that sector to produce a single distinct commodity. In another sector labour and a specific type of capital produce a pair of commodities just as in the original Gruen–Corden case. An application of the Gruen and Corden model is also found in Findlay (1993).

The point of each of these special settings is that Heckscher–Ohlin models in the \( n \times n \) case need not be difficult to analyse. However, the most popular two-factor model in the many commodity case may well
be more valuable in that it focuses attention on which good or pair of goods a country produces in an
international setting. Trade allows a great degree of specialization, and this version of the Heckscher–
Ohlin model allows something that the special \( n \times n \) models, as well as the \( (n + 1) \times n \) specific-
factors model, do not, viz. treating the pattern of production as endogenous (see also Jones, 2007a;
2007b).

Joint production

Both the Stolper–Samuelson theorem and the Rybczynski theorem are essentially reflections of the
asymmetry between factors and commodities. This asymmetry is characterized by the assumption that
productive activities are non-joint: in the non-degenerate cases more than one input is required to
produce, separately, each output. Thus each commodity price change is a positive weighted average of
the changes in rewards to factors used to produce that commodity. This implies that regardless of the
ranking of commodity price changes, there is some factor reward that would rise relative to any
commodity price rise and at least one factor reward which would rise by relatively less (or fall by more)
than any commodity price change. Allowing joint production potentially destroys this asymmetry and
thus the basis for the magnification effects.

There is a small literature dealing with this issue (Jones and Scheinkman, 1977; Chang, Ethier and
Kemp, 1980; Uekawa, 1984). Much depends on the range of output proportions in any productive
activity compared with the range of input proportions. For example, in the 2×2 case suppose one activity
produces primarily the first commodity, but also a small amount of the second, while the other activity
reverses these proportions. Furthermore, suppose this ‘output’ cone of diversification contains the
standard ‘input’ cone of diversification. In this case traditional magnification effects underlying the
Stolper–Samuelson and Rybczynski theorems remain valid. New results emerge if these cones intersect
or the input cone contains the output cone. (Cones can be made comparable by using distributive shares
of inputs and outputs in activities.)

Joint production does not, by itself, interfere with the status of the factor-price equalization theorem
(Jones, 1992; but see Samuelson, 1992, for an alternative view). However, joint production does suggest
an alteration of the Heckscher–Ohlin theorem. Instead of concentrating on the link between factor
endowments and the location of commodity outputs (and therefore trading patterns), the focus is on the
location of productive activities. Each activity requires, as before, an array of inputs, and the allocation
of endowment bundles among countries helps to determine where these activities are located. The
pattern of commodity trade must then reflect, as well, the output composition of these activities.

Concluding remarks

The theory of international trade that has developed from the seminal writings of Heckscher and Ohlin is
fundamentally based on the twin observations that countries differ from each other in the composition of
their factor endowments and that productive activities are distinguished by the different relative
intensities with which factors are required. As this theory has been developed four core propositions
have served to summarize its content. The strict validity of each of these propositions has been seen to
depend upon further specification of the technology (for example, ruling out factor intensity reversals,
joint production, and non-constant returns to scale, and imposing, for some results, that countries share the same technology), demand (for example, requiring all individuals to possess identical homothetic taste patterns), or dimensionality (for example, requiring a small number of factors and commodities, or a matching number of both). To conclude this discussion of the core propositions it is possible to point out the less precise, broad message of each.

The Heckscher–Ohlin theorem

Production patterns reflect different compositions of endowments and, unless demand differences are significant, so will patterns of trade. International trade encourages specialization in production in those activities requiring factors in proportions similar to the endowment bundle and allows a country to import commodities whose factor requirements are far from proportions found at home. In some of the writings on ‘new trade theory’, assumptions are made that all varieties of a certain type of product are produced using the same factor proportions. By assumption this rules out the Heckscher–Ohlin theorem as an explanation of trade patterns. However, if varieties differ in quality, each variety could differ in factor requirements as well, serving to re-establish the relevance of the Heckscher–Ohlin theorem.

The factor-price equalization theorem

Even if the international mobility of factors of production is ruled out by national frontiers, free trade in commodities helps to even out disparities in demand relative to supply of factors and to diminish the discrepancy between factor returns among countries. Two or more countries sharing the same technology will find that free trade brings factor returns to absolute equality if their endowments are sufficiently similar and they produce in common a sufficient number of commodities (at least equal to the number of distinct productive factors).

The Stolper–Samuelson theorem

Changes in relative commodity prices, such as those brought about by trade or interferences in trade, have strong asymmetric effects on factor rewards. If no joint production prevails, some factors find their real rewards unambiguously raised and other rewards are unambiguously lowered by relative price changes. If, further, the number of factors equals the number of produced commodities, as in the original 2 × 2 setting, and production is non-joint, relative commodity price changes can be constructed which, without the aid of any direct subsidies, will raise the real reward of any particular factor regardless of its taste pattern.

The Rybczynski theorem

Unbalanced growth in factor supplies tends, at given commodity prices, to lead to stronger asymmetric changes in outputs. If the numbers of factors and commodities are evenly matched and production is non-joint, this asymmetry entails that growth in some, but not all, factors (when commodity prices are given) serves to force an actual reduction in one or more outputs. By similar reasoning, differences in the
composition of endowments among countries with similar technologies results in stronger asymmetries in production patterns when all face free trade commodity prices. If tastes are somewhat similar, these endowments differences are apt to support the trading patterns described by the Heckscher–Ohlin theorem.

Article

Hedging is the purchasing of an asset or portfolio of assets in order to insure against wealth fluctuations from other sources. A hedge portfolio is any asset or collection of assets purchased by one or more agents for hedging. A grain dealer may hedge against losses on an inventory of grain by selling grain futures; a Middle Eastern businessman may hedge against political turmoil (and the resulting losses) by buying gold; a pension fund may hedge against capital losses on its equity portfolio by buying stock index put options.

1. A competitive equilibrium model of hedging
The fundamental concepts of hedging can best be described in the state space model. Consider a one-period economy with $M$ agents and one end-of-period consumption good. For simplicity, assume that there is no consumption at the beginning of the period. Each agent possesses a real asset which produces a random amount of the consumption good at the end of the period. Agents have homogeneous beliefs. There are $N$ possible states of nature, with probabilities $\Pr(1), \ldots, \Pr(N)$. The agents have concave, possibly state-dependent utility functions and wish to maximize the expected utility of end-of-period consumption. Let $U_j(C_j, \theta_i)$ denote the end-of-period utility of agent $j$ given that his consumption is $C_j$ and the state of nature is $\theta_i$.

A financial asset is a claim to a random amount of end-of-period output which is traded between agents at the beginning of the period. A hedge portfolio is a particular type of financial asset or collection of financial assets which protects an agent against some particular risky outcome(s).

The analysis is simplest if we assume that the hedge portfolio consists of a mixed asset-liability with positive payoffs in some states and negative payoffs in other states, balanced so as to give a competitive equilibrium price of zero. Under this formulation a hedge portfolio is a portfolio which pays off positively in states where the agent would otherwise have a high marginal utility of consumption (that is, ‘bad’ states) and negatively in states where he would otherwise have a low marginal utility of consumption. If the agent's marginal utility is equalized across the relevant states after purchasing the hedge portfolio, then he is fully hedged; if the hedge position lowers but does not eliminate the disparity, then he is partially hedged.

Who takes the other side of the hedging transaction? There are three possibilities. First, if there exist two agents who have real asset cash flows which vary inversely, then they can trade in a way which allows both to hedge simultaneously. For example, the grain dealer who holds an inventory of grain may be able to sell a futures contract to a bread producer who has committed himself to using grain at a later stage of his production process. Both parties consider themselves as hedging. Second, one agent may be less risk-averse towards certain states of nature than another. The less risk-averse may be willing to sell the hedge asset to the more risk-averse at a price which produces mutual gains in expected utility. Third, the hedging agent may be able to trade small quantities of the hedge asset with many agents, who can then eliminate all or most of the risk of the trade by combining the asset with many others (that is, by diversifying away the risk). For example, insurance companies can sell fire insurance policies to many individuals and leave very little risk to be absorbed by the company's shareholders.

Let the number of distinct types of assets be $K$ and let $Y$ denote the $N \times K$ matrix of their payoffs in the $N$ possible states of nature. The set of available trades is $\text{span}(Y^*)$ where $\text{span}(\cdot)$ denotes the subspace spanned by the matrix. In an economy without frictions, agents will create new financial assets until all mutually beneficial trade opportunities are in $\text{span}(Y^*)$. All mutually beneficial trades have been consummated if there exist positive scalars $\lambda_1\ldots\lambda_M$ such that

$$\lambda_j U_j'(C_j, \theta_i) = \lambda_h U_h'(C_h, \theta_i) \quad i = 1, \ldots, N; \quad j, h = 1, \ldots, M$$

(1)
where $U'$ denotes the first derivative with respect to consumption. The invisible hand drives agents towards creating all the types of financial assets which can lead to mutually beneficial trades. However, there are many external factors which can offset this tendency. If agents have some control over outcomes, then moral hazard problems may limit hedging opportunities. For example, agents may not be able to hedge against changes in labour income if work requires imperfectly observable effort. If agents have special knowledge, then adverse selection can similarly limit trade. If a car owner knows more about its quality than a prospective buyer, then the owner cannot sell his car at a reasonable price when he experiences financial distress. The administrative costs of trade can also limit hedging before the full efficiency condition (1) is fulfilled.

The model described above is static. In an intertemporal model, dynamic strategies increase the set of hedging opportunities beyond the linear span of the matrix of asset payoffs. Agents can create a rich set of payoff claims by dynamically varying the proportions invested in the individual assets. With continuous trading, this process reaches its natural limit: if an asset price follows Brownian motion, then the continuously adjusted portfolio consisting of only the risky asset and riskless asset can be constructed which replicates the payoff to any put or call option on the risky asset.

The proliferation of complex financial assets, such as options on futures and interest rate and currency options, and the increased sophistication of traders has led to a bewildering array of dynamic hedging strategies, especially by large institutional investors. Portfolio insurance provides a good example of the kind of sophisticated new hedging instrument which can be created with a dynamic trading strategy.

Consider a pension fund with a large equity portfolio and an aversion to large capital losses on this portfolio. The portfolio insurance strategy can put a floor on the random rate of return to the pension fund's portfolio. The return floor can be any rate lower than the available riskless rate (it can be a negative net return, so that the fund bounds its losses rather than assuring itself a small gain). The strategy works as follows. At the starting date of the insurance strategy, the fund has most of its money invested in equities and a small proportion in a riskless asset (that is, government notes). If the equities fall in price, the fund sells some of the equities and places the cash in the riskless asset. If equity prices continue to fall, the fund increases the proportion of investment in the riskless asset. If there is a sustained fall in equity prices, the fund will end the insurance programme invested entirely in the riskless asset. It will have earned a rate equal to the pre-chosen minimally acceptable return. The fund makes a ‘soft landing’ at this minimal value: the proportion of money invested in the riskless asset approaches 1 as the value of the portfolio approaches the minimally acceptable level.

Portfolio insurance is not a free lunch. In exchange for the return floor, the pension fund sacrifices some of the upside potential of pure equity investment. For example, if the equity market declines sharply and then rises, the fund will miss the upturn, since it will have defensively decreased its position in equities before the upturn.

There are numerous other dynamic hedging strategies, not only in equity markets but in fixed income, currency and options markets. In terms of the volume of trade, hedging in financial markets now greatly outpaces activity in commodities futures markets, the original and classic example of markets often used for hedging.

2 Risk premia and hedging

An economically interesting question is whether agents ‘pay a premium’ to hedge. Assume again that
the current price of the hedge portfolio is set to zero by appropriate balancing of the asset and liability sides of the hedge (a futures contract is a natural example). If the expected cash flow is negative (positive) next period, then the hedge portfolio carries a positive (negative) implicit asset pricing risk premium. If the expected cash flow is zero, then the implicit asset pricing risk premium is zero. If we used returns rather than prices, then the expected return premium would have the opposite sign from the asset pricing premium.

Much of the early literature on hedging was centred on hedging in commodities futures contracts. One of the key questions was whether agents who sold futures pay a positive risk premium. Keynes (1930) considers this problem for the case of commodities futures contracts. He argues that the natural supply of short sellers (sellers of futures contracts) outnumbers long hedgers (buyers) in this market. Therefore, the implicit risk premium for holding a futures contract should be negative, in order to induce other agents (henceforth called speculators) to absorb the excess hedging demand of short hedgers. This will be true if the futures price increases on average over the life of the contract, so that the expected cash flow from holding the contract is positive.

The empirical evidence for this positive trend (sometimes called normal backwardation) in commodities futures market prices is weak at best. Keynes's analysis implicitly assumes that the commodity futures market is isolated from other assets so that hedgers must pay other agents (the speculators) a premium to induce them to take a position in the market. In an integrated set of asset markets, hedgers need not pay any premium to induce other agents to trade. Rather, the existence of a risk premium depends upon the covariance between the payoffs to the hedge asset and the economy-wide risks faced by all the agents. If the hedge asset is uncorrelated with market-wide risks, then it will carry no risk premium, even though it may have a high value to a particular hedger due to his specific income stream. The hedge asset which protects against market risk will carry a risk premium.

There is another source of return to speculators, which is not captured in the competitive pricing model. Speculators may charge an explicit or implicit bid ask spread when trading with hedgers. If hedgers buy and hold for a long period, then this is equivalent to the asset pricing risk premium described above. However, if hedgers trade frequently, then the bid ask spread can lower their realized returns, and raise the realized returns of speculators, without affecting the observed long-run return premium of the hedge asset as reflected in transactions prices. This may explain the lack of empirical evidence for normal backwardation in commodities futures market. This effect of the bid ask spread was not recognized in most of the early literature on commodity futures markets.

The bid ask spread need not be explicit. Even open-floor markets will contain a set of implicit bid ask spreads, to the extent that traders’ strategies reflect a greater willingness to sell at higher prices and to buy at lower ones. One can view the feverish activity which is common in floor trading as speculators searching for transactions at the outer edges of an implicit bid ask spread. Hedgers, who are off the floor and are more anxious to complete a particular trade, take the losing side of the implicit spread.

3 The role of hedgers in a market with heterogeneous information

The model in sections 1 and 2 assumes homogeneous information across agents. If agents have differential information about the payoffs to assets, then the trading strategies of rational agents cannot take this simple competitive form. Agents must treat trade opportunities as signals of the information of other agents about the value of the trade.
The presence of differential information can lead to fewer hedging opportunities and/or raise the expected cost of hedging. Milgrom and Stokey (1982) show that rational agents will not trade solely because they have different beliefs about the value of an asset. If agents are distinguished merely by their differential information, then they will refuse all trades, since the willingness of the other agents to trade signals that the terms are unfavourable. This means that a financial asset market will fail to open in the absence of other motives for trade. This is a market failure due to adverse selection. The need of some agents for hedging can provide an additional reason for trade which overcomes the adverse selection problem and eliminates the market failure. Hedgers will be willing to trade even if they suspect that the other party to the transaction has superior information. Informed agents will be gaining at the expense of hedgers, but they will also be providing an insurance or liquidity service to hedgers, and so hedgers may be willing to trade with them despite their informational disadvantage. This in turn has the side effect of permitting superior information to be reflected in market prices.

I follow Glosten and Milgrom (1985) and assume that there exists a costless, competitive, risk-neutral market maker who intervenes in all trades. This is for analytical convenience and is not necessary to the basic model. Suppose that certain agents (hedgers) have a strong preference for a given asset, that is, their preference is such that they will buy (and sell) some non-zero amount at a price higher (lower) than the market-clearing equilibrium price. This implies that they are willing to trade even if they must pay a bid ask spread around the equilibrium price. Informed agents, henceforth speculators, will also trade despite a bid ask spread as long as the expected profit from their superior information is larger than the bid ask spread. The market maker’s resulting equilibrium bid ask spread will allow the hedgers to trade at an expected loss and the speculators at an expected gain, leaving the market maker with an expected profit of zero (the equilibrium condition). The market maker will respond to the net demands of all traders (which partially reveals the net demand of speculators) to adjust the bid and ask prices, and so (partially) capture in the market price the superior information of speculators.

One interesting feature of this model is the symbiotic roles of speculators and hedgers. Without speculators (informed traders), the hedgers would lose liquidity; without hedgers, speculators would lose the opportunity to profit from their superior information. Without both speculators and hedgers, the price in the market would no longer provide a useful signal for agents making production and consumption decisions. Kyle (1984) develops a model in which the symbiotic relationship is made clear and describes the effects of more or fewer speculators or hedgers on the informational efficiency and liquidity of the market. Some of the results are counter-intuitive: for instance, increasing the number of hedgers, who are uninformed, can increase the informational efficiency of prices.

4 Hedging in a mean variance model

The mean variance preference model provides a useful framework for empirical and applied analysis of hedging. Suppose that an investor’s utility is given by the expected value of his random end-of-period endowment, $X$, minus some multiple of the variance of this endowment:

$$U(X) = E[X] - a\, \text{var}[X]$$
Let the hedging instrument have a current price of zero and random end-of-period payoff $Y$. It is easy to show that the investor’s optimal position in the hedging instrument is

$$w = \frac{E[Y]}{(2 \sigma \var{Y})} - \frac{\sigma \var{X, Y}}{\var{Y}}.$$  

(See Rolfo, 1980, for the derivation). The first additive part of this optimal hedging position, $E[Y] / (2 \sigma \var{Y})$, is called the speculative hedge. The second part, $-\sigma \var{X, Y} / \var{Y}$, is called the pure hedge. Some analysts (such as Duffie, 1989) argue that in practice uninformed hedgers should ignore the speculative hedge and set the hedge position equal to the pure hedge. The justification is that the speculative hedge requires predictions about the expected payoff on the hedging instrument, whereas the pure hedge uses only the covariance of the hedging instrument and the random endowment. In many cases, covariances are more stable over time and more precisely estimated than expected payoffs. Setting the hedge position equal to the pure hedge is equivalent to minimizing variance instead of optimizing over a mean variance criterion.

The mean variance preference model provides a useful link to empirical analysis of hedging. Suppose that we observe a sample of realized random endowments and hedging instrument payoffs. Consider an ordinary least squares regression of the random endowment on the payoffs to the hedging instrument:

$$X = \alpha + \beta Y + \varepsilon.$$  

The coefficient $\beta$ estimates (minus) the pure hedge. The R-squared from this regression estimates the proportion of endowment variance which is eliminated by setting the hedge position equal to the pure hedge.

5 Risk premia on hedge portfolios and general equilibrium pricing

In section 2, I described two types of hedge portfolios – those with and those without risk premia – and how the distinction between them depends on the covariance between the hedge portfolio returns and the market-wide risks in the economy. In this section, I describe the relationship between hedge portfolios which protect against market-wide risks and the general equilibrium pricing of assets.

Let $Q_t$ denote the discounted expected utility of lifetime consumption for some agent at time $t$: 
\[ Q_t = E_t \left[ \sum_{\tau = t+1}^{\infty} \rho^\tau U(C_{\tau}, \theta_{\tau}) \right] \]

where \( \rho \) is the agent's discount factor and \( U(.,.) \) is his utility function. Let \( f_t \) denote the change in discounted expected utility given the change in the agent's time \( t \) wealth:

\[
  f_t = \frac{\partial Q_t}{\partial W_t}
\]

where \( W_t \) is his wealth at time \( t \). Note that, at time \( t - 1 \), \( f_t \) is a random variable. Let \( r_{it} \) denote the return from time \( t - 1 \) to \( t \) of the \( i^{th} \) financial asset. If the agent holds an equilibrium amount of this asset then the following first-order condition is satisfied:

\[
  E_{t-1}[r_{it} f_t] = \frac{\partial U(C_{t-1}, \theta_{t-1})}{\partial C_{t-1}}
\]

which can be rewritten (using \( E[ab] = E[a]E[b] + \text{cov}[a, b] \)) as:

\[
  E_{t-1}[r_{it}] = r_{0t} + \left( \frac{1}{Y} \right) \text{cov}_{t-1}[r_{it}, f_t]
\]

where \( Y = \frac{\partial U(C_{t-1}, \theta_{t-1})}{\partial C_{t-1}} \) and \( r_{0t} \) is the expected return on an asset with a riskless payoff at time \( t \).

Suppose that, at time \( t - 1 \), \( f_t \) equals a sum of a set of \( K \) uncorrelated random variables \( Z_{1t}, \ldots, Z_{Kt} \):

\[
  f_t = Z_{1t} + \ldots + Z_{Kt}
\]
The variables $Z_{1t}, \ldots, Z_{Kt}$ describe the $K$ random shocks which affect the agent's marginal utility. They could be interest rate movements, output shocks, inflation shocks, and so on. Assume that there exists a set of $K$ portfolios with returns $r_{1t}^*, \ldots, r_{Kt}^*$ such that the $j^{th}$ portfolio has perfect negative correlation with $Z_{jt}$:

$$\text{cov}_{t-1}[r_{jt}^*, Z_{jt}] = \sqrt{\text{var}_{t-1}[r_{jt}^*] \text{var}_{t-1}[Z_{jt}]} \frac{1}{2}. \tag{4}$$

These portfolios are potential hedges against the $K$ types of risks which affect the investor. (The agent will short sell the portfolio to hedge since the portfolio return varies inversely with marginal utility.) I call $r_{1t}^*, \ldots, r_{Kt}^*$ an indexing set of hedge portfolios since the portfolios index the random shocks to the agent's marginal utility. Using (3) and (4) we can rewrite (2) as:

$$E_{t-1}[r_{it}] = r_{0t} + \beta_{1it} \pi_{1t} + \ldots + \beta_{Kit} \pi_{Kt} \tag{5}$$

where

$$\beta_{ijt} = \frac{\text{cov}_{t-1}[r_{it}, r_{jt}^*]}{\text{var}_{t-1}[r_{jt}^*]}$$

and

$$\pi_{jt} = E_{t-1}[r_{jt}^* - r_{0t}].$$

Equation (5) is an asset pricing relationship: it says that the expected return on any asset equals the riskless return plus a linear combination of the covariances of the asset's return with an indexing set of hedge portfolios.
6 Explaining corporate hedging

The analysis in the previous sections considers hedging from the perspective of an individual investor and consumer. In practice, most financial hedging activity is undertaken by corporations rather than by individuals. If corporations issue widely held common stock, then hedging activity between them appears unnecessary. The shareholders of the corporation are its ultimate risk bearers, and they will not benefit from hedging activity at the corporate level. So, for example, an investor with shares in both an oil-producing industry and an oil-consuming industry will not want firms in the two industries to hedge with oil futures, taking opposite hedge positions (one long oil futures and the other short oil futures). From the shareholder's perspective, the cash flows from these offsetting hedges will be diversified away at the portfolio level. The ultimate shareholder pays the transactions costs of hedging by the corporations, but does not experience any aggregate risk reduction in his portfolio.

There are several explanations for the prevalence of corporate hedging. One explanation relies on the costs of financial distress. By hedging, the corporation lowers the probability of bankruptcy or near-bankruptcy, and so increases its average market value. Another explanation relates corporate hedging to the agency costs of hiring managers to run the firm. The firm's managers have a non-diversified exposure to the profitability of the firm; hedging by the corporation more closely aligns the interests of the shareholders and managers, and also allows the shareholders to pay the managers less on average since the managers’ risk exposure is reduced. A third explanation relies on the progressiveness of the corporate tax system, which encourages corporations to hedge so as to smooth taxable earnings and thereby lower their average tax bill.

Bibliography

**How to cite this article**

Hedonic price functions describe the equilibrium relationships between characteristics of products and their prices. They are used to predict prices of new goods, to adjust for quality change in price indexes, and to measure consumer and producer valuations of differentiated products. They emerge as market outcomes from both competitive and non-competitive markets. The functional form is determined by the distribution of buyers and their preferences, the distribution of sellers and their costs, and the structure of competition in the market.

A hedonic price function describes the equilibrium relationship between the economically relevant characteristics of a product or service (or bundle of products) and its price. For example, in a simple labour economics model the hedonic wage function might describe how the wages of a worker depend on education, experience and skill. In a simple housing economics model, the hedonic house price might describe how the price of a house depends on geographic location, size, and quality. In each case, the hedonic price function describes equilibrium (not necessarily competitive) valuations of the economically relevant characteristics of the product.

In empirical applications, statistical estimates of hedonic price functions have primarily been used to calculate quality adjusted price indexes for goods and to measure consumer valuations or producer costs of product characteristics. They have been used to study markets for agricultural products, automobiles, labour, houses, computers, and myriad other differentiated commodities. They have been used to measure quality change in private goods markets and to measure consumer valuations of changes in public goods such as clean air, schools or transport infrastructure. In all these applications, hedonic methods are crucial because the goods in question are not homogenous and their value to buyers and sellers varies systematically with characteristics.

Key questions to be answered when developing a hedonic model to analyse a product market are what are the economically relevant characteristics of the product and what is the market environment that generates the hedonic equilibrium price. Given answers to these questions, a key theoretical goal of hedonic analysis is to determine the theoretical relationship between these market equilibrium prices and underlying structural features of the economy such as producer costs and consumer preferences. Two key empirical goals of hedonic analysis are to understand when statistical estimates of hedonic relationships provide good out-of-sample predictions of prices and to understand what structural information these statistical relationships provide about costs and preferences.

1 General hedonic demand

Hedonic models make various assumptions about whether the space of feasible characteristics is discrete or is a continuum, and whether the characteristics embodied in different products can be bundled or unbundled. This section discusses a general model of hedonic demand that encompasses these special cases. The supply side of the market and various
notions of equilibrium are discussed in section 2.

Each consumer who participates in the hedonic market derives utility from a vector of characteristics \( z \in Z_m \subseteq \mathbb{R}^n \). The bundle \( z \) is obtained either by buying a single product that embodies \( z \) or by buying a set of products that together produce \( z \). In either case the hedonic cost or price is \( p(z) \). The set \( Z_m \) is the feasible set given current market conditions. The set \( Z_m \) could be a finite set or it could be a continuum. Each consumer also has the option not to participate in the hedonic market, in which case they obtain reservation utility \( u_0 \).

Assume that characteristics are defined so that utility is increasing in each element of \( z \). Also, assume that utility is decreasing in \( p(z) \).

Every consumer is represented by a type \( x \in X \subseteq \mathbb{R}^P \). The space \( X \) is the space of all consumer types. The vector \( x \) is a vector of consumer characteristics (such as income, education or preference parameters) that affects utility. Consumer heterogeneity is an important feature of hedonic models.

Given hedonic price \( p(z) \), consumer \( x \) chooses \( z \in Z_m \) to maximize utility \( u(x, z, p(z)) \). That is, they solve

\[
\max_{\{z \in Z_m\}} \left\{ u(x, z, p(z)) \right\}
\]

The solution \( z = d(x) \) is the hedonic demand function (or correspondence) for consumer \( x \).

Several features of the model are important. First, \( z \) is a complete list of the product characteristics that both affect consumer utility and are known to the consumer at time of purchase. In the housing market example, \( z \) could measure geographic location, age of the dwelling, lot size, number of rooms, size of the yard, and so on. Second, there may be additional characteristics of the good that affect \textit{ex post} utility but that are not known to the consumer at time of purchase. In such cases, the utility function should be interpreted as the expected utility from purchasing a good with known characteristics \( z \). Third, buyer utility depends on \( x \) and on \( z \). Two consumers, \( x_1 \) and \( x_2 \), with \( \neq x_2 \), will generally choose different bundles \( (z_1, p(z_1)) \) and \( (z_2, p(z_2)) \) and will obtain different levels of utility.

1.1 Continuous choice version

To specialize to the case where \( Z_m \) is a compact convex subset of \( \mathbb{R}^n \), both \( u \) and \( p \) are differentiable and the consumer maximization problem has an interior solution, the first-order condition describing the consumer’s hedonic demand is

\[
\frac{\partial u(x, z, p(z))}{\partial z} + \frac{\partial u(x, z, p(z))}{\partial p} \frac{\partial p(z)}{\partial z} = 0
\]

which can be rewritten as

\[
\frac{\partial p(z)}{\partial z} = - \left( \frac{\partial u(x, z, p(z))}{\partial z} \right) \left( \frac{\partial u(x, z, p(z))}{\partial p} \right)
\]

The marginal price at \( z \) equals the marginal rate of substitution of the consumer \( x \) who chooses \( z \). In the quasi-linear utility case \( u(x, z, p(z)) = u(x, z) - p(z) \) and eq. (3) becomes
These results are the basis for the intuition that the slope of the hedonic price function measures consumers’ marginal willingness to pay. Figure 1 illustrates. Consumers $x_1$ and $x_2$ optimally choose bundles $z_1$ and $z_2$ respectively. At $z_1$, the marginal price equals the marginal willingness to pay of consumer $x_1$. However, it is less than the marginal willingness to pay of consumer $x_2$. At $z_2$, the marginal price equals the marginal willingness to pay of $x_2$ but is greater than the marginal willingness to pay of $x_1$. 

Figure 1
The hedonic price function reveals precise information about consumers $x_1$ and $x_2$ at points $z_1$ and $z_2$ respectively. At all other person-location pairs, it reveals only bounds on willingness to pay. It also reveals very little about how consumers $x_1$ and $x_2$ will react to large changes in the shape of the price function. More precise information requires the estimation of consumer preferences.

### 1.2 Discrete choice version

If the marginal conditions in (3) and (4) are replaced by inequalities, the qualitative interpretations above apply equally to economies in which $Z_m$ is finite. Suppose there are $J$ elements in $Z_m$. Let $z_j$ be the $j$'th element in $Z_m$ and let $P_j = P(z_j)$ for $j = 1, \ldots, J$. In the quasi-linear case, if consumer $x$ chooses $z_j$, then

$$u(x, z_j) - p_j \geq u(x, z_k) - p_k$$

for all $k \in \{1, \ldots, J\}$.

Consider the set of consumers who choose $z_j$ and for whom

$$u(x, z_j) - p_j = u(x, z_k) - p_k$$

(5)

for some $k \neq j$. These consumers are indifferent between bundle $z_j$ at price $p_j$ and bundle $z_k$ at price $p_k$. The difference in prices between $z_j$ and $z_k$ exactly compensates for the difference in utilities. For these indifferent consumers, willingness to pay for $z_j$ over $z_k$ is

$$p_j - p_k = u(x, z_j) - u(x, z_k).$$
This is the discrete analog of the marginal willingness to pay.
Equation (5) only holds for those who are indifferent between \( j \) and \( k \). For those who are not indifferent, the willingness to pay for \( z_j \) over \( z_k \) is strictly larger than the price. That is

\[
    u(x, z_j) - u(x, z_k) > p_j - p_k.
\]

When the set of available alternatives \( Z_m \) is finite, the hedonic price function provides a precise measure of willingness to pay for consumers who are indifferent between options and provides bounds on willingness to pay for consumers who strictly prefer one option to others.

1.3 Single product demand version

In single product demand models, the vector \( z \) measures the characteristics of the unique product type that is chosen. These models assume that households cannot buy two separate products with characteristics \( z_1 \) and \( z_2 \) and combine their characteristics to obtain some other bundle \( z_3 \) (Rosen, 1974). These models do allow consumers to choose both a product type \( z \) and a quantity. To see this, rewrite the utility function in (1) as

\[
    u(x, z, p(z)) = \max_{\{q\}} \left\{ b(x - q\varphi(z), z, q) \right\}
\]

where \( q \) is the quantity of product type \( z \) and \( x \) is income. This is the primary model used to study location choices and demand for land in urban economic models. See Fujita (1991).

1.4 Home production version

Home production models assume that consumers purchase a vector of goods in quantities \( q \in \mathbb{R}^m_+ \) at market prices \( \pi \in \mathbb{R}^m_+ \) and produce the bundle \( z \) from the goods purchased. See Gorman (1980), Lancaster (1966), and Muellbauer (1974). In home production hedonic models, consumers have a technology \( f : \mathbb{R}^n \to \mathbb{R}^n \) describing the production possibility frontier. Given purchases of \( q \) units of market goods, any bundle \( z \) that satisfies the restriction \( f(z, q) = 0 \) is feasible.

Given market prices \( \pi \) and technology \( f \), the cost of obtaining the bundle \( z \) is

\[
    p(z) = \min_{\{q\}} \left\{ \pi \cdot q \quad \text{subject to} \quad f(z, q) = 0 \right\}
\]

Thus, the hedonic price \( p(z) \) is the minimum cost of obtaining bundle \( z \) given market prices \( \pi \) and technology \( f \). Given \( p(z) \), consumers maximize the utility given in (1). The single-product demand model is a special case of the home production model.

In the Gorman–Lancaster version of the model, the technology is linear and \( f(z, q) = z - Aq \) where \( A \) is a \( n \times n \) matrix. Each market good contains a fixed quantity of characteristics. The total amount available for consumption is the sum of characteristics across all goods purchased.
1.5 Hedonic cost of living index

In each of these models, one can calculate various hedonic cost of living indexes. See Pollak (1989) for details of many alternatives. This section discusses one alternative.

Consider a consumer who purchases a vector of quantities of homogenous goods $q$ with linear prices $\pi$ and a single differentiated product with characteristics $z$ and hedonic price $p(z)$. When prices are $(\pi, p)$, the cost of obtaining utility level $u_0$ is

$$
\xi(\pi, p, u_0) = \min_{q, z} \left\{ n \cdot q \text{ subject to } u(q, z) \geq u_0 \right\}
$$

(7)

If prices change from $(\pi_0, p_0)$ to $(\pi_1, p_1)$, then the constant utility hedonic cost of living index is

$$
\frac{\xi(\pi_1, p_1, u_0)}{\xi(\pi_0, p_0, u_0)}.
$$

This cost index hold utility constant and allows consumers to alter consumption of $q$ and $z$ in response to changing prices. When consumer preferences are unknown, this theoretical index cannot be calculated. With data on prices and quantities, empirical alternatives include the Laspeyres index and the Paasch index.

Let $(q_0, z_0)$ solve (7) when prices are $(\pi_0, p_0)$ in period zero. Let prices in period one be $(\pi_1, p_1)$. Then a hedonic Laspeyres index is

$$
L(q_1, p_1, q_0, p_0, x_0, z_0) = \frac{\pi_1 \cdot q_0 + p_1(z_0)}{\pi_0 \cdot q_0 + p_0(z_0)} \cdot \frac{\xi(\pi_1, p_1, u_0)}{\xi(\pi_0, p_0, u_0)}.
$$

This index holds the consumption bundle $(q_0, z_0)$ constant at initial levels. Like the standard Laspeyres index, it is an overestimate of the cost of living index because it ignores a consumer’s ability to alter consumption in response to changing prices. If some components of $z$ are exogenous (for example, public goods like air quality or public safety), alternative indexes can be defined by including the time varying exogenous elements of $z$ as arguments in the cost function.

One major problem with the index is that the set of available products often changes rapidly over time. If product $z_0$ is not traded in period 1, then $p_1(z_0)$ will not be observed. Pakes (2003) shows that an estimate of $p_1(z_0)$ based on observed prices is an upper bound under certain circumstances. A better option is to calculate the virtual price $p_1^{\text{V}}(z_0)$ that makes the household indifferent between purchasing $z_0$ at price $p_1^{\text{V}}(z_0)$ and purchasing $z_1$ (the product actually chosen in period 1) at price $p_1(z_1)$. The virtual price satisfies

$$
p_1^{\text{V}}(z_0) = p_1(z_1) - (u(x, z_1) - u(x, z_0)).
$$

Data on prices and quantities can be used to bound the virtual price. Precise results require estimation of consumer preferences.
Another major problem is that statistical authorities, as discussed in section 3, do not observe the elements of \( z \) that enter consumer preferences. A third major problem is that time constraints and cost constraints place severe limitations on data collection and analysis for use in practical price index calculations. Triplett (2004) provides a comprehensive overview of these issues.

2 Market equilibrium

Hedonic prices emerge as equilibrium outcomes from a market environment. They might emerge from a purely competitive environment in which neither buyers nor sellers have power to influence prices or they might emerge from an imperfectly competitive environment in which either buyers or sellers have market power. They may be observed in arm's-length transactions or unobserved as in black-market wage contracts or implicit marriage contracts. In general, the hedonic price function in a market is a nonlinear function of the characteristics \( z \). Its functional form is determined by the distribution of buyers and their preferences, by the distribution of sellers and their costs, and by the type of equilibrium in the market. Special cases exist where more can be said. If bundles of characteristics can be unbundled, arbitrage leads to a linear hedonic price (Rosen, 1974). In the Gorman–Lancaster model, the hedonic price function is piece-wise linear (see Pollak, 1983, or Heckman and Scheinkman, 1987). In the Tinbergen (1956) model, the hedonic price is quadratic. When both buyer utility and seller costs depend on \( z \) only through an index \( q(z) \), the hedonic price function satisfies \( p(z) = \tilde{p}(q(z)) \).

2.1 Competitive hedonic equilibrium

Consider a one-dimensional Tinbergen–Rosen model in which consumers of type \( x \in \mathbb{R}^+ \) choose \( z \in \mathbb{R}^+ \). Assume that consumer utility is \( u(x, z) = x \partial(z) \) where \( x \frac{\partial \tilde{z}(z)}{\partial z} > 0 \). Note that \( \frac{\partial^2 u(x, z)}{\partial x \partial z} = \frac{\partial \tilde{z}(z)}{\partial z} > 0 \). Assume that the distribution of consumer types is described by the distribution function \( F_x(x) \) with density function \( f_x(x) \) and support \( \mathbb{R}^+ \).

Treat the supply side symmetrically. Assume that firms of type \( y \in \mathbb{R}^+ \) have costs of producing one unit of product \( z \) of \( c(y, z) = \frac{\xi(z)}{y} \) where \( \frac{1}{y^2} \frac{\partial^2 \xi(z)}{\partial z} > 0 \). Note that \( \frac{\partial^2 c(y, z)}{\partial y \partial z} = \left( -\frac{1}{y^2} \right) \frac{\partial \xi(z)}{\partial z} < 0 \). The distribution function describing the distribution of firms is \( F_y(y) \) with density \( f_y(y) \) and support \( \mathbb{R}^+ \).

Given a differentiable price, consumers solve

\[
\max_{\{z\}} \left\{ x \partial(z) - \rho(z) \right\}.
\]

Assume there is a unique interior optimizer. The consumer first order condition is

\[
x \frac{\partial \partial(z)}{\partial z} - \frac{\partial \rho(z)}{\partial z} = 0.
\]

This equation implicitly defines the buyer demand function \( z = \partial(x) \) and the inverse demand function \( x = \tilde{\partial}(z) \). Note that the consumer second order condition implies that \( \frac{\partial \tilde{\partial}(z)}{\partial z} > 0 \). As a result, the distribution function describing the distribution of demand is

\[
F_x(\tilde{\partial}(z)) = \mathbb{P}_x \left( \frac{\partial \rho(z)}{\partial z} / \frac{\partial \tilde{\partial}(z)}{\partial z} \right).
\]
By the same reasoning, the firms’ first-order conditions define the inverse supply function
\[ y = \mathcal{Y}(z) = \left( \frac{\partial \mathcal{Y}(z)}{\partial z} \bigg/ \frac{\partial p(z)}{\partial z} \right) \]
which also is monotonic. As a result the distribution of supply can be written
\[ F_y \left[ \frac{\partial \mathcal{Y}(z)}{\partial z} \bigg/ \frac{\partial p(z)}{\partial z} \right]. \]

An equilibrium hedonic price function is one that equates the distributions of supply and demand. Formally, a function \( p(z) \) is an equilibrium price function if it satisfies the differential equation
\[
F_X = \left( \frac{\partial p(z)}{\partial z} \bigg/ \frac{\partial \mathcal{Y}(z)}{\partial z} \right) = F_y \left( \frac{\partial \mathcal{Y}(z)}{\partial z} \bigg/ \frac{\partial p(z)}{\partial z} \right)
\]
for almost all \( z \in \mathbb{Z}^m \) and if \( p(z_{\min}) \) ensures that all buyers and sellers obtain at least their reservation utilities.

Some simple conclusions stem from this analysis. First, since \( \frac{\partial^2 u(x,z)}{\partial z \partial x} > 0 \) and \( \frac{\partial^2 c(y,z)}{\partial y \partial z} < 0 \), the equilibrium involves positive assortative matching between buyers and sellers. Second, the equilibrium price depends on \( u \), the preferences of buyers, \( c \), the costs of sellers, and on \( F_x \) and \( F_y \), the distributions of both types of agents. Third, the price function is the envelope of seller cost and buyer utility.

In more general cases and in cases of higher dimension, the differential equation (8) often does not have nice numerical properties. However, one can solve the equilibrium problem by solving the associated social welfare maximization problem which is an optimal transportation problem (an infinite dimensional linear programming problem with special structure). Recent results in this area include Gretsky, Ostroy and Zame (1999) and Chiappori, McCann, and Nesheim (2006).

### 2.2 Oligopoly hedonic equilibrium

When there is imperfect competition in hedonic markets, firms set prices to maximize profits. Assume individual demand is derived from the discrete choice model in section 1.2. Let \( p = (p_1, \ldots, p_J) \) and \( z = (z_1, \ldots, z_J) \). Given \( p \) and \( z \), let \( D_j(p, z, x) \in [0, 1] \) be the demand of consumer \( x \) for product \( j \). Let \( f_j(x) \) be the density of consumer types with support \( X \).

Aggregate demand for good \( j \) is
\[
q_j(p, z) = \int_X D_j(p, z, x) f_x(x) dx.
\]

Given the strategies of all firms \( K \neq \mathcal{K} \), firm \( j \) solves
\[
\max_{\{f_j, p_j\}} \left\{ p_j q_j(p, z) - c(j, q_j, z_j) \right\}.
\]

The first order conditions are
A pure strategy Nash equilibrium is a set of strategies \((z_j, p_j)\) for each firm \(j = 1, \ldots, J\) such that each firm maximize profits given the strategies of its competitors. In a Nash equilibrium, the equilibrium hedonic prices \(p\) and characteristics \(z\) are determined by the distribution of buyers and their preferences, the costs of the competitors and by the competitive structure of the market. Buyers preferences \(u\) and the distribution \(f_x\) determine the structure of demand. This demand structure combined with the costs of competitors and the number of competitors determine the fierceness of competition. See, for example, Berry, Levinsohn, and Pakes (1995).

3 Estimating hedonic prices

3.1 Ideal case: \(z\) is perfectly observed

The theory of hedonic prices places no restrictions on the hedonic price functional form. The lack of theoretical predictions has led to controversy about functional form in empirical hedonic price work. Different researchers have used linear models, log linear models, Box–Cox models, and fixed-effect models. To estimate hedonic quality adjustments for use in price indexes, many statistical authorities adopt the even more restrictive ‘time-dummy’ model in which the hedonic price function takes the form

\[
p_t = \beta_0 + \beta_1 z_{1t} + \beta_2 z_{2t} + \beta_3 D_t + \varepsilon_t
\]

where \(D_t\) is a vector of time dummies. See Triplett (2004) for a detailed discussion. This version restricts the hedonic price function to be linear in characteristics and to have coefficients that are constant over time. The time-dummy model is rarely theoretically justified and the constant coefficient restriction is usually rejected in empirical tests. Nevertheless, Triplett (2004) argues that in many cases of interest to statistical authorities the restriction works as an approximation and does not make much empirical difference for estimates of hedonic price indexes.

There is no theoretical justification for restrictive parametric empirical models of hedonic prices unless prior knowledge of the market and the products traded exists to support the restrictions. When data-sets are large and the dimension of \(z\) is small, there is little empirical justification for parametric models either. In such cases, hedonic price functions should be estimated nonparametrically unless prior knowledge sufficient to restrict the model exists. Such nonparametric regressions can be easily estimated on desktop computers. When sample size is small or the dimension of \(z\) is large, however, then unrestricted nonparametric methods are often impractical. In these cases, prior information should first be used to impose structure on the hedonic relationship. In some cases, it is then feasible to use semiparametric methods to estimate the hedonic relationship without imposing further structure. In many (if not most) cases, however, there is no choice but to impose further structure that is supported neither by data nor by theory. If the primary use of the method is to predict prices out-of-sample, then goodness of fit and stability with respect to changing market conditions can be useful criteria to choose functional form. If the primary use is to
estimate marginal willingness to pay in some dimension, then semiparametric methods that allow for flexibility in the dimension of interest might be of most use. Tests for robustness should be implemented and interpretations of results should consider potential misspecification biases.

3.2 Practical case $z$ is imperfectly observed

Empirical estimates of hedonic price functions may be biased due to omitted variables or mismeasured variables. Assume the goal is to estimate the hedonic price $p(z)$ and that the methods used will rely on estimation of conditional expectations. Discussion of estimation of $\ln(p(z))$ or methods based on other statistics such as the median would proceed along similar lines.

Let $z = (z_1, z_2)$ be the set of all hedonic characteristics and let $\hat{z} = (\hat{z}_1, \hat{z}_2)$ be the set of variables that the econometrician observes. Assume that $z_1$ is observed without error so that $\hat{z}_1 = z_1$. Assume that $\hat{z}_2$ is a vector of proxy variables (or instrumental variables) and that $z_2 = g(\hat{z}_2, \varepsilon_2)$ where $\varepsilon_2$ is a vector of unobservables. Let $p(z_1, \varepsilon_2)$ be the theoretical hedonic price function. Observed prices $\hat{p}$ satisfy

$$\hat{p} = p(z_1, g(\hat{z}_2, \varepsilon_2)) + \eta$$

(12)

where $\eta$ is measurement error, $E(\eta) = 0$, and $\eta$ is assumed independent of $(\hat{z}_1, \hat{z}_2, \varepsilon_2)$. The unobserved characteristic case, is the case where $g(\hat{z}_2, \varepsilon_2) = \varepsilon_2$ and $f_{\varepsilon_2}(\varepsilon_2|\hat{z}_1, \hat{z}_2) = f_{\varepsilon_2}(\varepsilon_2|\hat{z}_1)$. Then $\varepsilon_2$ is the unobserved characteristic of the product.

Under these assumptions, the expectation of $\hat{p}$ conditional on $(\hat{z}_1, \hat{z}_2)$ is

$$E(\hat{p}|\hat{z}_1, \hat{z}_2) = \int p(z_1, g(\hat{z}_2, \varepsilon_2)) f_{\varepsilon_2}(\varepsilon_2|\hat{z}_1, \hat{z}_2) d\varepsilon_2 = h(z_1, \hat{z}_2)$$

(13)

where $f_{\varepsilon_2}(\varepsilon_2|\hat{z}_1, \hat{z}_2)$ is the density of $\varepsilon_2$ conditional on $(\hat{z}_1, \hat{z}_2)$. This is the best predictor (in the integrated squared error sense) of $\hat{p}$ given data on $(\hat{z}_1, \hat{z}_2)$. However, in general $h(z_1, \hat{z}_2) \neq p(z_1, \hat{z}_2)$ and little can be said about the relationship between the two without more information.

Researchers have employed instrumental variables techniques or prior information that places structure on $g$, on $p$, or on $f_{\varepsilon_2}$ to cope with this problem. See Chay and Greenstone (2005) and Bajari and Benkhard (2005) for examples.

4 Estimating hedonic preferences

In most cases, the full set of consumer characteristics that affect choices is not observed. The econometrician observes only a subset of consumer characteristics such as education, income, age, and household structure. For example, suppose the consumer has two characteristics $(x, \varepsilon)$ and $x$ is observed while $\varepsilon$ is not. Recall the consumer first order condition

$$\frac{\partial p(z)}{\partial z} = \frac{\partial u(x, \varepsilon, z)}{\partial z}$$

(14)
This equation defines the hedonic demand function \( z = d(x, \varepsilon) \).
When data on \((x, z, p)\) are available, \( u \) cannot be estimated directly using (14) because \( z \) is an endogenous variable. As in Figure 1 where households with different values of \( x \) choose different value of \( z \), households with different values of \( \varepsilon \) will choose different values of \( z \).

Additional restrictions can help identify \( u \). Ekeland, Heckman, and Nesheim (2004) show that the utility function can be identified nonparametrically if \( \frac{\partial u}{\partial z} \) is additively separable. That is if,

\[
\frac{\partial u(x, \varepsilon, z)}{\partial z} = u_0(x) + u_1(z) + \varepsilon
\]

where \( u_0 \) and \( u_1 \) are arbitrary nonparametric functions.

More generally, Heckman, Matzkin and Nesheim (2005) prove that the demand function \( d(x, \varepsilon, z) \) can be estimated using data on \((z, x)\) alone if \( \varepsilon \) is statistically independent of \( x \). They further show that the function \( u \) is not identified with data from a single market unless prior information is used to restrict \( u \). For example, if marginal utility is weakly separable so that

\[
\frac{\partial u(x, \varepsilon, z)}{\partial z} = v(q(z, x), \varepsilon)
\]

where \( q \) is a known function, then the function \( v \) can be estimated.

Heckman, Matzkin and Nesheim (2005) also show how to use multi-market data to estimate the unrestricted equation (14). Because cross-market variation in prices is tied to cross-market variation in the distributions of buyers and sellers, it is functionally independent of within market variation in \( z \) and \( x \). As a result, this cross-market variation in prices can then be used to identify and estimate the function \( u \).

Heilbroner, Robert L. (1919–2005)

William Milberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Robert Heilbroner was among the most popular historians of economic thought in the 20th century and a prominent critic of neoclassical economics and free-market capitalism. His *The Worldly Philosophers* explained how the great economists struggled to understand Western capitalism's rapid economic growth and accompanying inequities and social tensions. Heilbroner's probing ‘scenarios’ of capitalism's future drew mainly from the works of Smith, Marx and Schumpeter. His insistence that economic issues are integrally tied to moral and psychological concerns gave his work a rare depth and spoke to the political nature of all social thought.

Article

One of the most prominent critics of the economics profession and of free-market capitalism, Robert Heilbroner was also responsible for motivating generations of college students to become economists. *The Worldly Philosophers: The Life, Times and Ideas of the Great Economists*, Heilbroner's classic treatment of the history of economic thought, captivated generations of readers with its elegantly written, witty, and probing discussions of how these thinkers struggled to understand Western capitalism's rapid economic growth, and industrialization and its accompanying inequities and social tensions. First published in 1953, *The Worldly Philosophers* is in its seventh edition, has been translated into 22 languages, and remains one of the best-selling books on economics of all time. Heilbroner went on to publish 25 books and over 100 articles on the history of economics and the future of capitalism,
focusing at various times on the role of the state, big business, technology, morality, psychology, private property and power. His influence went well beyond the academy, as his books were written in an accessible style and elucidated issues of concern to a broad public. He was a regular contributor to *The New Yorker* and *The New York Review of Books*, and for years served on the editorial board of the interdisciplinary journals *Dissent* and *Social Research*.

Robert Heilbroner was born in New York City in 1919, attended Horace Mann School for Boys and graduated summa cum laude from Harvard University in 1940. He worked briefly for the Office of Price Administration in Washington, D.C., before serving in the army as an interpreter in Japan in the Second World War. After the war Heilbroner came back to New York and worked as a freelance writer while he studied at the New School for Social Research. Invited to join the economics faculty at the New School, Heilbroner was granted a doctorate from the New School for his already published book *The Making of Economic Society*. Heilbroner spent his entire career at the New School for Social Research, where he helped build the programme in political economy that remains to this day one of the few Ph.D. programmes in the United States which emphasizes heterodox economics and the history of economic thought.

Heilbroner was a democratic socialist, as critical of authoritarian Soviet socialism as of dogmatic, free-market capitalism. In lucid prose, Heilbroner conveyed the consequences for everyday life of the deep and seemingly abstract economic forces which create and distribute income and wealth. His identification of these forces as embedded in politics and culture reinforced their everyday relevance.

**Economics in context**

The purpose of economics, Heilbroner wrote, was ‘to give meaning to economic life’. Such meaning, he argued, is necessarily forward looking: ‘There is a deep human need to be situated with respect to the future … to rescue us from a conception of social existence as all contingency and chance’ (1990a, p. 1112). Heilbroner believed that any effort to understand contemporary society required a serious consideration of the history of ideas and societies. Like his mentor Adolph Lowe, Heilbroner relied heavily on the insights of Smith, Marx and Schumpeter in his own efforts to analyse such large questions as the prospects for socialism, the viability of capitalism, and such problems as the trend of dangerous environmental degradation or the inequalities raised by the globalization of production and finance. He described these three economists as ‘great scenarists’, not because any of their long-run predictions proved right – mostly, he admitted, they were wrong – but because they provided ‘a plausible framework within which to face that most fearsome of psychological necessities – looking into the future’. Heilbroner considered these scenarios to be ‘the most significant accomplishment of economics’ (1995, pp. 5–6).

Heilbroner insisted on understanding capitalism as a particular stage in the long history of human efforts to solve the ‘economic problem’ of material provisioning and social reproduction. Knowledge of how different societies have confronted these problems gives crucial perspective to our own efforts to do so today. Thus the starting point for understanding contemporary economic life is to identify the distinguishing features of the current economic system: capitalism. Modern economics, Heilbroner argued, has largely avoided this first crucial step, ignoring rather than illuminating the rich array of social, psychological and moral forces that propel capitalist societies. ‘[B]ehind the veil of conventional economic rhetoric’, he wrote in a short autobiographical essay (2000, p. 287), ‘we can easily discern an
understructure of traditional behavior – trust, faith, honesty, and so on – as a necessary moral foundation for a market system to operate, as well as a concealed superstructure of power.’ Heilbroner noted with outrage that even the word ‘capitalism’ had disappeared from the economics textbooks. He saw economics as an ‘explanation system’ of capitalism, and insisted on the relevance of economics to large questions of political economy – the role of the state, the sustainability of environmental health, the problem of world poverty and the danger of nuclear war – rather than small questions of optimal allocation under conditions of scarcity.

Capitalism's nature and logic

Rejecting neoclassicism, Heilbroner turned to Smith and Marx for the central building blocks of social analysis, since both identify a logic of capitalist development which explains capitalism's endurance and its inherent limitations. Marx is especially important because of his focus on the particularity of the capitalist drive for the expansion of wealth and the exigencies of power, politics and psychology brought on by this accumulation drive. As Heilbroner elaborated in a series of books written in the 1980s – *The Nature and Logic of Capitalism, Marxism For and Against*, and *Behind the Veil of Economics* – all efforts to solve the economic problem of material provisioning, be they organized by tradition, command or markets, are aimed at the production of a material surplus above the needs of subsistence. Only in capitalism, however, does this take a general form – self-expanding value. The commodity is but a way station towards the accumulation of value in ‘a never-ending metamorphosis of M-C-M’ (1988, p. 37). This circuit of capital hinges on the institution of private property in the means of production, which ‘organizes and disciplines’ society and serves as an instrument of power ‘because its owners can establish claims on output as their quid pro quo for permitting access to their property’ (1988, p. 39). Profit goes to owners of capital and not only validates the activities of particular owners but perpetuates the M-C-M circuit. As Heilbroner writes, ‘Profit is for capitalism what victory is for a regime organized on military principles...’ (1988, p. 41).

The wage relation is crucial to understanding capitalism's uniqueness. Workers are free to offer their labour power for wages, unlike forced labour in many traditional and especially feudal and slave societies. But private property relations keep workers from retaining the full value of their efforts. A second unique feature of capitalism is the distinctiveness of its private and public realms, each relying on the other for its sustenance. Capitalism thus has a unique political agenda in that the precise role and scope of the state vis-à-vis the private sector is constantly contested and debated. Despite the freedom embodied in the wage relation and the reliance of the private sector on the state, capitalism has functioned under both democratic and anti-democratic political systems. Heilbroner himself was an outspoken advocate for an active role for government in creating a decent society and productive economy. In *The Debt and the Deficit: False Alarms, Real Possibilities* (1989, co-authored with Peter Bernstein) Heilbroner argued for Keynesian deficit spending and capital budgeting by the US government.

For all its identifiable deep structures and logic, capitalism for Heilbroner is constantly changing, buffeted by other social forces. This is partly the result of history's dialectical nature: as problems are resolved through social change, the new conditions present a new set of problems. In *The Future as History* and *An Inquiry into the Human Prospect* Heilbroner focused on various implications of this unsettling aspect of social reality, in particular long-run environmental consequences of economic
development. Capitalism is all the time and everywhere contingent on independent ideas, political struggles and ethical dilemmas, and these have resulted in a variety of capitalisms around the world. For Heilbroner, theories of economic determinism – be they Marxist or neoclassical – that reduce capitalism to a system of markets cannot adequately explain social change, since economics, politics and morality are linked: ‘[T]he engines of history do not draw all their energies from economic drives and institutions. If socialism failed, it was for political, more than economic reasons; and if capitalism is to succeed it will be because it finds the political will and means to tame its economic forces’ (1996, p. 195).

The paradox of progress

If it was Marx who best articulated the ‘nature and logic’ of capitalism, it was Smith who provided the most important insights into the psychology of individuals in capitalist society. Heilbroner considered Smith's *Theory of Moral Sentiments* to be as important as *The Wealth of Nations* and insisted that the socialized individual of *Theory of Moral Sentiments* was not only consistent with but necessary to the successful working of the nascent capitalism described in *The Wealth*. Smith's writings on empathy and, most importantly, subservience (‘the principle of authority’) and the drive for self-betterment are the psychological foundations of the ‘society of perfect liberty’; that is, they are the psychological dynamics that make capitalism function. Like the other classical economists, Smith also emphasized capitalism's dark side. Capitalism's advance brings unprecedented wealth creation and the possibility of ‘perfect liberty’. It also brings stagnation, poverty, inefficiency, systemic corruption and moral decay. The result was what Heilbroner termed ‘the paradox of progress’. For Heilbroner these insights were important not only for students of intellectual history but also for those seeking to understand the prospects for capitalism today. ‘Capitalism's uniqueness in history’, he wrote in *Twenty-First Century Capitalism*, ‘lies in its continuously self-generated change, but it is this very dynamism that is the system's chief enemy’ (1993, p. 130). Both of these insights – the embeddedness of the economy in a broader social, political and psychological fabric, and the inherent problems in capitalist development – Heilbroner attributes to Adam Smith, although they are not part of the canonical reading of Smith as a proponent of laissez-faire.

Smith's influence on Heilbroner went beyond the issue of the psychology of individual agents in capitalism and into the existential question of the purpose of theory itself. In his *Essays on Astronomy* (published in 1758 and excerpted in Heilbroner, 1986), Smith wrote that ‘[T]he repose and tranquility of the imagination is the ultimate end of philosophy…Philosophy, by representing the invisible chains which bind together all these disjointed objects, endeavors to introduce order in this chaos of jarring and discordant appearances, to ally this tumult of the imagination.’ Discussing this passage, Heilbroner wrote that ‘We theorize … to restore our peace of mind’ (1986, p. 16).

Analysis and vision in economics

Heilbroner's embrace of the classicals and rejection of the neoclassicals hinged on the Schumpeterian distinction between ‘analysis’ and ‘vision’. Schumpeter (1954, p. 41) defined vision as the ‘preanalytic cognitive act’ that is inevitable and ideological. Analysis is the largely deductive process that follows
from the theory's foundations. As intellectual historian, Schumpeter separated economic analysis from its vision, leading to the *History of Economic Analysis*, published posthumously. Heilbroner embraced the Schumpeterian categories, and especially the notion that vision is an inevitable part of the process of theorizing, since ‘All systems of thought that describe or examine societies must contain their political character, knowingly and explicitly, or unknowingly and in disguise.’ (1990b, p. 109) But Heilbroner resisted Schumpeter's separation of vision and analysis, since connecting the two allowed a greater appreciation of how economic scenarios are formed. *The Worldly Philosophers* was enormously popular not only because it included juicy biographical details about the early economists but because Heilbroner revealed the lively imagination and political engagement of the ‘great scenarists’. Vision, for Heilbroner, embodied much of the creativity that informs economic problem-solving and modelling. And it is through the vision that ethical and epistemological principles are brought into theory. Vision is the expression of the inescapable need to infuse ‘meaning’ – to discover a comprehensive framework – in the world’ (1990a, p. 1112). For Heilbroner, it was precisely the persistent denial of the role of vision that leaves modern economics so limited as a tool for understanding social life. In *The Crisis of Vision in Modern Economic Thought*, Heilbroner (and co-author William Milberg) developed this theme in the context of contemporary debates in macroeconomics.

In the final chapter of the seventh edition of *The Worldly Philosophers*, Heilbroner wrote of ‘the end of economics’, playing on the dual meaning of end as both purpose and termination. For all its technical sophistication, modern economics has largely failed to accomplish the purpose of a worldly philosophy: to give meaning to economic life. Heilbroner saw the narrowness of modern economics as an abandonment of the grand aspiration for social thought that Smith, Ricardo, Malthus, Marx, Mill, Keynes and Schumpeter each held in their day. Heilbroner lamented, ‘The new vision is Science, the disappearing one capitalism’ (1953, p. 314). Heilbroner was an important public intellectual of the second half of the 20th century. While he remained to his last days a severe critic of modern economics, his personal warmth, his kindness, his humaneness, his commitment to equality, opportunity and democracy, and his love of deep and serious debate on pressing social issues endeared him to a broad group of professional economists, social scientists, students and a socially-concerned public.

Article

Walter Perrin Heller was a leading 20th-century economic theorist, and an early member of the University of California, San Diego, faculty (from 1974 to his death in 2001). He annually taught the UCSD graduate core microeconomic theory course on welfare economics.

Heller came from an academic family distinguished in the economics discipline: his father, Walter W. Heller, was Professor of Economics at the University of Minnesota and served as chairman of the President's Council of Economic Advisers in the Kennedy and Johnson US presidential administrations. Walter P. Heller's undergraduate education took place at Oberlin College and at the University of Minnesota, particularly under the guidance at Minnesota of Professor Leonid Hurwicz (1990 recipient of the US National Medal of Science). Heller's intellectual home was Stanford University. He received his Ph.D. there in 1970 with the dissertation advice of Nobel Prize winner Kenneth J. Arrow. For three decades he participated in the Stanford summer economic theory workshop at the Institute for Mathematical Studies in the Social Sciences (IMSSS) and its successor, the Stanford Institute for Theoretical Economics (SITE). Prior to joining the UCSD faculty, he was on the economics faculty of the University of Pennsylvania.

Heller served as an associate editor of the Journal of Economic Theory and on the executive committee of the American Economic Association. His research treated the stability of economic growth, microeconomic foundations of macroeconomics and of the demand for money, and resource allocation under conditions of market failure due to incompleteness or monopoly. In the late 1980s and the 1990s, the research focused on a fundamental issue in the theory of unemployment, namely, coordination failure, or the inability – even of complete markets in price equilibrium – successfully to match supply
and demand, workers and employers. Kenneth Arrow remarked at Heller's memorial service at Stanford on 16 July 2001:

Economic theory backed by serious mathematical reasoning was just beginning to be recognized when Walt started his graduate work … Walt was one of the leaders in using new ways – not merely for clarification – but for changing the way the economy was considered. He contributed to many aspects of [economic] theory … His long-standing project of studying the coordination failures of the economic system brought out, in an essentially novel way, the previously unclarified meaning of Keynesian insights. This work … is a vital continuing part of modern economic thought …

Stability of economic growth: A growth model over time in general competitive equilibrium (at each instant) may nevertheless be on an inter-temporally inefficient path (Hahn, 1966; 1968; Malinvaud, 1953). Further, an efficient path may be unstable (Samuelson and Solow, 1956). Heller (1971; 1975) demonstrated that inefficiency and instability depend on myopia; in the presence of complete inter-temporal capital markets (futures markets for capital), stability and efficiency of the growth path are established.

Demand for money: Heller was among the first to apply the full formal structure of an Arrow–Debreu model to the analysis of a monetary economy (1972; 1974; 1976 with R. Starr). The Baumol–Tobin money demand model with transaction costs (Tobin, 1956) is shown to be consistent with full general competitive equilibrium.

Foundations of macroeconomics: The Keynesian consumption function was long recognized anecdotally to be a result of capital market imperfection, but Heller and Starr (1979b) represents the first mathematical formalization of this notion. Unemployment equilibrium was long thought inconsistent with Walrasian general equilibrium pricing; Heller and Starr (1979a) demonstrate that expectations of uncleared markets may be self-fulfilling in equilibrium even at competitive equilibrium prices.

Coordination failure: When the formation of markets is itself a resource using activity, then some markets may not form or announce prices in equilibrium (1986; 1992; 1999) with resulting inefficiency and unemployed resources. In a model with a non-competitive (oligopoly or monopoly) sector, even with a full set of markets, there may be multiple Pareto ranked equilibria (1998).

Heller's work is elegantly written so that the underlying intuition is clear and is supported by mathematical structure. The Walter P. Heller Prize for excellence in research – instituted by Heller's colleagues – is awarded annually to a UCSD graduate student.

Heller, Walter Wolfgang (1915–1987) was born in Buffalo on 27 August 1915. He grew up in Seattle and Milwaukee, and graduated from Oberlin College. He received a doctorate in economics from the University of Wisconsin, where he studied with Harold M. Groves, who greatly influenced a generation of public finance scholars. He spent his entire academic career as professor of economics at the University of Minnesota.

Heller made important scholarly contributions to the study of public finance, but his major claim to fame was his highly successful term as chairman of the Council of Economic Advisers under Presidents John F. Kennedy and Lyndon B. Johnson from 1961 to 1964. After leaving the government, he was influential as a consultant and adviser to presidents, Congress and business. He wrote widely on current economic developments, tax policy, and state-local finance, and was also known as a stimulating lecturer and commentator on economic policy issues. In 1974, he served as president of the American Economic Association.

Heller began his professional career as an expert on state and local taxation. He wrote his doctoral dissertation on the administration of state income taxes, and later originated the idea of federal revenue sharing with the states and local governments. The details of revenue sharing were developed by a task force appointed by President Johnson, but it was enacted by Congress only after it was recommended by President Richard M. Nixon in 1972. The revenue sharing legislation was extended until the end of September 1986.

During the Second World War, Heller moved to the Treasury Department, where he contributed to the development of tax policy to finance the war. In 1947–8, he was tax adviser to the US Military Government in Germany, where he played an important role in designing the currency and fiscal reforms that helped launch the post-war German economic revival. He also served as a consultant to the
Treasury Department during the late 1940s and early 1950s. He has been a strong advocate of progressive taxation and was one of the first to recognize that unnecessary deductions and tax preferences narrow the income tax base, require higher marginal tax rates to raise the necessary revenues, and distort economic decisions.

As chairman of the Council of Economic Advisers, Heller supported innovative macroeconomic policies to promote economic growth and stability. He persuaded President Kennedy to propose a major tax cut to stimulate demand, advocated the enactment of an investment tax credit and liberalized depreciation allowances to increase investment incentives. His Council developed the first, and most successful, voluntary wage-price guidelines to help contain inflationary pressures as the economy moved to full employment.

Heller's Council pioneered fiscal analysis based on the concepts of potential gross national product – the output the economy would produce at full employment – and the full-employment surplus. It is also noted for its advocacy of the neoclassical Keynesian synthesis of fiscal and monetary policies required to achieve full employment and increase economic growth. To reach full employment, it proposed the use of stimulating budget and monetary policies. To increase growth at full employment, it stressed the need for a full-employment surplus and monetary ease to support private investment in plant and equipment, combined with public investments in education, research, and development. It also urged the dismantling of barriers to free trade among nations to achieve the benefits of international specialization and exchange.

As a result of the policies pursued by the Kennedy and Johnson administrations, the nation enjoyed a long period of economic growth and prosperity without inflation. From the fourth quarter of 1960 to the fourth quarter of 1964 (when Heller left his CEA post), US real GNP grew at an average annual rate of 4.9 per cent, consumer prices rose 1.2 per cent a year, and long-term federal bond yields never exceeded 4.2 per cent.

Heller combined his advocacy of sound economic policies with an understanding of the need to help the disadvantaged and underprivileged. He helped to persuade President Johnson to design and implement an anti-poverty programme to provide economic opportunities for low-skilled workers and a decent income for those who cannot earn their own livelihood. ‘We cannot relax our efforts to increase the technical efficiency of economic policy’, he wrote in 1966. ‘But it is also clear that its promise will not be fulfilled unless we couple with improved techniques of economic management a determination to convert good economics and a great prosperity into a good life and a great society.’

Hennipman, Pieter (1911–1994)

Arnold Heertje

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Austrian economics; Chamberlin, E. H.; Hennipman, P.; homo economicus; interpersonal utility comparisons; monopoly; Pareto optimal redistribution; Pierson, N. G.; Robbins, L. C.; Tinbergen, J.; welfare economics; unanimity; Wicksell, J. G. K.

Article

Dutch economist born in Leiden, 12 September 1911, who died in Amsterdam on 3 July 1994. Hennipman belongs to the three most important economists of the Netherlands, the two others being Nicolaas Gerard Pierson (1839–1909) and Jan Tinbergen (1903–1994). He studied at the Faculty of Economics of the University of Amsterdam, and was taught economic theory by H. Frijda and economic history by N.W. Posthumus. He took his Master's degree in 1934, and in 1938 became reader in economics at the University of Amsterdam, next to his beloved teacher Frijda. He continued his work on his dissertation and received his doctorate in July 1940, in time to enable Frijda, who soon after had to flee from the Nazis, to act as his director of his thesis. Of Hennipman's impressive work on economic motive and economic principle a much-enlarged edition appeared after the Second World War in 1945. The book presents a detailed historical-critical survey of the manifold varieties of homo economicus, concluding that the scope of economics is not restricted to the behaviour of such an animal. It is argued that the concept of economic welfare is subjective and devoid of specific content and that economics cannot be normative. His work shows the influence of the Austrian subjectivist way of thinking and Lionel Robbins' Essay (1932). In 1945 Hennipman became Professor of Economics at the University of Amsterdam.

From 1945 to 1972 Hennipman was managing editor of the Dutch Journal De Economist, nowadays published in English. Many articles have appeared which reveal evidence of his vast knowledge of the literature and demonstrate his ability to encourage authors to improve their manuscripts by his constructive and well-founded comments. In 1951, invited by E.H. Chamberlin, Hennipman participated in a conference held by the International Economic Association on monopoly, competition and their regulation. Hennipman's paper ‘Monopoly: Impediment or Stimulus to Economic Progress?’ received

great praise at the conference from J.M. Clark, G. Haberler, F.H. Knight and F. Machlup (Hennipman, 1954). In 1962 he published his essay on the theory of economic policy, of which a shortened version in English is published in Hennipman's book *Welfare Economics and the Theory of Economic Policy* (Hennipman, 1995). The analysis builds further on his dissertation by applying to the theory of economic policy the principles set out in his work on economic motive and economic principle. This essay is without doubt one of the highlights of non-mathematical economic literature. He contributed to the publication of the Walras correspondence, edited by W. Jaffé in 1965 (Jaffé, 1965).

Following his retirement in 1973 Hennipman was very active on methodology, the history of economic thought and, in particular, welfare economics. Publications during the last decade of his life mainly concern welfare economics: for example, a pair of articles exploring the historical and analytical relations between Pareto optimality and Wicksellian unanimity. A major theme in Hennipman's work is the contention that welfare economics is a non-normative theory, as he convincingly spelled out in major debates with Ezra Mishan and Mark Blaug (Hennipman, 1995). Interpersonal comparisons of utility and Pareto optimal redistribution are discussed by Hennipman from this point of view.

It is only due to his incredible and miraculous modesty that the international audience of economists had to wait until after his death for an accessible publication of his work in English. This event also explains that his influence on the development of international economics literature fell short of what would have been justified by the high quality and relevance of his contributions, which are innocent of mathematics and do not reflect empirical research. He influenced both students and professors by allowing them access to his vast knowledge of almost all areas of economic theory and his analytical insights. There is no doubt that he became the leading Dutch economist, in particular since the war, albeit still in the shadow of Jan Tinbergen, who had built his international reputation during the years of the Great Depression of the 1930s.

Hermann was born in Dinkelsbuhl, Germany. His career spanned the half-century or more in which German economics came to terms with English classical political economy, first welcoming it and then rejecting it, particularly in its Ricardian variety. After teaching mathematics in a secondary school, Hermann was appointed to the chair in what was still called Kameralwissenschaften [Cameralism] – an old title soon to be discarded – at the University of Munich in 1827. He made his reputation with Staatswirthschaftliche Untersuchungen [Investigations into Political Economy] (1832), a book which owed much to The Wealth of Nations but little to the writings of either Malthus or Ricardo. The book was organized around the simple but appealing idea that all economic variables are the outcome of the forces of demand and supply, so that economic analysis consists essentially of an investigation of the factors lying behind demand and supply. The book revelled in endless definitions and classifications of types of goods, wants, costs, capitals, and so on, but did not clutter the analysis with endless attacks on the deductive method of the English school. Together with Rau (1792–1870), Hermann thereby laid the foundations on which Mangoldt (1824–68) and Thünen (1783–1850) were soon to build a German brand of classical economics. No wonder Marshall much admired ‘Hermann's brilliant genius’ and frequently quoted Hermann's treatise in his own Principles of Economics (1890).

Hermann became a Director of the Bavarian Statistical Bureau in 1839 and organized the first official life table covering an entire German state. As a member of the Frankfurt Parliament in 1848, he advocated the unification of all German states.
Herskovits, Melville Jean (1895–1963)

George Dalton

conventional economics; economic anthropology; formalism; Herskovits, M. J.; Knight, F. H.; Marxism; non-market economies; Polanyi, K.; substantivism

Article

Herskovits was born in Bellefontaine, Ohio, and died in Evanston, Illinois. He studied history at the University of Chicago (BA, 1920) and anthropology at Columbia University (Ph.D., 1923) as a student of Franz Boas. He taught at Columbia and Howard universities before going to Northwestern in 1927, where he spent the rest of his academic career. Herskovits did anthropological fieldwork in West Africa, the Caribbean and Brazil, and was among the first American anthropologists to specialize in African societies as well as blacks in the Caribbean and the United States. He started the first Program of African Studies in the United States, at Northwestern.

Herskovits was an early contributor to the field of study now established as economic anthropology. The first edition of his book on this topic was called The Economic Life of Primitive Peoples (1940), the revised edition being Economic Anthropology (1952).

Herskovits is best remembered by economic anthropologists for his views on a theoretical issue of importance that arose in his controversy with Frank Knight, who reviewed the 1940 edition of Herskovits's book. In the 1940 edition, Herskovits criticized the conventional economics of Marshallian microtheory for its uselessness to anthropologists trying to understand the underlying principles which explain the working of primitive economies – such as African tribal economies not yet changed by European colonial rule – primitive economies lacking capitalism's core attributes of machine technology, modern money, and market organization for the transaction of inputs and outputs. In his book review, Frank Knight criticized Herskovits for misunderstanding the ‘abstract’ and ‘intuitive’ nature of economic theory. (I doubt that Knight's portrayal of economics, as stated there, would be shared today by many economists.) Knight's review, together with a rejoinder by Herskovits, are reprinted in Economic Anthropology (1952).

The relevance of conventional economic theory to the analysis of pre-industrial, non-capitalist
economies remains an unresolved issue to this day. It is an issue much more important today because of the much greater interest now in the study of early and primitive economies, and in the study of the large, diverse set of developing economies in the Third World. This inability to agree on the relevance of conventional economics to the analysis of non-market economies finds expression in economic anthropology's literature of acrimonious theoretical dispute and in the existence side by side of three radically different theoretical systems all employed by archaeologists, anthropologists and historians to analyse non-capitalist economies: formalism (that is, conventional microeconomic theory); Marxism; and substantivism (that is, Karl Polanyi's system of analysis described in his *Trade and Market in the Early Empires*, 1957, and his *Primitive, Archaic, and Modern Economies*, 1971).

Although ‘heterodox economics’ is a widely used term, precisely what it means is debated. I argue that heterodox economics refers to a body of economic theories that holds an alternative position vis-à-vis mainstream economics; to a community of heterodox economists who identify themselves as such and embrace a pluralistic attitude towards heterodox theories without rejecting contestability and incommensurability among heterodox theories; and to the development of a coherent economic theory that draws upon various theoretical contributions by heterodox approaches which stand in contrast to mainstream theory.

Keywords

Association for Heterodox Economics; Austrian economics; capitalism; class; evolutionary economics; feminist economics; heterodox economics; institutional economics; interdependencies; Marxian economics; Post Keynesian economics; radical economics; scarcity; social economics; Sraffian economics; pluralism; political economy; mainstream economics; social provisioning

‘Heterodox economics’ refers to economic theories and communities of economists that are in various ways an alternative to mainstream economics. It is a multi-level term that refers to a body of economic theories developed by economists who hold an irreverent position vis-à-vis mainstream economics and are typically rejected out of hand by the latter; to a community of heterodox economists who identify themselves as such and embrace a pluralistic attitude towards heterodox theories without rejecting contestability and incommensurability among heterodox theories; and to the development of a coherent economic theory that draws upon various theoretical contributions by heterodox approaches which stand in contrast to mainstream theory. Thus, the article is organized as follows. The first section outlines the emergence of ‘heterodox economics’ in the sense of a body of heterodox theories; the second section
Heterodox economics: The New Palgrave Dictionary of Economics
deals with heterodox economics as a pluralist community of heterodox economists; the third section
situates heterodox economics relative to mainstream economics; and the fourth section delineates
heterodox economics in terms of theory and policy.

**Heterodox economics as a group of heterodox theories**

Heterodox as an identifier of an economic theory and/or economist that stands in some form of dissent
relative to mainstream economics was used within the Institutionalist literature from the 1930s to the
1980s. Then, in 1987, Allan Gruchy used ‘heterodox economics’ to identify Institutional as well as
Marxian and Post Keynesian theories as ones that stood in contrast to mainstream theory. By the 1990s,
it became obvious that there were a number of theoretical approaches that stood, to some degree, in
opposition to mainstream theory. These heterodox approaches included Austrian economics, feminist
economics, Institutional-evolutionary economics, Marxian-radical economics, Post Keynesian and
Sraffian economics, and social economics; however, none of the names of the various heterodox
approaches were suitable as a general term that could represent them collectively. While terms such as
‘non-traditional’, ‘non-orthodox’, ‘non-neoclassical’ and ‘non-mainstream’ were used to collectively
represent them, they did not have the right intellectual feel or a positive ring. Moreover, some thought
that ‘political economy’ (or ‘heterodox political economy’) could be used as the collective term, but its
history of being another name for Marxian-radical economics (and its current reference to public choice
theory) made this untenable. Therefore, to capture the commonality of the various theoretical approaches
in a positive light without prejudicially favouring any one approach, a descriptive term that had a
pluralist ‘big-tent feel’ combined with being unattached to a particular approach was needed. Hence,
‘heterodox’ became increasingly used throughout the 1990s in contexts where it implicitly and/or
explicitly referred to a collective of alternative theories vis-à-vis mainstream theory and to the
economists who engaged with those theories.

The final stage in the general acceptance of heterodox economics as the ‘official’ collective term for the
various heterodox theories began c. 1999. First there was the publication of Philip O’Hara's
comprehensive *Encyclopedia of Political Economy* (1999), which explicitly brought together the various
heterodox approaches. At the same time, in October 1998, Fred Lee established the Association for
Heterodox Economics (AHE); and to publicize the conference and other activities of the AHE as well as
heterodox activities around the world, he also developed from 1999 an informal ‘newsletter’ that
eventually became (in September 2004) the *Heterodox Economics Newsletter*, now received by over
1,600 economists worldwide (see http://www.heterodoxnews.com). These twin developments served to
establish ‘heterodox economics’ as the preferred terminology by which these groups of economists
referred to themselves.

**Heterodox economics as a community of heterodox economists**

‘Heterodox economics’ also denotes a community of heterodox economists, which implies that the
members are not segregated along professional and theoretical lines. The segregation of professional
engagement has not existed among heterodox associations, with the exception of two instances in the
mid-1970s. For example, from their formation in 1965–70, the three principal heterodox associations in
the United States, AFEE, ASE, and URPE (see Table 1 for full names), opened their conferences to Institutionalist, social economics, radical-Marxian, and Post Keynesian papers and sessions; appointed and/or elected heterodox economists to the editorial boards of their journals and to their governing bodies who also were members of other heterodox associations or engaged with Post Keynesian economics; and had members who held memberships in other heterodox associations, engaged with Post Keynesian economics, and subscribed to more than one heterodox economics journal. Moreover, a number of heterodox associations formed since 1988, such as AHE, EAEPE, ICAPE, SDAE and SHE, have adopted an explicitly pluralistic approach towards their name, membership and conference participation: for a list of heterodox associations, dates formed and primary country or region of activity, see Table 1. Finally, the informal and explicit editorial policies of heterodox journals have, from their formation, accepted papers for publication that engage with the full range of heterodox approaches; and this tendency strengthened since the mid-1990s as heterodox economics became more accepted. To illustrate this point, from 1993 to 2003 the eight principal English-language generalist heterodox journals – *Cambridge Journal of Economics, Capital and Class, Feminist Economics, Journal of Economic Issues, Journal of Post Keynesian Economics, Review of Political Economy, Review of Radical Political Economics*, and *Review of Social Economy* – cited each other so extensively that no single journal or subset of journals was isolated; hence they form an interdependent body of literature where all heterodox approaches have direct and indirect connections with each other. Thus, in terms of professional engagement since the mid-1990s, the heterodox community is a pluralistic integrative whole.

Theoretical segregation involves the isolation of a particular theoretical approach and its adherents from all other approaches and their adherents; that is to say, theoretical segregation occurs when there is no engagement across different theoretical approaches. However, it does not exist within heterodox economics currently, nor has it existed in the past among the various heterodox approaches. From the 1960s to the 1980s heterodox economists engaged, integrated or synthesized Institutional, Post Keynesian and Marxist-radical approaches, Institutional and Post Keynesian approaches, Post Keynesian and Marxian-radical approaches, Post Keynesian and Austrian, Austrian and Institutional, feminist and Marxian-radical approaches, Institutional and Marxist-radical approaches, Institutional and social economics, ecological and Marxian-radical approaches, and social and Marxian economics. Thus by 1990 many heterodox economists could no longer see distinct boundaries between the various approaches. Moreover, from the 1990s to the present day heterodox economics has continued the past integration efforts of engaging across the various heterodox approaches. Hence, it is clear that the heterodox community is not segregated along theoretical lines, but rather there is cross-approach engagement to such an extent that the boundaries of the various approaches do not simply overlap – they are, in some cases, not there at all. The ensuing theoretical messiness of cross-approach engagement is evidence, to detractors, of the theoretical incoherence of heterodox economics, whereas to supporters of progress it is evidence of a more theoretically coherent heterodox economics – a glass half-empty of coherence as opposed to a glass half-full of coherence.

**Heterodox critique of mainstream economics**

Mainstream economics is a clearly defined theoretical story about how the economy works; but this story is theoretically incoherent. That is, mainstream theory is comprised of a core set of propositions – such as scarcity, equilibrium, rationality, preferences, and methodological individualism and derivative beliefs, vocabulary, symbols and parables – while there is a range of heterogeneous theoretical developments beyond the core that do not call into question the core itself in totality. As a result, critiques of the theory vary in that they can deal with the internal coherence and/or empirical grounding of the theory; they can be directed at the theory at a particular point in time or at specific components of theory (such as methodology, concepts qua vocabulary, parables qua stories and symbols); and they can
be initiated from a particular heterodox approach. What emerges is a varied but concatenation of particular and extensive critiques that generate an emergent encompassing rejection of mainstream theory, although any one particular critique may not go that far. Although the internal critiques and critiques of models that tell theoretical stories show that the theory is incoherent, they do not by themselves differentiate mainstream from heterodox theory. This, however, can be dealt with in terms of specific critiques of the core propositions. That is, each of the heterodox approaches has produced critiques of particular core propositions of the theory, while each core proposition has been subject to more than one critique; in addition, the multiple heterodox critiques of a single proposition overlap in argumentation. To illustrate this point, consider the critiques of the concept of scarcity. The Post Keynesians argue that produced means of production within a circular production process cannot be characterized as scarce and that production is a social process, while Institutionalists reject the view that natural resources are not ‘produced’ or socially created to enter into the production process, and the Marxists argue that the concept is a mystification and misspecification of the economic problem – that it is not the relation of the isolated individual to given resources, but the social relationships that underpin the social provisioning process. The three critiques are complementary and integrative and generate the common conclusion that the concept of scarcity must be rejected as well as the mainstream definition of economics as the science of the non-social provisioning process analysed through the allocation of scarce resources among competing ends given unlimited asocial wants of asocial individuals. Other critiques of the core propositions exist and arrive at similar conclusions. Together, the three critiques – internal, story qua model and core propositions – form a concatenated structured heterodox critique that rejects and denies the truth and value of mainstream theory.

**Heterodox economics: theory and policy**

Since the intellectual roots of heterodox economics are located in traditions that emphasize the wealth of nations, accumulation, justice, social relationships in terms of class, gender, and race, full employment, and economic and social reproduction, the discipline of economics, from its perspective, is concerned, not with prediction per se, but with explaining the actual process that provides the flow of goods and services required by society to meet the needs of those who participate in its activities. That is, economics is the science of the *social* provisioning process, and this is the general research agenda of heterodox economists. The explanation involves human agency in a cultural context and social processes in historical time affecting resources, consumption patterns, production and reproduction, and the meaning (or ideology) of market, state, and non-market/state activities engaged in social provisioning. Thus heterodox economics has two interdependent parts: theory and policy. *Heterodox economic theory* is an empirically grounded theoretical explanation of the historical process of social provisioning within the context of a capitalist economy. Therefore it is concerned with explaining those factors that are part of the process of social provisioning, including the structure and use of resources, the structure and change of social wants, structure of production and the reproduction of the business enterprise, family, state, and other relevant institutions and organizations, and distribution. In addition, heterodox economists extend their theory to examining issues associated with the process of social provisioning, such as racism, gender and ideologies and myths. Because their economics involves issues of ethical values and social philosophy and the historical aspects of human existence, heterodox economists make ethically based *economic policy* recommendations to improve human dignity, that is, recommending
ameliorative and/or radical, social and economic policies to improve the social provisioning and hence
well-being for all members of society and especially the disadvantaged members. To do this properly,
their economic policy recommendations must be connected to heterodox theory which provides an
accurate historical and theoretical picture of how the economy actually works – a picture that includes
class and hierarchical domination, inequalities, and social-economic discontent.
Given the definition of economics as the science of the social provisioning process and the structure of
the explanation of the process combined with the pluralistic and integrative proclivities of heterodox
economists, there has emerged a number of elements that have come to constitute the provisional
theoretical and methodological core of heterodox theory. Some elements are clearly associated with
particular heterodox approaches, as noted by O’Hara (2002, p. 611):

The main thing that social economists bring to the study [of heterodox economics] is an
emphasis on ethics, morals and justice situated in an institutional setting. Institutionalists
bring a pragmatic approach with a series of concepts of change and normative theory of
progress, along with a commitment to policy. Marxists bring a set of theories of class and
the economic surplus. Feminists bring a holistic account of the ongoing relationships
between gender, class and ethnicity in a context of difference ... And post-Keynesians
contribute through an analysis of institutions set in real time, with the emphasis on
effective demand, uncertainty and a monetary theory of production linked closely with
policy recommendations.

However, other provisional elements, such as critical realism, non-equilibrium or historical modelling,
the gendering and emotionalizing agency, the socially embedded economy, and circular and cumulative
change, emerged from a synthesis of arguments that are associated only in part with particular heterodox
approaches.
The core methodological elements establish the basis for constructing heterodox theory. In particular,
the methodology emphasizes realism, structure, feminist and uncertain agency qua individual, history,
and empirical grounding in the construction of heterodox theory, which is a historical narrative of how
capitalism works. The theory qua historical narrative does not simply recount or superficially describe
actual economic events, such as the exploitation of workers; it does more in that it analytically explains
the internal workings of the historical economic process that, say, generates the exploitation of workers.
Moreover, because of its historical nature, the narrative is not necessarily organized around the concepts
of equilibrium/long period positions and tendencies towards them. Because the narrative provides an
accurate picture of how capitalism actually works and changes in a circular and cumulative fashion,
economists use their theory to suggest alternative paths that future economic events might take and
propose relevant economic policies to deal with them. In constructing the narrative, they have at the
same time created a particular social-economic-political picture of capitalism.
The core theoretical elements generate a three-component structure–organization–agency economic
theory. The first component of the theory consists of three overlapping interdependencies that delineate
the structure of a real capitalist economy. The first interdependency is that the production of goods and
services requires goods and services to be used as inputs. Hence, with regard to production, the overall
economy (which includes both market and non-market production) is represented as an input–output
matrix of material goods combined with different types of labour skills to produce an array of goods and
services as outputs. Many of the outputs replace the goods and services used up in production and the rest constitute a physical surplus to be used for social provisioning, that is for consumption, private investment, government usage and exports. A second interdependency is the relation between the wages of workers, profits of enterprises, and taxes of government and expenditures on consumption, investment, and government goods as well as non-market social provisioning activities. The last interdependency consists of the overlay of the flow of funds or money accompanying the production and exchange of the goods and services. Together, these three interdependencies produce a monetary input–output structure of the economy where transactions in each market are a monetary transaction; where a change in price of a good or the method by which a good is produced in any one market will have an indirect or direct impact on the entire economy; and where the amount of private investment, government expenditure on real goods and services, and the excess of exports over imports determines the amount of market and non-market economic activity, the level of market employment and non-market labouring activities, and consumer expenditures on market and non-market goods and services. These elements of course have parallels in non-heterodox economics, but the ideas are developed differently.

The second component of heterodox theory consists of three broad categories of economic organization that are embedded in the monetary input–output structure of the economy. The first category is micro market-oriented, hence particular to a set of markets and products. It consists of the business enterprise, private and public market organizations that regulate competition in product and service markets and the organizations and institutions that regulate the wages of workers. The second is macro market-oriented and hence is spread across markets and products, or is not particular to any market or product. It includes the state and various subsidiary organizations as well as particular financial organizations, that is, those organizations that make decisions about government expenditures and taxation, and the interest rate. Finally, the third category consists of non-market organizations that promote social reproduction and include the family and state and private organizations that contribute to and support the family. The significance of organizations is that they are the social embeddedness of agency qua the individual, the third component of heterodox theory. That is, agency, which are decisions made by individuals concerning the social provisioning process and social well-being, takes place through these organizations. And because the organizations are embedded in both instrumental and ceremonial institutions, such as gender, class, ethnicity, justice, marriage, ideology, and hierarchy qua authority, agency qua the individual acting through organizations affect both positively and negatively but never optimally the social provisioning process.

Conclusion

If mainstream economics suddenly disappeared, heterodox economics would be largely unaffected. It would still include the various heterodox traditions; there would still be an integrated professional and theoretical community of heterodox economists; and its heterodox research agenda would still be directed at explaining the social provisioning process in capitalist economies and argue for economic policies that would enhance social well-being. In this regard, heterodox economics is not out to reform mainstream economics. Rather, it is an alternative to mainstream economics: an alternative in terms of explaining the social provisioning process and suggesting economic policies to promote social well-being. Since the mid-1990s the community of heterodox economics has grown, diversified and
integrated. The previously isolated are now part of a community, heterodox associations exist in countries where previously no heterodox associations had existed, and developments in heterodox theory and policy are occurring at breakneck speed. In short, heterodox economics is now an established feature on the disciplinary landscape and the progressive future of economics.

**Abstract**

Many time series studies, including in particular those estimated by generalized method of moments, involve disturbances that are serially correlated and, possibly, conditionally heteroskedastic. The serial correlation and heteroskedasticity often are of unknown form. Corrections for serial correlation and heteroskedasticity are required for inference and efficient estimation. This article surveys procedures to implement such corrections.

**Article**

Heteroskedasticity and autocorrelation consistent (HAC) covariance matrix estimation refers to calculation of covariance matrices that account for conditional heteroskedasticity of regression disturbances and serial correlation of cross products of instruments and regression disturbances. The heteroskedasticity and serial correlation may be of unknown form. HAC estimation is integral to empirical research using generalized method of moments (GMM) estimation (Hansen, 1982). In this article I summarize results relating to HAC estimation, with emphasis on practical rather than theoretical aspects.

The central issue is consistent and efficient estimation of what is called a ‘long-run variance’, subject to the constraint that the estimator is positive semidefinite in finite samples. Positive semidefiniteness is desirable since the estimator will be used to compute standard errors and test statistics. To fix notation, let \( h_t \) be a \( q \times 1 \) stationary mean zero random vector. Let \( \Gamma_j \) denote the \( q \times q \) autocovariance of \( h_t \) at lag \( q \), \( \Gamma_j \equiv \text{E} h_t h_{t-j}' \); of course, \( \Gamma_j = \Gamma_{-j}' \). The long run variance of \( h_t \) is the \( q \times q \) matrix

\[
S = \sum_{j=-\infty}^{\infty} \Gamma_j = \Gamma_0 + \sum_{j=1}^{\infty} (\Gamma_j + \Gamma_j').
\]

Apart from a factor of \( 2\pi \), the symmetric matrix \( S \), which I assume to be positive definite, is the spectral density of \( h_t \) at frequency zero. As discussed below, techniques for spectral density estimation are central to HAC estimation. For an arbitrary stationary process, the sum in the right-hand side of (1) may not converge, and may not be positive definite even if it
does converge. But here and throughout I assume unstated regularity conditions. As well, I use formulas that allow for relatively simple notation, for example assuming covariance stationarity even when that assumption can be relaxed. The cited papers may be referenced for generalizations and for technical conditions.)

To illustrate how estimation of \( S \) figures into covariance matrix estimation, consider the following simple example. As in Hansen and Hodrick (1980), let us suppose that we wish to test the ‘rationality’ of a scalar variable \( x_t \) as an \( n \) period ahead predictor of a variable \( y_{t+n+1} \), for \( n \geq 0 \): the null hypothesis is \( E_t y_{t+n+1} = x_t \), where \( E_t \) denotes expectations conditional on the information set used by market participants. The variable \( x_t \) might be the expectation of \( y_{t+n+1} \) reported by a survey, or it might be a market determined forward rate. Let \( u_t \) denote the expectational error:

\[ u_t = y_{t+n+1} - E_t y_{t+n+1} = y_{t+n+1} - x_t. \]

(The expectational error \( u_t \), which is not realized until period \( t + n + 1 \), is dated \( t \) to simplify notation.)

One can test one implication of the hypothesis that \( x_t \) is the expectation of \( y_{t+n+1} \) by regressing \( y_{t+n+1} \) on a constant and \( x_t \), and checking whether the coefficient on the constant term is zero and that on \( x_t \) is 1:

\[ y_{t+n+1} = \beta_0 + \beta_1 x_t + u_t \equiv X_t' \beta + u_t; \quad H_0: \beta = (0, 1)' . \]

Under the null, \( E X_t u_t = 0 \), so least squares is a consistent estimator. As well, \( X_t u_t \) follows a moving average process of order \( n \). Thus the asymptotic variance of the least squares estimator of \( \beta \) is \( (E X_t X_t')^{-1} S (E X_t X_t')^{-1} \), where

\[ S = \Gamma_0 + \sum_{j=1}^n \Gamma_j (\Gamma_j + \Gamma_j') , \quad \Gamma_j \equiv E X_t u_t (X_{t-j} u_t - j)'. \]

This example maps into the notation used in (1) with \( h_t = X_t u_t \), \( q = 2 \) and a known upper bound to the number of non-zero autocovariances of \( h_t \). Clearly one needs to estimate \( E X_t X_t' \) and \( S \) to conduct inference. A sample average of \( X_t X_t' \) can be used to estimate \( E X_t X_t' \). If \( n = 0 \), so that \( h_t \) is serially uncorrelated, \( S = E X_t u_t (X_t u_t)' \) and estimation of \( S \) is equally straightforward; White’s (1980) heteroskedasticity consistent estimator can be used. The subject at hand considers ways to estimate \( S \) when \( h_t \) is serially correlated. I note in passing that one cannot sidestep estimation of \( S \) by applying generalized least squares. In this example and more generally, generalized least squares is inconsistent. See Hansen and West (2002).

To discuss estimation of \( S \), let us describe a more general set-up. In GMM estimation, \( h_t \) is a \( q \times 1 \) orthogonality condition used to identify a \( k \)-dimensional parameter vector \( \beta \). The orthogonality condition takes the form

\[ h_t = Z_t u_t \]

for a \( q \times \ell \) matrix of instruments \( Z_t \) and an \( \ell \times 1 \) vector of unobservable regression disturbances \( u_t \). The vector of regression disturbances depends on observable data through \( \beta \), \( u_t = u_t(\beta) \). In the example just given,

\( q = 2 \), \( \ell = 1 \), \( Z_t = X_t \), \( u_t(\beta) = y_{t+n+1} - X_t' \beta \). The example just given is overly simple in that the list of instruments typically will not be identical to right-hand side variables, and the model may be nonlinear. For a suitable \( k \times q \) matrix \( D \), the asymptotic variance of the GMM estimator of \( \beta \) takes the form \( D S D' \) (for example, \( D = (E X_t X_t')^{-1} \) in the example just given). In an overidentified model (that is, in models in which the dimension of the orthogonality condition \( q \) is greater than the number of parameters \( k \)) the form \( D \) takes depends on a certain weighting matrix. Let \( h_t \beta \) be the \( q \times k \) matrix \( \partial h_t / \partial \beta \).

When the weighting matrix is chosen optimally, \( D = (E h_t \beta' S^{-1} E h_t \beta)^{-1} E h_t \beta' S^{-1} \) and the asymptotic variance \( D S D' \)
simplifies to \( (Eh_t \beta ' S^{-1} Eh_t \beta) ^{-1} \). The optimal weighting matrix is one that converges in probability to \( S \), and thus the results about to be presented are relevant to efficient estimation as well as to hypothesis testing. In any event, the matrix \( Eh_t \beta \) typically is straightforward to estimate; the question is how to estimate \( S \). This will be the focus of the remainder of the discussion.

We have sample of size \( T \) and sample counterparts to \( u_t \) and \( h_t \), call them \( \hat{u}_t = u_t(\hat{\beta}) \) and \( \hat{h}_t = h_t(\hat{\beta}) \). Here, \( \hat{\beta} \) is a consistent estimate of \( \beta \). In the least squares example given above, \( \hat{u}_t \) is the least squares residual, \( \hat{u}_t = y_t + n + 1 - x_t \hat{\beta} \), and \( \hat{h}_t = x_t \hat{u}_t = x_t (y_t + n + 1 - x_t \hat{\beta}) \). One path to consistent estimation of \( S \) involves consistent estimation of the autocovariances of \( h_t \). The natural estimator is a sample average,

\[
\hat{\Gamma}_j = T^{-1} \sum_{t=1}^{T} \hat{h}_t \hat{h}_{t-j}' \quad \text{for } j \geq 0.
\]

For given \( j \), (4) is a consistent \((T \rightarrow \infty)\) estimator of \( \Gamma_j \).

I now discuss in turn several possible estimators, or classes of estimators, of \( S \): (1) the truncated estimator; (2) estimators applicable only when \( h_t \) follows a moving average (MA) process of known order; (3) an autoregressive spectral estimator; (4) estimators that smooth autocovariances; (5) some recent work, on estimators that might be described as extensions or modifications of ones the estimators described in (4).

### 1. The truncated estimator

Suppose first that it is known a priori that the autocovariances of \( h_t \) are zero after lag \( n \), as is the case in the empirical example above. A natural estimator of \( S \) is one that replaces population objects in (1) with sample analogues. This is the truncated estimator:

\[
\hat{S}_{TR} = \hat{\Gamma}_0 + \sum_{j=1}^{n} (\hat{\Gamma}_j + \hat{\Gamma}_j').
\]

In the more general case in which \( \Gamma_j \neq 0 \) for all \( j \), the truncated estimator is consistent if the truncation point \( n \rightarrow \infty \) at a suitable rate. Depending on exact technical conditions, the rate may be \( n/T^{1/2} \rightarrow 0 \) or \( n/T^{1/4} \rightarrow 0 \) (Newey and West, 1987). The truncated estimator need not, however, yield a positive semidefinite estimate. With certain plausible data generating processes, simulations indicate that it will not be p.s.d. in a large fraction of samples (West, 1997). Hence this estimator is not used much in practice.

### 2. Estimators applicable only when \( h_t \) follows an MA process of known order \( n \)

Such a process for \( h_t \) holds in studies of rationality (as illustrated above) and in the first order conditions from many rational expectations models (for example, Hansen and Singleton, 1982).

Write the Wold representation of \( h_t \) as \( h_t = e_t + \Theta_1 e_{t-1} + \ldots + \Theta_n e_{t-n} \). Here, \( e_t \) is the \( q \times 1 \) innovation in \( h_t \). Let \( \Omega \) denote the \( q \times q \) variance covariance matrix of \( e_t \). Then it is well known (for example, Hamilton, 1994, p. 276) that
heteroskedasticity and autocorrelation corrections: The New Palgrave Dictionary of Economics

\[ S = (I + \Theta_1 + \cdots + \Theta_n) \Omega (I + \Theta_1 + \cdots + \Theta_n)' \]  \hspace{1cm} (6)

Suppose that one fits an MA(\(n\)) process to \(\hat{h}_t\) and plugs the resulting estimates of the \(\Theta_i\) and \(\Omega\) into the formula for \(S\). Clearly the resulting estimator is \(T^{1/2}\) consistent and positive semidefinite. Nevertheless, to my knowledge this estimator has not been used, presumably because of numerical difficulties in estimating multivariate moving average processes.

Two related estimators have been proposed that impose a smaller computational burden. Hodrick (1992) and West (1997) suggest an estimator that requires fitting an MA(\(n\)) to the vector of regression residuals \(\hat{\delta}_t\) (or, in Hodrick’s, 1992, application, using MA coefficients that are known a priori). The computational burden of such MA estimation will typically be considerably less than that of MA estimation of the \(h_t\) process, because the dimension of \(u_t\) is usually much smaller than that of \(h_t\). For example, \(\hat{\delta}_t\) will be a scalar in a single equation application, regardless of the number of orthogonality conditions captured in \(h_t\). Write the estimated MA process for \(\hat{\delta}_t\) as \(\hat{\delta}_t = \varepsilon_t + \Psi_1 \varepsilon_{t-1} + \cdots + \Psi_n \varepsilon_{t-n}\), where the \(\Psi_j\) are \(\mathcal{E} \times \mathcal{E}\). (Note that \(\varepsilon_t\), the \(\mathcal{E} \times 1\) innovation in \(u_t\), is not the same as \(e_t\), the \(q\times1\) innovation in \(h_t\).) Then a \(T^{1/2}\) consistent and positive semidefinite estimator of \(S\) is

\[ \hat{S}_{MA-E} = T^{-1} \sum_{t=1}^{T-n} \hat{\delta}_{t+n} \hat{\delta}_{t+n}' = (Z_t + Z_{t+1} \hat{\Psi}_1 + \cdots + Z_{t+n} \hat{\Psi}_n) \varepsilon_t \]  \hspace{1cm} (7)

where, again, \(Z_t\) is the \(Q \times \mathcal{E}\) matrix of instruments (see eq. (3)).

Eichenbaum, Hansen and Singleton (1988) and Cumby, Huizanga and Obstfeld (1983) propose a different strategy that avoids the need to estimate a moving average process for either \(u_t\) or \(h_t\). They suggest estimating the parameters of \(\hat{h}_t\)'s autoregressive representation, and inverting the autoregressive weights to obtain moving average weights. Call the results \(\hat{\Theta}_1, \ldots, \hat{\Theta}_n\), with \(\hat{\Omega}\) the estimate of the innovation variance–covariance matrix. The resulting estimator

\[ \hat{S} = (I + \hat{\Theta}_1 + \cdots + \hat{\Theta}_n) \hat{\Omega} (I + \hat{\Theta}_1 + \cdots + \hat{\Theta}_n)' \]  \hspace{1cm} (8)

is positive semidefinite by construction. The rate at which it converges to \(S\) depends on the rate at which the order of the autoregression is increased.

3 Autoregressive estimators

Den Haan and Levin (1997) propose and evaluate an autoregressive spectral estimator. Suppose that \(h_t\) follows a (possibly) infinite-order vector autoregression (VAR)

\[ h_t = \sum_{j=1}^{\infty} \Phi_j h_{t-j} + e_t, \hspace{0.5cm} EE_t e_t' = \Omega. \]  \hspace{1cm} (9)

Then (Hamilton, 1994, p. 237)
The idea is to approximate this quantity via estimates from a finite-order VAR in $\hat{h}_t$. Write the estimate of a VAR in $\hat{h}_t$ of order $p$ as

$$
\hat{h}_t = \Phi_1 \hat{h}_{t-1} + \cdots + \Phi_p \hat{h}_{t-p} + \hat{e}_t, \quad \hat{\Omega} = T^{-1} \sum_{t=p+1}^{T} \hat{e}_t \hat{e}_t',
$$

(10)

Then the estimator of $\hat{S}$ is

$$
\hat{S}_{AR} = \left( I - \sum_{j=1}^{p} \hat{\Phi}_j \right)^{-1} \hat{\Omega} \left( I - \sum_{j=1}^{p} \hat{\Phi}_j \right)^{-1}'.
$$

(11)

Den Haan and Levin (1997, Section 3.5) conclude that if $p$ is chosen by BIC, and some other technical conditions hold, then this estimator converges at a rate very near $T^{1/2}$ (the exact rate depends on certain characteristics of the data). A possible problem in practice with this estimator (as well as with the estimator described in the final paragraph of Section 2, which also requires estimates of a VAR in $\hat{h}_t$) is that it may require estimation of many parameters and inversion of a large matrix. Den Haan and Levin therefore suggest judiciously parametrizing the autoregressive process, for example by using the BIC criterion equation-by-equation for each of the $q$ elements of $\hat{h}_t$.

4 Estimators that smooth autocovariances

In practice, the most widely used class of estimators is one that relies on smoothing of autocovariances. Andrews (1991), building on the literature on estimation of spectral densities, established a general framework for analysis. Andrews considers estimators that can be written

$$
\hat{S} = \hat{\Gamma}_0 + \sum_{j=1}^{T-1} k_j (\hat{\Gamma}_j + \hat{\Gamma}_j').
$$

(12)

for a series of kernel weights $\{k_j\}$ that obey certain properties. For example, to obtain a consistent estimator, we need $k_j$ near...
heteroskedasticity and autocorrelation corrections: The New Palgrave Dictionary of Economics

zero (or perhaps identically zero) for values of \( j \) near \( T-1 \), since autocovariances at large lags are estimated imprecisely, while \( k_j \to 1 \) for each \( j \) is desirable for consistency. We would also like the choice of \( k_j \) to ensure positive definiteness. The two most commonly used formulas for the kernel weights are:

\[
\text{Bartlett: for some } m \geq 0; \quad k_j = 1 - \left[ j / (m + 1) \right] \text{ for } j \leq m, k_j = 0 \text{ for } j > m. \\
\text{(13a)}
\]

\[
\text{Quadratic spectral (QS): for some } m > 0, \text{ and with } x_j = j / m: \\
k_j = \left[ 25 / 12 \pi^2 x_j^2 \right] \left[ \sin(6 \pi x_j / 5) / (6 \pi x_j / 5) \right] - \cos(6 \pi x_j / 5). \\
\text{(13b)}
\]

If we let \( z_j = 6 \pi x_j / 5 \), the QS formula for \( k_j \) can be written in more compact form as
\[
\left\{ \sin(z_j) / z_j \right\} - \cos(z_j). \\
\text{(3)}
\]

Call the resulting estimators \( \hat{S}_{BT} \) and \( \hat{S}_{QS} \). For example,
\[
\hat{S}_{BT} = \hat{r}_0 + \sum_{j=1}^{m} \left[ 1 - j / (m + 1) \right] (\hat{r}_j + \hat{r}_j') . \\
\text{(14)}
\]

The vast literature on spectral density estimation suggests many other possible kernel weights. For conciseness, I consider only the Bartlett and QS kernels. To operationalize these estimators, one needs to choose the lag truncation parameter or bandwidth \( m \). I note that for both kernels, consistency requires \( m \to \infty \) as \( T \to \infty \), even if \( h_t \) follows an MA process of known finite order, as in the example given above. Thus one should not set \( m \) to be the number of non-zero autocovariances. Subject to possible problems with positive definiteness, setting \( m = n \) is fine for the truncated estimator (5) but not for estimators that use nontrivial weights \( \{ k_j \} \).

Andrews shows that maximizing the rate at which \( \hat{S} \) converges to \( S \) requires that \( m \) increase as a suitable function of sample size, with the ‘suitable function’ varying with kernel. For the Bartlett and QS, the maximal rates of convergence are realized when

\[
\text{Bartlett: } m = \gamma T^{1/3} \text{ (or } m = \text{ (integer part of } \gamma T^{1/3} \text{)) for some } \gamma \neq 0; \text{ QS: } m = \gamma T^{1/5} \text{ for some } \gamma \neq 0, \\
\text{(15)}
\]

in which case \( \hat{S}_{BT} \) converges to \( S \) at rate \( T^{1/3} \) and the mean squared error in estimation of \( S \) goes to zero at rate \( T^{2/3} \); the comparable figures for QS are \( T^{2/5} \) and \( T^{4/5} \). Since both estimators are nonparametric, they converge at rates slower than \( T^{1/2} \); since faster convergence is better, the QS rate is preferable to that of the Bartlett. Indeed, Andrews (1991), drawing on...
Priestley (1981), shows that for a certain class of kernel weights \( \{k_j\} \), the mean squared error of QS rate is optimal in the following sense: a \( T^{4/5} \) rate on the asymptotic mean squared error is the fastest that can be achieved if one wants to ensure a positive definite \( \hat{S} \), and within the class of kernels that achieve the \( T^{4/5} \) rate, the QS has the smallest possible asymptotic mean squared error.

As a practical matter, the formulas in (15) have merely pushed the question of choice of \( m \) to one of choice of \( \gamma \); putting arbitrary \( \gamma \) in (15) yields convergence that is as fast as possible, but different choices of \( \gamma \) lead to different asymptotic mean squared errors. The choice of \( \gamma \) that is optimal from the point of view of asymptotic mean squared error is a function of the data (Hannan, 1970, p. 286). Let 

\[
S^{(0)} = \sum_{j=-\infty}^{\infty} \Omega_j \cdot (\hat{S} \cdot \sum_{j=-\infty}^{\infty} \Omega_j)
\]

\[
S^{(1)} = \sum_{j=-\infty}^{\infty} j \cdot \Omega_j \cdot \sum_{j=-\infty}^{\infty} \Omega_j
\]

\[
S^{(2)} = \sum_{j=-\infty}^{\infty} j^2 \cdot \Omega_j \cdot \sum_{j=-\infty}^{\infty} \Omega_j
\]

For scalar \((q=1)\) \( S \) optimal choices are:

\[
\text{Bartlett: } \gamma = 1.1447 \cdot \left( \frac{S^{(1)}}{S^{(0)}} \right)^{2/3}; \quad \text{QS: } \gamma = 1.3221 \cdot \left( \frac{S^{(2)}}{S^{(0)}} \right)^{2/5}.
\]

(See Andrews, 1991, for the derivation of these formulas.)

Andrews (1991), Andrews and Monahan (1992) and Newey and West (1994) proposed feasible data dependent to procedures to estimate \( \gamma \), for vector as well as scalar \( h_t \). Rather than exposit the general case, I will describe two ‘cookbook’ procedures that have been offered as reasonable starting points in empirical work. One procedure relies on Andrews (1991) and Andrews and Monahan (1992), and assumes the QS kernel and estimation of \( \gamma \) via parametric models. The second relies on Newey and West (1994), and assumes a Bartlett kernel and nonparametric estimation of \( \gamma \). I emphasize that both papers present more general results than are presented here; both allow the researcher to (for example) use any one of a wide range of kernels.

Let there be a \( q \times 1 \) vector of weights \( w=(w_1, w_2, \ldots, w_q) \) whose elements tells us how to weight the various elements of \( S \) with respect to mean squared error. The weights might be sample dependent, and den Haan and Levin (1997) argue that there are benefits to certain sample-dependent weights, but a simple choice proposed by both papers is: \( w_i=0 \) if the corresponding element of \( h_t \) is a cross product of a constant term and a regression disturbance, otherwise \( w_i=1 \). Andrews’s loss function is the normalized expectation of \( \sum_{j=1}^{q} w_j (\hat{S}_j - \hat{\gamma})^2 \), while Newey and West’s loss function is the normalized expectation of \( [w' (\hat{S} - \hat{\gamma}) w]_2 \); the normalization is \( T^{4/5} \) for QS and \( T^{2/3} \) for Bartlett.

Both procedures begin with using a vector autoregression to prewhiten, and end with re-colouring. The basic justification for prewhitening and re-colouring is that simulation evidence indicates that this improves finite sample performance.

1. Prewhitening: Estimate a vector autoregression in \( \hat{h}_t \), most likely of order 1. Call the residuals \( \hat{\eta}_t \)

\[
\hat{\eta}_t = \hat{\mathcal{A}} \hat{h}_t + \mathcal{A} = \sum_{t=2}^{T} \hat{h}_t \hat{h}_{t-1} \left( \sum_{t=2}^{T} \hat{h}_{t-1} \hat{h}_{t-1} \right)^{-1}.
\]

2. Let \( \tilde{\Gamma}_j \) denote the \( j \)th autocovariance of the VAR residual \( \hat{\eta}_t \).

\[
\tilde{\Gamma}_j = (T-1)^{-1} \sum_{t=2}^{T} \hat{h}_t \hat{h}_{t-j}.
\]

3. Let \( \{\tilde{\Gamma}_j\} \) denote the autocovariances of \( \hat{h}_t \), and choosing \( m \) optimally as described in steps 2a or 2b below,
construct an estimate of the long run variance of the residual of the VAR just estimated. Call the result $\hat{\mathbf{S}}^\dagger$.

- 2a. Andrews and Monahan (1992): Fit a univariate AR(1) to each of the $q$ elements of $\hat{\mathbf{h}}_t^\dagger$. Call the resulting estimate of the AR coefficient and variance of the residual $\hat{\rho}_j$ and $\hat{\sigma}_j^2$. Compute

$$\hat{\mathbf{S}}_2 = \sum_{i=1}^q w_i (4 \hat{\rho}_i^2 \hat{\sigma}_i^2) / (1 - \hat{\rho}_i)^8, \quad \hat{\mathbf{S}}_0 = \sum_{i=1}^q w_i \hat{\sigma}_i^4 / (1 - \hat{\rho}_i)^4, \quad \hat{\gamma}_{QS} = 1.3221 \left[ \hat{\mathbf{S}}_2 / \hat{\mathbf{S}}_0 \right]^{1/5}, \quad \hat{\mathbf{m}}_{QS} = \hat{\gamma}_{QS} T^{1/5}.$$ (18)

Then plug $\hat{\mathbf{m}}_{QS}$ into formula (13b). Call the result $\hat{k}_j$. Compute $\hat{\mathbf{S}}^\dagger = \hat{\mathbf{S}}_0 + \sum_{j=1}^{T-1} \hat{k}_j (\hat{\mathbf{r}}_j^\dagger + \hat{\mathbf{r}}_{j-1}^\dagger).$

$$\hat{\mathbf{S}}^{(1)} = w' \hat{\mathbf{r}}_0 w + 2 \sum_{i=1}^n w' \hat{\mathbf{r}}_i^\dagger w, \quad \hat{\gamma}_{BT} = 1.1447 \left[ \hat{\mathbf{S}}^{(1)} / \hat{\mathbf{S}}^{(0)} \right]^{2/3}, \quad \hat{\mathbf{m}}_{BT} = \text{integer part of } \hat{\gamma}_{BT} T^{1/3}.$$ (19)

Then compute $\hat{\mathbf{S}}^\dagger$ according to (14), using $\hat{\mathbf{m}}_{BT}$.

- 3. Re-colouring: compute $\hat{\mathbf{S}} = (I - \hat{\mathbf{A}})^{-1} \hat{\mathbf{S}}^\dagger (I - \hat{\mathbf{A}})^{-1}$.

These two recipes for estimates of $\mathbf{S}$ can serve as a starting point for experimentation for alternative choices of $m$ and alternative kernels.

What is the simulation evidence on behaviour of these and other proposed estimators? In answering this question, I focus on sizing of test statistics and accuracy of confidence interval coverage: accuracy in estimation of $\mathbf{S}$ is desirable mainly insofar as it leads to accuracy of inference using the relevant variance–covariance matrix. The simulations in papers cited in this article suggest the following. First, no one estimator dominates others. This means in particular that the rate of convergence is not a sufficient statistic for performance in finite samples. The truncated estimator often and the autoregressive estimator sometimes perform more poorly than the slower converging QS estimator, which in turn sometimes performs more poorly than the still slower converging Bartlett estimator. Second, given that one decides to use QS or Bartlett, performance generally though not always is improved if one prewhitens and uses a data-dependent bandwidth as described in the recipes above. Third, the QS and Bartlett estimators tend to reject too much in the presence of positive serial correlation in $h_t$, and have what I read as a DGP dependent rejection rate (sometimes over-reject, sometimes under-reject) in the presence of negative serial correlation in $h_t$. The truncated estimator is much likelier to fail to be positive semidefinite in the presence of negative than positive serial correlation. Finally, the performance of all estimators leaves much to be desired. Plausible data-generating processes and sample sizes can lead to serious mis-sizing of any given estimator. Nominal 0.05 tests can have empirical size as low as 0.01 and higher than 0.25.

### 5 Some recent work

Because simulation studies have yielded disappointing performance, ongoing research aims to develop better estimators. I close by summarizing a few of many recently published papers.

1. I motivated my topic by observing that consistent estimation of $\mathbf{S}$ is a natural element of consistent estimation of the variance–covariance matrix of a GMM estimator. Typically we estimate the variance–covariance matrix because we wish to
construct confidence intervals or conduct hypothesis tests. A recent literature has evaluated inconsistent estimators that lead to well-defined test statistics, albeit statistics with non-standard critical values. These estimators set lag truncation (or bandwidth) equal to sample size. For example, for the Bartlett estimator, these estimators set \( m = T - 1 \) (see Kiefer, Vogelsang and Bunzel, 2000; Kiefer and Vogelsang, 2002). Simulation evidence indicates that the non-standard statistics may be better behaved than standard statistics. Jansson (2004) provides a theoretical rationale for improved performance in a special case, with more general results in Kiefer and Vogelsang (2005). Phillips, Sun and Jin (2006; 2007) propose a related approach, which under some assumptions will yield statistics with standard critical values.

2. Politis and Romano (1995) propose what they call a ‘trapezoidal’ kernel. A trapezoidal kernel is a combination of the truncated and Bartlett kernels. For given truncation lag \( m \), let \( x_j = j / (m + 1) \). Then for some \( c, 0 < c < 1 \), the trapezoidal weights satisfy: \( k_j = 1 \text{ if } 0 \leq x_j \leq c \), \( k_j = (x_j - 1) / (c - 1) \text{ for } c < x_j \leq 1 \). Thus for \( 0 \leq j \leq c(m + 1) \), the autocovariances receive equal weight, as in the truncated kernel; for \( c(m + 1) < j \leq m + 1 \), the weights on the autocovariances decline linearly to zero, as in the Bartlett kernel. Such kernels have the advantage that, like the truncated kernel, their convergence is rapid (near \( T^{1/2} \)). They share with the truncated kernel the possibility of not being positive semidefinite. The authors argue, however, that these kernels are better behaved in finite samples than is the truncated kernel.

3. Xiao and Linton (2002) propose ‘twicing’ kernels. Operationally, one first computes an estimate such as one of those described in Section 4. One also constructs a multiplicative bias correction by smoothing periodogram ordinates via a ‘twiced’ kernel. For a properly chosen bandwidth and kernel, the mean squared error of the estimator is of order \( T^{8/9} \) (versus \( T^{4/5} \) for the QS and \( T^{2/3} \) for the Bartlett, absent any corrections). As well, Hirukawa’s (2006) version of the Xiao and Linton estimator is positive semidefinite by construction. (The rate results for this estimator and that described in the previous paragraph do not contradict Andrews’s, 1991, optimality result for the QS kernel, because these procedures fall outside the class considered by Andrews.)

Abstract

This biographical review of the life and works of John Hicks covers his contributions to numerous fields, and in each case assesses the particular contributions for which he was responsible. The fields concerned are The Theory of Wages, Value Theory, Welfare Economics, The Keynesian Revolution, Monetary Theory, Growth and Capital Theory, and Other Topics. An extensive bibliography of Hicks's writings is provided. Two points that are stressed are the unusual departure point for Hicks's thought in the general equilibrium ideas of European economists, and the radical effect on Hicks of Keynes's ideas.

Article

1 Biography and intellectual development
Hicks was born in Warwick. He studied at Oxford (1922–6) and taught at the London School of Economics (1926–35). He was Professor at Manchester University (1935–46), from where he moved to Oxford, first as Fellow of Nuffield College, and from 1952 until he retired, from teaching but not from writing, as Drummond Professor of Political Economy and Fellow of All Souls College. In 1935 he married Ursula Webb, a distinguished public finance specialist, and he collaborated with her in the preparation of numerous works on public finance, its theory and its application to various countries. Ursula Hicks, as she was subsequently known, died in 1985. John Hicks was a member of the Royal Commission on the Taxation of Profits and Income in 1951. He became a Fellow of the British Academy in 1942, a Knight in 1964, and was awarded the Nobel Prize in Economics (jointly with Kenneth J. Arrow) in 1972. He died in 1989.

Hicks was the product of a generation which was the last to produce in abundance all round economic theorists – economists who could turn their minds to almost any theoretical problem. Its leading lights, among whom Hicks is certainly to be counted, left their marks on most of the major new branches and issues of economics as these in turn attracted the interest of themselves and their contemporaries. Hicks's powerful and original mind first made itself felt in what is now called microeconomics, particularly in *The Theory of Wages* (1932, 2nd edition 1963) and with R.G.D. Allen, ‘A Reconsideration of the Theory of Value’ (*Economica*, 1934) and in welfare economics. However his best-known work, *Value and Capital* (1939), goes beyond microeconomics to offer an economic dynamics and discussion of monetary theory which reaches into the new macroeconomics.

Before Keynes's *General Theory* fundamentally altered the way in which economists viewed their subject, the theory of value, including the theory of the firm, shared the field with monetary theory. Hicks was first a value theorist, but he never neglected monetary theory, and it was an area to which he was frequently to return. It was a value theorist with an interest in monetary economics who provided in ‘Mr Keynes and the “Classics”’ (*Econometrica*, 1937) an exposition of Keynes's *General Theory* that was probably more directly influential than the original. There followed work on the trade cycle, *A Contribution to the Theory of the Trade Cycle* (1950); on growth, *Capital and Growth* (1965); and an unusual approach to capital theory, *Capital and Time: A Neo-Austrian Theory* (1973).

Each decade of Hicks’s life seemed to find him more eclectic and innovative than the last. Indeed, his willingness to speculate about and write on areas in which he had not seeped himself as a specialist was a notable feature of his later writing. Striking examples are *A Theory of Economic History* (1969), in which Hicks undertook the risks inherent in proposing a grand theory of economic history, and *Causality in Economics* (1979), in which he entered ground normally reserved for philosophers and statisticians. These works can be criticized, but as their author always commands a well-provisioned base camp in the economics which is his own, they are never merely amateurish. Hicks is an economist of outstanding breadth and erudition.

With hindsight it is remarkable that the author of such a formidable theoretical corpus should write (‘Commentary’ in the 1963 edition of *The Theory of Wages*, p. 306): ‘… at first I regarded myself as a labour economist, not a theoretical economist at all’. Lionel Robbins is given the credit for interesting Hicks in theory: ‘… he moved me from Cassel to Walras and Pareto, to Edgeworth and Taussig to Wicksell and the Austrians – with all of whom I was more at home at that stage than I was with Marshall and Pigou’ (p. 306). It would be foolish to attempt to explain why Hicks became the distinctive economist that he was to become. However the above snatches of autobiography probably go some way to explaining why *Value and Capital* turned out to be a book like no other that an English economist had

written before.
Hicks's huge output (for the papers see the three-volume *Collected Essays on Economic Theory*, 1981–3) is all the more remarkable when one considers that he seldom simply reacted to the work of others. There are no papers by Hicks pointing out mistakes by other writers, and none which embody minor changes to or extensions of existing models. Naturally Hicks produced work which follows paths opened up by others. However when he did so, as in *A Revision of Demand Theory* (1956), or with the famous IS–LM model, his approach was so distinctive that the commentary is recognizably a contribution of Hicks. Other writers feature mainly in footnotes and even such a powerful contribution as Samuelson's treatment of Walrasian stability earns no more than two pages in the Second Edition of *Value and Capital*. There is a streak of self-centredness and parochialism in Hicks which mirrors that to be found in other English economists of his generation and those before. It would be insufferable in an economist less gifted and genuinely self-critical.

2 The theory of wages

Writing later (1963) of the first edition of *The Theory of Wages* its author remarks that ‘… there has been no date this century to which the theory that I was putting out could have been more inappropriate.’ However, Hicks was careful not to attribute the shortcomings of his first book to the misfortune of publishing in the worst year of the depression and a few years ahead of the reassessment of the theory of the firm brought about by the writings of Chamberlin and Joan Robinson and, worse fortune still, ahead of the *General Theory*. In this he was right. *The Theory of Wages* set out to examine the determination of wages under supply and demand in a competitive market. This admittedly limited task is important, and had it been perfectly accomplished it would not be sensible to criticize the resulting work for not solving other problems, such as wages under imperfect competition or the consequences of nominal wage bargaining, weighty though those problems might be. However the truth is that there were shortcomings in Hicks's treatment even given its chosen emphasis. It was not as good a book as Hicks was later to show that he could write, though it was surely a better book than the later Hicks's embarrassment at its shortcomings allowed him to admit.

G.F. Shove (whose fairly hostile review Hicks reprinted in the Second Edition) identified a number of the shortcomings. Notable among these is the relatively weak treatment of the supply side of labour markets and the consequently limited ability to treat unemployment. Shove also seems to accuse Hicks of failing to provide a treatment of the general equilibrium of many labour markets, which must be counted a rather common failing among labour economists. Shove, not surprisingly, was clear on minimum cost and the adding-up problem where Hicks's account needed improvement – it was after all Shove's bread and butter at the time. A point which Shove missed is that Hicks always discussed differences in the productivity of different workers as equivalent to differences in the quantity of effective labour provided per hour of work. In other words, like Marx before him, he fudged the problem of aggregating different types of labour.

These legitimate criticisms apart, there were very considerable merits. By concentrating on the long-run determinants of wage rates Hicks was able to examine some of the most interesting influences at work. He saw changes in the demand for labour as consisting of two components quite analogous to the income and substitution effects in demand that he was to investigate later. A lower wage rate leads to an expansion of output, because the cost curve has fallen, which induces a higher demand for labour. In
addition a lower wage rate induces the adoption of more labour intensive methods of production, which increases the demand for labour for a given output. The analysis of this last effect lead to the discovery of the new concept of the elasticity of substitution, not quite as neat in Hicks's formulation as in Joan Robinson's later presentation, but this was the original. In general, Hicks's definition of the elasticity of substitution is different from Joan Robinson's, but the two are equivalent in the two-factor case. Many topics discussed only briefly and not deeply analysed were far ahead of their time. There is the idea that because capital tends to accumulate faster than labour, technical progress tends to be labour saving – the induced bias of technical progress as we would now say. There is the first ever attempt to model a labour dispute which may culminate in a strike, and more besides.

In a passing discussion in *The Theory of Wages* its author records a fascinating fact. Many wage rates in inter-War Britain were tied to the value of the output concerned, and for that reason were automatically flexible. Once account is taken of such arrangements, the remaining pure flexibility of money wages is exceedingly small. This provided an opportunity, not taken, to bring Hicks's analysis to bear on an event that must have impressed itself on the young Oxford undergraduate: the 1926 miners’ strike that led to the failed General Strike. Britain restored Sterling convertibility in 1925 at the pre-war rate of $4 to the pound. The resulting over-valuation of Sterling made much British industrial activity internationally uncompetitive. At the time the world price of coal in dollars had fallen sharply, with the consequence that British coal was worth less in dollars, and even less in over-valued Sterling. The coal miners’ contracts required sharp cuts in their wages, for which reason they went on strike. Tying miners’ wages to the price of coal implied too much wage flexibility in these circumstances. Britain's coal-mining sector needed to contract, which should have raised the marginal product of labour in terms of coal, where the existing contracts held that number constant.

## 3 Value theory

This area and welfare economics are fields to which Hicks contributed the writings that would have made him a great economist if he had done nothing else. In making the 1972 Nobel Prize award to Hicks jointly with Arrow the Committee mentioned ‘general equilibrium and welfare economics’. The reference in Hicks's case was clearly to *Value and Capital* on the one hand, and to the various papers which established the Kaldor–Hicks criterion in welfare economics on the other. Hicks's paper with R.G.D. Allen, ‘A Reconsideration of the Theory of Value’ (1934) was written when both authors were at the London School of Economics, but its pedigree goes back to Slutsky, who had discovered the income and substitution effects in demand as early as 1915. However Slutsky's work was almost entirely unknown to economists in the West, and this included, as Hicks informs us, himself and Allen (‘...I never saw Slutsky's work until my own was very far advanced, and some time after the substance of these chapters had been published in *Economica* by R.G.D, Allen and myself’ (1939, p. 19)).

*Value and Capital* is a work so rich in ideas that a short account of it cannot hope to do it justice. It showed that the basic results of consumer theory could be obtained from ordinal utility; it expounded what became known as the ‘Hicksian substitution effect’, obtained by varying income as relative prices changed so as to maintain an index of utility constant; it developed the parallel results for production theory; and it popularized among English speaking economists the notion of a general equilibrium of markets. Unlike Arrow, his fellow Nobel laureate, Hicks did not take the existence argument beyond equation and variable counting. There was about the Walrasian approach, Hicks concluded, ‘... a certain
sterility’ (1939, p. 60). The way to overcome this was to consider the ‘laws of change’ of a general equilibrium system. This lead Hicks to the first ever attempt to analyse the stability of a system of multiple exchange.

It is fascinating that both Hicks and Samuelson, working entirely independently, both came up with the idea that dynamics might rescue general equilibrium theory from emptiness. Paul Samuelson in various papers of the 1940s and in his *Foundations of Economic Analysis* (1947) adopted an entirely different approach from that of Hicks. Consider a system of \( M \) markets with prices \( p_1, p_2, \ldots, p_M \) and excess demands for the goods \( X_1, X_2, \ldots, X_M \). Making the dependence of excess demands on all prices explicit, this system can be written as:

\[
\begin{align*}
X_1(p_1, p_2, \ldots, p_M) &= 0 \\
X_2(p_1, p_2, \ldots, p_M) &= 0 \\
& \quad \vdots \\
X_M(p_1, p_2, \ldots, p_M) &= 0
\end{align*}
\] (3.1)

In equilibrium prices are such that all excess demands are zero. Now consider one good, which may be taken without loss of generality to be good 1. Select any value for \( p_1 \) and suppose that there are unique values of the remaining prices such that the excess demands for goods 2 to \( M \) are zero. If the excess demands for the other goods are always maintained at zero by changes in their prices, all other prices become implicit functions of \( p_1 \). The Hicks stability condition is then the one that would be required of a single market – \( X_1 \) should decrease with \( p_1 \). Full stability requires that this condition should be satisfied for each good in turn.

At first sight the condition appears to be asymmetrical but as the condition must be satisfied by all goods, there is no genuine asymmetry involved. However each test does involve a certain kind of asymmetry, and this is what Samuelson objected to. When we look at good 1 we implicitly assume that prices in other markets react more rapidly to disequilibrium than does the price of good 1. When we look at good 2 we make the same implicit assumption for the price of good 2, and so on. What Samuelson did was to make the time rate of change of each price a function of the excess demand in its own market hence arriving at the system of simultaneous differential equations:

\[
\begin{align*}
\frac{dp_1}{dt} &= X_1(p_1, p_2, \ldots, p_M) \\
\frac{dp_2}{dt} &= X_2(p_1, p_2, \ldots, p_M) \\
& \quad \vdots \\
\frac{dp_M}{dt} &= X_M(p_1, p_2, \ldots, p_M)
\end{align*}
\] (3.2)
The Hicksian stability condition can be shown to be neither necessary nor sufficient for the stability of (3.2). Hicks however defended his own approach, on the ground that it answers a different but interesting question, in the Second Edition of *Value and Capital* (Additional note C). Parts III and IV of *Value and Capital* record the effect of a road-to-Damascus-like change of vision by Hicks. It seems that while preparing his great work on price theory, Hicks read Keynes, and, to borrow a modern term, it blew his mind. He could no longer find any real satisfaction in the static formalism of Walrasian equilibrium theory, and what he then did shows the full extent of his originality. In these later Parts of the book that eventually resulted he adapted the static theory of the earlier parts to create an economic dynamics which borrowed equally from the Marshallian–Keynesian tradition of the short period and the Walras–Wicksell tradition of long-period equilibrium. The key idea was the concept of temporary equilibrium – an equilibrium of current markets in which future markets make their influence felt indirectly, through the expectations held by agents, which influence their behaviour in current markets. From this emerged the concept of the elasticity of expectations, an idea which proved to be crucial in much later work on macroeconomic theory.

### Welfare economics

Hicks's writings on welfare economics are largely accounted for by work on four closely connected fields of interest: the foundations of welfare economics, including the famous compensation test; the valuation of social income; the definition and measurement of consumer surplus; and, lastly, the measurement of capital.

Hicks was one of the pioneers of the ‘new welfare economics’, an approach which owed its inception to Kaldor's ‘Welfare propositions in economics and interpersonal comparisons of utility’ (*Economic Journal*, 1939). The problem at issue is inescapable and fundamental to the justification of the recommendations of economists. By the time the debate arose, cardinal utility was no longer generally accepted and the need was felt to differentiate between ‘scientific’ propositions and ‘value judgements’. The notion of a ‘Pareto improvement’ – a change that would make no individual worse off, and at least one better off – was familiar but was seen to be limited as a basis for recommendations, as nearly all actual changes made at least one person or group worse off. In Robbins's telling example, economists could not state scientifically that the abolition of the Corn Laws was a good thing because this reform made landlords worse off.

Hicks's suggested solution to the difficulty was the same as that proposed by Kaldor – a compensation test. A reform should be counted an improvement if the gainers could afford to compensate the losers and still be better off. In ‘The Foundations of Welfare Economics’ (*Economic Journal*, 1939), Hicks discussed the question of whether compensation must be paid for the improvement to count without a sense of how crucial this question was to prove to be. It was of course central to the issue posed by the Scitovsky example, which showed that the Kaldor–Hicks rule could lead to contradictory recommendations if compensation were not paid. A well-argued solution to this problem was proposed by I.M.D. Little (1950), but this required explicit value judgements concerning whether income distribution had improved or not in a movement from one position to another, hence negating the original intention of the exercise, which had been to remove value judgements from welfare economics.
Hicks seemed to see these developments as fairly unimportant qualifications to the original idea. In ‘The Measurement of Real Income’ (1958), he writes of the ‘new welfare economists’; ‘They were indeed over-confident in their belief that they had found a means of direct comparison which will always work. But I still maintain that they did find a means of direct comparison which will often work’ (reprinted in Collected Essays, Vol. I, p. 168). For a statement of Hicks's mature views on these questions see ‘The scope and status of welfare economics’ (1975). Perhaps the most interesting thing to notice about Hicks's long involvement with the foundations of welfare economics is that he seems never to have wholly accepted the conclusion upon which the majority of economists have been willing to settle. Briefly put, this view says that value judgements are an inescapable element in welfare evaluations and this should be accepted and the judgements made explicit. Hence the design of policy by the means of the maximization of an explicit social welfare function – the welfare weights of cost-benefit analysis – never engaged Hicks's interest.

It is evident that the problem of the measurement of income is closely allied to the issue of welfare improvements and Hicks, as would be expected, contributed to this area as well. Hicks discussed social accounting in his text book The Social Framework (1942), and the valuation of social income in a paper of that title in Economica (1940). Hicks concluded that the measurement of income could mean measurement in terms of utility or measurement in terms of cost, and that the two measures were in general different. The most interesting issue to which this gave rise was the problem of how to treat indirect taxation and government expenditure on goods and services in the valuation of social income. This led Hicks into controversy with Kuznets (Economica, 1948; see also Essay 7 in Volume I of the Collected Essays). The usual practice is to measure prices at factor cost and to value public services at cost. Hicks's original position may be briefly summarized as follows:

(i) As there is no market test where public goods are concerned the taxation which pays for them is not a reliable measure of their value to the consumer; and (ii) even if consumers were to be regarded as implicitly choosing public expenditure exactly as they choose private expenditure, the appropriate price weights would not be average costs but marginal costs. For a mature statement, see the Addendum to Essay 7 in Volume I of the Collected Essays.

Between 1941 and 1946 Hicks published a number of papers on consumer surplus in the Review of Economic Studies that did much to revive interest in a concept which had seemed to lose its validity when measurable utility went out of fashion. His most important contribution to the controversial question of the measurement of capital, significantly entitled ‘Measurement of Capital in Relation to the Measurement of Other Economic Aggregates’, is in F.A. Lutz and D.C. Hague (1961).

5 The Keynesian revolution and the theory of money

Hicks's first response to the General Theory is described in detail in ‘Recollections and documents’ (Economica, 1973, included in Economic Perspectives, 1977). However the response for which he is best known was an expository piece ‘Mr Keynes and the “Classics”’ (1937) that perfectly fulfilled the innate demand for a more readily accessible account of the essentials of Keynes's argument. It is important to make clear that what was provided was more than an haut vulgarization of Keynes, because the paper has been widely criticized for vulgarization and still more for seriously misrepresenting what the General Theory is about. This case has never been rigorously argued and it is...
hard to see how it could succeed. Hicks reproduced rather faithfully Keynes's various specifications, but by working with a two-sector model produced a framework which resulted in a simple diagram – the IS–LM diagram – which became to macroeconomic textbooks what the benzene ring diagram is to textbooks of organic chemistry. It is no surprise therefore that Keynes on reading the paper wrote to Hicks that he had ‘… next to nothing to offer by way of criticism’. Certainly there is more in the General Theory than just the IS–LM model. In particular there is the idea of a long-term under-consumption problem, no less worrying for being loosely formalized. Nevertheless, the IS–LM framework is there, as is what Samuelson later called the neoclassical synthesis, however much Keynes's latter-day disciples may dislike it.

In fact Hicks's way of presenting the argument is in some ways superior to that adopted in the *General Theory* because the original IS–LM model brings out very clearly how the relative price of capital and consumption goods enters into the determination of the solution – a point which is somewhat obscure in Keynes. How ironic therefore that one of the arguments later advanced against the IS–LM model, admittedly with simpler versions than Hicks's in mind, was that it omitted an essential feature of Keynes – relative prices of capital and other goods.

Hicks's IS curve is based on the striking observation that if the capital stocks in the two sectors of the economy are given, and if the money wage is known, then outputs in the two sectors depend on the nominal prices of their products through short-term profit maximization conditions. Given these outputs and prices, the value of nominal total income follows. The output of the investment sector depends on the rate of interest through the marginal efficiency of capital relation. Then, given the rate of interest, the nominal price of the investment good follows and the part of income generated in that sector. Now choose an arbitrary value, which can be thought of as a guess at the level of total nominal income. As the part of nominal income generated in the investment goods sector is known, given the rate of interest, the guess implies a certain level of nominal income to be generated in the consumption good sector. We now have a value of total income and a value of total consumption, both in nominal terms. If these values are consistent with the consumption function our guess for the value of total income was correct and we have discovered the level of income on the IS curve for the rate of interest with which we were working.

We have discussed only the IS curve but the LM curve is relatively uncomplicated – there is less going on behind it. The beauty of this elegant and lucid way of expounding Keynes's model is that it brings out clearly the vital role played in the model by aggregation assumptions which have the effect that the model decomposes, so that parts of it can be dealt with in partial isolation from the complete system. The simple specifications of the determinants of investment and the consumption function produce this result. The role played by income and working in terms of nominal values – which are equivalent to wage units, as the nominal wage has been taken as given – are all brought out clearly.

In the hands of others the IS–LM model often became merely a model of an economy with all prices fixed and was often misused, as when it was applied to long-run questions for which it is not suitable. However it made the *General Theory* intelligible to a whole generation, not because it left out the subtleties, it was never intended to substitute for the text, but because it perfectly captured the part of Keynes's message which is most amenable to formalization.

*A Contribution to the Theory of the Trade Cycle* (1950) provides an example of the type of model that explains cycles as the outcome of the interaction between the multiplier and the accelerator. These systems are linear in their simplest formulations when they lead to cycles which are almost certainly
either damped or anti-damped. Three different ideas have been proposed to yield an outcome in conformity to the stylized model of a capitalist economy with regular cycles of constant amplitude. The underlying solution may be anti-damped and buffers, in the form of a floor on or a ceiling to the level of economic activity, may be added to keep the solution within bounds. The system may be made non-linear, which is equivalent to buffers which make their influence felt continuously rather than abruptly. Finally, the underlying solution may be damped, in which case the cycle will have to be kept alive by the frequent intervention of random shocks. Hicks's main model embodies the last type of approach. From 1937 Hicks continued to write regularly on questions of macroeconomics. Volume II of his Collected Essays contains a selection of his best work in this vein. Essay 18, ‘Methods of dynamic analysis’, proposes the distinction between the fixprice and the flexiprice economy which was to be developed in Capital and Growth. In his Yrjö Jahnsson lectures, The Crisis in Keynesian Economics (1974), Hicks offers reflections on the Keynesian theory and particularly on the impact of inflation on a Keynesian model. Hicks never remained far from monetary theory. Critical Essays in Monetary Theory (1967), shows the richness of his early writings on monetary economics, while Essay 19 in Volume II of the Collected Essays gives a good indication of his later work. It is tempting to say that if Hicks had written nothing but his work on monetary economics he would be counted a considerable economist. However the truth is that he could not have written on monetary economics as he did write had he not been the broad economic theorist that he was. Hicks always placed monetary theory centrally in equilibrium theory. This was the distinctive idea of his first paper on the subject, ‘A Suggestion for Simplifying the Theory of Money’ (Economica, 1935), and it is a theme which he was to carry through all his later work.

6 Growth and capital theory

Hicks's two other books with ‘Capital’ in their titles, Capital and Growth (1965) and Capital and Time: A Neo-Austrian theory (1973a), have little else in common. Capital and Growth was Hicks's response to the frantic interest in growth theory which infected the 1960s. It was a characteristically personal response in which Hicks tried to apply the framework for dynamic analysis that he had developed in Value and Capital to the construction of a growth model. The analogue of the static problem of Part I of Value and Capital was now the steady state growth path, but once again Hicks found the most interesting question to be the dynamic adjustment to equilibrium, and once again he attacked this problem with an approach which was all his own. The ‘traverse’ was the history of the movement of an economy from one steady state to another. This approach to growth theory was not very influential and the reason was not so much that the new interest in growth had extinguished interest in equilibrium theory. Rather it was that equilibrium theory and its sister economic dynamics had moved on a great deal since Value and Capital. Hicks, who had taught a generation how to do general equilibrium economics, was no longer talking a language that most economic theorists found congenial. Capital and Time was not the product of the latest fashion in economic theory but was surely the result of long meditation starting from that wonderfully fruitful comparative ignorance of Marshall and Pigou as against the Austrians and other continentals, noted above. Hicks always conceded a place to the old classical idea that capital accumulation means more ‘waiting’. In Value and Capital (1939a, pp. 197–8) however, he pointed out that the conclusion that the rate of interest is the marginal product of waiting is
a special case of more general rules which apply to an intertemporal equilibrium. This conclusion, that Austrian models of capital are special cases of the more general von Neumann model of capital accumulation, remains valid. However special cases permit of special results, and Hicks's analysis of the Austrian model was remarkably successful in showing how that framework permits some strong and definite conclusions to be drawn.

7 Other topics

We consider only *A Theory of Economic History* (1969) and *Causality in Economics* (1979), as these constitute the most audacious of Hicks's expeditions far from the mainstream of economic theory. A longer review of Hicks's work would have to find space to discuss his writings on economic policy (for a sample of which see *Essays in World Economics*, 1959) and on the history of economic thought (for some of which see Volume III of the Collected Essays), but here we merely note that these are serious omissions from the present survey.

We begin with *Causality in Economics*. This book was not the eventual product of long years of mental rumination, but the result, its author tells us frankly, of dissatisfaction with the 1974 International Economic Association conference on ‘The Micro-foundations of Macroeconomics’ which Hicks attended. It is book of interesting ideas on economics which are reluctantly regimented by a Sergeant-Major called ‘causality’. This gentleman turns out to be only remotely related to the ‘causation’ of Aristotle or Kant. Hicks's definition of causality is reminiscent of Hume, but without the idea that the validity of induction is importantly involved. Causation is seen as conjunction of events, possibly in a complex form. This idea is an old one and was very effectively criticized by the Cartesians but their contribution is not considered. As an essay in philosophy *Causality in Economics* cannot be taken seriously. The economics of course is of a higher standard. The last chapter provides a statement of Hicks's views on the meaning of probability and on econometric methodology. These are *obiter dicta*, not the fruits of profound investigation.

*A Theory of Economic History* is as ambitious a sortie into foreign territory as *Causality in Economics*, but is the product of more thought and reading and must be regarded as much more successful. The main idea, that economic history is tied up with the development of the market, is one that few would question. However most historians would be tempted to take cover behind a safe position according to which developments of ideas, knowledge, social institutions, etc., would all be seen as progressing in parallel with the development of the market, which consequently would enjoy no special status as a motive force. Put simply, Hicks's account gives a much more leading role to the market, although he does not of course go so far as to argue that the market drives history.

Such a strong argument could not fail to attract criticism, particularly from professional historians. A long book would have done the same but a very short book was a particularly provocative target. As the argument gave a lot of attention to the ancient world this proved to be a contested area. However while *A Theory of Economic History* was criticized it received respectful criticism. It may be only a way of looking at economic history but it was generally judged to be a good way. Hicks's reply to his critics may be found in *Economic Perspectives* (1977, pp. 181–4).

8 Retrospect
Schumpeter argued that the ideas of a great economist are more or less in place by the age of 40 – the rest is nurturing and polishing. At first glance Hicks appears to be an exception. He was 65, for example, when his theory of economic history was announced to the world. Yet probably on closer examination he will be seen to conform to the Schumpeter pattern. In the case of the *A Theory of Economic History* he tells us in the foreword that he had nursed the idea for years. There is indeed a powerful sense of direction to Hicks's intellectual journey. He often returns to old themes and new themes are examined from older perspectives. Probably after 40 Hicks was only nurturing and polishing, but it is no contradiction of that claim to say that the second half of his life produced some of his most creative work.

It remains to mention some particular qualities of Hicks the man. First, he wrote beautifully, in a style that is very correct from the formal point of view, yet almost conversational in its flow and ease. Secondly, his greatness justified a little vanity, and he was not wholly free of that minor vice. That said, he was always approachable, and he never attempted to win an argument by pulling rank or flaunting his formidable distinction.

Keywords
direct and indirect taxation; federal finance; Hicks, U. K.; local public finance; public finance; tax incidence; taxation of expenditure; taxation of income

Article

An Irish-born economist specializing in public finance, Lady Hicks's long career spanned teaching and research at the London School of Economics and Political Science, University of Liverpool, and the University of Oxford (latterly as Foundation Fellow of Linacre College), as well as the holding of many visiting posts in foreign universities and service as a member of advisory missions on fiscal matters, notably in the Caribbean, India and Africa.

She made three significant contributions to her specialism, the theory and practice of public finance. Her paper ‘The Terminology of Tax Analysis’ (1946) questioned the usefulness of the distinction between direct and indirect taxes and argued persuasively for distinguishing between taxes on income and taxes on expenditure (outlay), the dichotomy now used in national accounting. She also explored the difference between the formal incidence of taxes (the liability to pay taxes) and the effective incidence (the determination of tax burdens). Second, in collaboration with her husband, Sir John Hicks, she endeavoured to produce coherence between what the aims of government should be and how fiscal institutions should be organized to achieve them (1947, Part 3). Third, she applied a unique knowledge of fiscal systems to the study of federal and local finance particularly in developing countries (for example, 1961).

No account of her contribution would be complete without mentioning her immense influence as a teacher of students of public finance from all parts of the world and her part in the foundation of the Review of Economic Studies (together with Abba Lerner and Paul Sweezy), of which she was Managing Editor from 1933 to 1961.

Hicksian and Marshallian demands

Eugene Silberberg

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Soon after the presentation of demand in Alfred Marshall's *Principles of Economics* in 1890, a debate ensued concerning whether money income or some sort of real income should be held constant as the price of the good changed. By the mid-20th century, these two conceptions of a demand function became known as the Marshallian and Hicksian functions, respectively. The issue is critical to the interpretation of the area to the left of the demand curve between two prices as some sort of consumer surplus, that is, the gain from purchasing a good at the lower price.

Article

Although earlier writers had formulated the concept of a (downward sloping) demand curve, the analysis took on much great refinement with the publication of Alfred Marshall's *Principles of Economics* in 1890 (and continuing until 1920 with the eighth edition). In Chapter III, Marshall derived the law of demand from a postulate of diminishing marginal (cardinal) utility. He measured utility in terms of money, constantly reminding us, however, of the necessity to assume that the marginal utility of money remained constant. Although it would be reasonable to conclude that the demand function he had in mind is the standard formulation $x_i = \frac{x^v_i}{p_1 \cdot \ldots \cdot p_{n+1} \cdot M}$, where the $p_i$'s are the prices of the $n$ goods and $M$ is money income, Marshall never wrote out an expression such as the above. Although he was very clear that the demand curve represented diminishing marginal values of the good to an individual, he never specified the *ceteris paribus* conditions we are now familiar with.

However, as early as 1894 in the original *Dictionary of Political Economy* edited by R. Palgrave, Edgeworth gave the now current interpretation, stated above. (See the interesting footnote 5 in Friedman, 1949). However, Marshall’s suggestion that individuals purchase additional quantities only if the additional utility they gain is at least as great as the price paid suggests that the demand price represents the maximum the individual will pay for an additional unit. In that case, it would be utility, rather than money income, that was being held constant along the demand curve. To obscure things further, in Chapter VI of the same book, ‘Consumer’s surplus’, Marshall insists that the adding up of demand prices to generate the consumer surplus, or net benefits of all the units purchased, is valid only when the marginal utility of income is constant, or the same across individuals within a market demand curve. These remarks about marginal utility spawned an industry of economists working on consumer surplus for the first 75 years of the 20th century. The matter finally came to an end in the 1970s when the derivations of the demand functions with either money income or utility as an argument were clarified.

The Marshallian demand functions

---

There are two main threads motivating the entire literature on Hicksian and Marshallian demands: first and foremost, consumer's surplus, and second, providing a rigorous discussion of the pure substitution term in the Slutsky equation. For convenience I limit the discussion to the case of two goods. The Marshallian demand functions are the solutions to the constrained maximum problem

$$
\text{maximize } U = U(x_1, x_2) \\
\text{subject to } p_1 x_1 + p_2 x_2 = M
$$

where, of course, $x_1$ and $x_2$ are two goods; their prices $p_1$ and $p_2$ and income $M$ are assumed exogenous. The Lagrangian for this model is $L = U(x_1, x_2) + \lambda(M - p_1 x_1 - p_2 x_2)$. Differentiating partially with respect to $x_1, x_2$ and $\lambda$ yields the necessary first-order conditions (NFOC)

$$
L_1 = U_1(x_1, x_2) - \lambda p_1 = 0 \tag{1a}
$$

$$
L_2 = U_2(x_1, x_2) - \lambda p_2 = 0 \tag{1b}
$$

$$
L_\lambda = M - p_1 x_1 - p_2 x_2 = 0 \tag{1c}
$$

The sufficient second-order condition (SSOC) is that the bordered Hessian determinant of $L$ be positive:

$$
H = \begin{vmatrix}
    U_{11} & U_{12} & -p_1 \\
    U_{21} & U_{22} & -p_2 \\
    -p_1 & -p_2 & 0
\end{vmatrix} > 0
$$

(In the case of $n$ goods, the border-preserving principal minors of $H$ alternate in sign. See, for example, Silberberg and Suen, 2000.) On the assumption that the SSOC holds, the NFOC can be solved simultaneously for the demand functions with money income as a argument, now universally termed the Marshallian demand functions.
In the parlance of intermediate microeconomics texts, when a price changes, ‘money income is held constant’. But this is just an imprecise way of stating that the demand for any good is a function of the price of that good, the prices of all other relevant goods, and, in particular, money income. Substituting the Marshallian demand functions (3a) and (3b) into the utility function yields the maximum utility for given prices and money income, \( U^*(p_1, p_2, M) \). This is the indirect objective (utility) function for this model. By the envelope theorem (see Silberberg and Suen, 2000)

\[
U^*_p = \frac{\partial U^*}{\partial p_i} = -\lambda^M x^M_i \quad i = 1, 2
\]

Equation (4a) reveals that the Lagrange multiplier is the marginal utility of income. On the assumption that the constraint is preventing the consumer from gaining a higher utility, \( \lambda^M > 0 \). Equation (4a), known as Roy’s identity, shows that (maximum) utility varies inversely with price, as previously indicated, since consumption levels are assumed positive. The traditional comparative statics of this model proceeds by substituting eqs. (3) into the NFOC and differentiating with respect to \( M \) and, say, \( p_1 \). Since \( p_1 \) enters twice of the first-
order equations, two terms are produced in the expression for $\frac{\partial x_1^M}{\partial p_1}$. In 1916, Slutsky identified these terms as a substitution effect (which is always negative) and an income term. Rather than replicate these somewhat tedious calculations, we proceed to the more modern analysis.

**The Hicksian demand functions**

Consider now an alternative formulation of consumer behaviour, that of minimizing the expenditure needed to achieve a specified utility level at given prices:

\[
\text{minimize } M = p_1 x_1 + p_2 x_2 \\
\text{subject to } U(x_1, x_2) = U^0
\]

The Lagrangian for this model is $L = p_1 x_1 + p_2 x_2 + \lambda (U^0 - U(x_1, x_2))$. Differentiating with respect to $x_1, x_2$ and $\lambda$ as before produces the following NFOC and SSOC:

\[
L_1 = p_1 - \lambda U_1(x_1, x_2) = 0 \\
L_2 = p_2 - \lambda U_2(x_1, x_2) = 0 \\
L_\lambda = U^0 - U(x_1, x_2) = 0
\]

\[
H = \begin{vmatrix}
-\lambda U_{11} & -\lambda U_{12} & -U_1 \\
-\lambda U_{21} & -\lambda U_{22} & -U_2 \\
-U_1 & -U_2 & 0
\end{vmatrix} < 0
\]
On the assumption that the SSOC holds, eqs. (5) can be solved simultaneously for the Hicksian demand functions

\[ x_1 = x_1^U(p_1, p_2, u^0) \]  

(7a)

\[ x_2 = x_2^U(p_1, p_2, u^0) \]  

(7b)

and the Lagrange multiplier

\[ \lambda = \lambda^U(p_1, p_2, u^0) \]  

(7c)

Eliminating \( \lambda \) from eqs. (5a) and (5b) produces the same ‘tangency’ relation as eliminating \( \lambda \) from (1a) and (1b):

\[ \frac{u_1}{u_2} = \frac{p_1}{p_2} \]  

(8)

In both models, the consumer chooses the point on an indifference curve where the budget or expenditure line has the same slope as the indifference curve. Alternatively, the consumer chooses a mix of goods such that

\[ \frac{u_1}{p_1} = \frac{u_2}{p_2} \]  

(9)

That is, the individual consumes each good until the marginal benefit (utility) per dollar is the same across all commodities. At the margin, all goods consumed are perfect substitutes. Given an increment of income, the consumer would be indifferent as to how to spend it, since he or she has already equalized the marginal utility of a dollar across all goods.

However, the comparative statics of these two models are not the same. For the Hicksian demand functions, when a price changes utility is held constant. That is, the consumer is
constrained to slide along the same indifference curve. Thus, the responses to changes in prices are, by definition, the pure substitution effects. In the Marshallian case, as a price changes utility changes also, in the opposite direction.

Substituting the Hicksian functions (7a) and (7b) into the objective function, we obtain the expenditure function $M = M^*(p_1, p_2, U^0)$. This is the indirect objective function in this model; it gives the minimum expenditure needed to achieve utility level $U^0$ at prices $p_1$ and $p_2$. Since $M^*(p_1, p_2, U^0)$ is a minimum expenditure, by definition, $M^* \preceq M$, so that the function $F = p_1 x_1 + p_2 x_2 - M^*(p_1, p_2, U^0)$ has a (constrained) minimum (of zero) with respect to not only $x_1$ and $x_2$, but also $p_1$, $p_2$, and $U^0$. The Lagrangian for this ‘primal-dual’ problem is

$$L = p_1 x_1 + p_2 x_2 - M^*(p_1, p_2, U^0) + \lambda(U^0 - U(x_1, x_2))$$

The first-order equations with respect to $x_1$, $x_2$ and $\lambda$ are just eqs. (5); with respect to $p_1$, $p_2$ and $U^0$ we have

$$L p_1 = F p_1 = x_1 - M^* p_1 = 0$$  \hspace{1cm} (10a)

$$L p_2 = F p_2 = x_2 - M^* p_2 = 0$$  \hspace{1cm} (10b)

$$L U^0 = M^* U^0 - \lambda = 0$$  \hspace{1cm} (10c)

Eqs. (10a) and (10b) are sometimes referred to as Shephard's lemma (Shephard, 1970): the Hicksian demand functions are the first partials of the expenditure function. Moreover, since $p_1$ and $p_2$ do not enter the constraint, $F$ has an unconstrained minimum in $p_1$ and $p_2$. The second-order conditions include

$$F_{p_i p_j} = -M_{p_i p_j} \geq 0 \quad i, j = 1, 2$$  \hspace{1cm} (11)
so that the expenditure function is concave in prices. However, since \( M^*_p = x_i^U(p, p_2, u^0) \),

\[
\frac{\partial x_i^U}{\partial p_j} = M^*_p, \quad p_j \leq 0
\]  

(12)

The pure substitution effects, which are the ordinary slopes of the Hicksian demand curves, are negative. No such sign is implied for the Marshallian demand functions, since in the associated primal–dual problem, the prices enter the constraint, eliminating any implications about slope of the demand functions based on the curvature properties of the indirect utility function. Additionally, for the Hicksian demands, we find the reciprocity condition

\[
M^*_p = \frac{\partial x_1^U}{\partial p_1} = \frac{\partial x_2^U}{\partial p_2} = \frac{\partial x_3^U}{\partial p_3} = M^*_p = M^*_p
\]  

(13)

Homogeneity

The Marshallian demands are the solutions to eq. (8) and the budget constraint (1c). Suppose there is a proportionate increase in prices and money income. That is, \( p_1 \rightarrow t p_1 \), \( p_2 \rightarrow t p_2 \) and \( M \rightarrow M t \) where \( t > 0 \). But eqs. (8) and (1c) are unchanged by this proportionate increase in parameters; hence their solutions must be identical. Thus, \( x_i^M(t p_1, t p_2, M) = x_i^M(p_1, p_2, M) \); the Marshallian demand functions are homogeneous of degree zero in prices and money income. Consumers respond to changes in relative prices, not absolute prices. Similarly, the Hicksian demands are the solutions to eqs. (8) and the constant utility constraint (5c). If \( p_1 \rightarrow t p_1 \) and \( p_2 \rightarrow t p_2 \), these equations are unchanged, and therefore \( x_i^U(t p_1, t p_2, u^0) = x_i^U(p_1, p_2, u^0) \). With the use of these properties, the indirect utility function must also be homogeneous of degree zero in prices and income, while the expenditure function is homogeneous of degree one in all prices.

The Slutsky equation

Evgeny Slutsky (1916) published perhaps the seminal work in the economic theory of the consumer, in which he showed that a consumer's response to a change in price could be partitioned into two parts: a pure substitution effect which was always negative (that is, in the opposite direction to the price) and an income effect, whose sign was indeterminate. When a price, say \( p_1 \), decreases, the budget line pivots outward, intersecting the \( x_1 \) axis at a greater amount. Slutsky decreased the consumer's income by shifting the new flatter budget line back until it went through the original equilibrium. By such a ‘compensation’, Slutsky isolated the substitution effect. At various schools, particularly the University of Chicago, the Marshallian and Hicksian demand curves were referred to respectively as uncompensated and compensated demand curves. By the 1930s and 1940s, with the publications of John Hicks's Value and Capital (1939) and Paul Samuelson's Foundations of Economic Analysis (1947), the ‘pure’ substitution effect had become defined as the response to a price change when the budget line was shifted (parallel to itself) back to the original indifference curve, producing a response in consumption holding utility constant. (It was shown by J. Mosak and A. Wald, 1942, that, if \( p_1 \) changed by an amount \( \Delta p_1 \), the differences between the Slutsky and Hicks demands were of second-order smallness, that is, functions of powers of \( \Delta p_1 \) order two and higher. See also Silberberg and Suen, 2000, p. 304.)

By the 1940s, the profession had largely settled on the Hicksian interpretation of the pure substitution effect (though Friedman, 1949, stressed the operational advantage of Slutsky's measure). However, it was not until the 1970s that the demand functions (7a) and (7b) derived from constrained expenditure minimization came to be recognized as the analytical basis for the pure substitution effects. At that point, economists realized that the Slutsky equation showed the relationship between the Hicksian and Marshallian demand functions.
We now demonstrate this using the concept of ‘conditional demands,’ first developed by Robert Pollak (1969).

The Hicksian demand function is obtained from the Marshallian function by adjusting money income, when a price changes, to the minimum amount necessary to keep the consumer on the same utility level. Stated mathematically, this is the identity (for $x_1$, say)

$$ x_1^U(p_1, p_2, U^0) = x_1^M(p_1, p_2, M^*(p_1, p_2, U^0)) $$

(14)

Differentiating this identity with respect to $p_1$,

$$ \frac{\partial x_1^U}{\partial p_1} = \frac{\partial x_1^M}{\partial p_1} + \frac{\partial x_1^M}{\partial M} \frac{\partial M^*}{\partial p_1} $$

(15)

Applying the envelope theorem (10a) and rearranging, we get the classic Slutsky equation

$$ \frac{\partial x_1^M}{\partial p_1} = \frac{\partial x_1^U}{\partial p_1} - x_1^U \frac{\partial x_1^M}{\partial M} $$

(16)

The slope of the Marshallian demand equals the slope of the Hicksian demand (which is always negative in its own price) and an indeterminate income effect. If, however, the good is non-inferior, that is, the income effect is non-negative, then the Marshallian demand curve is necessarily downward sloping.

### Consumer's surplus

Most of the interest in the distinction between Hicksian and Marshallian demand functions was generated by the analysis of consumer's surplus. Marshall developed the concept as follows. (I use hamburgers and dollars in place of Marshall's quaintier example of tea and shillings.) Suppose, at a price of $10, a consumer will buy only one hamburger a month. At a price of $9, he will buy two; at $8, he will buy three, at $7, four, and so on. Since these prices measure the marginal values of hamburgers to this consumer at these consumption levels, we interpret these numbers as the maximum the consumer would pay for an additional hamburger. In that case, the amount the consumer would pay to consume four hamburgers rather than none would be $10 + $9 + $8 + $7 = $34. Marshall thus interpreted the area under the demand curve as the all-or-nothing value of that quantity of a good, or the total utility of those units, measured in units of money income. Additionally, at a price of $7, say, the consumer would spend $28 on the good, leaving the area to the right of the demand curve above the price, $6, as the consumer's surplus. This is the additional amount the consumer would have been willing to pay to consume the four units at a price of $7.

The question is: when can we interpret the area to the left of a demand curve in this fashion? Consider a decrease in the price of $x_1$ from $p_1^0$ to $p_1^1$. Mathematically,

$$ CS = - \int_{p_1^0}^{p_1^1} x_1 dp_1 $$

(CS = consumer's surplus)
For both the Hicksian and Marshallian demand curves, we can calculate this area, which has the units of dollars – not utility – being price times quantity. However, the important question is: when we calculate this amount, what question, if any, does it answer? In the case of the Hicksian demands, the answer is clear. If we use the envelope relation (10a),

\[
CS = - \int_{x_1}^{p_1} \frac{\partial U}{\partial p_1} d p_1 = - \int_{p_1}^{\rho_1} \frac{\partial M^*}{\partial p_1} d p_1 = M^*(p_1, p_2, u^0) - M^*(p_1, p_2, u^0)
\]

Because the Hicksian demands are the first partials of the expenditure function, the integral is simply the savings in expenditure the consumer enjoys when the price is lowered (or, likewise, the extra expenditure the consumer must make if the price increases). Thus the area to the left of a Hicksian demand curve is the amount consumers would be willing to pay, or have to be paid, to face the new price. Moreover, suppose two prices change. That is, suppose the price of \(x_1\) changes from $8 to $4, and we calculate a \(CS_1\) ($18 if we use the above linear demand curve). The demand curve for \(x_2\) will have now shifted. Suppose we now lower the price of \(x_2\) from $7 to $3, generating \(CS_2\), say, producing \(CS = CS_1 + CS_2 = $33\). Suppose we did the experiment in the reverse order – lowering the price of \(x_2\) first and then \(x_1\). Would we get the same answer for total \(CS\)? Indeed we would:

\[
CS = - \int_{p_1}^{\rho_1} \sum x_i U d p_i = - \int_{p_1}^{\rho_1} \sum \frac{\partial M^*}{\partial p_i} d p_i = - \int_{p_0}^{\rho_0} d M^* = M^*(p_1, p_2, u^0) - M^*(p_1, p_2, u^0)
\]

Because of the reciprocity condition (13), this integral is exact; the path of price changes does not affect the value of the integral.

In the case of the Marshallian demands, no such interpretations are possible (Silberberg, 1972). The Marshallian demands \(x_i^M\) are not the first partials of any function, so the area to the left of the demand curve given by (17) has no easy interpretation. Moreover, since for the Marshallian demands \(\frac{\partial x_i^M}{\partial p_2} \neq \frac{\partial x_j^M}{\partial p_1}\) (unless the utility function is homothetic) the integral corresponding to (19) for the Marshallian demand functions is path dependent. That is, depending on which price changes first, a different answer emerges, even if all the initial and final prices are identical in the two experiments. There is simply no unique measure of a change in utility in terms of income, except for some famous special cases. (See Silberberg and Suen, 2000).

Consider Figure 1, for some good \(x\). At the initial price \(OA\), the consumer purchases \(AB\). If the price decreases to \(OF\), she moves along her Marshallian demand curve \(x^M\), and consumes \(FD\). If, however, we were to keep her on the same initial indifference curve \(U^0\) as \(p\) decreased, she would move along the Hicksian demand curve to point \(E\). Point \(E\) would be to the left of \(D\) if the good is normal (non-inferior), since we are eliminating this (positive) income effect. If however, the consumer started at the lower price \(OF\) and the price were raised to \(OA\), and we now held her on the higher level of utility \(U^1\) she achieved at point \(D\), she would move up along the Hicksian demand curve associated with \(U^1\), leading her to point \(C\). Suppose the area to the left of the Hicksian demand curve \(BE\) is $20, the area to the left of the Marshallian demand curve \(BD\) is $25, and the area to the left of the Hicksian demand curve \(CD\) is $30. What questions, if any, do these numbers answer? The amount the consumer would pay to face price \(OF\) instead of \(OA\) is $20. If the price were initially \(OF\), the amount she would have to be paid to voluntarily face \(OA\) instead is $30. It seems odd, but it is true nonetheless that, for non-inferior goods, the amount one must be paid to face a higher price is greater than the amount we would pay to get the lower price. Lastly, there is simply no operational question for which $25 is the answer. However, Robert Willig (1976) investigated the actual empirical differences one would be likely to encounter; not too surprisingly, they turn out to be small.

hierarchical Bayes models

Siddhartha Chib and Edward Greenberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The standard Bayesian model is defined in terms of an outcome model and the prior density of the parameters. The latter depends on parameters called hyperparameters. A hierarchical Bayes model results when one or more of the hyperparameters are assumed to be random and modelled probabilistically. We discuss canonical versions of these models for the case when both the parameters and the hyperparameters are modelled in groups or blocks, provide relevant examples, and discuss how inference by Markov chain Monte Carlo methods makes even the fitting of complex hierarchical models practical and simple. The problem of model comparisons is also addressed.

Keywords

Bayes’ th; component densities; exchangeability; hierarchical Bayes models; hyperparameters; marginal likelihood; Markov chain Monte Carlo methods

Article

Suppose that $y$ is a univariate random variable or multivariate random vector and $\theta$ is a $d$-dimensional parameter vector that lies in $\mathcal{R}$, a subset of $\mathcal{R}^d$. The standard Bayesian model is then defined in terms of the density of $y$ given $\theta$ (the outcome model) and the prior density of $\theta$ (the prior model). Specifically, the Bayesian model is specified as

$$y|\theta \sim \rho(y|\theta) \text{ (outcome model: stage 1)} \quad (1)$$

and

$$\theta|\gamma \sim \pi(\theta|\gamma) \text{ (prior model: stage 2)} \quad (2)$$

where $\gamma$ is the vector of parameters in the prior density. These are called hyperparameters. We can assume that $\gamma$ is $g$-dimensional and lies in $\mathcal{G}$, a subset of $\mathcal{R}^g$. The labelling of the outcome model as stage 1 and the prior model as stage 2 is arbitrary, and the numbering can be reversed. The outcome model may be called the top or bottom level of the model because this difference in nomenclature has no significance.

Suppose that the researcher is not able to specify one or more of the hyperparameters in $\gamma$. In that case, the unknown hyperparameters can be assumed to be random and modelled probabilistically. This modelling of the hyperparameters leads to what is called a Bayesian hierarchical model (Berger, 1985; Lehmann and Casella, 1998). The simplest version of a Bayesian hierarchical model is defined in terms of the ingredients

$$y|\theta \sim \rho(y|\theta) \text{ (outcome model: stage 1)} \quad (3)$$
\( \theta | \gamma \sim \pi(\theta | \gamma) \) (prior model: stage 2) \n
(4)

\[ \gamma | \lambda \sim \psi(\gamma | \lambda) \] (hyperparameter model: stage 3), \n
(5)

where \( \psi(\gamma | \lambda) \) is the prior density of \( \gamma \). The hyperparameters \( \lambda \) in the stage 3 model are assumed known. In effect, a hierarchical model is a way of modelling the outcomes and the parameters through a sequence of easily interpretable steps.

In practice, it is often helpful to divide \( \theta \) into natural groups or blocks \( (\theta_1, \theta_2, \ldots, \theta_p) \), where, for instance, \( \theta_1 \) consists of the regression coefficients, \( \theta_2 \) the scale parameters and \( \theta_p \) the covariance parameters. Each of these separate blocks may then be modelled independently in terms of prior densities \( \pi(\theta_j | \gamma) \). In turn, \( \gamma \) may also be grouped into blocks \( (\gamma_1, \gamma_2, \ldots, \gamma_q) \) and, in the third stage, modelled independently through the densities \( \psi(\gamma_j | \lambda) \). The resulting three-stage hierarchical model then has the form

\[ \gamma | \theta \sim \rho(\gamma | \theta) \] (outcome model: stage 1) \n
(6)

\[ \theta | \gamma \sim \prod_{j=1}^{p} \pi(\theta_j | \gamma) \] (prior model: stage 2) \n
(7)

\[ \gamma | \lambda \sim \prod_{j=1}^{q} \psi(\gamma_j | \lambda) \] (hyperparameter model: stage 3). \n
(8)

This specification may be considered as the canonical hierarchical Bayes model.

Example 1: (Gaussian linear regression model). Suppose that \( y = (y_1, \ldots, y_n) \) is a vector of observations and \( \Theta \) consists of the two blocks \( (\beta, \sigma^2) \), where \( \beta \) is a \( k \)-vector of regression parameters. Now let

\[ \gamma | \theta \sim N_n(\gamma | X\beta, \sigma^2 I_n) \]

\[ \theta | \gamma \sim N_k(\theta | \beta_0, \Sigma_0) \sim \text{Student}(\sigma^2, \nu_0, \nu_0 \sigma^2 / 2) \]

where
Hierarchical Bayes models: The New Palgrave Dictionary of Economics

\[ N_k(\beta | \beta_0, \theta_0) = (2\pi)^{-k/2} |\theta_0|^{-1/2} \exp \left\{ -\frac{1}{2} (\beta - \beta_0) \theta_0^{-1} (\beta - \beta_0) \right\} \]

is the k-variate normal density, \( X \) is the \( n \times k \) matrix of covariates and

\[ IC \left( \sigma^2, \nu_0, \theta_0 \right) = \frac{1}{2} \left( \frac{\gamma}{\nu_0} \right)^{\nu_0/2} \left( \frac{1}{\sigma^2} \right)^{(\nu_0/2)+1} \exp \left\{ -\frac{\nu_0}{2\sigma^2} \right\}, \sigma^2 > 0 \]

is the inverse-gamma density. In this case, the hyperparameters \( \gamma \) consist of the four blocks of parameters \((\beta_0, \theta_0, \nu_0, \delta_0)\). The top level of the model is the model of the outcome and the bottom level the model of \( \theta \). If it is not possible to fix the value of \( \beta_0 \) for example, one may specify a prior, \( \beta_0 | \lambda \sim N_k(\beta_0 | \theta_0, \theta_0) \), where the hyperparameters of the third stage \( \lambda = (\theta_0, \theta_0) \) are pre-specified. Further discussion along these lines is provided by Lindley and Smith (1972).

Since the difficulty of specifying hyperparameters in the second stage model of the model arises in almost all applications, hierarchical Bayes modelling is of special interest and importance in Bayesian analysis. To further fix the ideas, the following example, which we develop further below, is instructive and should be studied carefully.

**Example 2:** (Gaussian clustered data model).

Clustered data arise when \( n_i \) observations are available for each subject \( i \) (\( i \leq n \)) in the sample. For example, in the panel or longitudinal set-up, there are observations across time for each subject. Let the observations on the \( i \)th subject be denoted by \( Y_i = (Y_{i1}, \ldots, Y_{in}) \). Assume that the observations are continuous. Binary or ordinal responses can be dealt with in much the same way by adopting the framework of Albert and Chib (1993). The data for all \( n \) subjects are collected in the vector \( y = (y_1, \ldots, y_n) \). It is common in this context to allow for unique cluster-specific effects. Let \( W_i = (W_{i1}, \ldots, W_{in})' \) be a \( n_i \times q \) matrix of observations on \( q \) covariates \( w_{ij} \) whose effect on \( y \) is assumed to be cluster-specific. Also suppose that \( X_{i1} \) is an additional \( n_i \times k_1 \) matrix of observations on \( k_1 \) covariates whose effect on \( y \) is assumed to be non-cluster-specific (fixed effect). Then under the assumption that the observations across clusters are independent, a model for the outcomes is

\[ \forall \theta \sim \prod_{i=1}^{n} N_{n_i}(\beta_{i1}|\beta_0, \sigma^2_{n_i}) \]

where the \( \beta_{i1} \) are the cluster-specific effects. If the numbers of clusters is large, as is usual in practice, it is useful to assume that the effects \( \beta_{i1} \) have some structure. One possibility is to assume that the \( \beta_{i1} \) are drawn from a common distribution

\[ \beta_{2i} | \theta \sim N_q(\beta, D) \]

independently across \( i \). This is called the exchangeability assumption since the joint distribution of the \( \beta_{2i} \) is invariant to permutation of the indices. Another possibility is the assumption that the \( \beta_{2i} \) are determined by a set of \( r \) cluster-specific covariates \( a_i \):

\[ \beta_{2i} | \theta \sim N_q(A_i \beta_{2i}, D) \]

where

\[ A_i = \begin{pmatrix}
    a_i' & 0' & \ldots & 0' \\
    0' & a_i' & \ldots & 0' \\
    \vdots & \vdots & \ddots & \vdots \\
    0' & 0' & \ldots & a_i'
\end{pmatrix} \]
\( \beta_2 = (\beta_{21}, \beta_{22}, \ldots, \beta_{2q}) \) is a \( k_2 = r \times q \)-dimensional vector and \( D \), as in the first example, is a \( q \times q \) matrix. Writing the second stage model in equivalent form as \( \beta_{2i} = A_2 \beta + D_i \) where \( b_i D \sim N(q(0, D)) \), and substituting this into the outcome model, it follows that the outcome model can be expressed as

\[
\forall \theta \sim \prod_{i=1}^{\gamma} N_{n_i}(\gamma_i X_i \theta + W_i \beta, \sigma_i^2),
\]

where \( \theta = (\beta, \sigma^2, b_1, \ldots, b_n) \), \( X_i = (X_{1i} : W_i A_i) \) is a \( n_i \times k \) matrix \( (k = k_1 + k_2) \) and \( \beta = (\beta_1, \beta_2) \). The second stage of the model could now be specified as

\[
\forall Y \sim N_k(\beta \theta_0, \Sigma_0) \prod_{i=1}^{\gamma} N_{n_i}(\gamma_i X_i \theta + W_i \beta, \sigma_i^2).
\]

Next suppose that there is enough prior information to fix \( (\beta_0, \theta_0, \gamma_0) \), but that \( D \) (equivalently \( D^{-1} \)) cannot be fixed directly. Then \( \gamma = D^{-1} \). A convenient assumption is

\[
\forall \lambda \sim \text{Wishart}(D^{-1} | \rho_0, R_0),
\]

where

\[
\text{Wishart}(D^{-1} | \rho_0, R_0) = \frac{c |D^{-1}(\theta_0 - q - 1)/2|^R_{\rho_0/2}}{|R_{1,0}|^{R_0/2}} \exp \left( -\frac{1}{2} \text{trace} (R^{-1} D^{-1}) \right) |D^{-1}| > 0,
\]

is the \( q \)-variate Wishart density,

\[
c = \left( 2^{\rho_0 q/2} \pi^{q(q-1)/4} \prod_{i=1}^{\gamma} \Gamma \left( \frac{\rho_0 + 1 - i}{2} \right) \right)^{-1}
\]

is its normalizing constant, and the stage 3 hyperparameters \( \lambda = (\rho_0, R_0) \) are known. Under these assumptions the full model is given by

\[
\forall \theta \sim \prod_{i=1}^{\gamma} N_{n_i}(\gamma_i X_i \theta + W_i \beta, \sigma_i^2),
\]
Putting a prior distribution on the hyperparameters $\gamma$ in this way has several advantages. For one, it produces a prior distribution on $\theta$ that is less dogmatic than a prior based on specified hyperparameters since the resulting prior distribution of $\theta$ is averaged over the possible values of $\gamma$ as dictated by the density $\psi(\gamma|\lambda)$:

$$\pi(\theta|\lambda) = \int \pi(\theta|\gamma) \psi(\gamma|\lambda) \, d\gamma.$$  

If the hyperparameter $\gamma$ is a scalar discrete quantity with support on the set $\{\gamma_1, \ldots, \gamma_G\}$, where $G$ is potentially infinite, then the mixing density $\psi(\gamma|\lambda)$ is a probability mass function of the type
\[ \delta_{\gamma_j}, \] where $\delta_{\gamma_j}$ is the indicator function of $\gamma_j, 0 < \gamma_j < 1$ and $\sum_{j=1}^{G} \gamma_j = 1$. The resulting conditional density $\pi(\theta|\lambda)$ is then a mixture of densities of the form

$$\pi(\theta|\lambda) = \sum_{j=1}^{G} p_j \pi(\theta|\gamma_j).$$

In this context, $\pi(\theta|\gamma_j)$ are called the component densities and $p_j$ are the component weights. Such mixtures of component densities provide a simple mechanism for modelling $\theta$ in a flexible way.

Of course, one could have started at the outset with the prior $\pi(\theta|\lambda)$ by combining stages 2 and 3, leading to the collapsed model

$$\gamma|\theta \sim p(\gamma|\theta)$$

which has the same structure as the standard 2-stage Bayesian model. This is not done, however, because the density of $\theta|\lambda$, even if tractable, is generally less easy to manage.

**Example 3:** (Gaussian linear regression model and Student-t prior). Suppose that $\mathcal{Y} = (\mathcal{Y}_1, \ldots, \mathcal{Y}_N)$ is a vector of observations and $\theta = (\beta, \sigma^2)$, where $\beta$ is a scalar regression parameter. Assume that
where $G(\cdot, \cdot)$ is the gamma density and the quantities $(\beta_0, \nu_0, \delta_0)$ and $\nu$ are known. Then the density of $\beta$ marginalized over $\beta_0^{-1}$ is Student-t, $T(\beta|\beta_0, 1, \nu)$, with location $\beta_0$, dispersion 1 and $\nu$ degrees of freedom. This Student-t prior density is not conjugate with the outcome model and therefore cumbersome to deal with.

Bayesian hierarchical models can have additional stages. For instance, a further stage can be added by placing a prior density on $\lambda$, which leads to the model

$$
y \sim \mathcal{N}(\gamma|\beta, \sigma^2/n)$$

$$
\beta \sim \mathcal{N}(\beta_0|\beta_0, B_0)\mathcal{IG}(\delta_0^{\nu_0}, \nu)$$

$$
B_0^{-1} \sim \mathcal{G}(\beta_0^{-1}, \nu / 2, \nu / 2)
$$

Bayesian hierarchical models can have additional stages. For instance, a further stage can be added by placing a prior density on $\lambda$, which leads to the model

$$
y \sim \mathcal{P}(y|\theta) \text{(outcome model: stage 1)}$$

where $\delta$ is the density of $\lambda$. Models with more than four stages are rare.

**Posterior distributions**

In a Bayesian analysis one is interested in deriving and summarizing the posterior distribution of $\theta$ given $y$. One obvious question concerns the form of this posterior distribution. Another question concerns the posterior distribution of the hyperparameters $\gamma$. Consider the canonical three-stage hierarchical model in (6)–(8). By Bayes's theorem,

$$
\pi(\theta|y) = \frac{\mathcal{P}(y|\theta) \pi(\theta)}{\mathcal{P}(y)}
$$
where \( \pi(\theta) = \int \pi(\theta | y) \pi(\gamma | \lambda) \, d\gamma \) and \( m(\gamma) = \int p(y | \theta) \pi(\theta) \, d\theta \), called the marginal likelihood, is the normalizing constant. Similarly, the posterior distribution of \( \gamma \) is

\[
\pi(y | \gamma) = \frac{p(y | \gamma) \pi(\gamma | \lambda)}{m(\gamma)},
\]

where \( p(y | \gamma) = \int p(y | \theta) \pi(\theta) \, d\theta \). Before we discuss the tractability of these distributions we state a general result about how much information the data \( y \) supply about \( \theta \) and \( \gamma \) beyond what is introduced by the prior densities \( \pi(\theta) \) and \( \pi(\gamma | \lambda) \). To measure this information we can use the Kullback–Leibler (KL) divergence measure, which, for any two densities \( f \) and \( g \), is defined as

\[
K(f, g) = \mathbb{E}_f \left[ \log \frac{f}{g} \right].
\]

where \( \mathbb{E}_f \) is the expectation with respect to the density \( f \). The following result was proved by Goel and Degroot (1981). The result and proof can also be found in Lehmann and Casella (1998).

**Theorem 1:** For the three-stage hierarchical model,

\[
K(\pi(\gamma | y), \pi(\gamma)) < K(\pi(\theta | y), \pi(\theta)).
\]

This result states that the KL divergence between \( \pi(\theta | y) \) and \( \pi(\theta) \) is greater than between \( \pi(\gamma | y) \) and \( \pi(\gamma) \). In other words, the data supply more information about \( \theta \) than they do about \( \gamma \). Equivalently, the prior and the posterior of \( \gamma \) are closer than the prior and the posterior of \( \theta \). This implies that less learning is possible about the hyperparameters \( \gamma \) than about the parameters \( \theta \).

Much less can be said about the form of the posterior densities. In general, the posterior densities \( \pi(\theta | y) \) and \( \pi(\gamma | y) \) are not tractable. But if we consider the density of \( \theta_j \) given \( (y, \gamma) \) and \( \theta_{-j} = (\theta_1, \ldots, \theta_{j-1}, \theta_{j+1}, \ldots, \theta_p) \), we have

\[
\pi(\theta_j | y, \theta_{-j}) \propto p(y | \theta) \pi(\theta_j | y),
\]

which is in closed form provided the prior density \( \pi(\theta_j | y) \) is conjugate with \( p(y | \theta) \). The density \( \pi(\theta_j | y, \theta_{-j}) \) is called the full conditional density of \( \theta_j \). Of course, the marginal density,

\[
\pi(\theta_j | y) = \int \pi(\theta_j | y, \theta_{-j}) \, d\theta_{-j},
\]

where the mixing distribution is the marginal posterior distribution of \( (y, \theta_{-j}) \), is almost never available in closed form.

The same sort of difficulty arises in finding \( \pi(\gamma | y) \). The problem is that the prior \( \pi(\gamma | \lambda) \) generally does not combine with \( p(y | \gamma) \) to produce a recognizable density. Nonetheless, just as in the case of \( \theta_j \), the calculations are easier if one considers the full conditional density of \( \gamma_j \). To see this, note that

\[
\pi(\gamma_j | y, \theta, \theta_{-j}) \propto p(y | \theta) \pi(\theta_j | y) \pi(\theta_j | \lambda) \propto \pi(\theta_j | y) \pi(\theta_j | \lambda),
\]

where the second line follows from the fact that the outcome model in stage 1 is free of \( \gamma \). Thus, provided \( \pi(\theta_j | y) \) is conjugate with \( \pi(\theta_j | \lambda) \), the full conditional density of \( \gamma_j \) can be derived in closed form.
Example 4: Consider again the clustered data model given in (9)–(11). The full conditional density of $b_i$ is obtained as
\[
\pi(b_i | Y, \theta, B, \gamma) \propto p(\gamma | \theta) \pi(b_i | Y) \propto N_n((\gamma X_i \beta + W_i b_i, \sigma^2 I_n)) N_q(b_i | 0, D).
\]

which, by standard Bayesian manipulations, is seen to be a $N_q(b_i | \hat{b}_i, B_i)$ density, where
\[
\hat{b}_i = B_i (\sigma^{-2} W_i' (Y_i - X_i \beta) \text{ and } B_i = (D^{-1} + \sigma^{-2} W_i' W_i)^{-1}.
\]

Turning now to the full conditional density of $D^{-1}$, we obtain
\[
\pi(D^{-1} | Y, \theta) = \pi(D^{-1} | b_1) \propto \pi(b_1 | D^{-1}) \pi(D^{-1} | \lambda) \propto \prod_{i=1}^n N_q(b_i | 0, D) \text{Wishart}_q(D^{-1} | \nu_0, R_0) = \text{Wishart}_q \left( D^{-1} | \nu_0 + n, \left( R_0^{-1} + \sum_{i=1}^n b_i b_i' \right)^{-1} \right),
\]

where in the first line we have used the fact that the full conditional density of $D^{-1}$ depends neither on $Y$ nor on $B$; in the second line, Bayes's theorem; in the third line, substitutions for the needed densities; and in the fourth line, by observation that the product of the normal and Wishart prior densities is an updated Wishart distribution with the stated parameters.

Computational issues

Difficulties in the computation of the marginal posterior densities of $\theta_j$ and $\gamma_j$ were previously an impediment to the development and application of hierarchical Bayesian models. These difficulties have largely been resolved through the use of Markov chain Monte Carlo (MCMC) methods. These methods typically proceed by simulating the full conditional distributions, $\pi(\theta_j | Y, \theta, \gamma)$ and $\pi(\gamma_j | Y, \theta, \gamma)$. Under general conditions, the recursive simulation of these distributions produces a Markov chain whose limiting invariant distribution is the posterior density of interest, $\pi(\theta, \gamma | Y)$. Although it is not possible in this discussion to provide the theory behind MCMC methods, as outlined in Tierney (1994), and Chib and Greenberg (1995), or the range of hierarchical Bayes models that have been thus processed, it is useful to illustrate the computations with the help of the simplest MCMC method, the so-called Gibbs sampling algorithm. This algorithm was introduced by Geman and Geman (1984) in the context of image processing, but the papers of Tanner and Wong (1987) and Gelfand and Smith (1990) brought it into the limelight.

Suppose that the various blocks $\{\theta_j\}$ and $\{Y_j\}$ are chosen to ensure that the associated set of full conditional densities $\{\pi(\theta_j | Y, \theta, \gamma)\}$ and $\{\pi(Y_j | Y, \theta, \gamma)\}$ are all tractable. Then one cycle of the Gibbs sampling algorithm is completed by simulating $\{\theta_j\}$ and $\{Y_j\}$ from each full conditional distribution, recursively updating the conditioning variables while moving through the set of distributions. The Gibbs sampler in which each block is revised in fixed order is defined as follows.

**Algorithm:** Gibbs sampling

1. Specify an initial value $\theta^{(0)} = (\theta_1^{(0)}, \ldots, \theta_p^{(0)})$ and $Y^{(0)} = (Y_1^{(0)}, \ldots, Y_q^{(0)})$.
2. Repeat for $j=1, 2, \ldots, n_0+M$:
   - Generate $\theta_1^{(j)}$ from $\pi(\theta_1 | Y, \theta_2^{(j-1)}, \ldots, \theta_p^{(j-1)}, Y^{(j-1)})$.
   - Generate $\theta_2^{(j)}$ from $\pi(\theta_2 | Y, \theta_1^{(j)}, \theta_3^{(j-1)}, \ldots, \theta_p^{(j-1)}, Y^{(j-1)})$.
   - Generate $\theta_p^{(j)}$ from $\pi(\theta_p | Y, \theta_1^{(j)}, \ldots, \theta_{p-1}^{(j-1)}, Y^{(j-1)})$.
   - Generate $Y_1^{(j)}$ from $\pi(Y_1 | Y, \theta_1^{(j)}, \theta_2^{(j)}, \ldots, \theta_q^{(j-1)}, Y^{(j-1)})$.
   - Generate $Y_2^{(j)}$ from $\pi(Y_2 | Y, \theta_1^{(j)}, Y_1^{(j)}, \theta_3^{(j)}, \ldots, Y_q^{(j-1)})$.
   - Generate $\ldots$
Generate \( Y^{(j)}_a \) from \( \pi(Y_{1}, Y^{(j)}_1, \ldots, Y^{(j)}_{\alpha - 1}) \) 

3. Return the values \( \{ \theta_{\alpha(0 + 1)}, \theta_{\alpha(0 + 2)}, \ldots, \theta_{\alpha(0 + M)}, \gamma_{\alpha(0 + M)} \} \).

Thus, in this algorithm, block \( \Theta_j \) is generated from the full conditional distribution

\[
\pi(\Theta_j | \Theta_1^{(j-1)}, \ldots, \Theta_{j-1}^{(j-1)}, \Theta_{j+1}^{(j-1)}, \ldots, \Theta_\alpha^{(j-1)}, \gamma^{(j-1)})
\]

where the conditioning elements for the \( j \)th block reflect the fact that the previous \((j-1)\) blocks of \( \Theta \) have already been updated, but the rest have not been. Note that the output from the first \( \alpha_0 \) cycles (the burn-in phase) is ignored to allow the effect of the initial values to wear off.

One additional point about MCMC methods is that the blocks must be carefully chosen. Sampling over unnecessary blocks can worsen the quality of the output produced by the algorithm, where quality is measured by how quickly the serial correlations of the sampled draws decline to zero. Chains whose serial correlations decline quickly are preferred because they are closer to the ideal of independent sampling.

**Example 5:** Consider again the hierarchical Bayesian model for clustered data given in (9)-(11). The joint distribution of the data and the unknowns is given by

\[
p(\gamma, \beta, D^{-1}) = \pi(\beta, \sigma^2, \{b_i\}, D^{-1}) p(\gamma | \beta) = \pi(\beta) \pi(\sigma^2) \pi(D^{-1}) \prod_{i=1}^{n} p(\gamma_i | \beta) n(b_i | D).
\]

(Wakefield et al. 1994) propose a Gibbs MCMC approach for joint distribution that is based on full blocking (that is, sampling each block of parameters from its full conditional distribution). Chib and Carlin (1999) suggest a number of reduced blocking schemes. One of the simplest proceeds by first sampling \( \beta \) marginalized over \( \{b_i\} \) and then sampling \( \{b_i\} \) conditioned on \( \beta \). This reduced blocking is possible because \( b_i \) in (18) can be marginalized out leaving a normal distribution that can be combined with the assumed normal prior on \( \beta \). In particular,

\[
p(\gamma | \beta, \sigma^2, D) = \int p(\gamma | b, D) n(b | D) db = V_i^{-1/2} \exp \left\{ \left( -1/2 \right) (\gamma_i - X_i \beta) ^t V_i^{-1} (\gamma_i - X_i \beta) \right\},
\]

where \( V_i = \sigma^2 I_{n_i} + W_i D W_i^t \). The reduced conditional posterior of \( \beta \) is therefore

\[
\pi(\beta | \gamma, \sigma^2, D) \propto \pi(\beta) \prod_{i=1}^{n} V_i^{-1/2} \exp \left\{ - \frac{1}{2} (\gamma_i - X_i \beta) ^t V_i^{-1} (\gamma_i - X_i \beta) \right\} \propto \exp \left\{ - \frac{1}{2} (\beta - \hat{\beta}) ^t B^{-1} (\beta - \hat{\beta}) \right\},
\]

where

\[
\hat{\beta} = \beta \left( \sigma_0^{-2} + \sum_{i=1}^{n} X_i ^t V_i^{-1} X_i \right) \] and \( B = \left( \sigma_0^{-2} + \sum_{i=1}^{n} X_i ^t V_i^{-1} X_i \right)^{-1}.
\]

The rest of the MCMC algorithm follows the steps of Wakefield et al. (1994). In full, we sequentially sample the following distributions many times:

\[
\beta \sim N_\beta(\hat{\beta}, B)
\]
Hierarchical Bayes models: The New Palgrave Dictionary of Economics

The second and fourth of these distributions were derived in Example 4.

Model choice

Another inferential concern in practice is the comparison of several hierarchical Bayesian models in order to judge the extent to which the various models are supported by the data. In the context of a hierarchical model for clustered data, for instance, one may be interested in determining the support for an additional cluster-specific effect or of an additional fixed effect. Questions of this type can be answered via Bayes factors, or ratios of marginal likelihoods. The marginal likelihood of a particular model $\mathcal{M}$ is the normalizing constant of the posterior density,

$$m(\gamma|\mathcal{M}) = \int p(\gamma|\mathcal{M}, \theta) \pi(\theta|\mathcal{M}, \gamma) \pi(\gamma|\mathcal{M}, \lambda) \, d\theta \, d\gamma,$$

(19)

the integral of the first stage outcome density function with respect to the prior density of $\theta$ and the prior density of the hyperparameters $\gamma$. If there are two models $\mathcal{M}_k$ and $\mathcal{M}_i$, the Bayes factor is the ratio

$$B_{k/i} = \frac{m(\gamma|\mathcal{M}_k)}{m(\gamma|\mathcal{M}_i)}.$$

(20)

Because MCMC methods deliver draws from the posterior density and the marginal likelihood is the integral with respect to the prior $\pi(\theta|\mathcal{M}, \gamma) \pi(\gamma|\mathcal{M}, \lambda)$, MCMC output cannot be used directly to average $p(\gamma|\mathcal{M}, \theta)$. Nonetheless, computation is feasible by the method of Chib (1995), a widely used method that we now briefly describe.

Chib (1995) begins by noting that $m(\gamma|\mathcal{M}, \lambda)$ can be expressed as

$$D_i \sim N_q\left(D_i\left(\sigma^{-2}W_i, (\gamma_i - X_i\beta), D_i = (D^{-1} + \sigma^{-2}W_i)^{-1}\right), i \leq n\right)$$

$$\sigma^2 \sim IG\left(\frac{\nu_2 + \sum r_i}{2}, \frac{\delta_0 + \sum r_i}{2} \| \gamma_i - X_i\beta - W_i b_i \|^2 \right)$$

$$D^{-1} \sim Wishart\left(\rho_0 + n, \left(\rho_0^{-1} + \sum_{i=1}^{n} b_i b_i^T\right)^{-1}\right)$$

where the second and fourth of these distributions were derived in Example 4.
for a given \((\theta^*, Y^*)\), usually taken to be a high density point such as the posterior mean. Thus, if we have an estimate \(\hat{\pi}(\theta^*, Y^* | M, Y)\) of the posterior ordinate, the marginal likelihood on the log scale can be estimated as

\[
\log m(Y | M) = \log p(Y | M, \theta^*) + \log \pi(\theta^* | M, Y^*) + \log \pi(\theta^* | M, \lambda) - \log \hat{\pi}(\theta^*, Y^* | M, Y).
\]

It turns out that it is possible to get an efficient estimate of the posterior ordinate. The basic idea is to write the posterior ordinate as

\[
\pi(\theta^*, Y^* | M, Y) = \pi(\theta_1^* | M, Y) \times \cdots \times \pi(\theta_{p-1}^* | M, Y, \theta_1^*, \ldots, \theta_{p-1}^*)
\]

\[
\times \pi(Y_1^* | M, Y, \theta^*) \times \cdots \times \pi(Y_{p-1}^* | M, Y, \theta^*, Y_1^*, \ldots, Y_{p-1}^*)
\]

and then to estimate each of these ordinates from the output of appropriate MCMC runs. To see what is involved, consider the ordinate \(\pi(\theta_j^* | M, Y, \theta_1^*, \ldots, \theta_{j-1}^*)\) that appears in this decomposition. By definition,

\[
\pi(\theta_j^* | M, Y, \theta_1^*, \ldots, \theta_{j-1}^*) = \int \pi(\theta_j^* | \gamma, \theta_1^*, \ldots, \theta_{j-1}^*, \theta_{j+1}^*, \ldots, \theta_p^*, Y) \pi(\theta_{j+1}^*, \ldots, \theta_p^*, Y | \gamma, \theta_1^*, \ldots, \theta_{p-1}^*) \, d\pi(\theta_{j+1}, \ldots, \theta_p, \gamma | \gamma, \theta_1^*, \ldots, \theta_{p-1}^*)
\]

is the full conditional density integrated with respect to the distribution \(\pi(\theta_{j+1}, \ldots, \theta_p, \gamma | \gamma, \theta_1^*, \ldots, \theta_{p-1}^*)\). To calculate this integral by Monte Carlo one can run an MCMC algorithm in which the blocks \((\theta_{j+1}, \ldots, \theta_p)\) are fixed at their starred values and sampling is over the remaining free blocks, namely \((\theta_j, \theta_{j+1}, \ldots, \theta_p, \gamma)\). This is called a reduced MCMC run. Let the sampled draws from this reduced run be denoted by \((\theta_j^{(r)}, \theta_{j+1}^{(r)}, \gamma^{(r)}), r=1, \ldots, M\). Then, provided the full conditional of \(\theta_j\) is in closed form, we have the estimate

\[
\hat{\pi}(\theta_j^* | M, Y, \theta_1^*, \ldots, \theta_{j-1}^*) = \frac{1}{M} \sum_{r=1}^{M} \pi(\theta_j^* | \gamma, \theta_1^*, \ldots, \theta_{j-1}^*, \theta_{j+1}^{(r)}, \ldots, \theta_p^{(r)}, Y^{(r)}).
\]

Each ordinate is estimated in this way from the output of the appropriate reduced runs. Notice that as more blocks are fixed, fewer distributions appear in the reduced runs.

**Example 6:** Consider again the hierarchical Bayesian model for clustered data. In this case, we can decompose \(\pi(\theta^*, Y^* | M, Y)\) as

\[
\pi(D^{-1}, \sigma^2, \beta | Y) = \pi(D^{-1}, \sigma^2 | Y) \pi(\beta^* | D^{-1}) \pi(D^{-1} | Y) \pi(\sigma^2 | Y, D^{-1}) \pi(D^{-1}) \pi(\sigma^2).
\]
so that all computations are marginalized over \( \{b_i\} \). The first term can be estimated by averaging the Wishart density given in Example 5 over draws on \( \{b_i\} \) from the full MCMC run. To estimate the second ordinate, which is conditioned on \( D^* \), we run a reduced MCMC simulation with the full conditional densities

\[
\pi(\beta|\mathcal{Y}, D^*, \sigma^2), \pi(\sigma^2|\mathcal{Y}, \beta, D^*, \{b_i\}), \pi(\{b_i\}|\mathcal{Y}, \beta, D^*, \sigma^2),
\]

where each conditional utilizes the fixed value of \( D \). The second ordinate is now estimated by averaging the inverse gamma full conditional density of \( \sigma^2 \) at \( \sigma^2^* \) over the draws on \( (\beta, \{b_i\}) \) from this reduced run. The third ordinate is multivariate normal as given in Example 5 and available directly.

If the full conditional densities are not in closed form, the marginal likelihood can be computed by the modified Chib method as discussed in Chib and Jeliazkov (2001).

Hierarchies lighten the burden of the enormous informational requirements of the price system under uncertainty by acquiring more knowledge and information than any individual can. They are thus useful for information handling. They can also allow agents to engage in collective actions by decreasing the risk of opportunistic behaviour. But trade-offs are involved because hierarchies impose costs, including communication among agents. This article reviews the literature on this trade-off and its implications for labour markets.

Keywords
bounded rationality; earnings distribution; firm size; hierarchy; incentive conflict; information economics; monitoring theories; principal and agent; queuing theory; uncertainty

Article
Hierarchy deals with individuals’ bounded rationality by allowing for more information to be used in decision-making than individual agents could possibly use and by allowing the most skilled agents to leverage their knowledge with the help of others. Hierarchy can also allow agents to engage in collective actions by decreasing the risk of opportunistic behaviour. These benefits of hierarchy do not come without costs. Hierarchies may be slow to react, may introduce noise into the communication process, and generally may require costly communication among agents. This entry reviews the literature on these trade-offs in multiple-layer, multi-agent hierarchies; that is, it leaves aside the simplest, one principal one agent-type model.

Processing information

Arrow (1974) first observed that the enormous informational requirements of the price system under
uncertainty (complete markets require one state-contingent price per commodity per state of the world) place a bound on its performance. A key role of hierarchy is to lighten this burden: hierarchies can acquire more information than any individual can, and thus are useful for information handling.

A large literature has explored this role of hierarchies in enhancing information processing. An example of this class of models is Radner (1993). Decision-making requires observing a linear combination of certain variables, and agents incur some cost of performing additive operations and some cost of communicating their results. All information must be processed. Under these conditions, organizations are asymmetric, to ensure that all agents are occupied. Bolton and Dewatripont (1994) extend this model to the case where cohorts of data arrive all the time; in this case, the optimal structures are balanced trees, and look more like the ones we arguably observe in reality. Radner and Van Zandt (1992), Van Zandt (1999) and Van Zandt and Radner (2001) take a further step by studying the problem of processing in real time, when the information relevant to a given decision is continuously arriving. The key objects of interest are the sign and size of the scale diseconomies resulting from hierarchy. That is, these authors aim to answer the question of the extent to which diseconomies of scale linked to human bounded rationality are the reason we see many firms, rather than one. The answer is not unambiguous. For example, Radner and Van Zandt (1992) find that returns to scale can vary from increasing to sharply decreasing, depending on the correlation of the data and on the cost of incorrect decisions. Vayanos (2003) extends substantially these models beyond associative operations, and considers situations with two realistic characteristics: the decisions of different agents interact; and the aggregation process entails information losses.

A separate branch of the literature, following Crémer (1980), has studied hierarchical resource allocation programmes under limited managerial processing power. Geanakoplos and Milgrom (1991) study a hierarchy in which managers can invest in information collection, but each manager can collect a limited amount of information. By decomposing hierarchically the allocation problem (so that a low-level manager allocates resources among shops, while lower-level managers allocate resources among groups of sources, and so on) the total amount of information used can be increased. Each manager is told by his superior how many resources he gets, and communicates that information to each subordinate. Managers aim to minimize the expected total costs of their units (there are no externalities). Under these conditions, the number of managers used is increasing in value of information and U-shaped in managerial ability (few managers are used if they are unproductive or if they are so productive that a few can achieve all savings). A more uncertain environment increases the number of managers needed and their average skill, and causes a decrease in their span of control.

**Organizing knowledge**

In Garicano (2000) a hierarchy, rather than a means to aggregate information, is a means to acquire and conserve experts’ knowledge. He considers a set of agents who face a large number of problems. They may or may not invest in learning their solution; they produce only if they do. Some problems are more common than others, and there is an *ex ante* known probability distribution of problem. Agents can ask other agents for help in solving their problems, but, crucially, they do not know who knows what. Garicano shows that an optimal organization has agents specializing in either production or problem solving; that production workers deal with routine problems and problem solvers specialize in the
exceptions; and that shape is pyramidal, with fewer agents in each successive layer. The organizing principle is management by exception. The key organizational trade-off is between acquiring knowledge and asking; that is, an extra hierarchical tier increases communication costs but also increases the utilization of expertise and results in lower knowledge acquisition costs. Given this trade-off, an increase in the cost of communication leads agents to learn more and ask less, and managers to learn less and deal with a smaller proportion of problems. Conversely, when the cost of acquiring knowledge rises, the role of the hierarchy increases as managers deal with a larger fraction of problems.

Beggs (2001) also investigates the phenomenon of ‘management by exception’, although with exogenous knowledge. He uses queuing theory to explore the optimal allocation of workers with exogenously given skills to the different layers of a hierarchy.

This type of organization of work is common in many contexts; for example, in law firms (Garicano and Hubbard, 2007) or in medicine. In this professional context, the role of the ‘juniors’ (associates, residents) is to handle the easier problems to conserve the valuable time of the seniors (attending physicians, partners) for the harder problems. Similarly, in a team engaged in technical support (Orlikowski, 1996), experts must answer customer calls, and production is organized so that juniors handle front calls, and transfer the calls they cannot handle to more senior experts.

Hierarchical allocation of talent to positions: the distribution of earnings

Another line of research has explored the relation between the distributions of income and the distributions of firm size and hierarchy. This literature has proposed that the reason why the distribution of income is more skewed than the underlying distribution of skills lies in how resources are allocated to individuals. Higher-ability managers raise the productivity of the resources they are assigned more than lower-ability managers. As a result, in equilibrium, more able managers are allocated more resources, and this leads the marginal value of their ability to increase faster than if they were working on their own. Lucas (1978) and Rosen (1982) generate full equilibrium models that yield both an equilibrium firm size and distribution of earnings. In both these papers, the manager increases the productivity under his control, which, depending on the model, may be the number of workers (Lucas, 1978), or efficiency units of labour, that is, total units of skill managed (Rosen, 1982). In these models, managerial human capital raises the marginal product of the workers or capital they are assigned, but managers’ span of control is generally limited implicitly or explicitly by managers’ time. Equilibrium assignment patterns involve scale of operations effects, which follow from the complementarity between managerial human capital and productive resources. The main equilibrium result from this class of models is that these production functions involve scale-of-operations effects: more skilled managers are assigned more resources to manage in equilibrium. As a result, the distribution of earnings is more skewed than the distribution of skills. Garicano and Rossi-Hansberg (2005) build on this line of research, but study a model of hierarchy with heterogeneous agents that extends Garicano (2000), and which involves matching between managers and workers – that is, managers do not care only about the efficiency units they manage (which would imply that a top lawyer at a law firm should be indifferent between managing two good associates or a large number of mediocre ones), but instead care about both the quality and quantity of workers. The model generates a continuum of hierarchies and an equilibrium allocation of workers to positions, as well as the income distributions. It allows for the simultaneous
exploration of changes in organization and in wage structure, and has been applied to issues such as the formation of cross-country teams (Antràs, Garicano and Rossi-Hansberg, 2006), or changes in organization and the wage structure as a result of the information technology revolution (Garicano and Rossi-Hansberg, 2005).

Monitoring and authority

An alternative class of theories study managers as agents able to fire underperforming agents or otherwise exercise their authority. Monitoring theories stem from Alchian and Demsetz (1972), who posit that hierarchies are a response to incentive problems associated with team production. In this view, lower-level individuals are directly involved in production, and upper-level individuals are specialized monitors. The view was elaborated formally by Calvo and Weillisz (1978) and Qian (1994). Their basic assumption is that supervision is necessary for ensuring performance. They study an efficiency wage setting like Becker and Stigler's (1974), where agents can work full-time and earn $w$ or shirk and be detected and fired with probability $p$, in which case they earn their reservation utility. Here, the principal can induce work by increasing the monitoring intensity $p$ through hierarchical supervision. The hierarchy then trades off the gains due to these lower wages against the cost of the supervisors. Aghion and Tirole (1997) formally introduce the idea of decision-making agents into the study of hierarchy with incentive conflicts. Delegation by a superior functions as a commitment not to intervene, and as such delegating authority increases incentives for agents to invest. Baker, Gibbons and Murphy (1999) extend such analysis to a context where delegation is in fact a relational contract in which the centre chooses not to exercise its power. Rajan and Zingales (2001) study how the shape and size of the hierarchy responds to the problem of providing incentives for employees to protect the resources of the entrepreneur and discouraging them from stealing them. Finally, Hart and Moore (2005) consider hierarchies as chains of authority that determine priority in decisions over asset allocation, and derive conditions where optimal hierarchies have generalist coordinators on top. Their theory helps explain why generalists – individuals who know about the interactions between classes of assets – should be senior to specialists.

Overall the models reviewed in this article have the potential to address an important missing link in economic theory: the absence of managers, and of occupations, from both the theory of the firm and the theory of the determination of wages.

Hildebrand, Bruno (1812–1878)

Hermann Reich

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

capitalism; communism; Engels, F.; German Historical School; Hildebrand, B.; List, F.; Müller, A.; self-interest; Smith, A.; socialism; statistics

Article

Hildebrand was born in Naumburg (Thuringia), the son of a clerk to the court. He studied in Leipzig and Breslau. In 1841 he was promoted full professor of Staatswissenschaften (of government, which included political economy) at the University of Marburg.

Hildebrand had always been an activist in the liberal and patriotic movement. He faced political persecution before the 1848 revolution, during which he was elected deputy of the Frankfurt National Assembly. In the subsequent period of restoration he was forced to emigrate to Switzerland, where he became not only a professor but also the director of a railway company, and founded the first Swiss statistical office (at Berne). In 1861 he was appointed professor at the University of Jena. He was founder (in 1862) and editor of the *Jahrbücher für Nationalökonomie and Statistik* and contributed to the establishment of the statistical office of the United Thuringian States (in 1864).

Hildebrand is considered as one of the founders of the German Historical School. He was opposed to the deductive method of the classicals and denied the existence of ‘natural laws’ in economic life (1863). His most important work was *Die Nationalökonomie der Gegenwart und Zukunft* (1848), where he discussed the theories of Friedrich List, Adam Müller, and especially those of Adam Smith. With his sharp criticism of self-interest and egoism as the central determinant of Smith’s economic system – and the emphasis on ethical principles and the historically changing patterns of economic development – Hildebrand launched the attacks on Smith and the classical economists that were subsequently continued by many German historical economists.

The largest part of his main work was devoted to a discussion of socialism and communism, which he sharply rejected. Hildebrand focused his attention on the then little known Friedrich Engels and his recently published *Conditions of the Working Class in England* ([1848], 1922, pp. 125–90). He particularly criticized Engel's euphemistic description of pre-industrial conditions and contrasted it with
empirical data that showed quite a different picture. While being aware of current social problems Hildebrand perceived capitalist development most optimistically and envisioned as its last stage of development – the so-called ‘credit economy’ – a society where an advanced banking system would provide credit to a worker according to his morals and character and where thereby the monopoly of the capitalist class on capital would be broken (Hildebrand [1864], 1922, pp. 354–5). This theory of stages has to be regarded as Hildebrand's capitalist utopia, his liberal answer to socialism and communism.

Hildebrand's importance and his influence on the German Historical School has generally been underestimated; after all Hildebrand was – as Max Weber remarked – the only one really to work with the historical method. He undertook statistical studies – he regarded statistics as an important tool for detailed historical and empirical research (1865) – and wrote historical monographs (1866). He thus anticipated much of the research programme of the ‘younger historical school’ and the Verein für Socialpolitik, which he joined – as the only economist of the ‘older historical school’ – as a charter member in 1873.

Hildebrand stood for a kind of progressive liberalism that intended to reshape Germany along the lines of England, which he admired.

Hilferding, Rudolf (1877–1941) 

Roy Green 

Edited by Steven N. Durlauf and Lawrence E. Blume 

Keywords 

banking industry; Bernstein, E.; Böhm-Bawerk, E. von; finance capital; Hilferding, R.; Kautsky, K.; labour theory of value; Lenin, V. I.; Luxemburg, R.; Marx, K. H.; organized capitalism; social democracy; socialism 

Article 

Hilferding blended Marxist economics and Social Democratic politics in a career cut tragically short by the rise of fascism in Germany. He studied medicine at the University of Vienna, but soon showed more interest in organizing the student socialist society. After graduating in 1901, he helped Max Adler to found the Marx-Studien (1904–23), a series which was to become the theoretical flagship of ‘Austro-Marxism’. The first volume contained a vigorous defence of the labour theory of value by Hilferding himself against Böhm-Bawerk's marginalist critique, Zum Abschluss des Marxschen Systems (1896). It earned him his intellectual spurs in the German-speaking socialist movement. 

At the same time, Hilferding was already contributing to debate within the German Social Democratic Party (SPD) through its journal, Die Neue Zeit. There, on the controversial ‘mass strike’ issue, he steered a course for the party leadership between Eduard Bernstein's ‘revisionist’ abandonment of the socialist goal and Rosa Luxemburg's revolutionary commitment to it (1903/4; 1904/5). He was rewarded with an appointment in 1906 as economics lecturer at the party school in Berlin, and then as foreign editor of the party newspaper, Vorwärts. From 1907, he also wrote regularly for the newly established journal of the Austrian Social Democrats, Der Kampf. 

Hilferding published his major work, Das Finanzkapital, in 1910; it was immediately hailed by such diverse figures as Kautsky (1911), Lenin (1916) and Bukharia (1917), as a path-breaking development of Marxist economic analysis. Essentially, Hilferding argued that the concentration and centralization of capital had led to the domination of industry and commerce by the large banks, which were transformed into ‘finance capital’ (1910, p. 225). The socialization of production effected by finance capital required a correspondingly increased economic role for the state. Society could therefore plan production by using the state to control the banking system:
The socializing function of finance capital facilitates enormously the task of overcoming capitalism. Once finance capital has brought the most important branches of production under its control, it is enough for society, through its conscious executive organ – the state conquered by the working class – to seize finance capital in order to gain immediate control of these branches of production . . . Even today, taking possession of six large Berlin banks would mean taking possession of the most important spheres of large-scale industry . . . (1910, pp. 367–8)

This chain of reasoning, however, tended to exaggerate not only the leverage of the banks over industry, but also the role of the state in the organization of production. While it convinced Hilferding that socialism could be introduced by a determined majority in parliament, it demonstrated to Lenin that socialism would not be possible unless the state was ‘overthrown’ by a determined minority outside parliament. Their common point of reference was the centrality of the state – rather than society – in the ‘latest phase of capitalist development’. It forced socialists to make a choice between parliamentarism and insurrection, the very nature of which contributed to the defeat of the labour movement in Germany and the rise of party dictatorship in Russia (Neumann, 1942, pp. 13–38). Although theory cannot be held responsible for the course of history, it may influence political judgements which tip the balance at decisive moments. Hilferding's generation lived through many such moments. When war broke out in 1914, Hilferding associated himself with the SPD minority which voted against war credits and which later formed the Independent Social Democrats (USPD). He spent most of the war on the Italian front, having been drafted into the Austrian army as a doctor, and returned to Berlin as editor of the USPD journal, *Freiheit*. Hilferding successfully opposed USPD affiliation to the Third International; his speech against Zinoviev at the Halle conference of 1920 – published under the title, ‘Revolutionäre Politik oder Machtillusionen?’ – was a decisive turning point. Once the embryonic Communist Party (KPD) forced a split on the issue, however, he saw no alternative to reunification with the remnants of the SPD.

During the 1920s, Hilferding turned his attention almost entirely to the political and economic problems facing the new German republic. He was a leading member of the Reich Economic Council, twice minister of finance and an active participant in the discussions on ‘workers’ councils’ and the government's ‘socialization’ programme. Hilferding's first stint as minister of finance lasted only seven weeks in the Stresemann government of 1923. Although he had no opportunity to implement his proposals, he devised a plan for currency reform involving the introduction of a *Rentenmark* backed by gold as part of an anti-inflation package. By the time Hilferding returned to the same post in the Müller government of 1928/9, economic conditions had worsened; his predicament was appreciated by Schumpeter who wrote, ‘we now have a socialist minister who faces the exceptionally difficult task of curing or improving a situation bequeathed by non-socialist financial policies’ (quoted in Gottschlacht, 1962, p. 24). A less sympathetic observer, however, portrayed Hilferding at this time as ‘the theorist of coalition politics in the period of capitalist stabilisation’ (see Gottschlacht, 1962, p. 204), blinded by theory to the imminent fascist danger.

Pursuing the logic of *Das Finanzkapital*, Hilferding had developed a theory of ‘organized capitalism’, a term he first used in 1915 in *Der Kampf*, and then explained more fully in 1924 in *Die Gesellschaft*. He
summarized the approach at the SPD's Kiel conference in 1927: ‘Organized capitalism means replacing free competition by the social principle of planned production. The task of the present Social Democratic generation is to invoke state aid in translating this economy, organized and directed by the capitalists, into an economy directed by the democratic state’ (see Neumann, 1942, p. 23). Ironically, this was the very position of an earlier Social Democratic leadership which Marx had singled out for criticism. Commenting on the demand for a ‘free state’ in the 1875 Gotha programme, Marx wrote:

It is by no means the goal of workers who have discarded the mentality of humble subjects to make the state ‘free’. In the German Reich the ‘state’ has almost as much ‘freedom’ as in Russia. Freedom consists in converting the state from an organ superimposed on society into one thoroughly subordinate to it; and even today state forms are more or less free depending on the degree to which they restrict the ‘freedom of the state’. (Marx, 1891, p. 354)

While Hilferding understood that in capitalist society power lay with capital and was exercised by the representatives of capital in the management structure of the great corporations, he failed to see that democratic control over the productive forces would require a change in the relationship of power within the corporation itself. Organized labour could use the state to accelerate this process of social transformation and to create the centralized institutional machinery necessary for the ‘associated producers’ to plan directly the whole economy; but the notion that the state itself could perform this task rested upon an illusion. In attempting to replace the domination of capitalist employers with the domination of a ‘democratic state’, Hilferding and the party leadership achieved only one practical result: ‘Unwittingly, they strengthened the monopolistic trends in German industry’ (Neumann, 1942, p. 21). The state domination which followed was far from democratic.

Hilferding, a Jew, was forced into exile after 1933, first in Switzerland via Denmark and then in France. In an unfinished manuscript, Das historische Problem, he set about revising his whole conception of the state. The problem was now said to consist ‘in the change in the relation of the state to society, brought about by the subordination of the economy to the coercive power of the state …’ (quoted by Bottomore, Introduction to Hilferding, 1981, p. 16, emphasis in original). Hilferding briefly presented his new approach in the New York Socialist Courier in 1940; there, like Marx, he drew a rueful comparison between Germany and Russia. The state had not ‘withered away’ under Soviet communism:

History, that ‘best of all Marxists’, has taught us another lesson. It has taught us that, in spite of Engels’ expectations, the ‘administration of things’ may become an unlimited ‘domination over men’, and thus lead not only to the emancipation of the state from the economy but even to the subjection of the economy by the holders of state power. (1981, p. 376 n.)

It was too late for Hilferding's brave reassessment to influence the course of events. In 1941, he died in the hands of the Gestapo.

Polly Hill was born on 10 June 1914 into a remarkable Cambridge family that includes Nobel Prize winning physiologist A.V. Hill (her father) and J.M. Keynes (her mother's brother) among its many distinguished members. She graduated from Cambridge in 1936 with a degree in economics. Her first job upon leaving university was with the Royal Economic Society as an editorial assistant, a position she held for two years (1936–8). Her next appointment was a one year (1938–9) research position with the New Fabian Research Bureau (which almost immediately re-amalgamated with the Fabian Society) where she wrote her first book, *The Unemployment Services* (1940). This book was concerned to expose the inefficiency and inhumanity of the system of unemployment relief and to make constructive proposals. Polly Hill's commitment to social justice never waned: economic inequality is the central theme of all her books.

At the outbreak of the war she was obliged, as an unmarried young woman, to become a temporary civil servant. She worked first, briefly, in the Treasury, then for a long time in the Board of Trade and finally in the Colonial Office. She resigned in 1951. After a period of unemployment she became a journalist for the weekly *West Africa*. She married in 1953 and moved to Ghana with her husband where, at the age of 40, she began her academic career. The academic posts she held there involved no teaching and she was able to become, as she put it, ‘a pupil of the migrant cocoa farmers of southern Ghana’. She began her fieldwork as an economist and collected data using the questionnaire method, producing her second book, *The Gold Coast Cocoa Farmer: A Preliminary Survey* (1956) with characteristic speed and efficiency. The prevailing orthodoxy had it that sedentary food farmers in southern Ghana had suddenly taken up cocoa farming at the end of the 19th century with such a degree of success that cocoa exports had risen from nil to over 50,000 tons by 1914 – the largest quantity for any country. Polly Hill had uncritically accepted this orthodoxy and her subsequent realization that most farmers appeared to be migrants who had bought their land was to have a profound effect upon her intellectual methods. She
abandoned the questionnaire method of data collection in favour of one that sought to develop generalizations on the basis of: (1) detailed fieldwork in one village; (2) fieldwork done by others elsewhere; (3) archival sources. She also began a lifelong struggle with development economists and other purveyors of orthodoxies based on casual empirical observation and ‘common sense’. She drifted towards anthropology and history where the qualities of her empirical findings were recognized for what they were: revolutionary. She spent three and a half years collecting detailed evidence to substantiate her claim that the cocoa farmers were migrants and made many fascinating discoveries in the process. For example, she found that the matrilineal farmers adopted an entirely different mode of migration from patrilineal farmers: the former bought family lands with the aid of their kin, and were prepared to grant usufructural rights to their male and female kinsfolk; the latter clubbed together in so-called ‘companies’, groups of non-kin, the land being divided into strips from a base line, according to the contribution each had made, with subsequent division on inheritance always being longitudinal. Upon hearing of this Professor Meyer Fortes, then Professor of Social Anthropology at Cambridge, encouraged her to apply for a Smuts Visiting Fellowship. This enabled her to write The Migrant Cocoa-Farmers of Southern Ghana: A Study in Rural Capitalism (1963) which is now widely regarded as a classic. (She was awarded a Ph.D. in social anthropology from Cambridge under new special regulations in 1966 on the basis of it.) Mainstream writers on development have by and large ignored the book even though it contains telling criticisms of aspects of W.A. Lewis’s work.

Following more fieldwork in Ghana, Nigeria and India she produced a further stream of books (1970a; 1970b; 1972; 1977; 1982; 1985; 1986) and many articles of outstanding quality which established her reputation as the world’s foremost economic anthropologist. She was appointed a Fellow of Clare Hall in Cambridge in 1965 and subsequently to the prestigious Smuts Readership in Commonwealth Studies (1973–9). Her publications documented in painstaking detail the complexity of agrarian relations in the tropical regions of the world in which she had worked. The books as a whole constitute an encyclopaedia of knowledge on the socio-economic conditions of poverty and economic inequality and her work ranged in scope from ‘agrestic servitude’ to ‘zamindars’. Her oeuvre was much more than a compilation of facts, though. Her own data and that of others are presented in a theoretical context which broadened as her own field experience widened. She was unrelenting in her empirically based critiques of development economists and her 1986 book Development Economics on Trial: The Anthropological Case for a Prosecution was a concerted attempt to make them see the error of their ways.

Hirshleifer, Jack (1926–2005)

Elizabeth Landaw and David K. Levine

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Jack Hirshleifer was one of the leaders of the ‘information and uncertainty’ revolution in economics. His work on the role of time and uncertainty in asset markets and the value of information plays a fundamental role in modern economic thought. Hirshleifer was also a leader in the ‘imperial’ school of economics, taking the lead in expanding economic thought to areas such as evolution and conflict, which traditionally were studied by other social science disciplines.

Article

Jack Hirshleifer was born on 26 August 1926 in Brooklyn, New York. He graduated at the top of his class of 855 students from Erasmus Hall High School in New York, then enrolled at Harvard in 1942, studying government and other social sciences. He was quickly drawn, however, to economics, which provided him with a ‘useful set of tools and methods’. In 1943 Hirshleifer's career as a budding economist went on hold when he enlisted for active service duty in the US Naval Reserve, serving on an aircraft carrier in the Pacific until 1945. This experience inspired in him a long-lasting and deep interest in military arms races. After the war, he resumed his studies at Harvard, receiving a Ph.D. in economics in 1950. Hirshleifer's research career started at the RAND Corporation in Santa Monica. In 1955 he became an assistant professor at the Graduate School of Business at the University of Chicago, and then returned to Los Angeles in 1960 as an Associate Professor of Economics at UCLA, becoming full professor two years later. In 1975 he became what is now called a ‘Distinguished University Professor’,
thus becoming a member of the most elite group of the University of California faculty. Hirshleifer was an economic theorist with broad-ranging interests. He not only wrote extensively in areas of general economic interest such as capital theory or economics of uncertainty and information, but also wrote and often laid out the foundations for areas outside the traditional scope of economics, including conflict theory and evolutionary modelling.

Some of Hirshleifer's early work focused on the intertemporal theory of interest and investment. Today, this research helps us better understand such topics as intertemporal choice, decisions under uncertainty, the choice of discount rate for public investments, or liquidity and the term structure. His early interest in capital theory led not only to scores of influential articles but also to pioneering and detailed examination of the concepts of interest rate, investment and capital, which are integrated into his book *Investment, Interest and Capital* (1979) and later in the volume of collected articles, *Time, Uncertainty, and Information* (1989). The earlier book and associated articles became a framework for modern finance theory and for understanding investment decisions under uncertainty.

Hirshleifer also made a lasting contribution to the theory of speculation. He showed that differences in taste are not enough to explain speculation; rather, speculation must arise from differences in beliefs. He was the first to analyse speculation in a full general-equilibrium model, with different structures of market completeness carefully considered. Although not generally recognized as such, the 1975 *Quarterly Journal of Economics* paper is also the first paper to point out the indeterminacy of equilibrium when markets are incomplete.

Early in his career, Hirshleifer was instrumental in the information economics revolution and is considered today to be one of its founding fathers. He made the abstract ideas of contingent claims concrete through his examples and applications. In the process, he helped develop fundamental tools, such as the covariance of risks, the analysis of gambling and insurance, the Modigliani–Miller theorem, and the analysis of public investment. Most notably, his 1971 *American Economic Review* paper, ‘The Private and Social Value of Information and the Reward to Inventive Activity’, became highly influential and one of the most cited papers in the economics of information. The paper demonstrates that competitive markets need not reflect the social value of information. Hirshleifer's example of an inventor who can invest based on the knowledge of the impact of his invention shows that there can be an oversupply of inventive activity. This ‘race to be first’ has its reflection in the current literature on patent races, starting with Fudenberg et al. (1983) and continuing through such work as Gallini and Scotchmer (2001). It is the key to understanding a fundamental problem in intellectual property law, which the profession is only now coming to grips with. Hirshleifer also identifies what the profession now refers to as the ‘Hirshleifer effect’: new and more reliable information can have a negative social value if the early information on risks makes these risks uninsurable.

In addition to his founding contributions in information economics, Hirshleifer had a lifelong interest in conflict, beginning with his earliest work on war damages. Late in his career this area was the focus of his contributions, and he was a leader in extending economic methods to problems more traditionally studied in political science. Just as Hirshleifer was first drawn to economics for its methods and tools, he argued that the traditional assumptions of microeconomic theory are too narrow. One such idea, he maintained, the idea of cooperation or ‘mutually beneficial exchange via markets’, is only one form of many different forms of human interactions. An alternative way would be simply to take what you want away from other parties. This is still economics, since scarcity and competition and optimization and equilibrium are all involved. Conflicts, and indeed all struggles for power and influence, are important
economic activities, as important as exchange. He explored an economic approach to conflicts not only in the context of war but also crime, litigation, strikes and political campaigns. His work on conflict shows how ‘Peace is more likely to the extent that the decisiveness of conflict is low, or … if the stakes are small or the technology favors the defense. More surprisingly, perhaps, increased productive complementarity between the parties does not systematically favor peace…the poorer side is generally motivated to invest more heavily in fighting effort. So conflict can become an income-equalizing process’ (1991, p. 133). It is what Hirshleifer calls the ‘paradox of power’: poor or weaker contestants defeat large ones. Subsequent work shows how a narrow range of possible settlements increases the potential for conflict and how increasing returns followed by diminishing returns explains the monopoly on military force within the state, while also explaining the multiplicity of states. A number of his papers analysing conflict as opposed to cooperation are collected in Economic Behavior in Adversity (1987). Hirshleifer wrote broadly on expanding the domain of economic discourse to include the ‘rational’ evolutionary analysis of altruism and spite. He believed that the standard economic postulate of fixed preferences is wrong and instead argued that evolution plays a pivotal role in shaping not only people's physical make-up but also tastes. In one of his most influential papers, ‘The Expanding Domain of Economics’ (1985), Hirshleifer reviews how the economic logic of optimization, trade-off and of equilibrium can and should be applied to a wide variety of ‘non-economic’ problems. He writes that economics constitute ‘the universal grammar of social sciences’ (1985, p. 53) but that there is the wide area of ‘noneconomics’ that economists have to become aware of and get over their ‘tunnel vision about the nature of man and social interactions’.

The paper examines different kinds of altruistic preferences, including what would now be called by experimentalists the ‘warm-glow’ effect. As an application, Hirshleifer discusses Becker's 'rotten kid' theorem, showing how a selfish parent can gain from altruism. Still other theories of preferences, including models of status, such as the rat-race are examined. Hirshleifer opened up new areas; by now, much of this ‘non-economic’ economics is widely studied by economists, and models of altruism and status proliferate.

Key to Hirshleifer's contribution is the underlying point of view of ‘as-if’ rationality – altruism must provide some benefit to the altruist. This was the starting point of much of the modern evolutionary economics literature – for example, the work of Kandori, Mailath and Rob (1993) and Young (1993). From this perspective, Hirshleifer examined models such as the psychological model of ‘anger, gratitude, response’ and argued that this seemingly irrational behaviour does indeed benefit the individual. Yet Hirshleifer's view of evolution was an eminently practical one: it was firmly grounded in his desire to understand why voluntary exchange arises in some situations, but conflict in others.

Although not primarily an experimentalist, Hirshleifer, together with Glenn W. Harrison, conducted a fundamental experiment on the incentives to free ride (1989). As Hirshleifer surely imagined, increasing incentives to free ride lead to more free riding. The experiment introduced the ‘best-shot’ game, a public goods contribution game in which only the largest contribution to the public good matters. In this type of game it is socially and individually optimal for only one player to contribute, and, unlike many other types of public goods games, this theoretical prediction is exactly what happens in the laboratory. Hirshleifer's interest in risk and investment extended to public investment and cost–benefit analysis. Although the fact is not widely known, he co-authored an important study of alternative routes for bringing water from northern to southern California, as well as a follow-up years later after one of the projects was chosen and built. He was fond of saying that much of his scepticism of government arose...
from the fact that of three routes one was clearly worse than the other two – and that was the one that was actually built.

Jack Hirshleifer's love of social sciences, particularly economics, was one of his endearing traits. He liked nothing better than contemplating new puzzles and exchanging ideas with his colleagues. Although officially he changed his status to Professor Emeritus in 1991, he never ceased working, writing, reviewing, and lecturing. Colleagues would find him working every day in his office, door open, sitting behind his cluttered desk with an inviting smile. He continued to work until the very end of his life, and was proud that he was able to proofread – he sent back the galleys of the seventh edition of his very popular textbook, *Price Theory and Applications*. He hosted Thursday lunches at the UCLA Faculty Club, which became a gathering place famous for spirited discussions. A kind and approachable man dedicated to his work, Jack's rule was economics and not gossip. Those who knew him remember him for his personal warmth and sense of humour.

Although the two areas in economics that have especially felt the impact of Hirshleifer's work are information economics and conflict resolution, Hirshleifer shed light on many other fields including capital theory, finance, bioeconomics and experimental economics. With his insatiable intellectual curiosity, he was never short of good ideas, illustrating them through carefully worked out and accessible examples. He would plant many seeds and often leave to others to develop sophisticated theories. Yet with his standing concern for the value of rigorous scholarship, Hirshleifer was one of the pioneers who transformed economics into the scholarly science that it is today.

historical demography

Carl Mosk
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Historical demography deals with population dynamics prior to and during early phases of industrialization. Using family reconstruction historical methodology, demographers have found partial answers to Malthusian questions revolving around mortality and fertility rates in religious records yielding estimates for marriage, life expectancy and reproduction within marriage. Employing cause of death estimates and Hutterite index measures for the proportion of women married and the level of their reproduction within marriage, historical demographers have developed tentative answers to demographic transition queries. Historical demography has contributed much to our understanding of historical population dynamics.

R.; Malthusian economy; marriage; mortality; population dynamics; population growth

Article

Prior to European industrialization population grew in fits and starts, because the effects of the introduction of new crops like the potato or the reclaiming of uncultivated grasslands and forested slopes for irrigated rice paddy were short-lived, typically ushering in periods of stagnation. Why did pre-industrial populations increase in such a manner, slowly groping upward from one plateau to the next, perhaps even tumbling backward to ever lower plateaus before resuming forward progress? Was it fertility or mortality or an interaction of the two that constrained the growth process?

The impact of family reconstitution
Our understanding of the dynamics of pre-industrial populations has been immeasurably increased by research in historical demography, fuelled by the development of family reconstitution for analysing records of births, deaths and marriages lodged in religious quarters – Catholic, Anglican and Lutheran parishes, Buddhist temples – in clan genealogies and in military records. Developed in the 1950s and 1960s by French demographers, most notably by Louis Henry, the family reconstitution methodology exploits the fact that individuals are separately listed in vital registers that can be linked together to yield life histories moving from birth to marriage and to death. Henry's ingenuity lay in rigorously defining the period over which a family is under observation for the purposes of deducing its mortality and fertility history.

It should be emphasized that records of religious bodies, of clans and of military organizations are not the only sources that can be tapped by historical demographers. Other sources include censuses (Quebec initiated systematic census-taking in 1665); fiscal documents, for instance taxpayer lists (Japanese population counts for the rice tax paying population of the country are available from the early 17th century); property inventories and wills; archeological remains including preserved garbage dumps; cemetery data, both skeletons and gravestones; and eyewitness accounts recorded in literary documents. Hollingsworth (1969) offers a thorough review of the various methods, pinpointing strengths and deficiencies.

Still, it was the pioneering of a carefully elaborated family reconstitution methodology by French scholars working from records of parishes from the time of Louis XIV and Louis XV that opened the floodgates for systematic analysis of fertility and mortality in pre-industrial Europe and pre-industrial Asia. Particularly important was application of the methodology to England, where several thousand parish registers beginning prior to 1600 exist, and to Japan, where Akira Hayami and others have trained Henry's methodology upon Buddhist religious records (shū mon-aratame-chō) of births, deaths and marriages in analysing the population dynamics of villages during the Tokugawa (1600–1868) period. Hayami (1997) provides a useful history, replete with concrete examples, of the impact that historical demography has had on the understanding of pre-industrial population dynamics in Japan.

What is clear from the analysis of Buddhist registers for Japanese villages is that fertility within marriage was kept quite low in many parts of the country from the early 18th century onward, the intervals between births being drawn out through a combination of infanticide and taboos against having too many small offspring in the household at any one time. Whether Japanese peasants were concerned about excess competition for the family headship (only one child could take over the headship from the patriarch of the household), responding to a falling off in the demand for child labour on densely populated paddy rice fields, or whether they were attempting to maximize survivorship rates for each child allowed to live remains a matter for scholarly debate. What historical demography has shown is that the debate must be about why fertility was fairly low, not why mortality was fairly high.

Low- and high-pressure homeostatic equilibriums

Systematic analysis of the English parish data has yielded one of the crowning achievements of post-Second World War historical social science: the securing of over 3.5 million totals for baptisms, burials and marriages drawn from 404 carefully selected Anglican parish records by a research team at Cambridge University headed up by E. A. Wrigley and R. Schofield. Developing a novel technique for
projecting back population totals from the census of 1871 and from national level estimates of births and deaths generated from the 404 parish figures, Wrigley and Schofield (1981) were able to estimate population totals, and fertility (including the gross reproduction rate that gives the number of female births a woman is expected to have across her reproductive life) and mortality rates (including life expectancy at age zero) for England between 1550 and 1871. The Wrigley–Schofield 1981 volume was path-breaking not only in offering a remarkable data-set and a remarkable set of estimates for pre-industrial fertility and pre-industrial mortality. It was also path-breaking in contesting the standard Malthusian interpretations of pre-Industrial Revolution British population dynamics.

In the standard argument the force explaining fluctuations in population size and growth rates was mortality. The Black Death reduced the ranks of the populace in the 14th century. More generally, plagues occurring between 1350 and 1660 acted as negative exogenous shocks absorbed by the British population, peasants and aristocrats alike being decimated by these waves of disease. In the Malthusian model this mechanism for regulating numbers is the positive mortality check, and populations so regulated are described as operating in a high-pressure homeostatic equilibrium, feedback running from population increase to increased food prices to enhanced mortality, thereby reducing population.

Wrigley and Schofield (1981) suggested that pre-industrial England operated as a low-pressure rather than a high-pressure equilibrium system, fluctuations in fertility driving fluctuations in population size over the long run. Indeed, the authors went so far as to suggest that there was a 50-year lag at work, surges in real wages generating surges in marriage and in births over a 50-year period. In offering a theory based upon the idea that the real wage drives population growth through its impact upon births, Wrigley and Schofield (1981) put forward a novel interpretation of the iron law of wages. This proposition states that increases in real wages due to accumulation of capital or technological improvements are ultimately choked off by population increase initiated by the improvement in wages. The low-pressure homeostatic story accounting for the iron law of wages was not satisfactory to R. Lee, who devoted much effort to analysing the response of real wages to exogenous fluctuations in population size. For instance, Lee (1980) estimated an elasticity of minus one-and-a-half for the impact of population increase on real wages, a ten per cent increase in human numbers diminishing real earnings by 15 per cent. In Lee (1987), he pointed out that the 50-year lag is only one story that is consistent with the long-run movements in fertility and real wages advanced by Wrigley and Schofield.

In any event, the 50-year lag of Wrigley and Schofield and Lee's estimates for the impact of population increase on real wages are both based upon long-run movements in population, fertility and mortality. Equally interesting are the short-run dynamics for pre-industrial populations, fluctuations in climate – when the spring thaw permitting planting of new crops in the fields takes place, when the onset of cold fall temperatures dictates harvesting – driving movements in food prices, resulting in fluctuations in marriages, pregnancies, births and deaths. Analysing a large number of historical cases, Lee (1987) concluded that the vital rates do respond to upward and downward movements in food prices, pre-industrial societies being regulated in a homeostatic fashion that was responsive to exogenous changes in climate.

To examine more systematically the impact of fluctuations in food prices upon demographic behaviour in pre-industrial Europe and Asia, the Eurasian Project in Population and Family History has pioneered the use of longitudinal databases of household and individual records, eschewing the computation and analysis of aggregate demographic statistics generated from massive family reconstitution exercises like
that carried out by Wrigley and Schofield (1981). A good illustration of the type of analysis stemming from this approach is Bengtsson, Campbell, Lee et al. (2004). Generating results for Scania in southern Sweden, for eastern Belgium, for three villages in northern Italy, for a village in northern Japan, and for Liaodong in north-eastern China, the Eurasian Project suggests that demographic responses to short-run stress (that is, spikes in food prices) were fundamentally different in the West and in the East. In the East power, especially gender-based power, played a crucial role in shaping household demographic behaviour in the face of food scarcity, females getting less access to nutrition than males in the typical scenario. In the West, socio-economic status, especially ownership of land, mattered a great deal. When climatic variation forced up the price of foodstuffs, the landless suffered in Europe. In Asia it was young females who bore the brunt of the crisis.

Onset of the demographic transition

In addition to shedding light on Malthusian questions – on the relative importance of the positive mortality check and the preventive fertility check – historical demography has shed light on the question of when the fertility and mortality transitions began. To what extent did the onset of industrialization influence fertility and mortality? Is there evidence of fertility decline in early industrializing – or even completely pre-industrial – settings? The general overlap of industrialization and the demographic transition is evident. Heavily industrialized countries enjoy low fertility and low mortality. What is not evident is that there is a direct relationship between the onset of industrialization and the onset of mortality and fertility declines.

Nor is the short-run relationship between mortality and industrialization obvious. In the 19th century before the germ theory of disease had led to advances in sanitation (for example, chlorination of water) and the treatment of food and drink (for example, pasteurization of milk), densely populated cities were unhealthy places. Germs spread as waves of immigrants flocked into metropolitan centres rife with a diverse menu of infections, the immigrants coming from rural isolates too tiny to support the host of infectious diseases with which they were now assailed.

Only in the late 19th century and after did cities become healthy as knowledge of water purification, the importance of proper sewer systems, and flush toilets spread in the West. With the 20th century development of sulpha drugs followed by the chance discovery of penicillin and the mass manufacture of antibiotic drugs, the scale economies in distribution enjoyed by cities came to the fore. Preventing infection through public health and treating infectious cases came at a lower unit cost in dense, congested, jurisdictions that had once been mortality sink holes.

In the remainder of this article our focus will be on the onset of the fertility transition and its connections with industrialization.

The most important project that laid out the empirical groundwork for analysing questions about the onset of the fertility transition is the European Fertility Project that carried out at the Office of Population Research at Princeton University during the 1960s and 1970s under the direction of A. Coale. Coale and his colleagues wanted to construct measures of fertility and its components – reproduction within marriage, proportion married, the incidence of reproduction outside of marriage (illegitimate fertility) – that could be generated from a relatively small amount of data, data that they could secure for every province throughout 19th-century western Europe and Europe.

The European Fertility Project hit upon the ingenious procedure of comparing the actual fertility
experiences of the populations they were studying with the fertility experience of the Hutterites who thereby entered the historical demography literature as a much utilized standard. Why use Hutterite reproduction as a standard? Hutterite women in the period between the world wars married at very young ages and had as many children as possible. The Hutterite sect took very seriously the Biblical injunction to ‘be fruitful and multiply’. Moreover, the Hutterites who settled in the great plains of the United States and the prairies of Canada lived on large farms and had a strong demand for child labour. A typical Hutterite woman had a total fertility rate (the sum of the age specific birth rates, an approximation to the total number of children she would give birth to over her reproductive life) of more than 12. Using the Hutterite standard allows us to estimate the degree to which a population falls short of its maximal reproductive potential.

The Hutterite indices generated by the European Fertility Project measure the relative level of marital fertility, illegitimate fertility, proportion married and overall fertility for any jurisdiction that has counts of births classified by legitimacy status and counts of population classified by gender and marital status in the five-year age groups. The idea is to use figures on women and married women in the five-year age groups in a given population of interest to the researcher to compute the level of fertility and marital fertility that would occur if these women reproduced at the rate of Hutterite women in the cohorts of the 1920s and 1930s. The age specific rates (for five-year age groups) at which Hutterite wives reproduced are known and these are used in conjunction with the actual data on population and births to compute the Hutterite indices.

In assessing why populations fall below maximal reproductive potential it is important to separate out the impact of low proportions married from the impact of sharply diminished reproduction within marriage. The Hutterite index for marital fertility ($I_g$) for a given population is the ratio of the legitimate births occurring in that population to the number that would occur if the women reproduced at the rate of the Hutterites. The Hutterite index for proportion married ($I_m$) is the ratio of married women weighted by the Hutterite fertility schedule – take the number of married women in each age group and multiply this number by the corresponding level of Hutterite fertility for the age group, thereby giving heaviest weight to the most reproductive ages – divided by the total number of women weighted by the Hutterite schedule. The Hutterite index for illegitimate fertility ($I_h$) is the ratio of the number of illegitimate births to those that would occur had the unmarried women reproduced as the Hutterite women had reproduced. The overall Hutterite index of fertility ($I_f$) is the ratio of total births occurring in a population to those that would have occurred had the women been as fruitful as the Hutterite women. The last measure offers an overall summary for fertility.

Not surprisingly, the Hutterite indices for illegitimate fertility – in 19th-century Europe and Asia – tend to be low, typically falling below a value of 0.10. By contrast the Hutterite index for marital fertility in most 19th-century western European provinces tended to be fairly high, around 0.80 in many cases. One of the convenient properties of the Hutterite indices is their multiplicative property. If the index of illegitimate fertility is zero (typically it is close to zero), then the Hutterite index for overall fertility is the product of the Hutterite indices for marital fertility and proportion married, namely $I_f = I_g * I_m$.

To see why constructing these indices yields useful information about the nature of pre-transition fertility and the dating of the fertility transition, consider the following. In 19th-century western Europe prior to the sustained decline in marital fertility (the European Fertility Project defines the onset of the fertility transition as a drop in $I_g$ of ten per cent initiating irreversible decline, no subsequent return to the
pre-decline level occurring), a typical value for the Hutterite index for proportion married was around 0.5, the corresponding Hutterite index for marital fertility being between 0.8 and 0.9. Multiplying the two gives a value of between 0.4 and 0.45, meaning that in western Europe women reproduced far less than did the Hutterites, not because of what they did within marriage, but rather because they were not marrying very young or, in some cases, at all. By contrast in pre-decline Japan, China and Korea, the levels of $I_m$ were usually between 0.8 and 0.9, women marrying very early and almost universally. However, levels of reproduction within marriage $I_g$ were quite low in pre-transition Asia, around 0.5 in many cases. Again, taking the product, we get a range for $I_g$ between 0.4 and 0.45.

So, in both pre-transition Asia and pre-transition western Europe, overall levels of reproduction were modest, but for different reasons in the two regions. In Europe the key was late marriage and low proportions marrying. This was something Malthus approved of, believing that the path of demographic virtue lay in late marriage and abstinence outside of marriage. In Asia the key was relatively low levels of reproduction within marriage, something Malthus was less enthusiastic about. Indeed, he probably would have labelled it vice.

To return to the question of what the European Fertility Project's findings tell us about the relationship between industrialization and the fertility transition, some of the most striking findings of the project need stating. First, France was the region in western Europe enjoying the earliest decline in marital fertility, its irreversible fall beginning in the early 19th century, occurring prior to sustained industrialization there. Second, the irreversible decline in English marital fertility did not occur until the 1870s, a full century after the Industrial Revolution began there. Third, language and culture seem to have been important in shaping the spread of marital fertility decline. For instance in Belgium, language difference separates early-decline provinces from late-decline provinces. For these reasons the European Fertility Project concluded that stopping behaviour within marriage – having a specific number of offspring, then ceasing having more children altogether – was an innovation. As Coale and Watkins (1986) demonstrate, the consensus opinion in the European Fertility Project was that the innovation of regulating reproduction diffused through contact between individual households, this diffusion channelled through and within distinctive cultural groups.

In short, there is no simple story for western Europe involving the short-run relationship between the onset of industrialization and the onset of marital fertility decline. It is apparent that both are important to modernization. But the interaction of the two is certainly complex.

When we turn to Asia, the complexity of the relationship is even more evident. For instance, in Japan, China, Korea and Asiatic Russia marital fertility appears to have risen before it began its irreversible decline in the 20th century. Mosk (1983) offers one hypothesis about the rise in fertility in Japan that is consistent with the idea that there is a long-run linkage between industrialization and low marital fertility. His explanation rests on the idea that in the short run a rising standard of living may actually induce a rise in marital fertility provided marital fertility has been suppressed through infanticide and sexual taboos aimed at lengthening the intervals between live births. In particular, he argues that rural areas that were experiencing land reclamation due to the diffusion of rice seed varieties from the south-west to the north-east spawned new family managed farms, increasing the demand for child labour and easing pressure on parents concerned with finding marriage and/or farming opportunities for their offspring. Additionally, improved food consumption affected the length of intervals between live births considered optimal, promoting a rise in $I_g$ between the 1880s and the 1920s. Better-fed households felt
less constrained to space their births far apart lest they fall short of the nutritional resources required to guarantee survival for all of their youngsters. To these arguments one can add the fact that the opening of the country to international trade in the late 19th century created a strong export market for silk, which was produced by family labour especially in the north-east and the Japanese Alps.

In sum, the literature dealing with the overlap of industrialization and the onset of the demographic transition suggests that the interaction of the two secular transformations crucial to defining modernity is complex and intriguing. As with the issues involving the Malthusian economy, much is known. The general contours of the issues involved are clear enough. But, as with so many other things, the devil is in the details. At the detailed level, it is clear what we do not know is as important as what we know. In this sense historical demography has opened up as many questions for future research as it has provided answers to questions thrown up by previous generations of scholars.

A group of economists whose heyday was from 1875 to 1890 and whose major figures were John Kells Ingram (1823–1907), James E. Thorold Rogers (1822–1890), T.E. Cliffe Leslie (1827–1882), William Cunningham (1849–1919), Arnold Toynbee (1852–1883), William Ashley (1860–1927) and W.A.S. Hewins (1865–1931). H.S. Foxwell (1849–1936) was sympathetic to their approach but outside the group's mainstream. All were united by an inductive approach to economics, a determination to stress that no economic theory or policy could be appropriate to all times and places, and a conviction that classical and neoclassical economics alike were already too abstract to give state or citizen much practical help, and were getting worse.

The movement's most important forerunner was Richard Jones (1790–1855), whose criticisms of Ricardian economics – both for its hyper-deductive character and its pretensions to universality – enjoyed intelligent public attention without much persuasive power. Jones offered neither a historically relative political economy to put in Ricardianism's place nor even any substantial contribution to economic history. But, in any case, the time was not right for Jones's ideas to take hold. By the 1870s a number of factors had combined to prepare the ground for a far more influential historical critique of orthodox economics. There was the influence of John Stuart Mill, who in his later years both practised and lent his philosophical authority to a more inductive approach to political economy. Yet when Mill's influence was removed by his death in 1873, silencing the most authoritative voice in economics, the collapse of classical orthodoxy was further accelerated. And of its two main potential heirs, marginalism and historicism, it was the historicists who were more in tune with the general intellectual climate of the time.
As Darwinian ideas were absorbed into social science, the call went up for an evolutionary (and hence relativistic) science of political economy. (No one was to call for it more loudly than Marshall.) The Comtean critique of overspecialization within social science was still near its zenith, and applied with especial force to the increasingly narrow world of neoclassical economics. ‘Straight’ history was increasingly emphasizing its economic aspects in the work of F.W. Maitland, F. Seebohm and P. Vinogradoff. And, for those who were prepared to listen, Karl Marx was reiterating the potential scope and grandeur of economic dynamics.

The representatives of the English historical school drew on such influences with varying degrees of emphasis. Ingram used his presidency of Section F of the British Association (the social science section) to mount an explicitly Comtean attack on political economy’s ‘narrowness’ in 1878. Ashley painstakingly catalogued the aspects of Marxism with which he was and was not in agreement. The one conditioning factor which, oddly enough, was of limited influence was the work of the German Historical School of economists. English historicists might invoke the authority of their German contemporaries; Ashley and Hewins had important contacts with the later German Historical School; but it is hard to point to any German historicist as a major formative influence on any English counterpart.

What, then, was the detailed message of the Historical School? (In answering this question we shall be able to throw light on how far it should be regarded as a distinct ‘school’ at all.) First, as has already been mentioned, they were reacting against the narrow scope of orthodox economics. Thus, Ingram’s address of 1878, while accepting the arguments in favour of doing ‘one thing at a time’, warned that the social sciences were still branches of one subject ‘and the relations of the branches may be precisely the most important thing to be kept in view respecting them’. Ingram saw the narrow intellectual vision of orthodox economists as both cause and consequence of their neglect of moral issues, and further argued that once it was accepted that ‘the idea of forming a true theory of the economic frame and working of society apart from its other sides is illusory’ it necessarily followed that ‘the economic structure of society and its mode of development cannot be deductively foreseen but must be ascertained by direct historical investigation’ (Ingram, 1878).

But should one’s methodological stance in fact depend on one’s assessment of the appropriate intellectual boundaries of economics? J.A. Hobson was later to argue that the two issues had nothing whatever to do with one another. However, historicists to a man – albeit with different degrees of emphasis – followed Ingram’s lead in using their calls for a broader-based discipline to buttress their onslaught on unbalanced deductivism. The link was ‘economic man’, seen by historicists as an unreal psychological stereotype wholly unable to support the pyramids of deductive logic burdened upon him by Ricardians and Jevonians alike. Whether it was wealth or utility that he was supposed to maximize, he turned out very much the same, ‘an abstraction confounding a great variety of different and heterogeneous motives which have been mistaken for a single homogeneous force’ (Cliffe Leslie, 1879). Other Ricardian propositions which, in Leslie’s view, contradicted actual experience included the quantity theory of money and the contention that competition operated so as to equalize rates of profit across the economy. Leslie’s suggestion that the whole edifice of Ricardian economics be levelled to the ground, prior to economists making a fresh and cautious start, marked the high point of historicist iconoclasm. There were a number of different stopping-places (most of them inhabited by Ashley at one time or another) along the road from orthodoxy to this extreme point. Yet the historicists hang together as a school because of their common emphasis on factual and statistical thoroughness, on the relativity of economic doctrines, and on entering unfamiliar territory with an open mind and doing painstaking research before
allowing the first tentative inductive generalizations to filter through. The most orthodox of the school, Thorold Rogers, made the most impressive statistical contribution with his *History of Agriculture and Prices in England* (1866) which, among other objectives, sought to marshal the figures needed to refute Ricardian rent and wage theory. Ashley's verdict, however, that Rogers’ practice of merely illustrating his preconceived opinions with historical material was alien to a genuine historical method has been endorsed by modern commentators.

It would be wrong to conclude from the above that the Historical School was hostile to deduction as such. ‘Deduction’, said Ingram, ‘is a legitimate process when it sets out not from *a priori* assumptions, but from proved generalisations’. The historicist position, in effect, was that one had to ascertain by factual investigation exactly how amenable to deductive analysis different economic phenomena actually were. That the calculating maximizing spirit (where it existed) was amenable to Ricardian treatment was conceded on all sides. This point had been heavily stressed by Walter Bagehot (in his centenary essay on *The Wealth of Nations*) in the hope of rendering orthodox economics more plausible by demarcating its boundaries as those of the modern commercial world. Ashley's inaugural lecture at Harvard in 1893 endorsed this point; Cunningham's *Modern Civilisation in Some of its Economic Aspects* (1896) asserted that deductive analysis was coming into its own because ‘business of a modern type is being extended over a larger and larger area’. That this last tendency was – on balance – welcomed by Ashley and regretted by Cunningham may help explain the difference in their attitudes to Marshallian economics. Ashley (who was to become professor of commerce at Birmingham in 1901) shared Marshall's enthusiasm for most of what the modern businessman represented. In Cunningham, by contrast, distaste for the modern world and nostalgia for the Middle Ages predominated. But personal temperament counted for just as much in explaining the contrast between Ashley's relatively placatory attitude to Marshall and Cunningham's violently hostile one.

Marshall’s inaugural lecture at Cambridge in 1885 had met, head-on, the historicist assertion that the forces of custom and habit in economic life were strong enough to make orthodox economics, with its basic postulate of maximization, widely redundant. Marshall predicted that ‘economic science’ would soon be even more successful than it was already in ‘break[ing] up and explain[ing] economic customs’; asserted that statements that this or that economic arrangement was due to custom were little more than confessions of ignorance of true causes; and entrusted economic analysis with the illumination of such ignorance – the demonstration, for example, that ‘rents seldom diverge much for a long time from their Ricardian level in the East’ (Marshall, 1885). Cunningham, while regarding the whole lecture as a personal and public affront, fastened especially onto this last point, telling the British Association (1889) that ‘Professor Marshall, instead of accepting the description of mediaeval or Indian economic forms as they actually occur, sets himself to show that the accounts of them can be so arranged and stated as to afford illustrations of Ricardo's law of rent.’ Marshall's *Principles of Economics*, published the following year, opened with a long historical introduction which Ashley saw as a conciliatory gesture and Cunningham as a further provocation. (Today it reads as neither.) In ‘The Perversion of Economic History’ (*Economic Journal*, September 1892), Cunningham joyously rebuked what he saw as Marshall's hasty and amateurish style of historiography. It would all have read more convincingly if Cunningham had refrained from grotesquely out-of-context quotation, even at one point inserting a rogue word into Marshall's text to make it sound marginally more implausible. Marshall's reply to Cunningham's criticisms (it took Cunningham three years and seven polemics to induce it) was seen in most quarters as the final statement in the dispute (if only because the *Economic
Journal refused Cunningham the space for a counter-riposte.) Ashley, in his Harvard inaugural the following year, praised the historical chapters in the Principles and claimed that ‘to most of us the recent exchange of hostilities between two distinguished English economists has seemed almost an anachronism’.

The methodological debate, then, subsided after the early 1890s. But the protectionist controversy which began when Joseph Chamberlain disavowed free trade in 1903 saw survivors of the old historicists grouping reconstituted for a new battle. The episode is best approached via a general look at historicist attitudes to policy questions.

It is no coincidence that the entire Historical School, regardless of whether as individuals they were of the ‘left’ or the ‘right’, favoured an acceleration of the existing trend towards increased state intervention in the economy. Irish social reform, the recognition and legal protection of the trades unions, and the conditions of industrial and agricultural workers were all seen as urgent areas of responsibility for the state. The general view was well summarized by Foxwell (1885):

> We have been suffering for a century from an acute outbreak of individualism unchecked by the old restraints and invested with almost a religious sanction by a certain soul-less school of writers. The narrowest selfishness has been recommended as public virtue.

Ingram praised the German Historical School for upholding the power of the state as ‘the organ of the nation for all ends which cannot be adequately effected by voluntary individual effort’. Cunningham's Politics and Economics (1885) introduced his readers to ‘National Husbandry’, Cunningham's scheme for an economic policy holistic in its inspiration and nationalistic in its objectives: ‘the duty we owe to posterity [is] to make the future of our nation as great and noble as lies within our power.’

The link between holism (refusal to isolate the individual as a unit of analysis) and historical relativism was an irreproachably logical one: only if an individual can be isolated from his social context can a theory involving him be isolated from time and place. And Cunningham for one kept his readers’ eyes firmly on the fact that policy recommendations were as historically relative as economic principles, even suggesting at one point that the fact that a measure had worked well in very different circumstances was a consideration against proposing it here and now. Such pragmatism characterized much of the protectionist campaign. If free-trading economists were to be charged with inflexible dogmatism, intellectual arrogance and subservience to abstractions, it was essential that no such taint could be thought to cling to the protectionist cause. Ashley, indeed, never went beyond recommending temporary and selective tariffs for purposes of retaliation, and stressed that ‘with England as she has been for some centuries the notion that imports are paid for by money which might otherwise be spent at home is the crudest of popular fallacies’. Cunningham – eventually – did arrive at a more thoroughly protectionist stance than this, but it took him until 1910 to do so. And by 1910 the steam was running out of the protectionist campaign anyway, at least as far as the Historical School was concerned. Ashley's administrative responsibilities at Birmingham and Hewins's parliamentary ones virtually terminated their contributions to serious economic debate; Cunningham turned his attention to the relations between Christianity, political practice and social science. The Historical School’s achievements were complete by 1914.

How significant were they? Today their part in the foundation of economic history as a subject in its
own right is more obvious than their contribution to economics. Their lack of facility with marginal analysis – no historicist tried to master the neoclassical ‘paradigm’ and it must be doubted whether most of them would have been able to handle it even if they had tried – relegated them to outsiders’ roles once the dominance of neoclassicism was secured. Could they have prevented this dominance? The answer depends on whether one thinks that the inductive, historically based economics which they demanded but ostentatiously failed to supply could ever have been a feasible project. As it was, their lack of solid achievement inevitably weakened their position even as critics. Yet they forced both Marshall and his disciples to change both their thoughts and their presentation of these thoughts in a number of ways. Economic concepts were more carefully defined, and the bounds of their applicability more precisely demarcated. Policy recommendation became more cautious and less likely to be accompanied by exaggerated statements of the contributions of pure theory. The modern economist, said L.L. Price (1906),

evinces a readiness to recognise without reserve those qualifications of subtle delicate theory which a comparison with rough, unyielding facts must necessarily require. This reasonable attitude is largely due to the abiding influence of the vigorous controversy in which Cliffe Leslie bore a leading part.

The German Historical School was an influential heterodoxy in 19th-century political economy. It diverged from the classical school crucially in its scepticism that universal laws of social behaviour could be established. Its members were also more interventionist, tending to favour protection, regulation, colonization and the welfare state, though by no means unanimously on every point. In line with their relativity, they accepted that their policy recommendations, too, were historically contingent. Their influence among economists was greater in developing countries than in western Europe, but it has everywhere had a lasting impact on allied branches of social science such as sociology.

Keywords

Article

The German Historical School has a fair claim to be the most thoroughgoing and influential heterodoxy in 19th-century political economy. Scholars conventionally date its origins to 1843, with the publication of Wilhelm Roscher's *Outline of Lectures on Political Economy, according to the Historical Method*. Again by convention, the school is divided chronologically into three generations. The ‘older’ generation included Roscher (1817–94), Bruno Hildebrand (1812–78), and Karl Knies (1821–98). It was succeeded by a ‘younger’ generation, led by imperial Germany's most prominent economist, Gustav
Schmoller (1838–1917), and including Lujo Brentano (1844–1931), G.F. Knapp (1842–1926), K.T. von Inama-Sternegg (1843–1908), and Karl Bücher (1847–1930). A ‘youngest’ generation included Werner Sombart (1863–1941) and Arthur Spiethoff (1873–1957). All were professors of political economy or of Staatswissenschaft (‘state science’), and were widely known outside academic circles. A full account of the German Historical School would include many lesser-known figures, as well as several famous scholars who have often been associated with its agenda: Friedrich List (1789–1846), Adolph Wagner (1835–1917), Karl Lamprecht (1856–1915), and Max Weber (1864–1920), among others. There is no consensus date for the school's demise, but most would agree that by 1918 it was losing momentum, and that by 1945 it was a spent force.

In so far as they are remembered for belonging to the school, history has assigned to these economists the role of dramatic foil vis-à-vis classical political economy. Where the classicals were cosmopolitan children of the Enlightenment, the historical economists are remembered as romantics, idealists, nationalists; where the former were motivated to understand the nature and prospects of the commercial society taking shape around them, the latter were oriented to the economic past and its evolution towards the present; where the former were Newtonian in their aspirations for a master theory of the market order, the latter were satisfied to explore the peculiarities of specific situations; where the former offered a robust defence of private enterprise, the latter were just as robust in their vindication of state intervention; and where the classicals proved endlessly adaptable as circumstances varied, the German Historical School was sterile, a creature of one time and place. There is something to be said for each of these contrasts, but each of them can be – and has been – overdrawn, and the trend of recent scholarship has been to mitigate them.

Method

The Historical School partook of the ethic of professional historiography, seeking not to ransack the past but rather to understand it on its own terms. As history was an integral part of the Staatswissenschaft curriculum through which most German economists passed, it could hardly have been otherwise. But it is also fair to say that in this curriculum history was yoked, not to say subordinated, to the established discipline of Statistik, which had long meant the comparative study of social phenomena for purposes of effective statecraft. This more instrumentalist approach to historical inquiry is clearly in evidence in the works of the Historical School; it accords too with the participation of many members (notably Knies, Hildebrand, Inama-Sternegg, Bücher, Knapp, Brentano, Wagner, and Spiethoff) in the development and use of statistics in its more strictly modern sense, and the interest of many others (notably Roscher, Schmoller, Inama-Sternegg, and especially Bücher) in contemporary ethnography. In this sense they bear more than a passing resemblance to an Enlightenment polymath named Adam Smith, whom Roscher (1843, p. 150) named among the forefathers of historical economics.

But how would those copious data be used? A widespread view, born especially from the famous Methodenstreit between Schmoller and Carl Menger in the early 1880s, is that the historical economists took their scientific brief to include description, collation, and not much else; valid theoretical knowledge would emerge, if at all, only in the fullness of time and of its own accord. It is indeed true that in the heat of the dispute Schmoller made some ill-advised statements to this effect, and it is true also that he and his colleagues consistently denounced what they saw as the deductive excesses of Ricardian theory. However, in general they were far from denying the validity of deductive inference in...
principle (see Schmoller 1901–04, pp. 108–11); in practice they did engage in generalization and in theoretical speculation, sometimes so sweepingly as to make a classical economist blush. Prominent among the grander visions was their penchant for evolutionary ‘stage theories’ of economic development. It is these stage theories which have attracted the taint of holism, teleology, and crypto-Hegelian idealism. Once again, these charges are less than outrageous (see Weber, 1902–05) but significantly overstated. Turgot, Smith and Marx made similar efforts to reduce such broad historical processes to patterns of individual behaviour, which in turn are explicable in terms of the overall context. Even as it evolves, Roscher wrote in the introduction to his influential textbook, the economy remains ‘a natural product of the faculties and drives which make the human being human’ (1854, s.14). Perhaps the best single term to distinguish their brand of science is ‘relativity’. Unlike Newton and his admirers, who envisioned law-like relationships that were invariant as to time or place, the historical economists thought this a hopeless task for the human sciences. The theories they aspired to had fewer constants, more variables (psyche, environment, institutions, and so on) and in some versions a large error term – but they were still recognizable as theories. According to Roscher's formulation, the classicals had postulated rules, to which recent critics had pointed out myriad exceptions. ‘Now it would be above all necessary’, he went on, ‘to broaden the rules themselves to the point where those exceptions are incorporated’ (quoted in Eisermann, 1956, p. 150). Or, as Schmoller himself put it near the end of his career, German economists of his persuasion had achieved progress in economic theory the way Smith had, ‘by placing man and society at its center; but they did not thereby exclude the methods of natural science, or general concepts, or regularities. They did not claim that all the phenomena of economic life are individual and unique’ (1911, p. 434).

Policy

As regards policy recommendations, it is clear that the modal opinions of German historical economists were distinctly more interventionist than the Anglo-French norm. The renowned Verein für Socialpolitik (Association for Social Policy, arguably the world's first economic think tank) was founded in 1872 primarily by members of the school, with a mission that stood as a plain rebuke to the principle of laissez-faire. It is for this reason that the epithet Kathedersozialisten (‘socialists of the lectern’) was rather indiscriminately applied to them in their own day, and for this reason, too, that historians have come to view government activism as just as intrinsic to historical economics as any methodological precept. Paradigmatic in this view is Schmoller's belief in a ‘social monarchy’ and its capacity to reconcile the goals of private property, national development, and distributive justice through a programme of protection, regulation, and colonization. Once again, however, this generalization must be handled gingerly. It understates the diversity of political opinion within historical economics; specifically, it ill serves those economists who called for participatory government (Brentano, Bücher), who tended towards state socialism (Wagner, young Sombart), who opposed Bismarck's tariffs (Brentano, Bücher, Weber), and who doubted the capacity of regulation to improve upon market outcomes in general (Roscher, Hildebrand, Weber). It also ignores their essentially relativistic outlook: like List before them, who had promoted protection as the policy for his time but not for all time, the German historical economists – not excluding Schmoller himself – recognized the historical contingency of their specific recommendations.
Influence

It is also the case that the German Historical School was less parochial than has been suggested. It is true that the influence of German economists was conspicuously weak in francophone Europe through most of the 19th century, despite an early translation of Roscher's *Principles*, and despite the efforts of the Belgian economist Emile de Laveleye. This situation began to improve after about 1880, however, with the creation of the first chairs of political economy in the law faculties of the French universities. Since the new professors were perforce trained in law, and since French jurisprudence had already begun to fall under the sway of German historicism, they were better disposed to the historical economists than their predecessors (Gide, 1908). Charles Gide's critical appreciation of the German economists was characteristic of this younger generation, as was their reception by Paul Cauwès, François Simiand and Emile Levasseur. Historical economics fared better in the United Kingdom, thanks largely to the indigenous examples of Richard Jones, Henry Maine, John Lubbock, and others. T.E. Cliffe Leslie praised their endeavours, as did W.J. Ashley, William Cunningham, J.S. Nicholson, and W.A.S. Hewins. Alfred Marshall, whose name is not typically associated with historical economics, in fact affirmed that the school's work 'has thrown light on economic theory, has broadened it, has verified, and has corrected it' (1890, p. 74).

Despite these successes, in western Europe the German historical economists remained exotic specimens of a minor genus. Elsewhere they fared better, with their influence waxing in rough proportion with the developmental ambitions of the society in question. The historical school's rise to prominence in Gilded Age America (c.1876–1914), due largely to Germany's pre-eminence as a site for higher education in economics, has been well documented (Dorfman, 1955; Herbst, 1965; Rodgers, 1998). The American Economic Association (AEA) and the American Academy of Political and Social Science were both originally modelled on the Verein für Socialpolitik; all told, 20 of the first 26 presidents of the AEA had studied in Germany. While the leading American 'institutionalists' of the early 20th century did not have first-hand experience in Germany, they can be seen as carrying on the school's agenda: Thorstein Veblen its methodological dissent, W.C. Mitchell its statistical inquiries, J.R. Commons its social reformism. The Italian case offers a fairly close parallel. Young Italian economists were drawn to advanced study in Germany, and while the guardians of orthodoxy could inveigh against the trend of *germanismo economico*, they could not staunch the school's influence among economists such as Luigi Cossa, Vito Cusumano, Giacomo Luzzatti, and Achille Loria (Schiera, 1989). Elsewhere the German historical school achieved something close to intellectual hegemony by the turn of the 20th century, for example in Russia (Balabkins, 1988; Kingston-Mann, 1999; Barnett, 2004) and in Finland (Heinonen, 2002). Interestingly, its greatest influence relative to other schools was in Asia. In British India, the German dissent from orthodoxy was praised in the work of M.G. Ranade, G.K. Gokhale, R.C. Dutt, and G.S. Iyer, and left its imprint in the field of 'Indian Economics' that they founded. In Meiji Japan, meanwhile, the school established a decisive beachhead at the Imperial University in Tokyo in the early 1880s, thanks to direct German influence and especially to that of German-inspired American professors (Pyle, 1974; Sugiyama and Muzuta, 1988). A Society for Social Policy was founded there in 1897 on the model of the Verein für Socialpolitik, membership in which soon became an essential qualification for professional economists in that country.

Finally we turn to the question of the German Historical School's influence, or lack thereof, into the later
20th century and beyond. The school had a lasting impact on allied branches of social science. In economic sociology, Emile Durkheim's early works were fairly deeply engaged with historical economics (Steiner, 2003); Joseph Schumpeter held Schmoller up as a pioneer in the field (Schumpeter, 1926); and Max Weber was so deeply rooted in the school that he himself has occasionally been called a member. In the field of economic anthropology, Bronislaw Malinowski, Karl Polanyi and A.V. Chayanov had all been exposed to this literature in their youth (Kahn, 1990). It is only within economics itself that the German Historical School's star waned quickly after 1930. The reasons are no doubt complex and entwined with the drama of German political history; but surely the ‘formalist revolution’ in economic theory at large – where clarity and elegance gained great popularity, occasionally at the expense of verisimilitude and relevance – played a significant role. The matter is crystallized in J.M. Keynes's obituary for Marshall in 1924, where he characterized the school's work as 'learned but half-muddled'. One pictures Marshall nodding in reluctant agreement, and then asking aloud what more could be asked of true social science. For Keynes's successors, however, that indictment could hardly have been more damning.

How to cite this article

The history of economic thought (HET) is explored today for the most part within a sub-discipline of economics. (The literature on this topic is rather limited. Blaug, 1991 is an anthology of relevant articles. Two useful bibliographical works are Howey, 1982 and Stark, 1994. The history of economic thought in Britain is examined in Backhouse, 2004. Selected histories of economic thought are reprinted in Backhouse, 2000.) It shares a category in EconLit, the indexing service of the American Economic Association, with methodology, where it is called ‘Schools of Economic Thought’. Scholars in the sub-discipline conduct various kinds of studies: interpretive biographies, narrative accounts of the
growth of ideas and their impact on society, rational reconstructions of the emergence of theory, the
behaviour of scientific and intellectual communities, and more. Some 476 members of the American
Economic Association declared ‘methodology and the history of economic thought’ as a field of interest
in 2006. There are more than 1,000 scholars seriously interested in HET worldwide. The three main
journals in the field (History of Political Economy, Journal of the History of Economic Thought and
European Journal of the History of Economic Thought) have a combined circulation of about 2,000.
Approximately 200 scholars attend each of the annual meetings of the continental societies for the study
of HET, and the Japanese society has over 800 members.
The location and style of HET today are in contrast to those of the histories of most other scientific
disciplines, which are found usually not within the discipline under study but within one of the sub-
disciplines of history known as ‘history of science’ or ‘intellectual history’. Only the more humanistic
disciplines like literature and art history and, within the social sciences, political science tend still to
study their history within their known communities. Unlike those studying most other scientific
disciplines, historians of economics have generally been trained as economists rather than as historians;
this training gives them the perspective on their subject of insiders, but also, sometimes, the historical
skills of amateurs. Scholars of HET are likely to teach in economics, not in history.
From approximately the First World War until the 1960s HET was lodged comfortably in the ‘core’ of
economics. One or two courses were required of students at both the undergraduate and graduate levels,
taught alongside micro and macro theory and statistics. Economics faculty began their courses on almost
any subject with an introduction to the evolution of relevant theory. Indeed, HET was thought of as
simply an historical extension of theory, and practitioners as simply a special kind of theorist with a long
time horizon. Scholars of HET met other economists at conferences of the national and international
economics societies. They did not think of themselves as a separate sect within the discipline, and saw
no reason to have their own meetings or associations. They published in the mainstream economics
journals and in the publications of several friendly adjacent disciplines such as history, philosophy,
sociology and political science.
However, in the 1950s and 1960s this landscape changed. HET was banished from the core of
economics to the margins of the discipline, ostensibly to make room for more technical economic theory
and burgeoning econometrics. From being a requirement in the curriculum, HET became an option for
graduate and undergraduate students – if there was someone to teach it, and increasingly there was not.
The mainline professional societies and journals showed less and less hospitality to HET. Even the sister
sub-discipline, economic history, then in the grip of the cliometric revolution and under scrutiny itself
for relevance, seemed more and more uneasy about close relations with a subject that was ‘literary’.
More and more of the major postgraduate training programmes abandoned HET formally when those
who taught the subject retired and were not replaced.
The response to this crisis among those in HET in the 1960s was to regroup and create a new
infrastructure in which to operate, and a sub-discipline of HET effectively came into existence. The first
journal dedicated exclusively to the field, History of Political Economy, began in 1969, and the History
of Economics Society (HES) for specialists in the subject was established in 1974. Both of these new
institutions, although based in the United States, were intended to serve a worldwide community. Joint
sessions of the HES with the American Economic Association and other bodies of economists
continued, but the HES annual meetings became the most popular gatherings where specialists might
gather and interact. A paradoxical situation, then, exists in HET in the first decade of the 21st century.
While the memberships in societies and numbers of books and articles published annually is at least stable, coverage of the subject in the premier graduate training and research centres and in the mainstream periodicals of economics has steadily decreased almost to nothing. In the United States those few graduate students who specialize in the field do so usually through a jerry-built tutorial programme with a faculty mentor, and a dissertation dictated by the job market made up of only one essay in HET and two in more saleable fields. External funding for HET, unless it is camouflaged as policy studies or theory, is almost non-existent. So what then explains the impressive place gained by HET in the economics discipline at the middle of the 20th century and its precipitate fall, in prestige and respect, within the larger discipline at least, by the end of the century? The answer lies in the subject's own history, beginning in the 18th century. Five distinct historical periods can be discerned.

**Period I. The Enlightenment: HET as rhetoric**

HET began at about the same time as the discipline that it studies. The 18th-century Physiocrats clearly held in low regard many of the early thinkers on questions with which they were engaged; for example, they often denigrated the thinking of Colbert, the French Minister of Finance. But they used HET less as a weapon against those with whom they disagreed than to proclaim their own remarkable accomplishments. The Physiocrats assigned Pierre Samuel Du Pont de Nemours the task of historian. His short monograph, *De L'Origine et des progrès d'une science nouvelle* (1768), may be considered the earliest treatise in HET. Dupont claimed that Quesnay and his colleagues had for the first time discovered a body of doctrine that ‘following the nature of man, exposed the laws necessary for a government to make for man in all climates and in all countries’ (1768, p. 35). His book was mainly a celebration of this achievement.

Adam Smith was not as cautious in his criticism as were the Physiocrats. He was exceptionally well read, knew the economic literature of his day intimately, and was not shy about offering judgements. He cited some writers on economic topics in support of his views, from Aristotle onwards, and condemned others. But he did not in any sense produce a serious and balanced history of economic thought. He had favourites, such as his friend David Hume, and pointed out some whose ideas were intriguing, like Matthew Decker and Bernard Mandeville. But he did not present the work of his predecessors as constituting a unified body of thought or leading inexorably to his own. Smith praised the work of the Physiocrats, and especially that of ‘the very ingenious and profound author … Mr. Quesnay’. But he also condemned out of hand earlier thinkers who held fundamentally different views. About as charitable as Smith could be towards those who had expressed policy conclusions at variance with his own was that their ‘arguments were partly solid and partly sophistical’ (Smith, 1776, p. 433). Neither the Physiocrats’ self-congratulation nor Smith's imaginary debates with his predecessors were important contributions to a history of economic thought.

**Period II. Classical political economy: HET for cartography and doctrinal cleansing**

Thomas Robert Malthus and David Ricardo were neither very interested in nor respectful of their intellectual ancestors; they made occasional references to earlier work (Smith's Wealth of Nations was particularly important to them) but they made no systematic attempt to frame it as a whole. Not so their
immediate successors, the second generation of what came to be known as the classical economists: James Mill, Nassau Senior, Robert Torrens, James Ramsay McCulloch and others. These later classicals came increasingly to believe that, despite the continuing disputes over important points of theory, something approaching ultimate truth had been achieved in the work of the founders. Senior suggested in the 1820s even that the core of political economy could be expressed in a few simple propositions derived from the founding fathers’ work. From these propositions could be inferred both principles of high policy by which governments should abide, and principles to guide individual human action (Senior, 1827, pp. 35–6). Yet among the loose community of businessmen, journalists, public servants and others who pursued classical political economy during the first three-quarters of the 19th century there was relatively little agreement about what should be included in the canon. There were various elementary primers for those entering the field but no definitive textbooks (with the possible exception of J.S. Mill’s Principles in 1848), professorial oracles, or dominant professional periodicals to which one might turn for definitive judgements. Indeed, virtually anyone could make a claim for inclusion of his ideas in classical political economy simply by publishing in one of the many generalist reviews. It was to correct this condition of seeming doctrinal anarchy and inconsistency, and to impose some discipline upon an unruly conversation, that the classical economists turned to HET. Historical investigation could, perhaps, help map the new discipline and discern who and what were respectable contributions to political economy and who and what were not. Each of the doctrinal cartographers and cleansers had his own ideas of what orthodoxy should be imposed (Villeneuve-Bargemont, 1841, even named consistency with Christian theology as a criterion for inclusion). Some were Smithians, some Ricardians and some paid allegiance to an amalgam of doctrines. But their common purpose in going to the past was to sort out just what should guide the present. An example of a work to this end is the book View of the Progress of Political Economy in Europe since the Sixteenth Century (1847), which contained a course of lectures delivered by Travers Twiss, Professor of Political Economy in the University of Oxford. Twiss aimed to demonstrate that genuine works of political economy, as the subject had evolved since Adam Smith, employed the scientific method, which he described as testing theory by history so as to produce results that could benefit society: ‘leading doctrines are the conclusions of an enlarged experience, and are not, as many persons suppose, mere deductions from arbitrary premises skilfully assumed’ (1847, p. v). Twiss described the ill effects that could follow from the ‘unsound theory’ of such writers as Colbert and John Law. Twiss explained clearly how he proposed to use HET as a device to purge political economy of any false doctrines by which it had become corrupted. ‘I have attempted in the course of the above inquiry to assign to the chief writers their due shares respectively in furthering the progress of sound opinions, but I have purposely omitted the names of many authors of eminence, who have struggled to retard that progress, although they may have indirectly furthered it by the controversy which they have provoked’ (1847, p. viii). On several occasions John Ramsay McCulloch, like Twiss, gave an account of the progress of political economy as a morality tale. He pictured truth ultimately conquering error despite the strong forces massed against it. In his pioneering textbook Principles of Political Economy (first published in 1825) McCulloch included a chapter on ‘the rise and progress of the science’. He explained that dissension amongst early economists had tended to discredit the subject among scientists generally, and political economists needed to present a united front: ‘The differences which have subsisted among the most eminent of its professors have proved exceedingly unfavourable to its progress, and have generated a disposition to distrust its best-established conclusions’ (1825, p. 14). One of McCulloch’s primary
objectives was to sort out truth from falsehood, so that political economy could gain the reputation and influence that it deserved: ‘the errors with which this science was formerly infected are now fast disappearing; and a very few observations will suffice to shew, that it really admits of as much certainty in its conclusions as any science founded on fact and experiment can possibly do’ (1825, p. 15).

McCulloch's view was that there had to be broad agreement in any subject for it to be considered a science, and therefore the history must be presented as leading towards consensus. Histories of economic thought in the classical period often took on a distinctly nationalist tone. The cartographic function was perceived not only as filling in the map of the new discipline but also as making sure that some of the territory at least bore the home country's colours. Not all the map should be British red. The publication of these histories seems almost like the intellectual equivalent of the scramble for colonies that was in progress among the European nations at this time. Adolphe Blanqui, in what was as much an economic history of Europe as a history of economic thought, gave two chapters to Smith and Malthus wedged in between segments on the Physiocrats, Rousseau, the French Revolution and J.B. Say. He was relieved that the doctrines of the British ‘industrial school’ were no longer accepted without question thanks to the work of Sismondi and other French critics (Blanqui, 1837, p. 262). A similar work in Italian was by Luigi Cossa (1876).

**Period III. Neoclassical and historical economics: HET as literature review**

Beginning with the marginal revolution of the 1870s HET took on a new role derived from what had become fashionable in the physical sciences and mathematics: the literature review. If economists were to be seen as true scientists, insisted economists such as William Stanley Jevons, they must walk and talk like them. They must not use the history of their subject to demonstrate a stable orthodoxy, as McCulloch and others had sought to do. The past of a science contained not an accumulation of what was true but of what had been found to be false and had been displaced by current doctrine. In praising the accomplishments of the Austrian marginalists, Böhm-Bawerk used an evolutionary metaphor to describe HET as the study of illness in scientific infancy and childhood. The Austrians, he wrote, ‘are of the opinion that the errors of the classical economists were only, so to speak the ordinary diseases of the childhood of science … Their greatest fault was they were forerunners; our greatest advantage is that we came after’ (Böhm-Bawerk, 1973, p. 362). The essence of science was progress and change. The purpose of the literature review to be included with any major work in science should be twofold: to pay due respects to worthy ancestors, and more particularly to use the past to demonstrate how certain prior works led inexorably to the present, superior, one. The literature review in a work of theory while acknowledging worthy predecessors also established claims to priority in the novel ideas set forth. HET had come into the service of Whig history. Above all, the emphasis had to be on change rather than on stability. William Stanley Jevons insisted that attention to the past should be seen as liberating and not as stifling deference to orthodoxy. He observed how ‘in the other sciences the weight of authority has not been allowed to restrict the free examination of new opinions and theories; and it has often been ultimately proved that authority is on the wrong side’ (1871, pp. v–vi). In the books of the marginal revolutionaries the literature review was placed usually in the preface or in an appendix. Jevons used both. The marginalists were as ready as Twiss or McCulloch to dismiss some predecessors out of hand; but their dismissal was focused especially upon those who differed in particular methods or results from
the work currently being presented. All predecessors had necessarily been supplanted. Those who walked the right road, though too slowly, deserved to be remembered. Those who took the wrong road deserved to be condemned. Here is what Jevons wrote of McCulloch's heroes: ‘When at length a true system of Economics comes to be established, it will be seen that that able but wrong-headed man, David Ricardo, shunted the car of Economic Science on to a wrong line – a line, however, on which it was further urged towards confusion by his equally able and wrong-headed admirer, John Stuart Mill’ (Jevons, 1871, pp. li–lii). Jevons could congratulate Von Thunen, Dupuit, and Cournot; but for others, like John Stuart Mill, who were not on the right road to the marginal revolution, he had only contempt.

Each of the pioneer marginalists had his own way of incorporating a review of the literature into his text. In Menger the historical commentaries were long footnotes that so annoyed the translators of his Principles of Economics (1871) into English in 1950 that they appear there as a series of appendices. Marshall began with an introductory historical section on ‘the growth of economic science’ in the first edition of his Principles of Economics (1890) but shifted this material in the fifth edition (1907) to an appendix. Irving Fisher, lacking a single broad-based treatise of his own to which he could append an historical review of the literature, attached one to the translation of Augustin Cournot's Researches into the Mathematical Principles of the Theory of Wealth (1897). These reviews of the literature by the marginalists often have a strikingly unsystematic and personalized appearance with offhand comments that seem out of place in a carefully reasoned text. For example, the following comment by Marshall in a generally laudatory mention of Ricardo and his work seems to reflect more his own casual prejudices than a serious study of history. Marshall wrote:

his [Ricardos's] aversion to inductions and his delight in abstract reasonings are due, not to his English education, but, as Bagehot points out, to his Semitic origin. Nearly every branch of the Semitic race has had some special genius for dealing with abstractions, and several of them have had a bias towards the abstract calculations connected with the trade of money dealing, and its modern developments; and Ricardo's power of threading his way without slip through intricate paths to new and unexpected results has never been surpassed. But it is difficult even for an Englishman to follow his track; and his foreign critics have, as a rule, failed to detect the real drift and purpose of his work’. (Marshall, 1920, p. 629 n.)

Edwin Cannan's A History of the Theories of Production and Distribution in English Political Economy 1776–1848 (1917) was a generalized and highly critical literature review of what had become settled doctrine a half century before the ‘new’ economics of Alfred Marshall. It set out to demonstrate that only with marginal tools had economics become a science. Cannan's book was not like those of Twiss and McCulloch, which had sought to sift the wheat from the chaff in the confident belief that a pile of genuine truth would thereby be revealed. Cannan's message was that everything before marginal economics was hardly worth a glance because none of it was science.

The marginalists were not the only ones in the late 19th century to use HET to bolster the legitimacy of their approach. The Historical School also concluded that a literature review demonstrated the strength of their position. The essence of their claim was that the usefulness of economic theory was relative to
the circumstances in which the theory was applied. Different circumstances required different theory, and the history and appraisal of past theory had to keep in mind the tasks for which the earlier theory had been designed. The American historical economist E.J. James suggested that:

> the axioms and theorems which apply to one form of society may have little or no applications in another form, and any attempt to make such application may result in the most absurd conclusions … Nor will a theory which is adequate to the demands of an industrial state like England or America suit such a country [sic] as India or Africa. (Ingram, 1888, p. vii)

The historians wrote specifically in opposition to ‘The assertion of J.B. Say’ a doctrinal cleanser ‘that the history of Political Economy is of little value, being for the most part a record of absurd and justly exploded opinions’ (Ingram, 1888, p. 2). This they found to be an unjustified dismissal of early economic thought. The correct way to view the history of ideas, they were convinced, was as the record of how theory was useful at particular times and places and not either as a gradual but final movement towards some kind of ultimate truth, or as a steady accretion of scientific understanding. At the same time it must be conceded that the consequence of this posture by the historians was not very different from that of the marginalists; the details of HET, they implied, were largely of antiquarian interest. The difference between them was that the historical economists looked with more sympathy upon their predecessors, even those with whom they disagreed in their modern application. The most detailed history in English taking the historical approach was by the Irish economic historian, John Kells Ingram. Ingram's findings were in part similar to and in part a contrast to those of Cannan. He agreed with Cannan on the failings of the classical economists, and he insisted on the need to discover new theory. But his road map was different from that of Cannan. He found that the marginal successors were far too much like the classical economists they followed. He wanted a turn to modern science, but a different kind of science: an empirical science unconstrained by a body of high theory. He said: ‘the science must be cleared of all the theologico-metaphysical elements or tendencies which still encumber and deform it. Teleology and optimism on the one hand, and the jargon of “natural liberty” and “indefeasible rights” on the other, must be finally abandoned’ (1888, p. 241). Instead, economics must become an experimental science ‘forming only one department of the larger science of Sociology’ (1988, p. 242). Only in this way could economists change ‘the attitude of true men of science towards this branch of study, which they regard with ill-disguised contempt, and to whose professors they either refuse or very reluctantly concede a place in their brotherhood’ (1988, p. 240).

Other contemporary interpretations of HET in the same tradition as Ingram, that economic ideas were necessarily embedded in economic history, were posited by Price (1891) and Ashley (1894).

**Period IV. The golden age: HET as heuristic device**

Beginning around the First World War and continuing for almost half a century, HET went through a remarkable transformation. After serving in the 19th century as little more than a minor weapon in the arsenals of combatants in one professional conflict or another, and appropriately consigned to prefaces
and appendices by major figures and taken up extensively by no more than a few minor ones, HET came now to be pursued with energy and great seriousness by many of the leading figures in economics. Many of these converts produced significant book-length studies; others wrote articles. Some who did not devote years or an entire career to the subject still engaged in it soberly for the production of one or two studies before moving on. This new approach was not the ‘throwaway HET’ that had come before. Nor was it simply hagiography by members of a proud new community of professional economists. The authors in the golden age were committed to understanding problems through use of HET as an analytical device. They saw HET as heuristically significant. The golden agers did not think of HET as a separate new sub-discipline, as ultimately it was to become, but as an overlay of all economics, a distinct approach to all economic problems that should be explored as fully as other theoretical and empirical approaches. Moreover, the new interest was not confined to those holding any one ideological, methodological or doctrinal position. The following is an incomplete but illustrative list of some of those prominent economists who engaged in HET during this golden age apparently in search of answers to pressing questions: among the Austrian marginalists, J.A. Schumpeter, Gottfried Haberler, Karl Pribram, Erich Schneider, and Fritz Machlup; among English and American marginalists, John Hicks, Lionel Robbins, Frank Knight, George Stigler, and Jacob Viner; among the American Institutionalists, Wesley Mitchell, John R. Commons, Clarence Ayres, and John Kenneth Galbraith; among those intrigued with Marx, Eric Roll, Martin Bronfenbrenner, John Elliott, and Maurice Dobb; and among the new macroeconomists Piero Sraffa, G.L.S. Shackle, Gunnar Myrdal, and John Maynard Keynes himself. It was during this time that serious interpretive HET, rather than simply obituary notices, literature surveys, and review articles, entered the main publications of the profession, in writings by major figures such as those listed above, and lesser lights. HET was not only welcomed by the ‘top’ journals during the golden age, it became routinely the subject of presidential addresses and other ceremonial pronouncements. Most of the senior economists who took up HET also gave graduate courses in the field, and they encouraged some of their best graduate students to write dissertations in the area and to contemplate specializing in the field professionally.

Why this sudden turnabout? Why this unexpected fascination with history at the highest levels in the discipline? The most likely explanation lies in the circumstances of the time, which were certainly very different from those of the century before. Above all, a loss of confidence struck economics after the First World War. Before the war, economists of the mainstream such as Alfred Marshall, John Bates Clark, Léon Walras and Carl Menger concluded that they worked in an advancing science of a conventional sort and that they had the answers to most observable problems. The First World War, and the depression that followed, shattered all illusions that economic problems were that simple. No longer was it clear that relatively unconstrained rational men living in democracies and free market economies could count on enjoying peace and prosperity. The evidence seemed to prove the contrary and to suggest that all social constructs perfected during the Victorian age, including the global economy based on European empires, had to be re-examined from bottom up. Economics could not yet think of itself, as Keynes suggested it might be able to do some day, as analogous to dentistry seeking progress through technical improvements in familiar procedures. Where there had once been certainty now there was mainly doubt. And all of a sudden it seemed for many economists that HET might point the way toward undiscovered answers to some at least of the challenges newly arisen. HET was recognized as a vital tool in research. It could help economists find their bearings at several levels as they sought to be useful. Another factor behind the new interest in HET may have been the kind of scholar attracted to the
The questions that were coming to the fore were not of a type that could be addressed effectively by narrow technicians, and the questions attracted persons who insisted on supplementing conventional economic analysis with philosophical, sociological, psychological and historical enquiry. So what were these questions that prominent economists came to believe might be tractable through HET? They were methodological, including, how to reconcile and integrate the approaches of the different national traditions of marginalist economics, for example British and American partial equilibrium with the general equilibrium of the Walrasians? Were mathematical economics and econometrics essential to progress within the discipline, and how should they be used? More generally, was it possible to retain under one disciplinary tent economists who were so different in their approaches and objectives as the varieties of neoclassical marginalists, Institutionals, economic historians, Marxists, Keynesians and others? Was such heterogeneity virtue or vice? The questions were also theoretical; might early and forgotten theory cast light on such topics of sudden new concern as imperfect markets or business cycles? And some questions were directly policy oriented. What was the proper place for economics, and economists, in the policy process? Should the economists, rejecting the advice of most marginalist pioneers, sally forth from their ivory towers and connect directly with policymakers, perhaps even entering government as the German historians had done? If so, how? Should there be a ministry of economic affairs? Advisory councils to political leaders? Think tanks entirely outside of government? What about central planning? The Russian Revolution of 1917 raised this question for urgent public reconsideration even though it seemed to be settled for most professional economists by that date.

On all these questions, in contrast to the sense of self-confidence that characterized the first decade of the 20th century, when the most serious issues of economic policy were how to perfect the fine-tuning of the welfare economics of A.C. Pigou, the post-war mood demanded creative and fresh thinking. A notorious manifestation of this thinking across the disciplines was the hugely successful set of short biographies, *Eminent Victorians* (1918), by Lytton Strachey in which four prominent 19th-century institutions were held up for re-examination and reform: the military, the Church, the public schools and Victorian woman. Might this kind of historical enquiry reveal where the economy and economics had gone wrong, and show how they might be put back on the right track? Certainly Keynes believed so when he wrote *The Economic Consequences of the Peace* (1919), patterned substantially after *Eminent Victorians*.

Large structural questions without and within the economics discipline also were raised by the First World War and its aftermath. Was economics truly a science? This question became critical again during and after the Second World War, when public support for science, more than for other forms of enquiry, was contemplated and then implemented. These were years when the sub-disciplines of economics were just getting organized, and questions of boundaries and inclusions or exclusions had to be addressed. To some prominent scholars HET seemed a promising place to seek guidance. Jacob Viner's *Studies in the Theory of International Trade* (1937), Joseph Spengler's *French Predecessors of Malthus* (1942), Arthur Marget's *The Theory of Prices* (1938–42), Gottfried Haberler's *Prosperity and Depression* (1937), George Stigler's *Production and Distribution Theories* (1941) and Arthur Cole's *The Historical Development of Economic and Business Literature* (1957) were all milestones in HET and in the formation of the sub-disciplines of, respectively, international economics, economic demography, macro-economics, industrial organization and management science. Not all of those who pursued HET
in the golden age were the Renaissance men of the discipline. A few specialists did focus on single figures from the past, for example, Werner Stark on Bentham, Piero Sraffa on Ricardo, William Jaffé on Walras, and Joseph Dorfman on Veblen.

Not many of the giants of the golden age explained in detail the reasons for their new commitment to HET. Often the most we have to go on is an offhand remark or two. Jacob Viner said that his objectives were ‘to resurrect forgotten or overlooked material worthy of resurrection, to trace the origin and development of the doctrines which were later to become familiar, and to examine the claims to acceptance of familiar doctrine’ (Viner, 1937, p. xiii). For Joseph Schumpeter the study of HET was an integral part of discovering a vision of economic evolution, which contained the key to understanding the economy (Schumpeter, 1954). Frank Knight remarked that ‘A major lesson to be learned from the history of ideas is to realize the ‘glacial’ tardiness of men, including the best minds, in seeing what it later seems should have been obvious at the first look’ (1973, p. 46). Wesley Mitchell explored the question at some length at the start of his classes in HET at Columbia University and his reflections are revealing. In the transcription of his lectures, edited by Joseph Dorfman, Mitchell says that HET is necessary not so much to understand modern economics as to advance the subject through graduate education and research:

All that I contend for is that so long as the social sciences continue to make progress each generation of economists will find problems in the history of their science which earlier generations have not thought out, and that these problems will probably attract workers who feel their fascination; that is, I think there is a difference between the social sciences and the natural sciences, which makes the past history of their subjects more interesting and more pertinent to the workers in the social field than to workers in the natural-science field.

Our interest in the history of economics changes with the development of economics itself. The history of economics needs to be re-written by every generation of economists for the same reason that history at large needs to be re-written. (Mitchell, 1967, p. 2)

Mitchell's point was an important one. He suggested that HET was valuable especially for graduate students and young scholars who had the responsibility ultimately to move economic science forward. Without historical sensibility graduate students would be at a serious disadvantage on the research frontier. Mitchell said that the HET he was teaching was fundamentally different from that which had come before:

Working in this spirit we find ourselves concerned more with the larger aspects of economic history than our predecessors. What we can get light upon and what we therefore think most about is not the letter of the laws laid down, the traces of a man's thinking to be found in his predecessors, the logical inconsistencies which minute criticism may develop among his formulations – it is not these things which interest us so much as the type of problems the man attacks, his way of formulating them, what materials he had to work with, the general method he employed, the things he took for granted without inquiry, the grounds for the confidence he felt in his results, what use he
Mitchell suggested that HET should help economists gain ‘knowledge of ourselves and free us from over-narrow specialization’ (1967, p. 7). It would also ‘give us clearer insight into the conditions which promote or retard the progress of knowledge in the social sciences. Perhaps some at least among these conditions will prove to be amenable to control’ (1967, p. 7). HET might also give students the background with which to select among rival theoretical claims. ‘Some of them become neo-Marshallians, some neo-Marxists, some neo-Austrians, some mathematical theorists, some institutionalists. If anyone is going to make any such choice he ought to make it with open eyes; i.e. he ought to understand what other types of theory are; what they offer. If he knows, perhaps he wont become an ardent follower of any school’ (1967, p. 10). Finally, Mitchell noted that the sheer joy of historical inquiry should attract students to it. ‘The fascination of the work itself, the possibility of gaining keener insights and more certainty as we follow up our leads, may have more to do with the future progress of such work than the indirect gains it promises for economic theory’ (1967, p. 8). This golden age of HET came to an end in the 1950s and 1960s. The cause of its death is as much a puzzle as its birth. One explanation could be that most of the leading figures retired or left the field. But that is a description of what happened more than an explanation. Why did these leaders not have successors? Why was not the next generation of leaders in economics fascinated in the same way by the history of their subject? The best explanation seems to be that by the 1960s economics had once again regained its self-confidence and there was a reversion to the set of attitudes that prevailed before the First World War. Most of the issues that appeared after the war (depression, doctrinal conflict, war itself) seemed either to be answered or to have gone away by the 1950s. There was no longer a need to look backwards, it seemed, only ahead. One of the most powerful forces leading to a high level of self-confidence in economics was its own performance during the Second World War compared with that during the First. Macroeconomic understanding proved helpful in maintaining full employment with price stability, while optimizing models taken directly from applied microeconomics and sometimes including the new tool of game theory were found to be useful in processes as different as aiming a machine gun and planning air raids.

Period V. Building a new sub-discipline of HET

Most close observers of HET in the 1950s and 1960s might have predicted that its life within the economics discipline was over and that it was on its way to join the histories of other academic subjects in the deep recesses of history departments. At best it might leave a few champions within the larger discipline, such as Edwin Cannan proclaiming the faults of the old and the promise of the new. But this did not happen. HET lived on in economics, albeit without the powerful leaders of the golden age, without a place in most of the prominent research departments, and indeed without many opportunities for graduate training. So, without these assets how did the field survive? Several factors seem to have been in play.

The most important factor may have been the momentum carried over from the golden age. While most of those who had turned to history as a heuristic tool were gone by the 1960s, a few remained, and during this decade they joined in preparing a response to the new charge of irrelevancy. In the lead were
George Stigler, Lionel Robbins, Terence Hutchison, Joseph Spengler, Joseph Dorfman and Martin Bronfenbrenner. Also sympathetic but less directly involved were Kenneth Arrow, Kenneth Boulding, James Buchanan, John Chipman, Earl J. Hamilton, Paul Samuelson and James Tobin. But more important than this rearguard action by the last golden agers was a cadre of young and middle-aged scholars trained in HET and committed now to retaining it within the economics discipline. These children of the golden age were well placed in teaching jobs and their careers had often been encouraged by their mentors. From being an overlay of the economics discipline during the golden age, HET moved during the 1960s and 1970s to become an independent sub-discipline, led by, among others: in Britain, R. D.C. Black, Mark Blaug, Tony Brewer, A.W. Coats, David Collard, Ronald Meek, Denis O'Brien, Andrew Skinner, and Donald Winch; in the USA and Canada, William Allen, William Barber, Hans Brems, Robert Ekelund, Frank Fetter, William Grampp, Samuel Hollander, Todd Lowry, Larry Moss, Mark Perlman, Warren Samuels, Robert Smith, Vincent Tarascio, Carl Uhr, Anthony Waterman and Donald Walker; in Israel, Haim Barkai and Ephraim Kleiman; John Pullen, Michael White, and Peter Groenewegen in Australia. Outside the English-speaking world leadership was taken by, among others, Pier Luigi Porta, Maria Cristina Marcuzzo, and Pierangelo Garegnani in Italy; Erich Streissler in Austria, Heinz Kurz, Harald Hagemann, and Bertram Schefold in Germany; Arnold Heertje in the Netherlands; Yuichi Shionoya and Takashi Negishi in Japan; and Lars Jonung and Bo Sandelin in Sweden. In addition to building and supporting the infrastructure of specialized periodicals and societies, such as HOPE, JHET, EJHET, and others, these scholars helped to mobilize and sustain a variety of other resources that have strengthened the field: translations and republications of canonical writings, collected works and letters of major authors, variorum editions, and ephemera, as in the Kress-Goldsmith micro-film project of works published before 1800. Collections of manuscripts of prominent economists, saved sometimes at the last minute from the garbage dump, made possible for the first time the close study of the interactions among economists and how they constructed their articles and books. The most substantial of these is the Economists’ Papers Project at Duke University in the United States. In the United Kingdom the guide to archives prepared by Paul Sturgess documented where materials were located in that country. Access to manuscripts made possible meticulously documented biographies of great economists, for example, of Marshall by Peter Gronewegen (1995), of Hayek by Bruce Caldwell (2004) and of Keynes by Donald Moggridge (1992). Increasingly HET was defined as ending as recently as yesterday, and so oral history too became an essential tool of the historian.

An important movement that began in the 1960s was to explore ways in which HET could be incorporated more successfully into the curriculum of graduate students, economics majors, and even non-specialist liberal arts undergraduates. The teaching of HET in the golden age had been confined very largely to graduate and honours students using original sources and a few commentaries from the secondary literature. The textbooks that were available were by then very old – for example, those by Gray (1931), Gide and Rist (1909), and Haney (1911) – and not very appealing. The first rigorous new-style textbook, mainly for graduate students, was Mark Blaug’s Economic Theory in Retrospect (1962). It concentrated on expressing old ideas in modern guise. Other similar texts that joined it over the years were by Hans Brems (1986) and Jurg Niehans (1990). A plethora of textbooks for undergraduate courses were published with styles, degrees of rigour, and ideologies for most tastes (for example, those by Landreth, 1976; Ekelund and Hebert, 1975; Rima, 1967; and Spiegel, 1971). One of the pioneering works in this genre was William Barber’s History of Economic Thought (1967).
The New Palgrave Dictionary of Economics
publication landmark was Robert Heilbroner’s *The Worldly Philosophers* (1953) which, with sales reputedly above a million copies, attracted generations of undergraduates to a more extended investigation of HET. Although leaders of the economics discipline in the years after the golden age expelled HET from the graduate curriculum (not even Blaug's new textbook could stem that tide), it was important for the employment prospects of those trained in HET that the appeal of the subject as an elective course for undergraduates remained.

Progress in research in HET since the 1970s has helped to sustain the positive response to the challenge of the 1950s and 1960s. The creation of a new sub-discipline was strengthened by the flush of interest in the philosophy of science in the 1970s. There were stimulating attempts to use new interpretive tools derived from the writings of Thomas Kuhn (1962), Imre Lakatos (1970), and others to understand the history of economics. And Deidre McCloskey's examination of the rhetoric of economics (1998) reverberates still in HET. Other substantial research projects that were a stimulus to the new sub-discipline of HET, both as inspiration and as source of consternation, include Samuel Hollander's reconsideration and reinterpretation of classical economics (1973; 1979; 1985; 1996), Philip Mirowski's exploration of the linkages between the history of economics and progress in other disciplines (1989), Roy Weintraub's account of the mathematization of economics (2002b), and studies of developments in modern economics by Mary Morgan (1990), Esther-Mirjam Sent (1998), Judy Klein (1997), and others.

The emergence of a new generation of leaders of HET in the decades after the golden age, leaders who were able to gain secure positions in colleges and universities, has been a reassuring development. These include Jurgen Backhaus, Roger Backhouse, Bradley Bateman, Peter Boettke, Mauro Boianovsky, Bruce Caldwell, Jose Luis Cardoso, Avi Cohen, David Colander, William Coleman, John Davis, Robert Dimand, Neil De Marchi, Ross Emmett, Jerry Evensky, Evelyn Forget, Dan Hammond, Wade Hands, Robert Hebert, Kevin Hoover, Sue Howson, John King, Judy Klein, Robert Leonard, John Lodewijx, Harro Maas, Steven Medema, Perry Mehrling, Don Moggridge, Mary Morgan, Malcolm Rutherford, Margaret Schabas, Neil Skaggs, Karen Vaughn and Jim Wible. Often these scholars have combined their interest in HET with commitment to another sub-field of economics, sometimes by keeping their interests in HET quiet until they achieved tenure. These grandchildren of the golden age, as it were, have kept the momentum for the perpetuation of the new sub-discipline alive into the 21st century.

Certain developments outside HET as well as within helped to strengthen the field in the latter decades of the 20th century. A number of distinguished economists moved to history rather late in their careers. Usually they addressed questions still alive in their original sub-disciplines, but they have employed the historian's tools and perspectives. Examples of these mid-career migrants to HET include Walter Eltis, Geoff Harcourt, Don Patinkin, David Laidler and John Whitaker.

A second kind of migrant has been more problematic for HET. When the homogenization of economics reached a crescendo in the 1980s and 1990s, some of those who felt alienated or squeezed out of the discipline for methodological or ideological reasons found comfort and welcome in HET. Some who resisted the increasing technical complexity of the new theory also sought refuge in this cross-over. These refugees, while providing welcome additions to the ranks of HET and offering different perspectives on a variety of issues, have tended to mark the entire sub-discipline as made up of malcontents.

A third kind of migrant to HET came from specialized communities within economics that had become too small or marginalized to continue on their own. They sought and received hospitality within HET whether their interests were primarily historical or not. They include some Marxists, neo-Austrians, Post...
Keynesians, Institutionalists, Sraffians, and others.
HET has been enriched in recent years by visits, short or long, from members of other disciplines who
came not as refugees but attracted by specific research questions. They came from social, intellectual,
political and economic history, as well as from sociology, philosophy and political science. Prominent
visitors have included Peter Clark, Robert Skidelsky, Heath Pearson, S.M. Amadae and Yuval P. Yonay.

The prospect ahead

The future of HET is uncertain (Weintraub, 2002b). On the one hand, the strong infrastructure of
societies and publications is encouraging, as are the numbers of scholars who identify with the field. It is
gratifying, moreover, that the field has demonstrated persuasively its capacity to survive adversity and to
face challenges constructively. But though these are reasons for optimism for the future there are reasons
also for unease. And this leads to a final question. What uses will be found for HET in the future, and
can any of these be discerned from study of the past? The original use for HET in the rhetoric of policy
debates persists, but mainly on the surface. Libertarians wear Adam Smith ties and opponents of an
active government in the economy dismiss their opponents collectively as Keynesians, but in both cases
the combatants understand little beyond the labels. HET as doctrinal cleansing is still performed, but
mainly in review articles and chapters, such as those in the Journal of Economic Literature and the
various Handbook series, prepared not by specialists in HET but by high priests of the various sub-
disciplines. The more focused and celebratory literature reviews, such as those that gained popularity
after the marginal revolution, can be found still in Nobel Prize acceptance speeches and presidential
addresses, but neither serious history nor professional historians of economic thought are much
involved. In this spirit are the innumerable biographical and hagiographic dictionaries of ‘great
economists’ categorized in various ways, as women, dissenters, or something else. The use for HET
which was its greatest strength during the golden age, in the training of graduate students and in the
search for answers to large questions on the research frontier, has largely disappeared, and there seems
no immediate prospect of it being resurrected. Among the more recent uses for HET as a home for
refugees of various kinds and as a component in the undergraduate curriculum to relieve the tedium of
increasingly technical abstraction, only the latter seems secure and likely to grow in strength.
The overriding question remains: can a sub-discipline survive for long when it is little valued by the
discipline of which it is a part and where there is no graduate training available through which to sustain
and renew the leadership? One bright spot may be the liberal arts college, where breadth as well as depth
is still rewarded and which is likely to express forcefully in the labour market its preferences for kinds of
faculty training. Or it may take another loss of confidence within the economics discipline overall, such
as that experienced early in the 20th century, to cause economists to find once again something of
relevance in their past!

John Atkinson Hobson, a self-styled economic heretic, had a long and prolific career as an economist and political activist. His heresies included underconsumptionism and a critique of orthodox welfare economics based on ideas from John Ruskin, the former being elaborated into a theory of imperialism that influenced Lenin. He was belatedly recognized as a forerunner by Keynes in his General Theory, but this does not do justice to the range of Hobson's work.

Hobson was born in Derby in 1858 and died at home in Hampstead in 1940. He was educated at Derby School and Lincoln College, Oxford, where he read Greats from 1876 to 1880, but only gained a Third. He taught classics at Faversham and Exeter in 1880–81, before moving to London, where he supplemented his private income (from the Derby newspaper which his father had owned) with intermittent earnings from journalism, lecturing and his books (Clarke, 1978). A prolific writer, he propagated his economic views through more than 50 books and 700 articles, many of them in a series of organs of radical liberal and socialist leanings. Hobson thus left an oeuvre which is not easy to assess and in which formal inconsistencies are not difficult to find: but he conveys, nonetheless, a general vision of the scope and nature of economics that is both distinctive and coherent. His reputation has been coloured by his supposed role as a predecessor not only of Lenin and his theory of imperialism but also of Keynes and his concept of effective demand. Neither connection is wholly factitious but both have
Hobson has long been best known as an underconsumptionist. His first book (Mummery and Hobson, 1889) was written in collaboration with A.F. Mummery, a businessman, who seems to have been the senior partner. The book set out to expose fallacies in classical political economy as expounded by J.S. Mill. Its central proposition was that trade depression was caused by a deficiency in effective demand since it was the level of consumption in the immediate future that limited profitable production. It followed that there was a limit to the amount of useful savings which a community could make. Each individual could save with advantage to himself, but the overall result might be a position of underconsumption, for which over-saving was another name. Hobson was to seize on this self-defeating process as an example of what he called the protean fallacy of individualism – an idea that pervades his work in a far more general way than the particular concept of underconsumption. The polemical thrust of this early book was thus against the tendency of economists to extol thrift in so far as this neglected the crucial importance of maintaining sufficient demand. Hobson and Mummery provided an account (complete with a numerical example) of the accelerator, a concept commonly believed to have originated in the 20th century (1889, pp. 85–6; cf. Backhouse, 1990). Though the book attracted hostile comment from established economists, it did not, as Hobson alleged, blight his career. He carried on teaching economics as a university extension lecturer, the job for which he was well suited temperamentally (Kadish, 1990). Later, he was proud to proclaim himself an ‘economic heretic’ (Hobson, 1938).

This early statement of the underconsumptionist case was reiterated in two further books (Hobson, 1894; 1896) the second of which made use of the newly coined term ‘unemployment’, defining it in terms of involuntary leisure suffered by the working classes. He broadened rather than narrowed his dissent from neoclassical analysis through his distrust of marginalism, which he rejected on the ground that it rested upon an unreal individualism, marking a further breach with Marshallian orthodoxy (Hobson, 1901b; 1926a). A later book (Hobson, 1913), which was savagely reviewed by J.M. Keynes, sought to expose the errors of the quantity theory of money, recently popularized by Irving Fisher: this shows the extent to which Hobson was still thinking as a classical economist brought up on Mill, failing to fully take account of the innovations of his contemporaries such as Marshall and Fisher (Backhouse, 1990).

Hobson was to supplement his account of underconsumption with a theory of distribution (Hobson, 1900) which drew heavily upon the Fabian theory of rent. This theory built on a marginal productivity theory of distribution that had first been published in 1891 in the *Quarterly Journal of Economics*, alongside John Bates Clark’s article on the same subject. Hobson distinguished the costs of subsistence for any factor of production from its rent element, and argued that in principle surplus value might accrue to land, labour or capital. He further introduced the idea of ‘forced gains’ as an assertion of superior bargaining power in this process, with the result that ‘unearned income’ accrued to certain individuals and classes. He also assumed that the proportion of income which was in this sense economically functionless varied directly with the absolute level of income received. It followed that progressive taxation would not in practice impair any necessary incentive to production. This analysis was later elaborated (Hobson, 1909b) to distinguish a ‘productive surplus’ that covered the costs of growth from an ‘unproductive surplus’, distributed according to no functional principle. Morally this was the property of the community which had created it. If redistributive taxation could restore it to its rightful possessors, over-saving by the rich would be curtailed and underconsumption by the poor rectified. This functional view of the proper working of the economic system, with effort matched to
reward by rooting out parasitism, reappears constantly as a paradigm in Hobson's writings. He dignified it with the name ‘the organic law’ and often suggested an evolutionary provenance for it. But he also claimed the authority of John Ruskin, of whom he wrote an admiring study (Hobson, 1898), for seeing consumption, not production, as the qualitative end of economic activity. He sought to unite these ideas in one of the most frequently reprinted of his books (Hobson, 1894) by adopting the formula: ‘From each according to his powers, to each according to his needs.’

Hobson's view, taken from Ruskin, that attention should be focused on the human cost of economic activity was the basis for Work and Wealth: A Human Valuation (Hobson, 1914), which offered a systematic response to Pigou's welfare economics, the first systematic exposition of which had been published two years earlier. As in his writings on underconsumption, and distribution, he adopted terminology that emphasized, and possibly exaggerated, his differences with orthodoxy. Resting on clear value judgements about the worth of different activities, such an approach fell out of favour in the 1930s, and even before that failed to dislodge the Cambridge approach, especially in Britain. However, his work was much better received in the United States, where he had significant personal connections and where some institutionalists considered him the leading representative of English welfare economics.

In the early 1890s, Hobson was inclined to believe that protection and economic imperialism could mitigate underconsumption. As his political radicalism intensified, however, he dismissed protection as a device for safeguarding the incomes of the wealthy, thereby aggravating the problem of over-saving. In the wake of the scramble for China and the outbreak of the South African War (1899–1902) Hobson also developed a novel theory of economic imperialism. He identified speculative investment in undeveloped territories as a cause of imperialism and claimed that it arose from over-saving by a parasitic class at home. In this sense underconsumption was the economic taproot of imperialism (Hobson, 1902). What he vigorously rejected was the proposition that there was sufficient profit to the country as a whole from trade and investment in Africa to counterbalance the costs of aggression. In contrast to Lenin, therefore, Hobson denied that imperialism was a structural necessity of the metropolitan economy. It could and should be checked at home by a policy of redistributive taxation, which would have the reciprocal effect of cutting the taproot (ending over-saving) and stimulating domestic demand (ending underconsumption).

The economic implication was that Britain could easily make up any loss on foreign trade by generating wealth at home – an argument that could be used by protectionists. Nonetheless, it was the Liberal and Labour Parties, with their commitment to free trade, to which Hobson looked for reformist amelioration. He was confident that imperialism could be beaten by democratic means precisely because it did not serve the interests of the majority but only of a privileged section of the nation. In his most famous book, therefore, Hobson devotes more than twice as much space to the politics than to the economics of imperialism (Hobson, 1902). He needed to do so because the puzzle was how a policy that was bad business for the nation as a whole had come to be adopted. The answer was that finance was the ‘governor’ of an engine whose motor power came from the forces of nationalism and social psychology that fuelled the politics of self-assertion (Hobson, 1901a). His analysis of imperialism changed over time and was often strongly coloured by passing political events. In at least one book (Hobson, 1911) he commended cosmopolitan finance as a force for peace and saw imperialism as a step on the road to world economic development. During the First World War, he made a partial return to his earlier views and between the wars his position was often an uneasy compromise between the stances adopted in 1902 and 1911. The fact that he chose to republish Imperialism: A Study in 1938 virtually unaltered obscured
the complexity of his response to empire (Cain, 2002).

It will be apparent that Hobson was no single-minded underconsumptionist. In the early 1900s his energies were directed towards permeating the Liberal Party with a broad-based conception of economics that would justify it in rejecting the classical nostrums of laissez-faire in favour of interventionist policies designed to further social justice (Hobson, 1909b). The publication of Hobson's *The Industrial System*, which consolidated much of his previous work, opportunely coincided with Lloyd George's People's Budget of 1909 and offered a defence of the policy of redistributive taxation via the concept of the surplus. This aspect overshadowed the restatement of Hobson's underconsumptionist position; though he now went further than before in analysing the dynamic process by which over-saving reduced all real incomes in the economy until automatic checks came into play (Hobson, 1909b, ch. 18). One might call this Hobson's most accomplished exercise in macroeconomics.

It was in the context of the depression after the First World War that Hobson once more returned to this theme (Hobson, 1922; 1930), and it was in this period that his economic views enjoyed greatest publicity. He was now loosely identified with the Labour Party and found a natural application for his ideas in mounting an economic case for a ‘living wage’ (Hobson, 1926b). His central contentions on over-saving continued to be refined (King, 1994) and, amid widespread unemployment, they found a more sympathetic response, even among professional economists who had previously accepted a full-employment assumption. In particular, by 1930 Hobson was on cordial terms with J.M. Keynes, who had in earlier years scorned his work. But Keynes was still anxious to keep his distance, as he made clear (Keynes, 1930, pp. 160–1). The reason was that when Keynes wrote of over-saving he meant under-investment; whereas for Hobson saving and investment were two names for the same thing, and by over-saving he had always meant under-spending. It followed also that Keynes had more interest in policies of public works as a means of promoting investment, whereas Hobson concentrated on the case for redistribution as a means of stimulating consumption. It was not until Keynes had virtually finished the General Theory that he fully realized that he had done Hobson and Mummery an injustice; and so he paid them a handsome, if belated, tribute (Keynes, 1936, pp. 364–71).

hold-up problem

Yeon-Koo Che and József Sákovics
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Hold up arises when part of the return on an agent's relationship-specific investment is *ex post* experiorable by his trading partner. The hold-up problem has played an important role as a foundation of modern contract and organization theory, as the associated inefficiencies have justified many prominent organizational and contractual practices. We formally describe the main inefficiency hypothesis and sketch out the remedies suggested, as well as the more recent re-examination of the relevance of these theories.

Keywords

bargaining; Coase theorem; contract failure; fixed-price contracts; hold-up; incomplete contracts; ownership structures; relationship-specific investment; risk neutrality; underinvestment hypothesis; vertical integration

Article

Investments are often geared towards a particular trading relationship, in which case the returns on them within the relationship exceed those outside it. Once such an investment is sunk, the investor has to share the *gross* returns with her trading partner. This problem, known as hold-up, is inherent in many bilateral exchanges. For instance, workers and firms often invest in firm-specific assets prior to negotiating for wages. Manufacturers and suppliers often customize their equipment and production processes to the special needs of their partners, knowing well that future (re)negotiation will confer part of the benefit from customization to their partners. Clearly, the risk of the investor being held up discourages him or her from making socially desirable investments.

We first describe a simple model of hold up and illustrate the main *underinvestment* hypothesis (see Grout, 1984, and Tirole, 1986, for the first formal proof). A buyer and a seller, denoted B and S, can trade quantity $q \in [0, \bar{q}]$, where $\bar{q} > 0$. The transaction can benefit from the seller's (irreversible) investment. The investment decision is binary, $l \in \{0, 1\}$, with $l = 1$ meaning ‘invest’ and $l = 0$ meaning ‘not invest’. The investment $I$ costs the seller $k \cdot l$, where $k > 0$. Given investment $I$, the buyer's gross surplus from
hold-up problem: The New Palgrave Dictionary of Economics

consuming \( q \) is \( v_I(q) \) and the seller's cost of delivering \( q \) is \( c_I(q) \), where both \( v_I \) and \( c_I \) are strictly increasing with \( v_I(0) = c_I(0) = 0 \). Let \( \varphi_I = \max_{q \in Q} [v_I(q) - c_I(q)] \) denote the efficient social surplus given S's investment, and let \( q^*_I \) be the associated socially efficient level of trade. The net social surplus is then \( W(I) = \varphi_I - kI \). Suppose that

\[
\varphi_1 - k > \varphi_0,
\]

so it is socially desirable for S to invest.

A crucial assumption is that S's investment decision, although observable to the parties, is not verifiable, and therefore it cannot be contracted upon. For the moment, assume as well that the nature of trade is sufficiently 'inchoate' so that the parties can contract on \( q \) only after S's investment decision has been made. We model the negotiation of this contract à la Nash, yielding the efficient trading decision \( q_I \) and splitting the gross surplus \( \varphi_I \) equally between the parties. The seller thus appropriates only a fraction (a half, in this case) of her investment return, while she bears the entire cost of investment, \( k \), so her net payoff will be \( U_S(I) = \frac{1}{2} \varphi_I - kI \), following her investment. Suppose

\[
\frac{1}{2} \varphi_1 - k < \frac{1}{2} \varphi_0.
\]

Then, even though the investment is socially desirable, S will not invest. Hence underinvestment arises.

Organizational remedies

One interpretation of the inefficiency is the failure of the Coase Theorem. The parties cannot achieve the efficient outcome since the non-contractibility of S's investment decision prevents them from meaningfully negotiating over that decision ex ante. From this perspective, the hold-up problem entails a transaction cost of market/bargaining mechanisms, and, as Coase (1937) suggested, the transaction cost may be avoided or reduced via other organizational structures. Indeed, Klein, Crawford and Alchian (1978) and Williamson (1979) suggested vertical integration as an organizational response.

Just how the hold-up problem disappears or at least diminishes through integration is not clear, however, and requires a theory of how a particular ownership structure affects the parties’ exposure to hold up. This is precisely what Grossman and Hart (1986) and Hart and Moore (1990), hence forth GHM accomplish (see also Hart, 1995, for an excellent synopsis). According to them, the ownership of an asset gives the owner the right to determine the use of the asset that is contractually not specifiable. The parties will still
hold-up problem: The New Palgrave Dictionary of Economics

negotiate the terms of trade (presumably to achieve an efficient outcome), but this residual right – and thus ownership – matters, since it determines the status quo payoffs of the parties in the negotiation.

To illustrate how the status quo payoffs may affect the incentives, consider our model above and suppose that either B or S can own all assets necessary for the vertical operations. The former type of integration is called B-integration and the latter type is called S-integration. Fix i-integration and fix S's investment decision $i \in \{0, 1\}$. If they fail to agree on the trade decision, party $i$ can unilaterally realize the (status quo) payoff of $\psi_i^i(l)$ and party $j \neq i$ can realize the payoff of $\psi_j^j(l)$. It is reasonable to assume that, for $i = 1, 2$

**Assumption: GHM:**

(i) $\psi_i^i(l) + \psi_j^j(l) \leq \varphi, \ l \in \{0, 1\}$; (ii) $\psi_1^i(1) - \psi_1^i(0) < \varphi_1 - \varphi_0$; (iii) $\psi_0^i(1) > \psi_0^i(0)$ and $\psi_j^j(1) = \psi_j^j(0)$.  

Assumption GHM-(i) means that the status quo is welfare dominated by efficient trade; (ii) means that S's investment is specific to the relationship; and (iii) means that the investment improves the owner's status quo payoff but not the non-owner's.

Given the assumption that the parties split the surplus over and above the status quo payoffs, S's payoff will be

$$U_S^i(i) = \psi_S^i(l) + \frac{1}{2}(\varphi_1 - \psi_B(1) - \psi_S^i(l)) - \kappa l = \frac{1}{2} \varphi + \frac{1}{2}(\psi_S^i(l) - \psi_B(l)) - \kappa l.$$  

Hence, S's gain from investing under $i$-integration is

$$U_S^i(1) - U_S^i(0) = \frac{1}{2}(\varphi_1 - \varphi_0) + \frac{1}{2} \Delta^i - \kappa,$$

where

$$\Delta^i = \psi_1^i(1) - \psi_0^i(0) - [\psi_B(1) - \psi_B(0)].$$

Given assumption GHM-(ii) and -(iii), $\varphi_1 - \varphi_0 > 0 > 0 > 0$. Hence,

$$U_S^i(1) - U_S^i(0) > U_S^i(1) - U_S^i(0) > U_B^i(1) - U_B^i(0).$$
This shows that the S-\textit{integration} is the optimal ownership structure, dominating symmetric (non-integrated) structure, which in turn dominates B-\textit{integration} structure. In particular, if 
\[ U^S_0(1) - U^S_0(0) > 0 > U^S_1(1) - U^S_1(0), \]
then the investment is sustainable if and only if the seller has the asset ownership. This result reveals the main tenet of GHM that asset ownership can serve to reduce the owner's exposure to hold up.

\textbf{Remark 1.} The effects of alternative ownership structures may depend on the particular bargaining solution assumed. For example, the outside option bargaining or a Bertrand bidding solution may change the relative rankings of the alternative structures and may eliminate inefficiencies altogether. If the buyer's outside option is binding either from the buyer's owning more assets (that is, B-integration) or from the seller being subject to competition from another seller, then the seller is forced to make the buyer indifferent to that option, which causes the seller to internalize the social return of her investment. For this reason, B-integration may perform better than S-integration (Chiu, 1998; De Meza and Lockwood, 1998), or competition/non-integration may solve the hold-up problem (Bolton and Whinston, 1993; Che and Hausch, 1996; Cole, Mailath and Postlewaite, 2001; Felli and Roberts, 2001; MacLeod and Malcolmson, 1993).

\textbf{Contractual solutions}

In the above model, the trade decision is contractible only after the investment decision has been made. While this assumption resonates with many real business situations, it is difficult to reconcile with the fact that the parties can accurately calculate the payoff consequences of their behaviour (Maskin and Tirole, 1999). It is also crucial: if the parties \textit{can} contract on \( q \) prior to the investment decision, the underinvestment problem may be solved, without requiring the organizational remedies discussed above. To illustrate, suppose the parties sign a contract requiring them to trade \( \hat{q} \) for the total price of \( \hat{r} \). Unless renegotiated, this contract will give S a payoff of \( \hat{r} - c(\hat{q}) - k\hat{d} \) if she chooses \( \hat{l} \in \{0, 1\} \). If \( \hat{q} \neq q^*_l \), though, both parties will be better off by renegotiating to implement \( q^*_l \). Given the assumption that this renegotiation splits the surplus equally, S's \textit{ex ante} payoff will be

\[ \hat{U}^S(l; \hat{q}) = \hat{r} - c(\hat{q}) + \frac{1}{2} \left[ \phi_l - \nu(\hat{q}) - c(\hat{q}) \right] - k\hat{d}. \]

Hence, her net benefit from investing under this contract is

\[ \hat{U}^S(1; \hat{q}) - \hat{U}^S(0; \hat{q}) = \frac{1}{2} (\phi_1 - \phi_0) - \frac{1}{2} (\nu_1(\hat{q}) - \nu_0(\hat{q})) - \frac{1}{2} (c_1(\hat{q}) - c_0(\hat{q})) - k. \]
Whether a contract like this can create a sufficient incentive for S to invest depends on the nature of the investment made. Suppose first that the investment is *selfish*, so that it only decreases S's cost but does not affect B's valuation (that is, \( \nu_1(\cdot) = \nu_0(\cdot) \)). In this case, the trade contract can indeed protect S's incentive for investment. Observe that

\[
\varepsilon_0(q_1^*) - \varepsilon_1(q_1^*) = \nu_1(q_1^*) - \varepsilon_1(q_1^*) - [\nu_0(q_1^*) - \varepsilon_0(q_1^*)] \geq \psi_1 - \psi_0.
\]

By the same logic, \( \varepsilon_0(q_0^*) - \varepsilon_1(q_0^*) \leq \psi_1 - \psi_0 \). Since \( \varepsilon_1(\cdot) \) is continuous, there exists \( \hat{q}^* \) between \( q_0^* \) and \( q_1^* \) such that \( \varepsilon_0(\hat{q}^*) - \varepsilon_1(\hat{q}^*) = \psi_1 - \psi_0 \). Consequently, \( \hat{U}_5(1; \hat{q}^*) - \hat{U}_5(0; \hat{q}^*) = W(1) - W(0) \), so S will indeed invest whenever it is efficient to do so. Edlin and Reichelstein (1996) show that a fixed-price contract can provide efficient incentives for a selfish investment by either side and, with an additional condition, for selfish investments by both, in a more general environment with continuous investment. This result implies that, as long as the investments are selfish, the organizational remedies mentioned above will not be necessary.

**Remark 2.** Aghion, Dewatripont and Rey (1994) and Chung (1991) have noted that efficiency can be achieved for investments by both sides via a contract that manipulates the status quo payoff of one party in the same way as above and gives the full bargaining power to the other party at the renegotiation stage, thus making that party a residual claimant of the social surplus in the marginal sense. The idea of contractual manipulation of bargaining powers also appears in Hart and Moore (1988) and Nöldeke and Schmidt (1995).

### Contract Failure

Contracts may not restore efficiency if the investments are not selfish. Suppose the investment is *cooperative*: \( \varepsilon_1(\cdot) = \varepsilon_0(\cdot) \). So, S's investment increases B's valuation only, worsening the former's bargaining position. Such a cooperative nature of investments underlies many instances of the hold-up problem (for example, quality-enhancing R&D investment by a supplier and customization efforts by partners). In this case, any commitment to trade exacerbates rather than alleviates the investor's vulnerability to hold up. Formally, given \( \varepsilon_1(\cdot) = \varepsilon_0(\cdot) \), S's *ex ante* payoff will be

\[
\hat{U}_5(1; \hat{q}) - \hat{U}_5(0; \hat{q}) = \frac{1}{2}(\psi_1 - \psi_0) - \frac{1}{2}(\nu_1(\hat{q}) - \nu_0(\hat{q})) - k = \frac{1}{2}(\psi_1 - \psi_0) - k = U_5(1) - U_5(0) < 0.
\]
for any $\bar{Q}$. In other words, no such trade contract creates more incentives for S than the null contract. In fact, Che and Hausch (1999) demonstrated that all feasible contracts are worthless if investments are cooperative.

A similar result can be obtained if the investment is selfish, but it is difficult to predict the ‘type’ of trade that will benefit from the investment (Hart and Moore, 1999; Segal, 1999). Specifically, suppose that there are $n$ potential goods the parties may wish to trade but that only one of them becomes a ‘special’ type and only the special type will benefit from an investment. Assume that each of the $n$ goods has an equal chance of becoming that special type ex post, so the parties can predict the special type only with probability $1/n$. Adapted to our model, the surplus from trading the special type is $\varphi_I l$ given investment $l \in \{0, 1\}$, and the surplus from trading a ‘generic’ type is $\varphi_0$, regardless of the investment decision. Assume for simplicity that $q^*_l = 1$, for $l = 0, 1$. As the contract is renegotiable, under a contract requiring the parties to trade any good, S's ex ante payoff from choosing $l \in \{0, 1\}$, becomes

$$\tilde{U}_S(l) = \frac{1}{n} (\hat{r} - c_l(1)) + \frac{n-1}{n} (\hat{r} - c_0(1)) + \frac{1}{2} \left[ \varphi_1 - \frac{1}{n} \varphi_1 - \frac{n-1}{n} \varphi_0 \right] - k l.$$ 

In other words, S's investment influences her status quo payoff only when the good they contracted to trade turns out to be the special type, an event that arises with probability $1/n$. This feature weakens the ability of a contract to provide incentives, as can be seen from S's gain from investing:

$$\tilde{U}_S(1) - \tilde{U}_S(0) = \frac{1}{n} (c_0(1) - c_1(1)) + \frac{1}{2} \left[ \varphi_1 - \varphi_0 - \frac{1}{n} (\varphi_1 - \varphi_0) \right] - k = \frac{1}{2} \left( 1 + \frac{1}{n} \right) (\varphi_1 - \varphi_0) - k.$$ 

Further, as the environment becomes ‘complex’ in the sense that $n \to \infty$, S's incentive reduces to that under the null contract, thus rendering contracts virtually worthless.

Several implications can be drawn from these two results. First, the contract failure result implies that the true challenge of the hold-up problem may lie with the nature of specific investments – either the ‘cooperative’ nature or the ‘unpredictability of investment benefit’. Second, the general failure of contracting to protect against hold up lends credence and relevance to the GHM analysis of the ownership structures or organizational theory in general based on the hold-up problem as a source of inefficiency. Third, for the above results it is crucial for the parties to be unable to commit not to renegotiate their contract. Were such commitment available, they could devise a contract that would induce them to reveal truthfully S's investment decision, say, by having both parties report simultaneously about the decision and penalizing both of them for any inconsistency via zero trade and zero transfer. Then, S can easily be
induced to invest by a sufficient amount of bonus given to her only conditional on both parties reporting ‘S has invested’. If a contract is renegotiable, such a costless revelation of information is impossible to achieve: Inconsistent reports do not reveal the identity of the liar, and both parties cannot be simultaneously punished, since they will renegotiate back to the Pareto frontier.

**Remark 3.** Several elements are crucial for the contract failure result. First, it requires the existence of an opportunity to renegotiate following any contract-specified action. If there is some non-renegotiable action, then an efficient outcome may be achievable. Rogerson (1984) shows that liquidated damages achieve the efficient outcome if a contract can be breached non-renegotiably. Likewise, if in the last period of renegotiation the buyer can irrevocably determine the terms of trade, then buyer-option contracts can overcome the hold-up problem (see Lyon and Rasmusen, 2004). Contract failure re-emerges, however, in the case of cooperative investment if the parties discount delayed exercise of the option (Wickelgren, 2007). Second, risk neutrality is important for contract failure. If the parties were risk averse, then a lottery could be used to punish both parties even in the presence of renegotiation, and could achieve the first-best (Maskin and Tirole, 1999). Third, it is important for the contract to be bilateral. If a third party can be involved, efficiency can be achieved even when the contract is subject to renegotiation or collusion (Baliga and Sjostrom, 2005). Last, Watson (2006) gives a general treatment of how renegotiation opportunities arising at different stages interact with the technology of trade, and recognizes the relevance of modeling technological details of trade, i.e., whether the trade is individual or public.

**Dynamics**

The basic hold-up model assumes that there is a single opportunity to invest, followed by the distribution of the surplus. Not too surprisingly, if the interaction is repeated, inefficiencies can be greatly reduced, in accordance with the Folk Theorem for repeated games (see, for example, Klein and Leffler, 1981). More surprisingly, allowing for dynamic investment patterns can have a dramatic effect even in a one-shot interaction, as shown by Che and Sákovics (2004a). When the agents can continue to invest even after the negotiation of the terms of trade has started, the anticipated investment dynamics can influence the way the parties negotiate and improve the incentives for investment.

To see how this works, modify our running example by allowing S to invest in the following period if she has not invested in the past and no agreement has been reached yet. If the parties discount their future very little, S’s ‘invest’ can be sustained in a subgame-perfect equilibrium. In this equilibrium, hold up still arises on the equilibrium path in that S receives only the fraction of the gross surplus commensurate with his bargaining power. Yet this does not stop S from investing. Suppose S does not invest today but is expected to invest tomorrow in case no agreement is reached today. Then, there will be more surplus to divide tomorrow than there is today. Since the cost of tomorrow’s investment will be borne solely by the investor, the prospect of the investor raising his investment tomorrow causes his partner to demand more to settle today. The investment dynamics thus results in a worse bargaining position for the party upon not investing, and creates a stronger incentive for investing than would be possible if such investment dynamics – that is, the option to invest in the future – were not allowed. As a result, investment can be supported in equilibrium.

In sum, dynamics in the trading relationship and/or investment technology lessens either the risk of hold up or the degree of inefficiencies caused by it. This questions the relevance of the hold-up problem as a rationale for organization and/or contractual remedies. At the same time, the presence of dynamics alters
the nature of the incentive problems and calls for different types of contractual or organizational prescriptions against hold up than those proposed based on the static models, as seen by Baker, Gibbons, and Murphy (2002), Che and Sákovics (2004b) and Halonen (2002).

home production

Yongsung Chang and Andreas Hornstein
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Studying the incentives and constraints in the non-market sector – that is, home production – enhances our understanding of economic behaviour in the market. In particular, it helps us to understand (a) small variations of labour supply over the life cycle, (b) the low correlation between employment and wages over the business cycle, and (c) large income differences across countries.

Keywords

capital accumulation; Cobb–Douglas functions; elasticity of substitution; home production; hours worked; income differences; intertemporal substitution elasticity; IS–LM; labour supply; labour supply elasticities; leisure; Michigan Time Use Survey; national income accounts; neoclassical growth theory; non-market activity; real business cycles; stochastic growth model; technical progress; total factor productivity

Article

Studies such as the Michigan Time Use Survey (Hill, 1984; Juster and Stafford, 1991) indicate that a typical married couple allocates only about one-third of its discretionary time working for paid compensation in the market. The allocation of time for non-market activities, such as home production or leisure, may be as important for economic welfare as is the time spent working. Starting with Becker (1965) and Mincer (1962), the value of non-market activity has been explicitly incorporated into economic analysis in terms of forgone earnings. Since household decisions on the allocation of time to market and non-market activities are undertaken jointly, studying the incentives and constraints in the non-market sector – home production – enhances our understanding of economic behaviour in the market sector. We discuss three examples where the inclusion of home production has improved our understanding of macroeconomic issues: (a) low estimates of the labour supply elasticity from panel data; (b) low correlation between return to working and hours worked over the business cycle; and (c)
large differences in measured output across countries. In a standard neoclassical growth model with home production, a household derives utility not only from the consumption of market goods but also from the consumption of non-market goods. Non-market goods are produced in a home production sector using work effort and capital. The household's utility also depends on the consumption of leisure, which is the household's time endowment minus work effort supplied to the market and the home production sector. One usually assumes that the economy's technology is such that investment goods that can be used to augment the capital stock in the market and non-market sectors are produced only in the market sector of the economy. Important factors in the determination of the dynamics of a neoclassical growth model with home production are the substitution elasticity between the consumption of market and non-market goods, the substitution elasticity between capital and labour in market and home production, the relative capital intensity of production in the market and the home production sectors, and the correlation of total factor productivity in the two sectors. Examples of the neoclassical growth model augmented with home production are Benhabib, Rogerson and Wright (1991) and Greenwood and Hercowitz (1991).

**Business cycle analysis**

The allocation of hours worked – employment – is at the heart of business cycle analysis. Table 1 shows the standard deviations and correlation of the cyclical components of total hours worked and returns to working for the US economy, 1964–2003.

*Note:* All variables are logged and de-trended with the use of the Hodrick–Prescott filter. Hours worked \((n)\) represents the total hours employed in the non-agricultural business sector. Wages \((w)\) are the real hourly earnings of production and non-supervisory workers. Labour productivity \((y/n)\) is output divided by hours worked. The period covered is from 1964:I to 2003:II.

*Sources:* DRI-WEFA Basic Economics Database; Global Insight.

Two features are of great interest to macroeconomists. First, hours worked is substantially more volatile than the return to working. Second, hours worked is not highly correlated with the return to working. Employment in other countries also exhibits similar features (for example, Backus, Kehoe and Kydland, 1992). These facts present a serious challenge to modern business cycle theory that builds on the idea of intertemporal substitution of work effort. Intertemporal substitution assumes that people work relatively more hours in some years than in others because the return from working in the market is unusually high in those years (for example, Lucas and Rapping, 1969). According to Table 1, on the one hand it appears as if employment would have to be very elastic in its response to changes in the return to work, but on the other hand the returns to work appear to be only weakly correlated with the supply of work time.

**Estimates of labour supply elasticity**
Business cycle theory that builds on the stochastic growth model – for example, Kydland and Prescott (1982) – indeed requires a large intertemporal elasticity of substitution in order to account for the relatively large fluctuations of hours worked. Yet a substantial empirical literature based on micro data finds that households’ willingness to substitute hours is quite low – less than 0.5 (for example, MaCurdy, 1981; Altonji, 1986). Home production provides a potential resolution of this problem.

Most micro estimates of the intertemporal substitution elasticity rely on the variation of hours worked and wages over the life cycle of households. Rupert, Rogerson and Wright (2000) show that these estimates may underestimate the true willingness to substitute hours across time if one does not take into account the fact that households simultaneously decide on the supply of hours for market and non-market activities. Essentially, conventional estimates of labour supply elasticities suffer from an omitted variable bias: home work is positively correlated with market work and should be included in the estimation. For simplicity we assume that households’ preferences are log-linear in a consumption aggregator of market, $c_{mt}$, and home-produced consumption, $c_{ht}$, and work time, be it in the market, $n_{mt}$, or at home, $n_{ht}$:

$$u(c_{mt}, c_{ht}, n_{mt}, n_{ht}) = \log c_{mt} + c_{ht} - B \left( n_{mt} + n_{ht} \right)^{1+1/\gamma}$$

Then the optimal labour supply of a household that is $t$ years old can be written as

$$\log w_t = (1 / \gamma) \log (n_{mt} + n_{ht}) + A_t$$

where $w_t$ denotes the market wage rate, and $A_t$ represents other terms that may depend on age. The parameter $\gamma$ denotes the willingness to substitute total hours over time – intertemporal substitution elasticity. For conventional estimates of the labour supply elasticity, which ignore home production, time spent for home production activities represents an unobserved supply shifter for market labour. A typical worker faces a hump-shaped wage profile in his life: wage rates rise, reach a peak at age 45–55, and decline from then on. It is not unreasonable to assume that the consumption of non-market goods, and therefore hours worked in home production, is correlated with the market wage profile over the life cycle. For example, high earning years tend to be around the years in which one buys a house or has children, both of which call for more time spent in home production. The fact that home work and market work are positively correlated over the life cycle, but home work is omitted from the estimation equation, implies that the estimated inverse labour supply elasticity $1 / \hat{\gamma}$ will be biased upward.

**Wage–employment correlations**

One of the primary empirical patterns that have puzzled many business cycle theorists is the lack of a systematic relationship between employment and wages. On the one hand, Keynesian IS–LM models assume that real wages and hours worked lie on a stable, downward-sloped marginal product of labour schedule, and predict a strong negative correlation between real wages and hours worked (for example, Dunlop, 1938). On the other hand, real business-cycle models, such as that of Kydland and Prescott (1982), where productivity shocks shift the labour demand schedule along a relatively stable positively sloped market labour supply curve, tend to predict a strong positive correlation between wages and employment. Incorporating home production into the neoclassical growth model helps account for the low correlation between market work and wages as well as the large variation of employment. Technical progress not only augments the marginal product of labour in the market sector but also affects the marginal product of labour in the home production sector. Consider, for example, technical progress that is embodied in consumer durables, such as vacuum cleaners and washers. This kind of technological progress often reduces the required work effort in the home sector for household chores, and thereby shifts the supply curve of market work outward along a negatively sloped market demand for labour curve. Thus, while technical progress in the market sector causes a positive correlation between market hours and wages, technical progress in the non-market sector can cause a negative correlation between market hours and wages. If technical progress in the market is positively correlated with that in the non-market sector, then market hours may fluctuate substantially without any accompanying changes in real wages.

In general, the allocation of hours between the market and home depends on (a) the covariance structure of productivity in the market and home, (b) the substitution elasticity between market goods and home-produced goods, and (c) the substitution elasticity between capital and labour in the home production function – in particular, if the purchase of home capital (for example, a home theatre system) requires or saves hours in home production. Recently, rich structures between the market and home production have been introduced to study the various features of business cycles – for example, McGrattan, Rogerson and Wright (1997), Hornstein and Praschnik (1997), Fisher (1997), Einarsson and Marquis (1997), Ingram, Kocherlakota and Savin (1997), Perli (1998), Chang (2000), Gomme, Kydland and Rupert (2001).

Cross-country income differences

There are enormous income differences across countries, and such disparity has persisted over time. According to Heston, Summers and Aten (2002), the ratio of the average per capita GDP (based on purchasing power parity price) of the richest fifth of all countries to that of the poorest fifth of all countries was about 12 in 1960 and had doubled to almost 25 by 2000. In the standard neoclassical growth model, distortions to capital accumulation contribute to income differences. For a reasonably calibrated neoclassical growth model, the distortions that are required to account for the observed income differences are, however, unreasonably large. Parente, Rogerson and Wright (2000) show that the required distortions are substantially reduced once we distinguish between an economy's market sector whose output is measured in the national income accounts and a home-production sector whose output is not measured. With home production, distortions to capital accumulation not only reduce the capital stock but also can reallocate economic activity from the market sector to the non-market sector.
Moreover, the measured income differences overstate the true differences in welfare, and the unmeasured consumption from home production may explain how individuals in some countries can survive on the very low levels of reported income.

Consider the neoclassical growth model with log preferences in consumption, $c_m$, and leisure, $l$. Output, $y_m$, is produced using capital, $k_m$, and labour, $n_m$, as inputs to a constant returns to scale Cobb–Douglas production function, $y_m = k_m^\alpha (z_m n_m)^{1-\alpha}$. Output can be used for consumption and investment, $x_m$, to increase the capital stock: $k_m = (1 - \delta) k_m + x_m / \pi$, where $\delta$ is the depreciation rate. With capital accumulation distortions, investment increases the capital stock less than one for one: $\pi > 1$ (for example, Parente and Prescott, 1994). It is easily conceivable that there are substantial inefficiencies in capital accumulation in less developed economies (for example, inefficient governments, ill-protected property rights). Given commonly assumed preferences and technology, the investment rate and work effort on the balanced growth path will be independent of the magnitude of capital distortions, but the capital stock and output will decline with the capital distortion. Two countries that look alike in terms of the investment rates may nevertheless have very different output levels. Conditional on a reasonable parameterization of the economy, we would, however, have to assume capital distortions, $\pi \geq 100$, in order to account for observed output differences of a factor of at least 10 (for example, Parente, Rogerson and Wright, 2000).

A straightforward extension of the neoclassical growth model that includes home production assumes that preferences are defined over a consumption aggregator that includes market consumption and non-market consumption, $c_h$, from the home-production sector. The home-production sector also uses capital, $k_h$, and work effort, $n_h$, as inputs to a Cobb–Douglas production function. The household’s time endowment can now be used in the market and the non-market sectors, and market production can be used for investment in the market and the non-market sectors. If home production is less capital-intensive than market production, and market and non-market goods are sufficiently close substitutes, a higher capital distortion not only reduces total capital accumulation but also leads to a reallocation of the available capital and work effort from the market sector to the non-market sector. Parente, Rogerson and Wright (2000) argue that, for reasonable substitution elasticities between market and home-production consumption and capital shares in the home-production sector, capital distortions as low as $\pi = 15$ can account for income differences in the market sector of a factor of ten.

homogeneous and homothetic functions

J.-P. Crouzeix
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Homothetic orderings

Given a cone $E$ in the Euclidean space $\mathbb{R}^n$ and an ordering $\preceq$ on $E$ (i.e. a reflexive and transitive binary relation on $E$), the ordering is said to be homothetic if for all pairs $x, y \in E$

$$x \preceq y \Rightarrow \lambda x \preceq \lambda y \text{ for all } \lambda > 0.$$ 

For each $x \in E$, denote by $L(x)$ the indifference surface

$$L(x) = \{ y \in E : y \preceq x \text{ and } x \preceq y \}.$$

Hence, geometrically, if the ordering is homothetic, then for all $x \in E$ and $\lambda > 0$

$$L(\lambda x) = \{ \lambda y : y \in L(x) \}.$$ 

Homothetic functions

Recall that a real function $f$ on a set $E$ defines a complete (or total) ordering on $E$ via the relation
By definition, \( f \) is said to be homothetic if the ordering is homothetic (implying that the domain \( E \) of \( f \) is a cone). Thus utility functions which represent a homothetic ordering are homothetic.

Assume, now, that \( f \) is a homothetic and differentiable function on an open cone \( E \) of \( \mathbb{R}^n \). Assume also that \( \nabla f(x) \neq 0 \) for all \( x \in E \). Hence for all \( \lambda > 0 \) and all \( x \in E \) there exists \( k > 0 \) such that

\[
\frac{\partial f}{\partial x_i}(\lambda x) = k \frac{\partial f}{\partial x_i}(x), \text{ for } i = 1, 2, \ldots, n.
\]

In economic terms, this property means that the marginal rate of substitution remains constant along any ray from the origin. In fact, under some suitable assumptions, this property characterizes homothety of functions.

**Positively homogeneous functions**

A real function \( f \) defined on a cone \( E \) of \( \mathbb{R}^n \) is said to be positively homogeneous of order \( p \) if for all \( x \in E \)

\[
f(\lambda x) = \lambda^p f(x) \text{ for all } \lambda > 0.
\]

If \( p=1 \), the function is said to be positively homogeneous or linearly homogeneous. If \( p=0 \), then the definition becomes

\[
f(\lambda x) = f(x) \text{ for all } \lambda > 0 \text{ and } x \in E.
\]

Clearly, positively homogeneous functions of any order are homogeneous. Conversely, under some suitable assumptions on \( E \) and \( f \) (for instance \( E \) is the positive orthant in \( \mathbb{R}^n \) and \( f \) is increasing on \( E \)) then, if \( f \) is homothetic there exist a positively homogeneous function \( g \) of order 1 on \( E \) and an increasing function \( k \) on \( \mathbb{R} \) such that
homogeneous and homothetic functions: The New Palgrave Dictionary of Economics

\[ f(x) = k[g(x)] \text{ for all } x \in E. \]

(This property is sometimes used as an alternative definition of homothety for functions.) As a consequence, under reasonable economic assumptions, a homothetic preference ordering can be represented by a linearly homogeneous utility function.

Production functions are often assumed to be positively homogeneous of order \( p \). For example, the so-called Cobb–Douglas function

\[ f(x_1, x_2, ..., x_n) = K x_1^{\alpha_1} x_2^{\alpha_2} ... x_n^{\alpha_n} x_i > 0, \]

where \( K, \alpha_1, \alpha_2, ..., \alpha_n \) are positive constants, is homogeneous of order \( p = \alpha_1 + \alpha_2 + ... + \alpha_n \).

In consumer theory, demand functions are positively homogeneous of order zero in prices and wealth.

**Positively homogeneous convex (or concave) functions**

Since convexity is a fundamental concept in economics, special attention should be paid to positively homogeneous functions which are convex or concave.

Let \( E \) be a convex cone and \( f \) a real function on \( E \). Then a necessary and sufficient condition for \( f \) to be convex (concave) and positively homogeneous of order 1 on \( E \) is that for all \( x \in E \) and \( \lambda \geq 0 \) and for all pairs \( x, y \in E \)

\[ f(\lambda x) = \lambda f(x) \]

and for all pairs \( x, y \in E \)

\[ f(x + y) \leq (\geq) f(x) + f(y). \]

The producer's cost function illustrates a concave positively homogeneous function: assuming that only one output is produced using \( n \) inputs, the cost function is given by

\[ c(y, p) = \min_x \{ p^T x : F(x) \geq y \} \]
where $p_i, i = 1, 2, \ldots, n$, is the unit price of input $i$ and $F(x)$, the production function, is the maximal amount of output which can be produced with the input vector $x = (x_1, x_2, \ldots, x_n)$. Then, for a fixed price vector $p$, $c(y, p)$ is the minimal cost of producing $y$ units of the output. For $y$ fixed, $c(y, p)$ is concave and positively homogeneous of order 1 in $p$. Similarly, in consumer theory, if $F$ now denotes the consumer's utility function, the $c(y, p)$ represents the minimal price for the consumer to obtain the utility level $y$ when $p$ is the vector of utility prices.

A fundamental property is as follows. Let $f$ be a real continuous function on a closed convex cone of $\mathbb{R}^n$. Then $f$ is convex and positively homogeneous of order 1 if and only if there exists a closed convex set $S$ of $\mathbb{R}^n$ such that

$$f(x) = \sup \{ y'x \mid y \in S \}.$$  

This set $S$ is unique and the function is called the support function of $S$ (by symmetry, the same result holds when replacing convex by concave and $\sup$ by $\inf$). Duality in consumer's (as well as in producer's) theory is based on this property. We conclude with three examples of functions widely used in mathematics. A **semi-norm** on $\mathbb{R}^n$ is a convex positively homogeneous function $f$ of order one on $\mathbb{R}^n$ such that $f(x) = f(-x)$ for all $x$ (then $f(x) \geq 0$ for all $x$). A **norm** is a semi-norm for which $x = 0$ whenever $f(x) = 0$. Finally, given a convex set $C$ which contains the origin, the **gauge** of $C$ is the function $f$ defined by

$$f(x) = \inf \{ \lambda \geq 0 \mid x \in \lambda C \}.$$  

A gauge function is convex and positively homogeneous of order one. Moreover, if the origin belongs to the interior of $C$ and $C$ is balanced (i.e. $x \in C$ implies that $x \in -C$), then the gauge is a norm.

**Positively homogeneous quasi-concave (quasi-convex) functions**

Let $\succ$ be a preference ordering on a set $E$. In view of economic considerations, a common and reasonable assumption is the convexity of the ordering (i.e. for all $x \in E$, the set $\{ y \in E \mid y \succ x \}$ is convex). Then the utility functions which represent the ordering are quasi-concave but in general, a concave representation does not exist. However, in the case where the ordering is homothetic, it does. Indeed, a quasiconcave linearly homogeneous function which takes only positive (negative) values on the interior of its domain is concave [Newman] (by symmetry the same result holds for quasi-convex functions). It follows that a representable preference ordering which is homothetic and convex admits a...
representation by a concave linearly homogeneous utility function.

horizontal and vertical equity

Jean-Yves Duclos
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article describes the concepts of vertical and horizontal equity and provides some normative and positive justifications for them. It then outlines a few of the measures that have been proposed to assess whether government policies, and tax and transfer systems in particular, are vertically and horizontally equitable. It also points to useful references in the literature.

Keywords

concentration curve; discrimination; equality of opportunity; equality of resources; Hobbes, T.; horizontal equity; liability progression; Locke, J.; Lorenz curve; Nozick, R.; positioning; procedural equity; progressive and regressive taxation; Rawls, J.; redistribution of income; relative deprivation; residual progression; Sen, A.; social justice; utilitarianism; veil of ignorance; vertical equity; well-being

Article

Two broad principles govern the redistributive analysis of government policies. The first one, **vertical equity**, helps assess the distributive equity of a policy's impact on individuals with differing initial levels of welfare. The second, **horizontal equity**, serves to evaluate the policy's impact across individuals who are similar in all relevant ethical aspects – including their initial level of welfare.

In terms of taxation, the principle of vertical equity (VE) requires that the net fiscal burden increase with individuals’ capacity to pay (measured by pre-tax income, say). A strong form of this principle is usually accepted: it postulates that the capacity to pay increases more rapidly than income, and that the net tax burden should thus also rise faster than income, and should therefore be *progressive*. It can be shown that the application of this principle serves to decrease relative inequality in income, net of the tax burden. The principle of horizontal equity, in turn, stipulates that similar individuals should receive a similar tax treatment from the government. Application of this second principle also controls for the emergence of vertical disparities among initially similar individuals. Though the two principles are
generally applied to the monetary dimension of the impact of government policies, they can also prove pertinent to the analysis of other dimensions thereof.

**Vertical equity**

Concern about inequality in resource allocation has a long history in moral and political philosophy, and features prominently in all major religions. It is mostly based on a belief in the fundamental dignity that is equally shared by all human beings as well as on a natural social aversion to material and human deprivation. VE in government policies is one of the tools most often advocated to bring about greater equality in resource allocation. VE in resource distribution has also long been considered a condition for social cohesion and stability. Two thousand and four hundred years ago, Plato indeed expressed the following concern about equality:

> We maintain that if a state is to avoid the greatest plague of all – I mean civil war, though civil disintegration would be a better term – extreme poverty and wealth must not be allowed to arise in any section of the citizen-body, because both lead to both these disasters. That is why the legislator must now announce the acceptable limits of wealth and poverty. The lower limit of poverty must be the value of the holding. The legislator will use the holding as his unit of measure and allow a man to possess twice, thrice, and up to four times its value. (*The Laws*, Book V, quoted in Cowell, 1995, pp. 21–2)

A utilitarian justification for a concern for VE is that surveys on the subjects of happiness and health suggest that the consumption of unnecessary goods essentially represents a consumption for ‘positioning’ vis-à-vis others. Such consumption improves the individual's position relative to others but, in and of itself, yields little or no increase in the individual's welfare and decreases others’ relative sense of well-being, causing anxiety, stress, and hostility. Individuals also appear to have difficulty dealing with feelings of relative deprivation and exclusion, which can be detrimental to the good functioning of markets and institutions. The purpose of VE is then to reduce inequality in the distribution of welfare so as to mitigate the effects of inequality's negative externalities.

An influential ethical foundation for the principle of VE has also appeared since the 1970s in the writings of a number of philosophers, the most well-known probably being John Rawls and Amartya Sen (for example, Rawls, 1971; Sen, 1985). Rawls in particular has argued that in the absence of preferences and socio-economic interests (that is, behind a veil of ignorance; see, for instance, Harsanyi, 1955), individuals would agree that social justice implies maximizing the set of opportunities and well-being of the least well-off group, namely, equalizing opportunities ‘upwards’ so that the greatest possible well-being be available to all.

**Horizontal equity**

As already mentioned, the principle of horizontal equity (HE) stipulates that ethically similar individuals must be treated similarly by the government. ‘Ethically similar’ also implies having a similar level of well-being, since as seen above it can be ethically justified for governments to distinguish between poor
and rich. Two initially similar individuals must therefore find themselves at approximately the same welfare level after the effect of a government policy has been accounted for, regardless of the individuals' initial preferences or socio-economic characteristics. This is the classical formulation of the principle of horizontal equity. An important corollary is that government interventions should not reverse the ranking of individuals in the distribution of welfare, unless it can be shown that the initial ranking was unjust – this is the alternative and popular reranking formulation of the HE principle. The rationale for HE is primarily borne of a concern for procedural equity. Unlike for VE, it is not the result that is judged, but the process. For example, it can be argued that a reranking of two individuals by the government (in which one of the two receives assistance) can reduce the income distance (and vertical inequality) between the two, but this reranking must be considered horizontally inequitable if the initial ranking was not demonstrably unjust.

The HE principle is not only universally simple to appreciate, but it generally also garners more support from philosophers than the VE principle (though see Kaplow, 1989, for a critique). The most important ethical justification for HE is the avoidance of all forms of arbitrary discrimination in the government's treatment of citizens. Individuals of similar ethical worth should be treated and valued equally by the government. Notice that we are here dealing with individuals who are ethically similar, though not necessarily identical in all respects. Limiting the principle of HE to individuals who are identical in all points would strip it of virtually all practical relevance and would arguably leave governments too much latitude to practise arbitrary discrimination between individuals.

Drawing on the 17th-century social contract theories of Thomas Hobbes and John Locke, the foundations of this procedural justice were promoted inter alia by Nozick (1974), for whom the usual theories of justice place too much emphasis on outcomes in the redistribution of welfare, utility, or capacities. However, the bases for HE also follow from theories of vertical equity, since the unequal treatment of equals can only increase the distance between them. Robert Musgrave, an influential contributor to the development of the HE principle (see in particular Musgrave, 1959), summarizes this as follows:

The requirement of HE remains essentially unchanged under the various formulations of distributive justice, ranging from Lockean entitlement over utilitarianism and fairness solutions. That of VE, on the contrary, undergoes drastic changes under the various approaches. While HE is met by the various VE outcomes, this does not mean that HE is derived from VE. If anything, it suggests that HE is a stronger primary rule. (Musgrave, 1990, p. 116)

There are also various utilitarian foundations for the principle of HE. Government policies that discriminate between ethically comparable individuals give rise to resentment and insecurity amongst them and can also lead to social and political unrest. Exclusion and discrimination can have an impact on both individual welfare and on feelings of social cohesion; this is particularly for policies that discriminate among those that are alike since individuals often specifically compare their treatment with that of others who enjoy a similar standard of living or characteristics.

There are two major sources of horizontal inequity (HI). The first is that the impact of public policy often varies purposefully with individual characteristics and preferences, and the second is that public
Policy is typically non-deterministic by design and/or in application. Instances of HI occur in practice because of the difficulties faced by policies to account appropriately for household heterogeneity, and because of informational problems, administrative errors, incomplete take-up, tax evasion, randomness in the effect of programs and policies, and outright or implicit discriminatory behaviour by the government.

**Measurement**

**Local measures of VE and progressivity**

Let $X$ and $N$ represent respectively pre-tax income and post-tax incomes, and let $T(X)$ be taxes, with $N = X - T(X)$ — and suppose for a moment that the tax system is deterministic (or non-stochastic) and differentiable. Denote the average rate of taxation at pre-tax income $X$ by $t(X) = T(X) / X$, and the derivative of $t(X)$ and $T(X)$ at $X = x$ by $t'(x)$ and $T'(X)$. A tax $T(X)$ is said to be

- locally progressive at $X = x$ if the average rate of taxation increases with $X$, that is, if $t'(x) > 0$;
- locally proportional at $X = x$ if the average rate of taxation stays constant with $X$, that is, if $t'(x) = 0$;
- and locally regressive at $X = x$ if the average rate of taxation decreases with $X$, that is, if $t'(x) < 0$.

The elasticity of taxes with respect to $X$, also called liability progression, is then given by:

$$LP(X) = \frac{X}{T(X)} \cdot \frac{T'(X)}{t(X)} = \frac{T'(X)}{t(X)}.$$  \hspace{1cm} (1)

$LP(X)$ is the *local* ratio of the marginal tax rate over the average tax rate at $X$. A second local measure of progression, $RP(X)$, called residual progression, is the elasticity of net income with respect to pre-tax income:

$$RP(X) = \frac{\partial (X - T(X))}{\partial X} \cdot \frac{X}{N} = \frac{1 - T'(X)}{1 - t(X)}.$$  \hspace{1cm} (2)
A tax system is everywhere progressive if $RP(X) < 1$ everywhere.

**Lorenz and concentration curves**

For several reasons, we can expect the tax system to be stochastically linked to $X$, and can thus express taxes $T$ as $T = T(X) + \nu$, where $T(X)$ and $\nu$ are respectively a deterministic and stochastic tax determinant. The Lorenz curve $L_X(p)$ for $X$ is the proportion of the total $X$ that is held by those whose percentile in the distribution of $X$ is $p$ or lower. A frequent tool for measuring the VE of the tax $T$ is the concentration curve, defined as $C_T(p) = \int_0^p \frac{T(q)dq}{\mu_T}$, where $T(q)$ is the expected tax paid by those at percentile $q$ in the distribution of $X$, and where $\mu_T$ is the average of $T$ in the entire population. $C_T(p)$ thus shows the proportion of total taxes paid by the $p$ bottom proportion of the population. The concentration curve $C_N(p)$ for net incomes is analogously defined as the proportion of total $N$ that is enjoyed by those whose percentile in the distribution of $X$ is $p$ or lower. Finally, let $t$ be the average tax as a proportion of average pre-tax income: $t = \frac{\mu_T}{\mu_X}$. On the assumption of no reranking from the pre-tax to the post-tax distribution, the following conditions are then equivalent:

1. $t'(X) > 0$ for all $X$;
2. $\frac{\partial P(X)}{\partial X} > 1$ for all $X$;
3. $\frac{\partial P(X)}{\partial X} < 1$ for all $X$;
4. $L_X(p) > C_T(p)$ for all $p \in ]0, 1[$ and for any distribution of pre-tax income;
5. $L_N(p) > L_X(p)$ for all $p \in ]0, 1[$ and for any distribution of pre-tax income.

Progressive taxation thus makes the distribution of $N$ unambiguously more equal than the distribution of $X$, in the sense that it pushes up the Lorenz curve for incomes whatever the distribution of pre-tax incomes. Tax progressivity and vertical equity can in that sense be used interchangeably. Analogous results can be obtained for the more general case in which $T$ can be negative (in the context of a tax and benefit system, say; see Duclos and Araar, 2006, for more details). In the presence of reranking (when $T'(X) > 1$ or when the tax system is stochastic), result 5 does not hold anymore.

**Global measures of VE and progressivity**

There are two major approaches to measuring *global* progressivity: the tax-redistribution ($TR$) approach, and the income-redistribution ($IR$) approach.

1. A tax $T$ is $TR$-progressive if $C_T(p) < L_X(p)$ for all $p \in ]0, 1[$.
2. A tax $T$ is $IR$-progressive if $C_N(p) > L_X(p)$ for all $p \in ]0, 1[$.

For two taxes, $T_1$ and $T_2$, if $L^P_1(X) > L^P_2(X)$ at all values of $X$, then the tax 1 is necessarily more $TR$-progressive than the tax 2; if $RP_1(X) < RP_2(X)$ at all values of $X$, then the tax 1 is necessarily more $IR$-progressive than the tax 2. In the absence of reranking, a more $IR$-progressive tax system is one which
decreases inequality by more and is therefore more vertically equitable.

**Horizontal equity**

The literature on the measurement of HE has evolved very significantly since around 1980. There have been two sub-periods, the first of which focused on the measurement of reranking using concentration and Lorenz curves and indices based thereon. One central result is that $C_N(p)$ will never be lower than the Lorenz curve $L_N(p)$, and will be strictly greater than $L_N(p)$ for at least one value of $p$ if there is reranking in the redistribution of incomes. A tax $T$ will thus cause reranking (and hence horizontal inequity) if and only if $C_N(p) > L_N(p)$ for at least one value of $p$. The difference between the Lorenz curve of post- and pre-tax incomes can then be expressed as:

$$L_N(p) - L_X(p) = \frac{C_N(p) - L_X(p) - (C_N(p) - L_N(p))}{\text{VE: progressivity}}.$$

\[ (3) \]

This shows why a progressive tax system that causes reranking can push the Lorenz curve down and therefore increase inequality.

A recent promising approach to measuring classical HE has been to estimate the impact of the variability of taxes conditional on some initial value of pre-tax income. Capturing the impact of this variability can be done using many of the popular social welfare and inequality indices; see inter alia Aronson, Johnson, and Lambert (1994); Aronson and Lambert (1994); Lambert and Ramos (1997); Duclos and Lambert (2000); and Auerbach and Hassett (2002). This has typically led to total redistribution being expressible as the difference between VE and HI components.

**Further reading**

Classical texts on the concept and the measurement of VE and tax progressivity include Musgrave and Thin (1948); Slitor (1948); Blum and Kahn, Jr. (1963); Vickrey (1972); Fellman (1976); Jakobsson (1976); Kakwani (1977a; 1977b); Suits (1977); Reynolds and Smolensky (1977); Atkinson (1979); Plotnick (1981; 1982), King (1983); and Pfahler (1987). Recent literature surveys on the meaning and the measurement of HE can be found in Jenkins and Lambert (1999); Lambert (2001); and Duclos and Araar (2006).

Hotelling, Harold (1895–1973)

Kenneth J. Arrow

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Harold Hotelling was devoted mainly to mathematical statistics but had a deep influence on economics. His famous 1929 paper on stability in competition introduced the notions of locational equilibrium in duopoly, with implications for political competition. His application of the calculus of variations to the allocation of a fixed stock over time formed the basis of subsequent work on the subject. In his 1938 presidential address to the Econometric Society he argued that marginal-cost pricing was necessary for Pareto optimality even for decreasing-cost industries, and showed that suitable line integrals were a generalization of consumers’ and producers’ surplus for many commodities.

Article

Harold Hotelling, a creative thinker in both mathematical statistics and economics, was born in Fulda, Minnesota, on 29 September 1895 and died in Chapel Hill, North Carolina, on 26 December 1973. His influence on the development of economic theory was deep, though it occupied a relatively small part of a highly productive scientific life devoted primarily to mathematical statistics; only ten of some 87 published papers were devoted to economics, but of these six are landmarks which continue to this day to lead to further developments. His major research, on mathematical statistics, had, further, a generally
stimulating effect on the use of statistical methods in different specific fields of application, including econometrics.

His early interests were in journalism; he received his BA in that field from the University of Washington in 1919. Later in classes, he would illustrate the use of dummy variables in regression analysis by a study (apparently never published) of the effect of the opinions of different Seattle newspapers on the outcome of elections and referenda. The mathematician and biographer of mathematicians, Eric T. Bell, discerned talent in Hotelling and encouraged him to switch his field. He received an MA in mathematics at Washington in 1921 and a PhD in the same field from Princeton in 1924; he worked under the topologist, Oswald Veblen (Thorstein Veblen's nephew), and two of his early papers dealt with manifolds of states of motion.

The year of completing his PhD, he joined the staff of the Food Research Institute at Stanford University with the title of Junior Associate. In 1925 he published his first three papers, one on manifolds, one on a derivation of the F-distribution, and one on the theory of depreciation. Here, apparently for the first time, he stated the now generally accepted definition of depreciation as the decrease in the discounted value of future returns. This paper was a turning-point both in capital theory proper and in the reorientation of accounting towards more economically meaningful magnitudes.

In subsequent years at Stanford he became Research Associate of the Food Research Institute and Associate Professor of Mathematics, teaching courses in mathematical statistics and probability (including an examination of Keynes's Treatise on Probability) along with others in differential geometry and topology. In 1927, he showed that trend projections of population were statistically inappropriate and introduced the estimation of differential equations subject to error; he returned to the statistical interpretation of trends in a notable joint paper (1929a) with Holbrook Working, largely under the inspiration of the needs of economic analysis.

The same year he published the famous paper on stability in competition (1929b), in which he introduced the notions of locational equilibrium in duopoly. This paper is still anthologized and familiar to every theoretical economist. As part of the paper, he noted that the model could be given a political interpretation, that competing parties will tend to have very similar programmes. Although it took a long time for subsequent models to arise, these few pages have become the source for a large and fruitful literature.

The paper was in fact a study in game theory. In the first stage of the game, the two players each chose a location on a line. In the second, they each chose a price. Hotelling sought what would now be called a subgame perfect equilibrium point. However, there was a subtle error in his analysis of the second stage, as first shown by d'Aspremont, Gabszewicz, and Thisse (1979). Hotelling indeed found a local equilibrium, but the payoff functions are not concave; if the locations are sufficiently close to each other, the Hotelling solution is not a global equilibrium. Unfortunately, this is the interesting case, since Hotelling concluded that the locations chosen in the first stage would be arbitrarily close in equilibrium. In fact, the optimal strategies must be mixed (Dasgupta and Maskin, 1986, pp. 30–32).

His paper on the economics of exhaustible resources (1931a) applied the calculus of variations to the problem of allocation of a fixed stock over time. All of the recent literature, inspired by the growing sense of scarcity (natural and artificial), is essentially based on Hotelling's paper. Interestingly enough, according to his later accounts, the Economic Journal rejected the paper because its mathematics was too difficult (although it had published Ramsey's papers earlier); it was finally published in the Journal of Political Economy.
In 1931, he was appointed Professor of Economics at Columbia University, where he was to remain until 1946. There he began the organization of a systematic curriculum in theoretical statistics, which eventually attained the dignity of a separate listing in the catalogue, though not the desired end of a department or degree-granting entity. Toward the end of the 1930s, he attracted a legendary set of students who represented the bulk of the next generation of theoretical statisticians. His care for and encouragement of his students were extraordinary: the encouragement of the self-doubtful, the quick recognition of talent, the tactfully made research suggestion at crucial moments created a rare human and scholarly community. He was as proud of his students as he was modest about his own work. He also gave a course in mathematical economics. The general environment was not too fortunate. The predominant interests of the Columbia Department of Economics were actively anti-theoretical, to the point where no systematic course in neoclassical price theory was even offered, let alone prescribed for the general student. Nevertheless, several current leaders in economic theory had the benefit of his teaching. But his influence was spread more through his papers, particularly those (1932, 1935) on the full development of the second-order implications for optimization by firms and households (contemporaneous with Hicks and Allen) and above all by his classic presidential address (1938) before the Econometric Society on welfare economics. Here we have the first clear understanding of the basic propositions (Hotelling, as always, was meticulous in acknowledging earlier work back to Dupuit), as well as the introduction of extensions from the two-dimensional plane of the typical graphical presentation to the calculation of benefits with many related commodities. He argued that marginal-cost pricing was necessary for Pareto optimality even for decreasing-cost industries, used the concept of potential Pareto improvement, and showed that suitable line integrals were a generalization of consumers’ and producers’ surplus for many commodities. Here also we have the clearest expression in print of Hotelling's strong social interests which motivated his technical economics. His position was undogmatic but in general it was one of market socialism. He had no respect for acceptance of the status quo as such, and the legitimacy of altering property rights to benefit the deprived was axiomatic with him; but at the same time he was keenly aware of the limitations on resources and the importance in any human society of the avoidance of waste.

One of Hotelling's contributions which has had very extensive practical use is not contained in a paper. In 1947, the Director of the National Park Service asked a number of economists how to evaluate the benefits to visitors to national parks. Since the fee is small, the net benefit is undoubtedly considerable. Hotelling observed in a letter (Hotelling, 1947) that individuals incur considerable travel costs in coming to a park. Those individuals with the largest distance travelled can be assumed to receive zero net benefits, so that their gross benefits equal their travel costs. Nearer individuals receive a surplus that can easily be calculated.

Important as was his contribution to economics, most of his effort and his influence were felt in the field of mathematical statistics, particularly in the development of multivariate analysis. In a fundamental paper (1931b), he generalized Student's test to the simultaneous test of hypotheses about the means of many variables with a joint normal distribution. In the course of this paper, he gave a correct statement of what were later termed ‘confidence intervals’. In two subsequent papers (1933, 1936) he developed the analysis of many statistical variables into their principal components and developed a general approach to the analysis of relations between two sets of variates. The statistical methodologies of these papers and in particular the last contributed significantly to the later development of methods for estimating simultaneous equations in economics.
In 1946, he finally had the long-desired opportunity of creating a department of mathematical statistics, at the University of North Carolina, where he remained until retirement. He continued his active interest in economics there.

Space forbids more than the brief mention of his important work in the foundation of two learned societies, the Econometric Society and the Institute of Mathematical Statistics, both of which he served as President at a formative stage. He received many formal honours during his lifetime, including honorary degrees from Chicago and Rochester; he was the first Distinguished Fellow of the American Economic Association when that honour was created, as well as member of the National Academy of Sciences and the Accademia Nazionale dei Lincei, Honorary Fellow of the Royal Statistical Society and Fellow of the Royal Statistical Society.

Abstract

From 1830 to 2000 hours worked fell on two accounts: a drop in the market workweek and a decline in housework. The end result was that leisure rose. What caused this? The answer is technological progress. First, rising living standards implied that people could work less. Second, the introduction of new forms of leisure goods enhanced the value of time off. Third, time-saving household products reduced the need for housework. The time released allowed women to switch from home into market production. These points are illustrated with the use of historical evidence, economic theory, and numerical examples.

Article

Between 1830 and 2000, the average number of hours worked per worker declined, both in the marketplace and at home. Technological progress is the engine of such transformation. Three mechanisms are stressed:

- the rise in real wages and its corresponding wealth effect;
- the enhanced value of time off from work, due to the advent of time-using leisure goods; and
- the reduced need for housework, due to the introduction of time-saving appliances.

These mechanisms are incorporated into a model of household production. The notion of Edgeworth–Pareto complementarity/substitutability is key to the analysis. Numerical examples link theory and data.

Facts

Hours worked dropped precipitously over the course of the 19th and 20th centuries, both in the marketplace and at home. In 1830 the average workweek for an American worker in the marketplace was 70 hours. This had plunged to just 41 hours by 2002. At the same time there was a ninefold gain in real wages. Figure 1 shows the shrinkage of the market workweek and the leap forward in real wages. Likewise, the amount of time spent on housework dropped. A famous study of Middletown, Indiana, documented that in 1924 87 per cent of housewives spent more than four hours per day on housework (see Figure 2). None spent less than one hour. By 1999 only 14 per cent toiled more than four hours per day in the home, while 33 per cent spent less than one hour.

Figure 2
This decline in hours worked, both in the market and at home, was met by a rise in leisure. One implication of the increase in leisure is the uptrend in the share of personal consumption expenditure spent on recreation. This rose from three per cent in 1900 to 8.5 per cent in 2001, as Figure 3 illustrates. Additionally, the amount of time that a person needs to work in order to buy the goods used for leisure has fallen by at least 2.2 per cent a year – real wages grew at an annual rate of 1.65 per cent over the 1901–88 period. This price decline neglects the fact that many new forms of leisure goods have become available over time, or that old forms have improved. As the workweek – or the time spent on work both in the market and at home – dropped, more and more women entered the marketplace to work. This may seem a little paradoxical. Only four per cent of married women worked in 1890 as compared with 49 per cent in 1980 – again, see Figure 2.
What can explain these facts? The answer is nothing mysterious: technological progress. Three channels of effect are stressed here. First, technological progress increases wages. On the one hand, an increase in real wages should motivate more work effort since the price of consumption goods in terms of forgone leisure has fallen. On the other hand, for a given level of work effort a rise in wages implies that individuals are wealthier. People may desire to use some of this increase in living standards to enjoy more leisure. Second, the value
of not working rises with the advent of new leisure goods. Leisure goods by their very nature are time using. Think about the impact of the following products: radio, 1919; Monopoly, 1934; television, 1947; videocassette recorder, 1979; Nintendo and Trivial Pursuit, 1984. Third, other types of new household goods reduce the need for housework. These household goods are time saving. Examples are: electric stove, 1900; iron, 1908; frozen food, 1930; clothes dryer, 1937; Tupperware, 1947; dishwasher, 1959; disposable diaper (Pampers), 1961; microwave oven, 1971; food processor, 1975. Some goods can be both time using and time saving, depending on the context: the telephone, 1876; IBM PC, 1984. A model is now developed to analyse the channels through which technological progress can affect hours worked in the market and time spent at home.

Analysis

Setup

Let tastes be represented by

\[ U(c) + V(n), \quad \text{with } U_1, V_1 > 0 \text{ and } U_{11}, V_{11} < 0. \]

Here the utility functions \( U \) and \( V \) are taken to have the standard properties, while \( c \) and \( n \) represent the consumption of a market good and a non-market good. Now, suppose that the non-market good is produced in line with the constant-returns-to-scale production function

\[ n = H(l, d) = dH\left(\frac{l}{d}, 1\right), \quad \text{with } H_1, H_2 > 0 \text{ and } H_{11}, H_{22} < 0, \]

where \( H \) has standard properties, \( d \) represents purchased household inputs, and \( l \) is time spent in household production. The idea that non-market goods are produced by inputs of time and goods, just as market ones are, was introduced in classic work on household production theory by Becker (1965) and Reid (1934). Assume for simplicity that there is some indivisibility associated with \( d \). The household must use the quantity \( d = \bar{d} \) (This assumption is innocuous. Greenwood, Seshadri and Yorukoglu, 2005, Section 6, and Vandenbroucke, 2005, illustrate how it can easily be relaxed.) This fixed quantity of the household input sells at price \( q \), which is measured in terms of time. Last, an individual has one unit of time that he can divide between working in the market and using at home. The market wage rate is \( w \).

Now, define the function

\[ X(l, d) = \left( dH\left(\frac{l}{d}, 1\right) \right). \]

Household time, \( l \), and purchased household inputs, \( d \), are Edgeworth–Pareto complements in utility when \( X_{12} > 0 \) and substitutes when \( X_{12} < 0 \) (cf. Pareto, 1906, eqs. (63) and (64)). When \( l \) and \( d \) are Edgeworth–Pareto complements in utility, an increase in \( d \) raises the marginal utility from \( l \), or \( X_1 \), and likewise more \( l \) increases the marginal utility from \( d \), or \( X_2 \).

The individual’s optimization problem is

\[ W(w, q) = \max_l \{U(w(1-l) - qw) + X(l, d)\}. \]
The upshot of this maximization problem is summarized by the first- and second-order conditions written below.

\[ wU_1(w(1-l) - qw) = X_1(l, \delta) = V_1(\delta H\left(\frac{l}{\delta}, 1\right))H_1\left(\frac{l}{\delta}, 1\right). \]

(1)

and

\[ \Sigma = w^2U_{11} + X_{11} < 0. \]

The left-hand side of (1) represents the marginal cost of an extra unit of time spent at home. An extra unit of time spent at home results in a loss of wages in the amount \( w \). This is worth \( wU_1(w(1-l) - qw) \) in terms of forgone utility. The right-hand side gives the marginal benefit derived from spending an extra unit of time at home, \( X_1(l, \delta) \). The solution for \( l \) is portrayed in Figure 4.

Figure 4
The determination of time spent at home, \( l \)
Now, suppose that there is technological progress in household goods. In particular, let this be manifested by an increase in the amount of home inputs, $\delta$, that can be purchased for $q$ forgone units of time. How will this affect the amount of time spent at home? It is easy to calculate that

$$\frac{dl}{d\delta} = -\frac{\chi_{12}}{\bar{\xi}} \geq 0 \text{ as } \chi_{12} \geq 0.$$

Therefore, time spent on household activities will rise or fall depending on whether time and goods are complements or substitutes in household utility. When time and purchased inputs are complements in utility, an extra unit of $d$ raises the worth of staying at home. So, time spent at home should rise. Leisure goods, such as television, fall into this category. Such goods have contributed to the decline in work (either in the marketplace or at home) by both men and women. A detailed account of how this mechanism can contribute to the long-run drop in hours worked is provided by Vandenbroucke (2005). This case is shown in Figure 4 by a rightward shift in the marginal benefit curve from $MB$ to $MB''$, causing time spent at home to rise from $l^*$ to $l''$. The opposite is true when $d$ and $l$ are substitutes. This is portrayed in the figure by the leftward movement in the marginal benefit curve from $MB$ to $MB'$.

Time-saving household appliances, such as the microwave oven, are an example of this case. Such products have reduced the need for housework and have contributed to the increase in market work by women. Greenwood, Seshadri and Yorukoglu (2005) show how the increase in female labour-force participation can be explained along these lines. Therefore, technological advance in household products is consistent with the long-run decline in the market workweek (leisure goods) and the rise in female labour-force participation (time-saving appliances and goods).
When are two goods Edgeworth–Pareto complements or substitutes? From (1) the marginal benefit of time spent at home, \( X_1(l, \delta) \), is the product of two terms, the marginal utility from non-market goods, \( V_1(\delta H(l/\delta, 1)) \), and the marginal product of household time, \( H_1(l/\delta, 1) \). The marginal utility of housework is decreasing in \( \delta \), while the marginal product of household time is increasing in it. Thus, the net effect of an increase in \( \delta \) will depend upon whether the former falls faster with an increase in \( \delta \) than the latter rises. Specifically,

\[
X_{12} = -V_{11}H_1^2(l/\delta) - V_1H_{11}l/\delta^2 + V_{11}H_lH_1.
\]

so that

\[
X_{12} \leq 0 \text{ as } \frac{-l(H_{11})}{H_1} \leq \frac{-nV_{11}}{V_1} \frac{\delta(H-H_1)/\delta}{n}.
\]

In other words, whether or not \( X_{12} \leq 0 \) depends on whether the elasticity of the marginal product of labour with respect to the time–goods ratio, \(-l(H_{11})/H_1\), is smaller or larger than the elasticity of marginal utility with respect to the home good, \(-nV_{11}/V_1\), weighted by the share of purchased inputs in output, \(\delta(H-H_1)/\delta/n\). Thus, \(l\) and \(\delta\) are likely to be substitutes in utility when: (a) the responsiveness of the marginal product of \(l/\delta\) is small with respect to a change in \(\delta\); (b) the marginal utility of home goods declines quickly with more consumption; (c) when purchased inputs are important in production.

**Example 1:** (The impact of leisure goods on hours worked) Let \( U(c) = \varphi ln(c) \) and \( V(n) = (1 - \varphi) ln(n) \). Represent the household technology by the constant-elasticity-of-substitution production function \( H(l, \delta) = (\delta^\rho + \rho l)^{1/\rho} \). The household's budget constraint is \( \epsilon = w(1 - l - q) \). Given this set-up, the first-order condition (1) can be rewritten as

\[
\frac{\varphi}{1 - \varphi} = \frac{1 - q}{\delta \rho + \rho - 1}.
\]

Observe that a change in wages, \( w \), does not affect hours worked in the market, \( 1 - l \). The length of the workweek in the 1890s was about 42 per cent above that of the 1990s. In 1995 the typical worker spent about one-third of his available time working in the market. So, set \( 1 - l_{1995} = 1/3 \) and \( 1 - l_{1895} = 1.42 \times 1/3 \). Let \( \delta_{1895} = 0.1 \). The share of leisure goods in expenditures, \( s \), is given by \( s = q/(1 - l) \). Costa (1997) reports that this share was two per cent in the 1890s and six per cent in the 1990s. Thus, the time-price \( q \) is given by \( q_t = (1 - l_t)s_t \) for \( t = 1895 \) and 1995. Finally, pick \( \varphi = -0.6 \), which implies an elasticity of substitution between leisure time and leisure goods of 0.63. Proceed now in two steps. First, use (2) to back out the value of \( \varphi \) that is consistent with \( l = l_{1995}, q = q_{1995}, \) and \( \delta = \delta_{1895} \). This results in \( \varphi = 0.13 \). Second, use this equation to find the value of \( \delta \). This is in agreement with \( l = l_{1995}, q = q_{1995}, \) and \( \varphi = 0.13 \). This leads to \( \delta_{1995} = 0.63 \). Voilà, an example has now been constructed where the change in market hours matches exactly the corresponding figure in the US data. Additionally, the share of expenditure spent on leisure is in line with the data. In physical units, households in 1995 had 6.90 times more leisure goods than did households in 1895. This number depends upon the elasticity of substitution between leisure time and leisure goods. The higher the degree of complementarity (or the smaller is \( \rho \)), the less is the required increase in \( \delta \).

Remark: An example can be constructed in very similar fashion to show that labour-saving household inputs (or the case of Edgeworth–Pareto substitutes) can account for the rise in female labour-force participation. The interested reader is referred to Greenwood and Seshadri (2005, Example 5, p. 1256).
How will rising wages impact hours worked? It's easy to calculate that

\[
\frac{\partial l}{\partial w} = \frac{U_1 + w(1 - l - q)U_{11}}{\Sigma} > 0 \quad \text{as} \quad U_{11} < \frac{w}{\Sigma} - w(1 - l - q)U_{11}.
\]

On the one hand, a boost in wages increases the opportunity cost of staying at home. This should reduce the time spent at home, \( l \), and is represented by the substitution effect term, \( U_{11} \). On the other hand, higher wages make the individual wealthier. The individual should use some of this extra wealth to increase his time spent at home. This income effect is shown by the term, \( w(1 - l - q)U_{11}/\Sigma > 0 \). Thus, time spent at home can rise or fall with wages depending on whether the income effect dominates the substitution effect. In general, then, anything can happen, as the following two specialized cases for \( U \) make clear.

1. Let \( U(t) = \ln(t) \), the macroeconomist's favourite utility function. Here, \( U_1 = 1/t \) and \( w(1 - l - q)U_{11} = -1/t \). Therefore, the substitution and income effects from a change in wages exactly cancel each other out. Long-run changes in wages have no impact on hours worked in the market, \( 1 - l \).

2. Suppose \( U(t) = \ln(t - c) \), where \( c > 0 \) is some subsistence level of consumption. Now, \( U_1 = 1/(t - c) \) and \( w(1 - l - q)U_{11} = -c/(t - c)^2 \). Therefore,
\[
\frac{\partial l}{\partial w} = -c/[w(1 - l - q)^2] > 0.
\]
Consequently, rising wages lead to a fall in market hours, \( 1 - l \). The intuition is simple. At low levels of wages an individual must work hard to meet his subsistence level of consumption, \( c \). Achieving the subsistence level of consumption becomes easier as wages rise and this allows the individual to ease up on his work effort. Thus, this form for the utility function is in accord with a long-run decline in hours worked. Additionally, it is consistent with the observation reported in Vandenbroucke (2005) that unskilled workers laboured longer hours in 1900 than did skilled ones, while today they work about the same.

Can an increase in wages explain the decline in the workweek? The answer is 'yes', as the following example makes clear.

*Example 2: (The impact of rising wages on hours worked)* Let \( U(t) = \ln(t - c) \) and \( V(n) = \alpha n \). Represent the household technology by \( H(l, n) = l \). Equation (1) appears as

\[
1 - l = \frac{1}{\alpha} + \frac{c}{w},
\]

which gives a very simple solution for hours worked, \( 1 - l \). Let the time period for this example be 1830 to 1990. The real wage rate in 1990 (actually in 1988) was 9.15 times the wage rate of 1830 (Williamson, 1995). So, set \( w_{1830} = 1 \) and \( w_{1990} = 9.15 \). Following the discussion in Example 1, fix hours worked in 1830 and 1990, or \( 1 - l_{1830} \) and \( 1 - l_{1990} \), using the equations \( 1 - l_{1830} = 1.65 \times 1/3 \) and \( 1 - l_{1990} = 1/3 \). Employing these restrictions in conjunction with (3) leads to a system of two equations in the two unknown parameters \( \alpha \) and \( c \). Specifically, one obtains

\[
1 - l_{1830} = \frac{1}{\alpha} + \frac{c}{w_{1830}},
\]

and

\[
1 - l_{1990} = \frac{1}{\alpha} + \frac{c}{w_{1990}}.
\]
Solving yields \( \alpha = 3.26 \) and \( \epsilon = 0.24 \). The subsistence level of consumption, \( c \), amounts to 44 per cent of consumption in 1830, and eight per cent in 1990.

The 20th century saw the advent of labour income taxation. So perhaps the previous example should have focused on the rise of after-tax wages. This is easy to amend.

**Example 3: (The effect of higher labour income taxation on hours worked)** Take the setup from Example 3 with one modification, to wit the introduction of labour income taxation. In particular, suppose that wages are taxed at rate \( \tau \). A fraction \( \theta \) of the revenue the government receives is rebated back to the worker via lump-sum transfer payments, \( t \). The rest goes into worthless government spending on goods and services, \( g \) – or equivalently one could assume that it enters into the consumer’s utility function in a separable manner. Hence, the worker’s budget constraint reads \( c = (1 - \tau)w(1 - l) + l \), while the government’s appears as \( g + t = \tau w(1 - l) \). The first-order condition for this setting is

\[
\frac{(1 - \tau)w}{c} = \alpha.
\]

Combining the worker’s and government’s budget constraints yields \( c = (1 - \tau(1 - \theta))w(1 - l) \). Using this fact in the above first-order condition results in

\[
1 - l = \frac{1 - \tau}{\alpha(1 - \tau(1 - \theta))} + \frac{\epsilon}{w(1 - \tau(1 - \theta))}.
\]

Observe that when \( \epsilon = 0 \) and \( \theta = 0 \) (no rebate) an increase in the tax rate will have no impact on hours worked, because the substitution and income effects exactly cancel each other out. When \( \epsilon = 0 \) and \( \theta = 1 \) (full rebate) higher taxes will dissuade hours worked since only the substitution effect is operational. Alternatively, if \( \epsilon > 0 \) and \( \theta = 0 \) (no rebate), then it transpires that a rise in taxes will cause hours worked to move up. Here the negative income effect from the increase in government spending, which will result in more hours being worked, outweighs the substitution effect. Therefore, in general the effect of labour income taxation on hours worked is ambiguous. The result will depend on how the government uses the revenue it raises, and the functional forms and parameter values used for tastes and technology.

Take labour income taxes to be zero in 1830. Assume a rate of 30 per cent in 1990, in line with numbers reported by Mulligan (2002). Fix \( \theta = 0.33 \); its value for 1990 as measured by the National Income Product Accounts. By following the procedure in Example 3, it can be deduced that the observed fall in hours worked is occurs when \( \alpha = 2.86 \) and \( \epsilon = 0.20 \).

Furthermore, it can be inferred that the rise in wages accounts for 93 per cent of the fall, while the increase in taxes explains the remaining seven per cent. (For those interested, the decomposition is done as follows: Represent the right-hand side of (4) by \( \bar{L}(w, \tau) \). Then,

\[
(1 - l') - (1 - l) = \left[ L(w', \tau') - L(w, \tau) + L(w', \tau) - L(w, \tau) \right] / 2 + \left[ L(w', \tau') - L(w', \tau) + L(w, \tau') - L(w, \tau) \right] / 2.
\]

The first term in brackets is a measure of the change in hours worked, \( (1 - l') - (1 - l) \), due to the shift in wages from \( w \) to \( w' \), while the second term gives the change due to a movement in taxes from \( \tau \) to \( \tau' \).

All of the above examples are intended solely as illustrations of some secular forces that potentially influence hours worked. A quantitative assessment of the impact that taxes have on hours worked will depend upon the particulars of the model used. A serious study is conducted in Prescott (2004).

The real world seems to have experienced two conflicting trends: a decline in market work and a rise in female-labour participation. A more general model could be consistent with both of these facts. To see this, imagine a framework with two types of labour, male and female. There is a division of labour in the home. Men work primarily in the market. Females do housework and, time permitting, market work. Households purchase both time-saving and time-consuming household inputs. Female labour-force participation would rise as labour-
saving goods economize on the amount of housework that has to be done. Simultaneously, the market workweek would decline, due either to the introduction of leisure goods or to an income effect associated with a rise in wages. The value of leisure would rise for both men and women. Interestingly, Aguiar and Hurst (2006) document a dramatic increase in leisure for both men and women over the period 1965–2003. They construct various measures of leisure. They all showed a gain over the period under study. The narrowest definition rose by 6.4 hours a week for men and 3.8 hours for women, after adjustment for demographic changes in the population. This measure included time spent on activities such as entertainment, recreation, and relaxing. The authors’ preferred measure increased by 7.9 hours a week for men and 6.0 hours for women. This broader definition also included activities such as eating, sleeping, personal care, and childcare. Another manifestation of the rise in the value of leisure is the increase in the fraction of life spent retired. Kopecky (2005) relays that a 20-year-old man in 1850 could expect to spend about six per cent of his life retired, while one in 1990 should enjoy about 30 per cent of his life in retirement. She shows how the trend towards enjoying more retirement can be analysed in much the same way as the decline in the workweek.

Bibliography

**Abstract**

This entry presents recent work on portfolio behaviour of households and its possible departures from optimal behaviour. Topics include the role of household characteristics in influencing participation in stockholding and portfolio shares conditional on participation; portfolio implications of housing and housing debts; and portfolio coexistence of consumer debt, liquid assets and illiquid assets, with emphasis on credit card debt.

**Keywords**

age effects; asset allocation; asset ignorance; asset location; asset trading; bankruptcy; bequest motives; borrowing constraints; business equity; cohort effects; computational methods; conditional portfolio share; consumer debt; consumption risk; correlation between income risk and stock returns; credit card debt; credit cards; debt; debt refinancing; delinquency; diversification; earnings shocks; elasticity of substitution; Epstein–Zin preferences; equities; equity premium; financial wealth; fixed entry costs; fixed-rate mortgages; participation costs; home equity loans; homeownership; household finance; household portfolios; housing; housing collateral; hyperbolic discounting; interest-rate wedge; marginal investors; mortgages; mutual funds; real estate; refinancing; retirement; retirement accounts; risk aversion; social interactions; stockholding; stockholding participation rate; stockholding puzzle; stockholding risk; stocks; strategic default motive; time effects; trust; wealth distribution

**Article**

Household portfolios comprise the array of assets – financial (such as liquid accounts, stocks, bonds, and shares in mutual funds) and real (such as primary residence, investment real estate, and private businesses) – as well as liabilities held by a household, such as mortgages and consumer debt. This article focuses on three areas of active research – stockholding, housing, and credit cards – with respective household participation rates for the United States of the order of 50 per cent, two-thirds, and...
Household portfolios: The New Palgrave Dictionary of Economics

European participation rates vary. Stockholding participation approaches 60 per cent in Sweden and 40 per cent in the UK, but it is less than 20 per cent in France, Germany, and Italy. Homeownership rates are closer to that of the United States, but in some countries, such as Germany, the majority does not own a home. The features of credit cards vary across European countries. In some countries, households have only debit cards linked to accounts with overdraft facilities.

The study of household portfolios, or ‘household finance’, is a partner to corporate finance and asset pricing, and it bridges economics and finance by extending analyses of saving to incorporate portfolio choice. It has grown considerably since the early 1990s, along with the complexity of household portfolios, in the face of ‘supply side’ developments encouraging risky asset holding. Privatization of public utilities in Europe was often accompanied by broad campaigns to educate households on the nature and benefits of stockholding. The demographic transition encouraged introduction of tax-deferred retirement accounts, promoted through educational campaigns, first in the United States and subsequently in Europe. The internet facilitated provision of information, opening of accounts, and trading internationally.

The development of household-level databases has in turn facilitated empirical research by allowing study of overall portfolios and their links to demographics and attitudes. Modern computational methods have enhanced understanding of behaviour towards non-diversifiable, background risk regarding income or health expenditures. Observed portfolio behaviour often differs from predictions of standard models, creating puzzles variously attributed to inadequate models or ‘investment mistakes’.

Stockholding

Understanding household stockholding is important, as it embodies key aspects of behaviour towards risk. In most countries, the majority of households hold no stocks, even indirectly through mutual funds, retirement, or managed accounts (Guiso, Haliassos and Jappelli, 2001; 2003). Exceptions were Sweden and the United States in 2001 (57 per cent and 52 per cent, respectively), but the United States fell back to 48 per cent in 2004. Non-participation despite an expected return premium (‘equity premium’) is inconsistent with standard expected utility maximization and constitutes the ‘stockholding puzzle’ (Mankiw and Zeldes, 1991; Haliassos and Bertaut, 1995). For a non-stockholder, stocks dominate bonds in expected return and do not contribute to consumption risk as they have zero covariance with consumption.

Various explanations have been proposed for limited participation in stock markets, given its widespread nature. Restrictions preventing borrowing at the riskless rate and short sales of stock yield zero stockholding, but only for poor households with no assets (Haliassos and Michaelides, 2003). Positive correlation between labour income risk and stock returns, coupled with short sales constraints, could justify zero stockholding among households intending to short stocks to hedge income risk, but is exhibited in practice by households likely to hold stocks – for example, the more educated and entrepreneurs.

The most widely accepted cause of limited participation is fixed entry or participation costs, actual or perceived, that discourage small potential investors. Costs can be wide-ranging, from brokerage costs to costs of one's time devoted to monitoring the stock market. In their presence, factors contributing to higher costs or lower desired stockholding, such as risk aversion or low resources, become relevant for
non-participation. An interest-rate wedge between borrowing and saving rates coupled with an empirically based assumption that borrowing rates are roughly equal to the expected return on equity also generates limited stock demand. Although Davis, Kubler and Willen (2006) offered this as an alternative to fixed costs for explaining non-participation, it could usefully serve also as a complement. Empirical estimates by Paiella (2001) and Vissing Jorgensen (2002), and numerically computed costs in Haliassos and Michaelides (2003) imply that relatively small fixed costs could justify observed patterns of non-participation.

The empirical participation literature provides various findings consistent with the presence of fixed costs (see contributions in Guiso, Haliassos and Jappelli, 2001; Rosen and Wu, 2004). More educated, financially alert, healthy households that belong to ethnic or education groups traditionally targeted by the financial sector are likely to face lower entry costs and to be more likely to participate, consistent with empirical findings. Similarly, households with greater expressed willingness to bear risk and those who do not perceive binding borrowing constraints are more likely to plan sizeable stock holdings and thus to overcome any given entry costs.

Empirical studies also point to other, often ignored, factors, which seem relevant for non-participation by those unlikely to be small investors, such as the rich. Limited social interactions and associated opportunities to exchange stockholding experiences, or lower expressed willingness to trust others, contribute to non-participation (Hong, Kubik and Stein, 2004; Guiso, Sapienza and Zingales, 2005). This can justify non-stockholding by some rich, in addition to possible substitution of private businesses for stocks (Heaton and Lucas, 2000). Non-participation also arises naturally if there is widespread ignorance of certain assets. Guiso and Jappelli (2005) found that only one-third of Italian households have simultaneous knowledge of stocks, mutual funds, and managed accounts. Moreover, although most of the literature has largely ignored tax considerations, tax laws have been shown to affect asset allocation, asset location, and trading (Bergstresser and Poterba, 2004).
