Under central planning, countertrade was especially observed in international trade among countries belonging to the Council for Mutual Economic Assistance (Comecon, an economic organization of communist states) as well as in East–West trade. In particular in the 1980s, in the aftermath of the international debt crisis, countertrade became prevalent in international trade with developing countries and Eastern Europe. Before 1989 countertrade accounted for up to 40 per cent of total trade between East and West. After 1989, with the domestic debt crisis in transition countries, barter became dominant in domestic trade in these countries. While countertrade continues to be significant in North–South trade, reliable estimates are not available.

Explanations for countertrade

One of the most frequently cited explanations of countertrade is that it allows countries to overcome a shortage of hard currency. The observation that countertrading countries are highly indebted is taken as evidence that these countries face a shortage of foreign exchange and that their low creditworthiness makes it impossible to finance imports with a simple loan from an international bank (for example, OECD, 1981; 1985). This interpretation is not fully plausible because countertrade uses export goods which otherwise could have been used to generate foreign exchange to pay for future imports. Furthermore, if the foreign-exchange shortage were the main explanation of countertrade we would expect barter to be the prevalent form of countertrade since only barter does in fact avoid the use of hard currency. However, barter accounts for only a small portion of total international countertrade (Mirus and Schnitzer, 2002a). Mirus and Yeung (1987) find that countertrade in the form of simple barter or counterpurchase does not improve a country's foreign exchange position unless it improves economic efficiency in the sense that it leads to an increase in national income.

Empirical evidence points to another explanation, starting from the observation that in international trade contract enforcement is problematic and hence conventional contracts cannot be relied on as the main mechanism to sustain economic exchange. International countertrade (as well as domestic barter, as pointed out below) can be explained as an institutional response to such contractual problems arising in imperfect capital and goods markets. Difficulties in contract enforcement are an important impediment to international transactions in the world economy. In international trade, national sovereignty interferes with contract enforcement because national borders demarcate national jurisdictions. Such demarcations segment markets and impose severe transaction costs on exchanges across national jurisdictions. The hazards involved in international transactions are often disregarded, but they make headlines each time a sovereign debtor threatens to stop servicing its debt, as it happened in the international debt crisis in the 1980s or in the Russian financial crisis in 1998. If contract enforcement is weak, problems may arise on both ends of a business transaction: the seller may fail to deliver the goods, and the buyer may fail to pay for them. If buyers have no cash to pay, and thus face liquidity constraints at the time of delivery, the business transaction can take place only if the seller can trust the buyer to pay in due course. On the other hand, the buyer is willing to engage in a
business transaction only if she can trust the seller to deliver the right goods. Both problems are prevalent in international trade. Enforcing the payment of goods can pose serious problems. In the aftermath of the debt crisis, highly indebted countries were liquidity constrained and could not finance necessary imports. Given their level of indebtedness, debt repayment could not be relied on. The debtor country could create more liquidity by not repaying its debt rather than by receiving a new loan. There are also important problems arising on the seller's side. In international trade, the most conspicuous example is the technology transfer problem. It is often reported that explicit contracts cannot be relied on to make sure that developing countries receive the advanced technology promised (Parsons, 1987; Kogut, 1986). These countries often complain that firms from industrialized countries sell inferior technology to them, technology that is outdated and cannot be sold on Western markets.

**Solving the creditworthiness problem**

Countertrade can be interpreted as the institutional response to the lack of creditworthiness of countries and firms. Countertrade introduces a deal-specific collateral for the credit granted for the original import. This collateral protects the interests of the creditor for one particular business transaction and thus mitigates the contractual hazards associated with indebtedness that would otherwise prevent the transaction from taking place.

The argument that payments in kind may have advantages over payments in cash contradicts the conventional wisdom in the theory of money. The common view is that barter is inefficient because it does not overcome the 'double coincidence of wants problem' (where each trading partner wants to buy exactly what the other partner wants to sell and vice versa) as money does. A seller may need to accept goods for which she has no use herself. The point, however, is that goods have superior credit enforcement properties to those of money. Money is an anonymous medium of exchange. This anonymity can prove disadvantageous in trade with countries which lack creditworthiness, since the debtor in the developing country or eastern Europe can use it for purposes other than repaying debt.

Goods, by contrast, can more easily be earmarked as the property of the creditor and can thus serve as collateral. However, payment in goods is problematic if it is difficult to judge the quality of the goods offered as means of payment. Thus, it is important to choose goods that are very liquid and hardly anonymous, making it both easy to determine their value and easy to earmark. Goods can be ranked with respect to their liquidity and anonymity properties, providing an explanation for the export pattern of countertrade and barter (Marin and Schnitzer, 2002b).

**Solving the technology transfer problem**

Buyback contracts have been interpreted as incentive contracts that ensure the transfer of desirable quality technology and post-installation service performance if standard forms of internalization, like joint ventures or foreign direct investment, are not possible due to political and ownership constraints (Hennart, 1989; Chan and Hoy, 1991; Mirus and Yeung, 1993). But for the argument to work, it is essential that there be a technological relation between the two goods to be traded. However, buyback accounts for a surprisingly small fraction of all countertrade transactions. Thus, even though this explanation is theoretically appealing, it cannot explain the great majority of technology imports, which
take the form of counterpurchase. Interestingly, the technology transfer problem can be solved with a simple counterpurchase transaction as well, despite the lack of a technological link (Marin and Schnitzer, 1995). Although the lack of liquidity makes it difficult to finance imports, it is this very lack of liquidity that can actually help when it comes to dealing with problems on the supplier's side. The idea is that the export from the developing country serves as a hostage that deters cheating on technology quality and defaulting on the payment of the original import from the industrialized country. For this mechanism to work, the export has to be profitable to both the industrialized country firm and developing country, and the contract is so designed that the export becomes sufficiently less profitable for either party that does not fulfil its obligations in the original import, be it technology transfer or payment of the import. The technology seller offers high-quality technology because otherwise she loses her collateral for the credit as the developing country firm would lack the revenues that are generated with the technology and that are necessary to produce the export goods. This contractual arrangement makes the technology supplier internalize the externality her technology imposes on the developing country. The developing country party will deliver the export goods because the terms of the contract are designed such that this is more profitable than selling them otherwise. So although the import and the export are not technologically related, the countertrade contract establishes a financial link that improves the incentives of the parties involved. Thus, countertrade is a first-best substitute for foreign direct investment when these countries are reluctant to give access to foreign ownership in their markets. This goes to prove that, in an imperfect world in which contract enforcement is weak, as in developing countries or imperfect capital markets, something that seems to be worse – that contractual problems arise on both sides of the business transaction rather than on only one side – can improve contract enforcement. In international trade, the liquidity constraint helps to solve the technology transfer problem.

Other explanations

Some other possible explanations of countertrade are that developing countries use countertrade transactions to promote the export of ‘new’ goods – goods they have not previously exported to industrialized countries – in order to gain access to new markets and to diversify their exports (OECD, 1981; 1985). The empirical evidence gives some support for the view that countertrade has helped to stimulate and diversify exports. Other studies confirm that the goods exported by developing countries through countertrade arrangements are often goods for which export markets have yet to be established. Readily marketable products, like raw materials, are usually not available for countertrade. It can also be observed that a country removes goods from the countertrade shopping list once it has gained some experience with exporting these particular goods (Banks, 1983). Furthermore, it has been argued that countertrade corrects distortions in non-competitive markets (Caves, 1974). Using barter may allow competing more aggressively without openly violating collusive agreements. It may also allow more effective price discrimination. There is indeed some evidence that barter is used as a vehicle to change the terms of trade to allow price discrimination by Western monopolists (Caves and Marin, 1992). Mandated countertrade has also been discussed as a policy response to contracting failures arising from asymmetric information about goods valuations (Ellingson and Stole, 1996).
Barter trade in transition economies

Barter trade has received renewed attention in the 1990s, when it became a dominant phenomenon in domestic trade in a number of transition countries, most notably in the successor states of the former Soviet Union. After 1989, domestic barter in Russia increased manifold after macroeconomic stabilization in 1994, from five per cent of GDP to 60 per cent in 1998. In Ukraine, the share of barter in industrial sales is estimated to have been more than 50 per cent in 1997. Only since the financial crisis in August 1998 have barter and the use of other money surrogates started to decline again.

A number of different explanations have been put forward for this phenomenon. Some experts have viewed it as a tax-avoidance mechanism because it allows a distortion of the true value of profits, and thus reduces tax liabilities. Furthermore, since the banking sector acts as a tax collection agency that transfers firms' cash income in bank accounts to the state to pay for outstanding tax arrears, barter allows tax avoidance because it avoids payments in cash. While there may be some truth in this kind of argument, few firms report tax advantages as a major reason for using barter (Marin and Schnitzer, 2002a).

A more popular explanation refers to soft budget constraints and the lack of market discipline. The absence of hard budget constraints, so the argument goes, leads managers and workers to avoid the costs arising from restructuring by maintaining production in inefficient activities. Barter would allow concealing the true market value of output. But the empirical evidence suggests that barter is not a phenomenon of state-owned enterprises. Newly established private firms display an exposure to barter that is similar to or greater than that of state-owned firms or cooperatives (Marin and Schnitzer, 2002a).

The ‘virtual economy’ argument of Gaddy and Ickes (1998) has been one of the most influential explanations of barter in Russia. The virtual economy argument claims that barter helps to create the image that the manufacturing sector in Russia is producing value while in fact it is not. This argument rests on the assumption that the manufacturing sector is value-subtracting, and most participants in the economy have an interest to pretend that it is not. Barter allows the parties to keep up this illusion by allowing the manufacturing sector to sell its output at a higher price than its market value and the value-adding natural resource sector (Gazprom) to accept this high price because of a lack of other sources. This way the manufacturing sector survives by drawing resources from the natural resource sector. According to the argument, keeping up the illusion of a value-adding manufacturing sector is highly costly for the Russian economy at large because this cross-subsidizing from the value-adding natural resource sector to the value-subtracting manufacturing sector prevents the manufacturing sector from moving into valuable activity.

This argument appeals to experts of central planning and policy observers in transition economies, because the practice of cross-subsidizing across different activities in the economy was a widespread feature of central planning. But it raises a number of questions. If the natural resource sector is producing valuable output, why does the sector not have other opportunities than to subsidize the manufacturing sector? In fact, the natural resource sector is supposed to have significant bargaining power in the interaction with other sectors when it is producing goods which the market values highly. Why then does the sector end up subsidizing the rest of the economy? And in fact, evidence from barter transactions in the Ukraine suggests that, in contrast to the assertions of the virtual economy proponents, the electricity and gas industries in the natural resource sector gained from barter transactions, instead of
countertrade: The New Palgrave Dictionary of Economics

losing (Marin, 2002).

A more plausible explanation refers to the similarities between barter in international trade and barter in transition economies, and links the surge of domestic barter to a ‘lack of trust’ problem (Marin and Schnitzer, 2005). In transition countries, poorly developed legal and financial institutions made contract enforcement unreliable and imposed severe transaction costs on any economic activity. These costs became prohibitively large in times of historic change and revolution. Unstable business partner relationships and rapidly changing social norms limited the extent to which economic exchanges could be sustained by reputation, by repeated interactions or by embedding them in social networks. This led to a lack of trust, meaning that reliable input supplies on the one hand and credit enforcement on the other hand were difficult to sustain, resulting in economic disorganization and a tremendous output fall. In such an environment, barter can be used as a commitment device to overcome the problems of unreliable input supplies and credit enforcement, by linking transactions and specifying terms of trade that give the right incentives to adhere to the terms of the barter contract.

countervailing power

Christopher M. Snyder
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
antitrust; countervailing power; mergers; monopoly; oligopoly; pharmaceutical industry; returns to scale

Article

‘Countervailing power’ is a term coined by J.K. Galbraith (1952) to describe the ability of large buyers in concentrated downstream markets to extract price concessions from suppliers. Galbraith saw countervailing power as an important force offsetting suppliers' increased market power arising from the general trend of increased concentration in US industries. He provided examples such as a nationwide grocery chain extracting wholesale price discounts from food producers, and large auto manufacturers extracting price discounts from steel producers.

The concept of countervailing power was controversial in Galbraith's day (see Stigler's, 1954, criticism), and continues to be so today. Formalizing the concept is difficult because it is difficult to model bilateral monopoly or oligopoly, and there exists no single canonical model. Whether and how wholesale discounts to large downstream firms are passed through to final-good consumers is unclear. The concept has the controversial antitrust implication that horizontal mergers between downstream firms may be pro-competitive.

There are a number of theories explaining why large buyers obtain price discounts from sellers. A simple theory is that the cost of serving large buyers is lower per unit than that of serving small buyers. Serving large buyers may involve lower distribution costs. For example, the supplier may be able to ship its product to a large buyer's central warehouse rather than having to ship it to the individual retail outlets owned by small buyers. Serving large buyers may also involve lower production costs. For example, if the supplier's production function exhibits increasing returns to scale and the supplier serves one buyer at a time each production period, per-unit production costs will be lower when serving a large buyer.

Other theories involve more subtle strategic effects. A literature including Horn and Wolinsky (1986), Stole and Zwiebel (1996), Chipty and Snyder (1999), Inderst and Wey (2003) and Raskovich (2003) considers a model in which a monopoly supplier bargains under symmetric information separately and
simultaneously with each of a number of buyers. Each buyer regards itself as marginal, conjecturing that all other buyers consummate their negotiations with the supplier efficiently. If aggregate surplus across all negotiations is concave in quantity, the marginal surplus from a transaction involving a large quantity is higher per unit than that from one involving a small quantity. This higher per-unit marginal surplus for large buyers translates into a lower per-unit price. The aggregate surplus function would be concave, for example, if the supplier has increasing marginal production costs. Even if the supplier's cost function were linear, the total surplus function effectively becomes concave if the supplier is assumed to be risk averse, as in Chae and Heidhues (2004) and DeGraba (2005).

Size discounts also emerge if large buyers' outside options are better. In Katz (1987) and Sheffman and Spiller (1992), for example, the larger the buyer, the more credible are its threat of integrating backward and producing the good itself. Size discounts also emerge if the supplier's outside option is worse when facing a large buyer. In Inderst and Wey (2007), for example, if bargaining with a large buyer breaks down, it is difficult for the supplier to unload this large quantity on the other buyers since this involves marching down these other buyers' declining marginal surplus functions.

Size discounts also emerge if one departs from the bargaining model with a monopoly supplier and instead considers competing suppliers. In Snyder (1998), collusion is difficult to sustain in the presence of a larger buyer because the benefit from undercutting and supplying the buyer is greater. To prevent undercutting in equilibrium, suppliers collude on a lower price for large buyers. In Dana (2004) and Inderst and Shaffer (2007), by pooling their demands and buying as a group from one supplier, buyers can increase the intensity of competition among suppliers of differentiated products.

Several papers have begun to examine the question of whether a downstream firm's countervailing power translates into lower final-good prices, using a model with competing downstream firms (Dobson and Waterson, 1997; von Ungern-Sternberg, 1996; Chen, 2003). This work suggests that an increase in countervailing power can have the opposite effect, raising consumer prices and/or lowering social welfare.

Early empirical studies of countervailing power (see Scherer and Ross, 1990, for a survey) took the standard structure–conduct–performance regressions (regressions of supplier profits or markups on supplier concentration using cross-sectional observations at the industry level) and added a buyer-concentration variable, often finding a significantly negative coefficient. Later intra-industry studies found more nuanced circumstances under which buyer-size discounts emerge. Ellison and Snyder (2002) and Sorensen (2003) observed size discounts in pharmaceutical and hospital-services markets only if there were competing, not monopoly, suppliers. In an experimental study, Normann, Ruffle and Snyder (2007) observed buyer-size discounts only when the total surplus function exhibited a certain curvature, consistent with theory.

Courcelle-Seneuil, Jean Gustave (1813–1892)

Albert O. Hirschman
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

advisers; convertibility; Courcelle-Seneuil, J. G.; deregulation of banks; tariffs

Article

French economist and economic adviser. Born in the Dordogne, he studied law in Paris, then returned to his native region to manage an industrial firm. At the same time, during the July monarchy, he wrote for Republican newspapers and economic periodicals. After the 1848 revolution, he held briefly a high position in the Ministry of Finance. In the following years he became a frequent contributor to the *Journal des économistes*, and published a successful textbook on banking in 1852. In 1853, the Chilean government contracted him to teach economics at the University of Chile in Santiago, and to be available as official economic adviser; he stayed for ten years, until 1863, when he returned to France. While in Chile he published his most ambitious work in economics, the *Traité théorique et pratique d'économie politique* (1858), which the Chilean government arranged to bring out in a Spanish translation. After his return to France, he resumed his activity as prolific writer of books and articles on economic affairs. He also published several works on political and historical topics and translated into French John Stuart Mill's *Principles of Political Economy*, Summer Maine's *Ancient Law* and William Graham Sumner's *What Social Classes Owe to Each Other*. He was appointed councillor of state in 1879, and three years later was elected member of the Académie des Sciences Morales et Politiques. Throughout his life, Courcelle-Seneuil was a stalwart defender of free trade and laissez-faire. Charles Gide, the co-author (with Charles Rist) of a well-known history of economic doctrines, wrote about him in rather sarcastic terms:

> He was virtually the *pontifex maximus* of the classical school; the holy doctrines were entrusted to him and it was his vocation to denounce and exterminate the heretics. During many years he fulfilled this mission through book reviews in the *Journal des économistes* with priestly dignity. Argus-eyed, he knew how to detect the slightest deviations from the liberal school. (Gide, 1895, p. 710)
Courcelle-Seneuil's special interest, starting with the publication of a small book on bank reform in 1840, was the introduction of more freedom into banking or, to use a modern term, the ‘deregulation’ of this industry. Above all, he advocated the abolition of the Bank of France's exclusive right of issue. According to Gide, Courcelle-Seneuil was more esteemed in England and the United States than in France. In any event, adoption of his monetary and banking proposals was never seriously considered in his own country.

Once in Chile, Courcelle-Seneuil became a powerful policymaker and influential teacher. He arrived at a time when the international prestige of the laissez-faire doctrine was at its height and when gold booms and subsequent busts in California and Australia caused considerable fluctuations in Chile's agricultural exports to these areas, creating a need for flexible short- and long-term credit facilities. This combination of events, joined with the prestige emanating from the foreign savant, permitted him to obtain in Chile what he had failed to achieve in his own country: under his guidance, the administration of Manuel Montt (1851–61) promulgated a banking law that established total freedom for any solvent person to found a bank and permitted all banks to issue currency subject only to one limitation: the banknotes in circulation were not to exceed 150 per cent of the issuing bank's capital.

Courcelle-Seneuil's advice was also sought in connection with a new customs tariff and here again he achieved substantial change: the level of protection was severely cut back, although some tariffs were retained for revenue purposes.

But the principal influence exercised by Courcelle-Seneuil resided in his forceful teaching: as the University of Chile's first professor of economics, he was apparently successful in instilling doctrinaire zeal in his students, some of whom later became influential policymakers. Thus, Chilean historians have not only traced the abandonment of convertibility in 1878 to the permissiveness of the 1860 Banking Law and the lack of industrial development to the 1864 tariff; they also see Courcelle-Seneuil's indirect influence in the acquisition of the nitrate mines of Tarapacá by private foreign interests after Chile's victory over Peru in the War of the Pacific (1882) had given it title to the mines. Alienation of the mines was indeed recommended by a government committee dominated by Courcelle-Seneuil's disciples, who felt, like their teacher, that state ownership and management of business enterprises was to be strictly shunned. Secular inflation, industrial backwardness, domination of the country's principal natural resources by foreigners – all of these protracted ills of the Chilean economy have been attributed to the French expert.

Since the economically advanced countries were also those where economic science first flourished, they soon produced a peculiar export product: the foreign economic expert or adviser. Courcelle-Seneuil is probably the earliest prototype of the genre and his ironic career in Chile exhibits characteristics that were to remain typical of numerous later representatives. First, the adviser is deeply convinced that, thanks to the advances of economic science, he knows the correct solutions to economic problems no matter they may arise. Secondly, the country which invites the expert looks forward to his advice as to some magic medicine which will work even when (perhaps especially when) it hurts. Some countries seem particularly prone to this attitude. In Chile foreign or foreign-trained experts have played key roles at crisis junctures, from Courcelle-Seneuil in the mid-19th century to Edwin Kemmerer in the 1920s, the Klein–Saks Mission in the 1950s, and finally to the ‘Chicago boys’ in the 1970s. Thirdly, the influence of the adviser derives not only from the intrinsic value and persuasiveness of his message, but from the fact that he usually has good connections in his home country and can therefore facilitate access to its
capital market. Courcelle-Seneuil, for example, suspended his university courses in 1858–9 to accompany a Chilean financial mission that travelled to France in search of a railroad construction loan. Fourthly, the foreign adviser is often criticized for wishing to transplant the institutions of his own country to the country he advises, but his real ambition is more extravagant: it is to endow the country with those ideal institutions which exist in his mind only, for he has been unable to persuade his own countrymen to adopt them. Fifthly, history in general, and nationalist historiography in particular, is likely to be unkind to the foreign adviser. In retrospect he can easily become a universal scapegoat: whatever went wrong is attributed to his nefarious influence. This demonization is more damaging than the adviser himself could possibly have been: it forestalls authentic learning from past experience.

Cournot competition

Andrew F. Daughety
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Cournot's 1838 model of strategic interaction between competing firms has become the primary workhorse for the analysis of imperfect competition, and shows up in a variety of fields, notably industrial organization and international trade. This article begins with a tour of the basic Cournot model and its properties, touching on existence, uniqueness, stability, and efficiency; this discussion especially emphasizes considerations involved in using the Cournot model in multi-stage applications. A discussion of recent applications is provided as well as a reference to an extended bibliography of approximately 125 selected publications from 2001 through 2005.

Keywords

Article

The classic Cournot model is static in nature, with each (single-product) firm's strategy being the quantity of output it will produce in the market for a specific homogeneous good; as Kreps (1987) observed, Cournot's model was an early progenitor of Nash's famous paper. Many recent applications have involved multi-stage games; for example, each of $n$ firms might first simultaneously choose investment levels (say, in cost-reducing R&D) and then simultaneously choose output levels in the second stage. Often now used in such a manner, we will see that the Cournot model is doing well,
Cournot competition: The New Palgrave Dictionary of Economics

contributing to a range of new research, as it moves towards the two-century mark.

1 The basic one-stage model and associated concepts

Consider an industry comprised of \( n \) firms, each firm choosing an amount of output to produce. Firm \( i \)'s output level is denoted as \( q_i, i = 1, \ldots, n \); let the vector of firm outputs be denoted \( \mathbf{q} \equiv (q_1, q_2, \ldots, q_n) \). The firms' products are assumed to be perfect substitutes (the homogeneous-goods case); let \( Q \) denote the aggregate industry output level (that is, \( Q = \sum_{i=1}^{n} q_i \)). We will refer to the \((n - 1)\) vector of output levels chosen by firm \( i \)'s rivals as \( \mathbf{q}_{-i} \), so, let \( (\mathbf{q} - \mathbf{q}_i) \) also be the \( n \)-vector \( \mathbf{q} \). Market demand for the perfect-substitutes case is a function of aggregate output and its inverse is denoted as \( p(Q) \); furthermore, let firm \( i \)'s cost of producing \( q_i \) be denoted as \( c_i(q_i) \). Thus, firm \( i \)'s profit function is written as

\[
\pi^i(q) = p(Q)q_i - c_i(q_i).
\]

All elements of the model are assumed to be commonly known by the firms, though extensions allowing incomplete information are not uncommon.

A Cournot equilibrium consists of a vector of output levels, \( \mathbf{q}^{CE} \), such that no firm wishes to unilaterally change its output level when the other firms produce the output levels assigned to them in the (purported) equilibrium. Alternatively put (and reversing history), it is a Nash equilibrium of the normal-form game with quantities as strategies chosen from a compact space (for example, \( q_i \) in \([0, Q^*]\), for some appropriate \( Q^* \)), and with the \( \pi^i(q) \) as the payoff functions. Thus, \( \mathbf{q}^{CE} \) is a Cournot equilibrium if the following \( n \) equations are satisfied:

\[
\pi^i(q^CE) \geq \pi^i(\mathbf{q}_{-i}^{CE}, q_i) \quad \text{for all values of } q_i, \quad i = 1, \ldots, n.
\]

In analysing his model applied to a duopoly (he also considered the \( n \)-firm version), Cournot provided the notion of best-response functions. In the duopoly case, this is a pair of functions, \( \psi^1(q_2) \) and \( \psi^2(q_1) \), which provide the profit-maximizing choice of output for firm 1 and 2 (respectively), given conjectures about the output level chosen by the rival firm (that is, each firm's choice of its output level reflects a best-response property). Hence,

\[
\psi^i(q_j) = \arg \max q \pi^i(q_j, q_j), \quad i, j = 1, 2, \quad i \neq j.
\]

That is, we want \( \psi^i(q_j) \) to be the solution to firm \( i \)'s first-order condition:

\[
p(\psi^i(q_j) + q_j) + p'(\psi^i(q_j) + q_j)\psi^i(q_j) - c_i'(\psi^i(q_j)) = 0, \quad i, j = 1, 2, \quad i \neq j.
\]

We'll assume for now that the problem has a nice solution and that some sort of sufficiency condition holds (for example, strict quasi-concavity of profits), but the discussion below on existence and uniqueness of equilibrium shows that such classical assumptions are overly strong and are overly restrictive for some modern applications, such as those involving multi-stage games or discontinuous cost functions. More generally, \( \psi^i(q_j) \) could be a correspondence (a point-to-set map); we generally restrict the discussion below to functions, and assume as much differentiability as needed.

If output-level choices are best responses to conjectures about each firm's rival's choice of output, and if these conjectures are correct in equilibrium, then the resulting vector of output levels provides a Cournot equilibrium:

\[
q_i^{CE} = \psi^i(q_j^{CE}) \quad \text{for } i, j = 1, 2, \quad \text{and } j \neq i.
\]

In other words, the equilibrium occurs where the best-response functions cross when graphed in the space of output levels. Generalizing to \( n \) firms, this
Cournot competition: The New Palgrave Dictionary of Economics

condition can be written as \( q_i^{CE} = \psi_i(q_{-i}^{CE}) \) for \( i = 1, \ldots, n \). \( q^{CE} \) is a Cournot equilibrium if it consists of mutual best-responses for all the firms.

Some variations on the basic model are worth mentioning. If the cost function for a firm has both fixed and variable components, and if the fixed component is avoidable (that is, is zero at zero output), then the best-response function for the firm will be discontinuous at the positive output level where variable profits just cover the avoidable cost. This is important for two reasons. First, avoidable fixed costs are not unusual in many entry scenarios: think of an airline entering a market where there are already some competitors, with the avoidable cost being advertising. Second, this discontinuity could mean that the only equilibrium might involve some or all firms choosing to not enter (or to exit) the market, even if absent these avoidable costs \( q^{CE} \) would be strictly positive.

Another avenue for interaction would consider imperfect factor markets, so that instead of \( c_i(q_i) \) the cost function for firm \( i \) would be written as \( \ell_i(q_{-i}, q_i) \); then strategic interaction occurs not only through revenue but also via factor markets. Finally, if the model is one of short-run competition, then the output level of the firm may be restricted to be less than some predetermined capacity level; a simple version is that there are parameters \( k_i, i = 1, \ldots, n \), such that a constraint on firm \( i \)'s quantity choice is \( q_i \leq k_i, i = 1, \ldots, n \); this induces a vertical segment (at the capacity level) in a firm's best-response function. Such capacity levels might be choices made in an earlier stage.

Finally, a number of papers develop 'non-Cournot' models which generate Cournot-model results. Kreps and Scheinkman (1983) provide a two-stage model of capacity choice followed by price setting in a homogeneous-goods duopoly; the result is a unique subgame-perfect equilibrium with Cournot capacities and a market-clearing price consistent with the standard Cournot model (however, Davidson and Deneckere, 1986, show that this result is especially sensitive to the basis for rationing consumers over firms when out-of-equilibrium firm-level demand exceeds capacity). Klemperer and Meyer (1986) analyse a one-stage game wherein duopolists producing heterogeneous goods non-cooperatively choose either a price or a quantity as the firm's strategy; under either multiplicative or additive error in the demand function, if marginal costs are upward sloping, the outcome is that predicted by the Cournot model (applied to the heterogenous-goods case; see the discussion of this case in Section 2 below). The classic embedding of the Cournot model is that of Bowley (1924), the best-known developer of models with 'conjectural variations' (CV). This is a static story wherein the first-order conditions in the analysis include firm \( i \)'s conjecture of each rival's reaction to a small change in firm \( i \)'s quantity (for example, \( \partial q_j / \partial q_i \) need not be zero for each \( j \neq i \)); different values of the CV generate competitive, collusive, or Cournot outcomes (among others). Such a handy static embedding of alternative degrees of competition has been employed in a number of theoretical applications, and in a variety of empirical analyses trying to estimate market power. However, Daughety (1985) shows that a basic rationality requirement (that each firm's CV be the same as the actual slope of the best-response function) leads to the Cournot outcome, so that alternative CV values violate this form of rational expectations. Furthermore, Korts (1999) shows that empirical analyses using the CV approach to assess market power will generally mis-measure the degree of competitiveness of the industry.

2 Properties of the Cournot equilibrium
For most of this section we emphasize results for an \( n \)-firm, homogeneous-goods, complete-information model, where a firm's cost function depends only on that firm's output level. As suggested earlier, possibly one of the most important reasons for the continuing interest in the properties of the Cournot equilibrium is that Cournot competition is frequently used as a final stage in a variety of models; analysis employing such refinements as subgame perfection rely on a well-behaved subgame.

Existence, uniqueness and stability

Novshek (1985) provides an existence theorem that has quite practical uses (for expository purposes we consider a slightly less general version). Besides continuity and twice differentiability of the inverse demand function, \( p(Q) \), Novshek's existence theorem requires that: (1) \( p(Q) \) crosses the quantity axis at a finite value and is strictly decreasing for quantities below that cut point; (2) the marginal revenue for each firm is decreasing in the aggregate output of its rivals; and (3) each firm's cost function is non-decreasing and lower semi-continuous. Requirement (2) is written formally as
\[
\frac{\partial^2 \pi_i}{\partial Q_i \partial q_i} < 0
\]
for all \( i \). This is equivalent to the assumption that \( Q_i - q_i \) and \( q_i \) are strategic substitutes, which means that an expansion in \( Q_i \) implies that the optimal \( q_i \) falls. The third requirement means that costs cannot fall as the output level is increased and that cost functions can have jumps (discontinuities), as long as the functions are continuous from the left. This was a substantial improvement over previous existence theorems and it allows for an important case: avoidable fixed costs, such as those in the airline-entry example mentioned earlier. Amir (1996) applies an ordinal version of the theory of supermodular games to the existence issue (see Vives, 2005, for a recent survey of supermodular games; see also Amir, 2005, for a comparison of ordinal and cardinal complementarity in this context); this change of techniques allows for weaker demand conditions (primarily that \( \log p(Q) \) is concave) but requires a slightly stronger condition on each firm's cost function (marginal costs are positive, so models wherein marginal costs might be zero – as might occur with capacity competition – are left out) in order to guarantee that a Cournot equilibrium exists. As an example of the advantages concerning demand analysis, let
\[
p(Q) = (Q - \bar{Q})^2 \quad \text{for} \quad Q \leq \bar{Q}, \quad \text{and zero otherwise.}
\]
Such a function satisfies (1) above, is log-concave (actually, convex), but is excluded from consideration by Novshek's second condition.

Gaudet and Salant (1991) provide conditions for a Cournot equilibrium to be unique which address an important consideration when Cournot models are used in a subgame of a larger game: their theorem allows for degeneracy (one or more firms produce zero output but have marginal cost equal to the equilibrium price); thus, such firms are just at the shutdown point in the equilibrium. In a one-stage application this could be eliminated via a small perturbation in the parameters, but in a multi-stage application such an outcome need not be pathological, as some of the second-stage 'parameters' are strategic variables in the first-stage model (the authors provide a simple, full-information entry game to illustrate this). The sufficient conditions for uniqueness are (not surprisingly) more restrictive than those for existence (on the assumption that Novshek's conditions hold as well): (1) each firm's cost function must be twice continuously differentiable and strictly increasing; and (2) the slope of the marginal cost function is strictly bounded above the slope of the demand function. Thus, concave costs are allowed, to some degree, but the cost function cannot be 'too concave', even on subsets of its domain.
Cournot provided an explicit dynamic stability argument for his model by imagining sequential play by each agent (myopically best-responding in the current period to the existing output levels of all rivals); this is referred to as best-reply dynamics and when this process converges the solution is termed stable. Using best-reply dynamics to rationalize a static solution has, historically, been a source of substantial criticism, but nonetheless some papers use the requirement of Cournot stability to select an equilibrium when there are multiple equilibria (dynamic stability should not be confused with equilibrium refinement criteria in game theory such as strategic stability). A sufficient condition in the duopoly case is that \( \left| \frac{\partial \psi^1(q_2)}{\partial q_2} \right| \frac{\partial \psi^2(q_1)}{\partial q_1} < 1 \) (see Fudenberg and Tirole, 1991); see Seade (1980) for more general conditions (and problems) for best-reply dynamics in the \( n \)-firm case. For an approach employing an explicit evolutionary process via replicator dynamics with noise, with firms able to choose ‘behavioural’ strategies (including, but not limited to, best-reply), see Droste, Hommes and Tunistra (2002).

**Welfare**

Two types of inefficiency can occur in a Cournot equilibrium: the equilibrium price exceeds the marginal cost of production, and aggregate output is inefficiently distributed over the firms. Compare the first-order conditions for firms in a duopoly, each producing under conditions of non-decreasing marginal costs (that is, \( p(Q) + \frac{\partial p(Q)}{\partial q_i} q_i = c_i'(q_i), \quad i = 1, 2 \)) with those for a central planner choosing \( q_1 \) and \( q_2 \) so as to maximize total surplus: \( p(Q) = c_i'(q_i), \quad i = 1, 2 \). Clearly, if demand is downward-sloping at the equilibrium, aggregate output in the Cournot equilibrium will be less than what the social planner would choose. However, a second distortion can be seen in this comparison: under the social planner, each firm's marginal costs are equalized with the others'. This will hold only in a symmetric Cournot equilibrium (where \( q_1 = q_2 \)): production is, in general, inefficiently allocated across the firms. The maldistribution of production implies that strategic interaction readily may yield counter-intuitive welfare results. As a simple example, consider a duopoly wherein (inverse) industry demand is \( p = a - Q \) and firm \( i \)'s cost function is \( c_i(q) = c_i q, \quad i = 1, 2 \), with \( a > c_1 > c_2 > 0 \); that is, the linear demand, constant-but-unequal-marginal-cost case. It is straightforward to find the equilibrium and show that it is interior and unique. Let \( W \) be the sum of producers' and consumers' surplus. Then a little work shows that \( \frac{\partial W}{\partial c_1} > 0 \) if \( 11c_1 - 7c_2 - 4a > 0 \); to see that these conditions are non-empty, consider the parameter specification (\( a = 20, \quad c_1 = 13, \quad c_2 = 8 \)), which satisfies all the foregoing requirements. The point of the example is that a reduction of firm 1’s marginal cost leads to a decrease in equilibrium welfare. Thus, strategic interaction by the firms in the marketplace can lead to reversals of the usual welfare intuition that cost-improving technological change is beneficial. The reason this occurs is that the cost reduction results in an increase in the high-cost firm's equilibrium output level and a (smaller) decrease in the low-cost firm's output level; this increased inefficiency in aggregate production can be sufficient to overwhelm other efficiency improvements (such as the increase in industry output). This is similarly true if in the above model firm 2 is an incumbent monopolist (using simple monopoly pricing) and firm 1 an entrant: welfare will fall due to entry.

In the \( n \)-firm version of the constant-marginal-cost model, changes in the distribution of production costs
(holding the mean fixed) do not affect industry output; this is seen by summing over the first-order conditions, whence \( n p(Q) + p'(Q) Q = \sum_{i=1}^{n} c_i \). Bergstrom and Varian (1985) showed that (on the assumption that the pre- and post-change equilibria are interior) such mean-preserving changes in the marginal costs strictly improve welfare if and only if the variance of the marginal costs strictly increases; the reason is that the aggregate cost of production has decreased if the variance increases. Salant and Shaffer (1999) extend this idea to consider the effects of changes in first-stage parameters (for example, cost-reducing R&D investments) on second-stage costs in models wherein Cournot competition is employed in the second stage. They argue that, since aggregate production costs are *maximized* when all firms have the same costs, it is the asymmetric equilibria in such games (which are often assumed away) which may yield the most important outcomes to examine, from both a social and a private perspective.

Does entry necessarily reduce the equilibrium price? A recent contribution provides a clean result if we restrict attention to the symmetric case wherein all firms have the same twice continuously differentiable and non-decreasing cost function, and demand is continuously differentiable and downward-sloping. Amir and Lamson (2000) show that the equilibrium price falls with an increase in the number of competitors if, for all \( Q, p'(Q) < c''(Q) \) for all \( q \) in \([0, Q]\). Thus, even with some degree of returns to scale (for example, as might occur with U-shaped average costs), entry will reduce price, at least with identical firms. However, Hoernig (2003) shows that, even if the equilibria are stable and there are no returns to scale, price can rise with entry if products are differentiated.

If the products of the firms are imperfect substitutes (that is, products are differentiated), then (in general) there is no aggregate demand function \( p(Q) \); rather firm \( i \)'s inverse demand function would be written as \( p_i(q) \) and profits would be written as \( \pi_i(q) = p_i(q) q_i - c_i(q_i), \ i = 1, ..., n \). Welfare in this model can be contrasted with a reformulation of the model so that each firm chooses a price for its product; standard parlance is to call the price-strategy model the *(differentiated products)* Bertrand model (even though Bertrand's famous review of Cournot did not envision heterogeneity in products; see Friedman's 1988 translation of Bertrand's review). Without going into detail on the *(differentiated products)* Bertrand model, Singh and Vives (1984) have shown (for linear, symmetric demand and constant marginal costs in a duopoly setting) that, while profits under Cournot competition exceed those under Bertrand competition, total surplus is higher under Bertrand competition than under Cournot competition. Note that this result holds in the one-stage game. However, these results may be reversed in a two-stage application. For example, Symeonidis (2003) considers R&D investment with spillovers in a two-stage game, and shows that (at least for a portion of the parameter space) Cournot competition leads to higher welfare than Bertrand competition. The basic intuition is that, if profits are higher for second-stage Cournot competition than for second-stage Bertrand competition, and first-stage investment is inefficiently low in either case, then the increased second-stage profits may partly correct the inefficiently low first-stage investment, leading to an overall welfare gain for competition in quantities rather than prices.

Finally, convergence of a Cournot equilibrium to a competitive equilibrium, as the number of firms grows, was considered by Cournot in Chapter 8 of his book, and has been the subject of a number of papers; see Novshek and Sonnenschein (1978; 1987) for a general equilibrium treatment where appropriate replication of Cournot economies yields equilibria arbitrarily close to the Walrasian.
Cournot competition: The New Palgrave Dictionary of Economics

equilibrium; see Alos-Ferrer (2004) for an evolutionary model (which allows for memory) at the level of an industry.

3 Applications

The literature exploring and applying the Cournot model is vast; an earlier extended bibliography can be found in Daughety (1988/2005). The more recent literature employing the Cournot model is already becoming significant in size: a survey of articles in 16 top mainline and field journals, for the period 2001–5, netted approximately 125 articles exploring or applying the Cournot model in one of its various common forms. An online Excel file of (abbreviated) citations and some characteristics of each article (number of firms, number of stages, welfare considerations, informational regime, and topic classification), as accessed on 21 November 2006, is available at [http://www.vanderbilt.edu/Econ/faculty/Daughety/ExtendedCournotBib2001-2005.xls](http://www.vanderbilt.edu/Econ/faculty/Daughety/ExtendedCournotBib2001-2005.xls)

However, some excellent papers have undoubtedly been missed (not to mention papers from the 1990s), and space limitations preclude anything beyond the briefest of tours and just a taste of the literature, so only a very few can be discussed below. This section addresses five topics which account for a significant portion of the literature, three areas that overlap other fields, and two (comparatively) new areas of research.

Delegation

Vickers (1985) uses an n-firm, two-stage model to examine performance measures for managers. Restricting the manager's performance measure to be a weighted average of profits and output, with the weights determined by the owner of each firm in the first stage, he shows that the weight on output is non-zero. This makes each manager more aggressive (each chooses to produce a higher output level), thereby leading to lower profits per firm. Sklivas (1987) considers the differentiated-products Bertrand version and shows that owners choose weights on revenue and profits so as to make managers more passive (they post higher prices), leading to increased profits. Miller and Pazgal (2001) have unified this literature, showing that incentive schemes based on own and rival's profits result in an equilibrium which is insensitive to whether the firm chooses price or quantity as its strategic variable.

Information transfer

Vives (1984), Gal-Or (1985), and Li (1985) all consider variants of ‘information transfer’ models to examine the possibility of information sharing, whereby firms may choose to pool information on either demand or cost parameters. These models are analysed as Bayesian–Nash games, so that, before seeing a private signal about the parameter of interest (for example, the demand intercept), each firm chooses whether or not to share the information with the other firms; then information is received and production (or pricing) occurs in the second stage. The nature of the good (substitutes or complements), the type of information (common or individual), and the strategy space (quantities or prices) all affect whether firms will share information. Ziv (1993) relaxes the verifiability of information and finds that firms will send...
Cournot competition: The New Palgrave Dictionary of Economics

misleading information if they can; he then considers mechanisms for eliciting truthful messages.

Intellectual property

Katz and Shapiro (1985) and Kamien and Tauman (1986) consider the licensing of innovations in an oligopoly. Katz and Shapiro employ a three-stage duopoly game in which the innovation is developed, then a single license is auctioned, and then the firms compete. Kamien and Tauman use a two-stage, \( n \)-firm game with a posted price for the innovation (a fee or a royalty), followed by competition. More recently, Fauli-Oller and Sandonis (2003) consider optimal competition policy when considering licences as an alternative to merger. Anton and Yao (2004) allow for weak patent protection and consider how disclosure of information about an innovation (for example, through the patent application) can be a signalling device to influence competitors, but those same competitors may be able to employ the information to successfully use (infringe on) the patent; here small innovations are patented and substantial innovations are protected through secrecy.

Mergers

Salant, Switzer and Reynolds (1983) show that exogenously determined mergers of a subset of firms in the constant-marginal-cost set-up yields a problematical result: a sufficient condition for a merger to be unprofitable is that it involve less than 80 per cent of the industry, hardly a resounding endorsement of using such a model to analyse mergers. This result, however, is partly driven by the assumptions of homogeneous products, constant unit costs, and industry structure. Perry and Porter (1985) show that various mergers can be profitable if firms have sufficiently increasing marginal costs. Daughety (1990), using a two-tiered-industry, \( n \)-firm model, with \( m \) firms choosing output in the first stage (tier) and \( n - m \) firms choosing output in the second stage, shows that if \( 1 < m < n \), then, when \( m \) is comparatively small (\( m < n/3 \)), mergers of two second-tier firms to make a first-tier firm can be both profitable and social-welfare-enhancing, even though such mergers increase concentration and have no cost synergies (all firms have identical constant unit costs). Recently, Pesendorfer (2005), using a repeated game model with entry, has found that merger to monopoly may not be profitable, but merger in a non-concentrated industry can be; these differences from the previous literature partly reflect long-run versus short-run profitability computations.

R&D

D'Aspremont and Jacquemin (1988) considered cost-reducing R&D in the presence of spillovers, and considered both non-cooperative and cooperative R&D decision-making; there have been a number of recent papers on cost-reducing spillovers (see, for example, Zhao, 2001, for more on the negative welfare effects of cost-reducing innovation, and Symeonidis, 2003, cited in Section 2 above, as well as the work discussed below under the subject of auctions with competition). Toshimitsu (2003) considers the incentive and welfare properties of quality-based R&D subsidies for firms in a model of endogenously determined product quality (and thus product differentiation); subsidizing high quality is
welfare-enhancing (independent of whether the Cournot or Bertrand model is employed).

Other fields

Areas of ongoing effort which extend into other fields include experimental economics, the financial structure of the firm (see, for example, Brander and Lewis, 1986, on determinate debt-equity due to imperfect competition, and see Povel and Raith, 2004, extending Brander and Lewis via endogenously determined debt contracts); and international trade (see, for example, Brander and Spencer, 1985, analysing the strategic use of subsidies in international competition; Mezzetti and Dinopoulos, 1991, discussing domestic firm–union bargaining and import competition; and Spencer and Qiu, 2001, concerning relationship-specific investments and trade).

New topics

Finally, a few examples of comparatively new topics. While auctions with private information has long been an area of interest, the developing literature on auctions with competition has started to take seriously the combination of incomplete information and post-auction competition. For example, see Das Varma (2003) or Goeree (2003), who find that signalling by winners of an auction causes bids to be biased when post-auction interaction between the auction's winner and losers can be influenced by the size of the bid. A nice example is when firms have private information about how acquiring a cost-reducing innovation might affect the firm's production costs, and bidding for a licence for the innovation precedes Cournot oligopoly interaction; here signalling with a high bid suggests that the winner will have low costs and will produce a high level of output.

A second new area is networks; one recent example is Goyal and Moraga-Gonzalez (2001), who model bilateral agreements to share knowledge, and allow for the possibility of partial collaboration, via considering possible networks of relationships. They examine how the nature of the firms' interaction in markets can contribute to the instability of certain types of strategic alliances and the stability of other ones.

4 A broader perspective on Cournot competition

If alive to critique this essay, Cournot might view the interpretation of the term ‘Cournot competition’ being limited merely to the legacy of his oligopoly analysis to be an overly restrictive interpretation of the assignment. And well he should. Hicks (1935; 1939) argues that Cournot was the first to present a modern model of monopoly as well as the precise conditions for perfect competition; furthermore, as noted earlier, Cournot's eighth chapter concerned ‘unlimited competition’. In the 1937 Cournot Memorial session of the Econometric Society, A. J. Nichol (1938) observed that, if ever there was an apt illustration of Carnegie's dictum that ‘It does not pay to pioneer’, then Cournot's life and work would be it. Cournot's oligopoly model was essentially ignored for many years, or was relegated to dusty corners of microeconomics texts, but over recent decades it has come to be an essential tool in many an economist's toolbox, and is likely to continue as such.

Article

Cournot was born at Gray (Haute-Saône) on 28 August 1801 and died in Paris on 30 March 1877. Until the age of 15 his education was at Gray. After studying at Besançon he was admitted to the Ecole Normale Supérieure in Paris in 1821. In 1823 he obtained his licentiate in sciences and in October of that year was employed by Marshal Gouvion-Saint-Cyr as literary adviser to the Marshal and tutor to his son. In 1829 he obtained his doctorate in science with a main thesis in mechanics and a secondary one in astronomy. Through the sponsorship of Poisson in 1834 he obtained the professorship in analysis and mechanics at Lyon.

After a year of teaching he became primarily involved in university administration. In 1835 he became rector of the Académie de Grenoble and subsequently became inspector general of education and from 1854 to 1862 was rector of the Académie de Dijon. He became a Knight of the Legion of Honour in 1838 and an Officer in 1845. He was afflicted with failing eyesight and in the last part of his life was nearly blind. In 1862 he retired from public life but continued his own researches in Paris until his death. Cournot was a prolific writer. His writings can be broadly divided into three categories: (1) mathematics; (2) economics and (3) the philosophy of science and philosophy of history.

In considering Cournot as an economist it is necessary to place his major economic work, *Recherches sur les principes mathématiques de la théorie des richesses* (1838) in the context not only of *Principes de la théorie des richesses* (1863), which can be regarded as a literary version of his work of a quarter of
a century earlier, and his *Revue sommaire des doctrines économiques* (1877) which appeared in the last year of his life, but also of his writings on probability and the philosophy of science, in particular *Exposition de la théorie des chances et des probabilités* (1843) and *Matérialisme, vitalisme, rationalisme: Etudes des données de la science en philosophie* (1875).

It is possible to weave a broad cloth of interpretation taking into account not merely Cournot's other works but what appears to be known of his personality and the considerable social and political flux in France during the times in which he lived. Guitton (1968) has suggested that Cournot had a rather melancholic and solitary temperament and ‘did nothing to make his books attractive’. He notes that: ‘Cournot was a pioneer. He did nothing to court his contemporaries, and they, in turn, not only failed to appreciate him but ignored him.’ Palomba ([1981] 1984) provides a sketch of the historical background of his time, noting the growth of socialist ideas in Europe, the political actions and reactions to the French Revolution and the challenges to the concept of ownership. Rather than challenge or repeat the broad contextual interpretation of Cournot provided by Palomba, this article is confined primarily to the direct interpretation of his works in economics and supporting texts in the light of many of the developments in economics which are consistent with and may be indebted to his original ideas.

The texts followed here include the French given in the complete works of Cournot (1973) and the Nathaniel T. Bacon translation (1899) entitled *Researches into the Mathematical Principles of the Theory of Wealth*, which also contains an essay by Irving Fisher on Cournot and Mathematical Economics as well as a bibliography on Mathematical Economics from 1711 to 1897. The 1929 reprint of the 1897 edition was used.

The preface sets forth with great clarity Cournot's fundamental approach to political economy. He states:

> But the title of this work sets forth not only theoretical researches; it shows also that I intend to apply to them the forms and symbols of mathematical analysis. Most authors who have devoted themselves to political economy seem also to have had a wrong idea of the nature of the applications of mathematical analysis to the theory of wealth. But those skilled in mathematical analysis know that its object is not simply to calculate numbers, but that it is also employed to find the relations between magnitudes which cannot be expressed in numbers and between functions whose law is not capable of algebraic expression. Thus the theory of probabilities furnishes a demonstration of very important propositions, although without the help of experience it is impossible to give numerical values for contingent events, except in questions of mere curiosity, such as arise from certain games of chance. (p. 3)

Cournot continues in the preface to note that only the first principles of differential and integral calculus are required for his treatise. Professional mathematicians could be interested in it for the questions raised rather than the level of mathematics presented. He ends the preface with the caveat:

> I am far from having thought of writing in support of any system, and from joining the banners of any party; I believe that there is an immense step in passing from theory to governmental applications; I believe that theory loses none of its value in thus remaining preserved from contact with impassioned polemics; and I believe, if this essay is of any
practical value, it will be chiefly in making clear how far we are from being able to solve, with full knowledge of the case, a multitude of questions which are boldly decided every day. (p. 5)

The first chapter, ‘Of Value in Exchange or of Wealth in General’, provides insight into the breadth of Cournot’s concern for the social and historical context of wealth.

Property, power, the distinctions between masters, servants and slaves, abundance, and poverty, rights and privileges, all these are found among the most savage tribes, and seem to flow necessarily from the natural laws which preside over aggregations of individuals and of families; but such an idea of wealth as we draw from our advanced state of civilization, and such as is necessary to give rise to a theory, can only be slowly developed as a consequence of the progress of commercial relations, and of the gradual reaction of those relations on civil institutions. (pp. 7–8)

He notes that: ‘it is a long step to the abstract idea of value in exchange which supposes that the objects to which such value is attributed are in commercial circulation.’

In order to illustrate the distinction between the word wealth in ordinary speech and value in exchange, he presents an example of a publisher who destroys two-thirds of his stock expecting to derive more profit from the remainder than the entire edition. The economics of elasticity is developed more formally in Chapter 4 on demand, but the concept is clear.

Chapter 2, ‘On Changes in Value, Absolute and Relative’, begins by noting that ‘we can only assign value to a commodity by reference to other commodities’. This leads to a discussion of the use of a corrected money which would serve as ‘the equivalent of the mean sun of the astronomers’.

Chapter 3, ‘Of the Exchanges’, is the first in which formal mathematical manipulation is employed. He considers a silver standard in which all currencies are fixed in ratio to a gram of fine silver. He observes that the ratios of exchange for the same weight of fine silver cannot differ by more than transportation and smuggling costs. Given the volume of trade measured in silver he considers the arbitrage conditions for the $m(m-1)/2$ ratios among $m$ centres. Fisher (1892) notes, however, that Cournot did not appear to be acquainted with determinants as he did not attempt a general solution of the exchange equations he proposed, but limited his calculations to three centres of exchange.

It is in Chapter 4, ‘On the Law of Demand’, that the modernity of his approach stands out. He is interested in demand as it is revealed in sales at a given price. He represents the relationship between sales and price by the continuous function $D=F(p)$ and observes that this function generally increases in size with a fall in price and that the empirical problem is to determine the form of $F(p)$. He indicates an appreciation of the concept of elasticity of demand although he did not develop the formal measure.

Chapters 5 and 6 deal with monopoly without and with taxation; Chapter 7 is on the competition of producers and Chapter 8 on unlimited competition. The ninth chapter is on the mutual relations of producers and the tenth on the communication of markets. The final two chapters are somewhat macroeconomic in scope. Chapter 11 is entitled ‘Of the Social Income’ and 12 ‘Of Variations in the Social Income, Resulting from the Communication of Markets’.

As our commentary is primarily on Chapters 5–8, the order is reversed and 11 and 12 are dealt with first. Cournot explicitly avoids setting up the whole closed microeconomic system.
It seems, therefore, as if, for a complete and rigorous solution of the problems relative to some parts of the economic system, it were indispensable to take the entire system into consideration. But this would surpass the powers of mathematical analysis and of our practical methods of calculation, even if the values of all the constants could be assigned to them numerically. The object of this chapter and of the following one is to show how far it is possible to avoid this difficulty, while maintaining a certain kind of approximation, and to carry on, by the aid of mathematical symbols, a useful analysis of the most general questions which this subject brings up.

We will denote by *social income* the sum, not only of incomes properly so called, which belong to members of society in their quality of real estate owners or capitalists, but also the wages and annual profits which come to them in their capacity of workers and industrial agents. We will also include in it the annual amount of the stipends by means of which individuals or the state sustain those classes of men which economic writers have characterized as unproductive, because the product of their labour is not anything material or saleable. (pp. 127–8)

But, using a first order approximation, he studies the effect of a change in price and consumption of a good on social income as a whole under competition, under monopoly and when a new product is introduced.

Finally, although we make continuous and almost exclusive use of the word *commodity*, it must not be lost sight of (Article 8) that in this work we assimilate to commodities the rendering of services which have for their object the satisfaction of wants or the procuring of enjoyment. Thus when we say that funds are diverted from the demand for commodity A to be applied to the demand for commodity B, it may be meant by this expression that the funds diverted from the demand for a commodity properly so called, are employed to pay for services or vice versa. When the population of a great city loses its taste for taverns and takes up that for theatrical representations, the funds which were used in the demand for alcoholic beverages go to pay actors, authors, and musicians, whose annual income, according to our definition, appears on the balance sheet of the social income, as well as the rent of the vineyard owner, the vine-dresser's wages, and the tavern-keeper's profits. (p. 149)

The last chapter considers international trade and national income and uses a first order approximation rather than a closed equilibrium system to study the benefits of opening up trade.

Moreover (and this is the favourite argument of writers of the school of Adam Smith), it should be inferred from the asserted advantage assigned to the exporting market, and the asserted disadvantage suffered by the importing market, that a nation should so arrange as always to export and never to import, which is evidently absurd, as it can only export on
condition of importing, and even the sum of the values exported, calculated at the moment of leaving the national market, must necessarily be equal to the sum of the values imported, calculated at the moment of arrival on the national market. (p. 161)

Cournot also notes the problem of analysing a tariff war:

The question would no longer be the same if establishment of a barrier for the benefit of A producers might provoke, by way of retaliation, the establishment of another barrier for the benefit of B producers, against whom the first barrier was raised. The government of A would then have to weigh the advantage resulting from the first measure to the citizens of A against the drawbacks caused by the retaliation. The two markets A and B would thus again be placed in symmetrical conditions, and each should be considered as acting the double part of an exporting and importing market. (p. 164)

He closes his comments with:

We have just laid a finger on the question which is at the bottom of all discussions on measures which prohibit or restrict freedom of trade. It is not enough to accurately analyse the influence of such measures on the national income; their tendency as to the distribution of the wealth of society should also be looked into. We have no intention of taking up here this delicate question, which would carry us too far away from the purely abstract discussions with which this essay has to do. If we have tried to overthrow the doctrine of Smith's school as to barriers, it was only from theoretical considerations, and not in the least to make ourselves the advocates of prohibitory and restrictive laws. Moreover, it must be recognized that such questions as that of commercial liberty are not settled either by the arguments of scientific men or even by the wisdom of statesmen. (p. 171)

He closes his work with the observation about theory that:

By giving more light on a debated point, it soothes the passions which are aroused. Systems have their fanatics, but the science which succeeds to systems never has them. Finally, even if theories relating to social organization do not guide the doings of the day, they at least throw light on the history of accomplished facts. (p. 171)

Although the contribution of these last chapters is not as great as those to which we now turn, the spirit and style is that of a major theorist concerned deeply and objectively with application to practical affairs. In Chapters 5–9 Cournot develops his theory of monopoly, oligopoly and unlimited competition. This can be contrasted with Ricardo (1817) before and Walras (1874) after, who concentrated on unlimited competition with no aim at producing a unified theory involving numbers. In Chapter 5 Cournot deals with monopoly, considering increasing, decreasing and constant returns and in Chapter 6 the influence of taxation on a monopoly is considered. He notes direct taxes and indirect
taxes as well as bounties and their influences on both producers and consumers; and closes with an examination of two variations of taxation in kind. Chapter 7 provides a smooth transformation from single person maximization to non-cooperative optimization where agents who mutually influence each other act without explicit cooperation.

We say each independently, and this restriction is very important, as will soon appear; for if they should come to an agreement so as to obtain for each the greatest possible income, the results would be entirely different, and would not differ, so far as consumers are concerned, from those obtained in treating of a monopoly.

Instead of adopting $D = F(p)$ as before, in this case it will be convenient to adopt the inverse notation $p = f(D)$; and then the profits of proprietors (1) and (2) will be respectively expressed by

$$D_1 f(D_1 + D_2), \text{ and } D_2 f(D_1 + D_2),$$

i.e. by functions into each of which enter two variables, $D_1$ and $D_2$. (p. 80)

It is at this point that Cournot switches from price to quantity of a homogeneous product as the strategic variable used by the competitors. His words and the mathematics do not quite match. He says, ‘This he will be able to accomplish by properly adjusting his price.’ The first order condition for the existence of a non-cooperative equilibrium with quantity as the strategic variable is given. A diagram showing a stable equilibrium and another with a non-stable equilibrium are presented. The analysis is generalized to $n$ producers including the possibility of an extra group of producers beyond $n$, all of whom produce at capacity. He obtains $n$ symmetric equations for the firms with interior production levels and sets the others at capacity.

When he introduces $n$ different general cost functions for the $n$ firms he handles the situation with all having an equilibrium defined by the simultaneous satisfaction of the equations arising from the first order conditions. But he does not deal with the possibility that costs could be such that different subsets of firms could be active in different equilibria.

The criticism levelled by Bertrand (1883) in his review written well after Cournot's death concerns the modelling rather than the mathematics. As Cournot considered competition without entry among firms selling an identical product it was fairly natural to avoid the discontinuity in the payoff function caused by selecting price as an independent variable. But the observation of Bertrand matters for markets with a finite number of firms. The choice of strategic variable causes not only mathematical difficulties but raises questions concerning economic realism and relevance. Quantity, price, quality, product differentiation and scope can all be considered as playing dominant roles in different markets. But the general explanation of price and quantity as strategic variables was and is critical to the development of economic theory. Cournot provided the foundations for the understanding of quantity. Bertrand, whose review of the books of Cournot and Walras was somewhat tangential to his professional interests offered
only an example rather than a developed theory of price competition. It remained for Edgeworth (1925, pp. 111–42) to explore the underlying difficulties with the payoff functions for duopoly with increasing marginal costs; and it has only been since the 1950s with the advent of the theory of games that there has been an adequate study of the properties of non-cooperative equilibria in games with price and quantity as strategic variables, without or with product differentiation. The thesis of Nash (1951) on the existence of non-cooperative equilibria for a class of games in strategic form provided a broad general underpinning for the concept of non-cooperative equilibrium. It was then immediately observable that, although Cournot's work with equilibria of games with a continuum of strategies was not strictly covered by Nash's work, conceptually Cournot's solution could be viewed as an application of non-cooperative equilibrium theory to oligopoly (see Mayberry, Nash and Shubik, 1953). The broader investigation of the price model and the interpretation of the instability of the Edgeworth cycle in terms of mixed strategy equilibria has only taken place recently. This also includes a growing literature on how to embed both the Cournot and Bertrand–Edgeworth models into a closed economic system or Walrasian framework. A summary of much of this work is presented by Shubik (1984).

It is important to appreciate that the developments in the theory of monopolistic competition such as those of Hotelling (1929) and Chamberlin (1933) and J. Robinson (1933) were based upon the Cournot non-cooperative game model. Although it may be argued that Chamberlin's and Mrs Robinson's works possibly contained broader and richer models of competition among the few than that of Cournot, they represented a step backwards in their lack of mathematical sophistication and analysis. The Chamberlin discussion of large group equilibrium does have price as the strategic variable along with product differentiation and entry, but the solution concept is the non-cooperative equilibrium à la Cournot with the caveat that an attempt to produce a strict formal mathematical model of Chamberlin's large group equilibrium leads one to conclude that the game having price as a strategic variable is closer to Edgeworth's analysis than that of Cournot and a price strategy non-cooperative equilibrium may not exist.

In Chapter 8 Cournot shows his basic grasp of the important strategic difference between pure competition and oligopolistic competition. Using his own words, he states:

The effects of competition have reached their limit, when each of the partial productions \( D_2 \) is \textit{inappreciable}, not only with reference to the total production \( D = F(p) \), but also with reference to the derivative \( F'(p) \), so that the partial production \( D_k \) could be subtracted from \( D \) without any appreciable variation resulting in the price of the commodity. This hypothesis is the one which is realized, in social economy, for a multitude of products, and, among them, for the most important products. It introduces a great simplification into the calculations, and this chapter is meant to develop the consequences of it. (p. 90)

In modern mathematical economics, in the linking of competition among the few and the Walrasian system into a logically consistent whole, two approaches to the study of large numbers have been adopted. The first is replication and has its roots in Cournot and, more formally, Edgeworth (1881). Following Edgeworth this method was used in cooperative core theory by Shubik (1959). The second
Cournot, Antoine Augustin (1801–1877) : The New Palgrave Dictionary of Economics

Involves considering a continuum of economic agents where each agent can be regarded as a set of measure zero. Cournot clearly saw the need to consider a market in which each individual firm is too small to influence price. But it remained for Aumann (1964) to fully formalize the concept of an economic game with a continuum of agents.

After 25 years during which his seminal work in mathematical economics was essentially ignored, Cournot demonstrated his concern for his ideas by publishing *Principes de la théorie des richesses* (1863), where he offered a non-mathematical rendition of his early work. This book is of considerably greater length than its predecessor and is divided into four books: Book 1, Les Richesses (eight chapters); Book 2, Les Monnaies (seven chapters); Book 3, Le Système économique (ten chapters) and Book 4, L'Optimisme économique (seven chapters).

This book met with no more immediate success than his original work and is not as deep. For example the chapters on money, although they contain discursive and historical material of interest, have little material of analytic depth.

In spite of the indifference of the environment to his writings in economics, Cournot regarded his contribution as sufficiently important that some 14 years later, in the year of his death, he published his *Revue sommaire des doctrines économiques* (1877). This book was also longer, non-mathematical and of less significance than the work of almost 40 years earlier. But Cournot's own sense of having been at least partially vindicated after 40-odd years is indicated in his *avant-propos*:

I was at that point in 1863, when I had the desire to find out whether I had sinned in the substance of ideas or only in their form. To that end, I went back to my work of 1838, expanding it where needed, and, most of all, removing entirely the algebraic apparatus which intimidates so much in these subjects. Whence the book entitled: ‘Principes de la théorie des richesses’. ‘Since it took me,’ I said in the preface, ‘twenty-five years to lodge an appeal of the first sentence, it goes without saying that I do not intend, whatever happens, to resort to any other means. If I lose my case a second time, I will be left only with the consolation which never abandons disgraced authors: that of thinking that the sentence that condemns them will one day be quashed in the interest of the law, that is of the truth.’

When I took this engagement in 1863, I did not think that I would live long enough to see my 1838 case reviewed as a matter of course. Nevertheless, more than thirty years later, another generation of economists, to put it like Mr. the commander Boccardo, discovered that I opened up back then, though too timidly and too partially, a good path to be followed, on which I was even somewhat preceded by a man of merit, the doctor Whewell. While another Englishman, Mr. Jevons, was undertaking to enlarge this path, a young Frenchman, Mr. Leon Walras, professor of Political Economy at Lausanne, dared to maintain right in the Institute that it was wrong to pay so little attention to my method and my algorithm, which he used rightfully to expose a new theory, more amply developed.

Now, look at my bad luck. If I won a little late, without any involvement, my 1838 case, I lost my 1863 case. If one wanted in retrospective to make a case for my algebra, my prose
Cournot, Antoine Augustin (1801–1877) : The New Palgrave Dictionary of Economics

(I am ashamed of saying it) did not get better success from the publisher. The *Journal des Économistes* (August 1864) criticized me mainly ‘for not having moved on from Ricardo,’ for not having taken into account the discoveries that so many men of merit have made in twenty-five years in the field of political economy; thus the poor author that no one of the official world of French economists wanted to quote incurred the reproach of not having quoted others enough.

Cournot was central to the founding of modern mathematical economics. The average reader tends not to be aware that the textbook presentations of the ‘marginal cost equals marginal revenue’ optimizing condition for monopoly and ‘marginal cost equals price’ for the firm in pure competition come directly from the work of Cournot (including an investigation of the second order conditions).

He had to wait many years for recognition, but when it came in the works of Jevons, Marshall, Edgeworth, Walras and others, it moved the course of economic theory. Marshall notes (*Memorials of Alfred Marshall*, pp. 412–13, letter 2, July 1900) ‘I fancy I read Cournot in 1868’, this was when Marshall was 26, some 30 years after the book appeared. He acknowledges him both as a great master and as his source ‘as regards the form of thought’ for Marshall's theory of distribution. Jevons, in his preface to the second edition of *The Theory of Political Economy* records ‘I procured a copy of the work as far back as 1872’ and that it ‘contains a wonderful analysis of the laws of supply and demand, and of the relations of prices, production, consumption, expenses and profits’. He excuses himself for his lateness in coming to Cournot observing: ‘English economists can hardly be blamed for their ignorance of Cournot's economic works when we find French writers equally bad.’ Walras in the preface to the fourth edition of *Elements of Pure Economic* (Jaffé translation, p. 37) acknowledges his ‘father Auguste Walras, for the fundamental principles of my economic doctrine’; and ‘Augustin Cournot for the idea of using the calculus of functions in the elaboration of this doctrine’. His liberal references to Cournot include his discussion of monopoly and the description of supply and demand. The art of formal modelling is different from but related to the use of mathematical analysis in economics. The clarity and parsimony of Cournot's modelling stand out and have served as beacons guiding the development of mathematical economics.

An important feature missing from Cournot's seminal work is the discussion of the role of chance and uncertainty in the economy. He stressed the importance of chance in both his book *Exposition de la théorie des chances et des probabilités* (1843) and in *Matérialisme, vitalisme, rationalisme* (1875). Although economics was the only social science he attempted to mathematize, he was well aware of the simplifications being made in cutting economic analysis from the context of history and society.

The economist considers the body social in a state of division and so to say of extreme pulverization, where all the particularities of organization and of individual life offset each other and vanish. The laws that he discovers or believes to discover are those of a mechanism, not those of a living organism. For him, it is no longer a question of social physiology, but of what is rightfully called social physics (p. 56). We mention that these cases of regression which imply abstractions of the same kind, if not of the same type and of the same value, reappear in various stages of scientific construction.

Cournot’s work on chance and probability does not appear to have provided any new mathematical
analysis, but he made three distinctions concerning the nature of probability. His book of 1843 was a text with the dual purpose of teaching the non-mathematician the rules of the calculus of probability and of dissipating the obscurities on the delicate subject of probability. He stressed the distinction between objective and subjective probability. His opening chapters provide a discussion of the appropriate combinatorics and frequency of occurrence interpretation of probability.

Cournot stressed the distinction between objective probability where frequencies are known and subjective probability. He noted:

> We could, since then, relying on the theorems of Jacques Bernoulli, who was already aware of their meaning and scope, pass immediately to the applications those theorems had in the sciences of facts and observations. However, a principle, first stated by the Englishman Bayes, and on which Condorcet, Laplace and their successors wanted to build the doctrine of ‘a posteriori’ probabilities, became the source of much ambiguity which must first be clarified, of serious mistakes which must be corrected and which are corrected as soon as one has in mind the fundamental distinction between probabilities which have an objective existence, which give a measure of the possibility of things, and subjective probabilities, relating partly to one's knowledge, partly to one's ignorance, depending on one's intelligence level and on the available data. (p. 155)

Subjective probability rests on the consideration of events which our ignorance calls for us to treat as equiprobable due to insufficient cause.

He added a third category which he entitled ‘philosophical probability’ (Chapter 17) ‘where probabilities are not reducible to an enumeration of chances’ but ‘which depend mainly on the idea that we have of the simplicity of the laws of nature’ (p. 440).

Cournot's views on probability appear to be intimately related to his concern for social statistics and economic modelling. Although he did not establish formal links between his mathematical economics models and chance he regarded history and the development of institutions as dependent on chance and economics as set in the context of institutions.

Cournot was at best an indifferent mathematician. Bertrand clearly dominated him in that profession. But from his own writings it is clear that Cournot was well aware of both his purpose in applying mathematics to economics and his limitations as a mathematician. At the age of 58 he wrote his *Souvenirs* which he finished in Dijon in October 1859. They were published many years later with an introduction by Botinelli (1913). In these writings Cournot provides his self-assessment as a mathematician.

> I was starting to be a little known in the academic world through a fairly large number of scientific articles. This was the basis of my fortune. Some of these articles ended up with Mr. Poisson, who was then the leader in Mathematics at the Institute, and mainly at the University, and he liked them particularly. He found in them philosophical insight, which I think was not all that wrong. Furthermore, he foresaw that I would go a long way in the field of pure mathematical speculation, which was (I always thought it and never hesitated to say it) one of his mistakes.
The general tenor of his *Souvenirs* is of a moderately conservative, quietly humourous, self-effacing man with considerable understanding of his environment and a broad belief in science and its value to society.

Regarding his work as a whole, his dedication and power as the founder of mathematical economics and the promoter of empirical numerical investigations emerges. He strove for around 40 years to have his ideas accepted. He did so with persistence and humour (referring to his major work as ‘mon opuscule’). He understood the need to wait for a generation to die. And before his death with the work and words of Jevons and Walras he saw the vindication of his approach.

creative destruction (Schumpeterian conception)

Arnold Heertje

Article

Schumpeter invented the phrase ‘creative destruction’ in his famous book on the development of capitalism into socialism (Schumpeter, 1942). In his view the process of creative destruction is the essential fact about capitalism and refers to the incessant mutation of the economic structure from within, destroying the old and creating a new.

In the footsteps of Karl Marx, Schumpeter argues that in dealing with capitalism we are dealing with an evolutionary process. It is by nature a form or method of economic change and not only never is, but never can be, stationary. The fundamental impulse that sets and keeps the capitalist engine in motion comes from new goods and new methods of production and transportation, created by the Schumpeterian entrepreneur, who is always on the outlook for new combinations of the factors of production (Heertje, 2006).

The process of creative destruction takes time. For that reason there is no point in appraising its performance within a static framework. A system may produce an optimal allocation of resources at every point of time and may yet in the long run be inferior to a system without such optimal allocation, because the non-optimality may be a condition for the level and speed of long-run performances; in other words, for dynamic efficiency. Furthermore, the process of creative destruction in Schumpeter's vision must be seen as the background for individual decisions and strategies. Economic theory has a tendency to concentrate on decisions about prices by firms, which are assumed to maximize profits, within a given structure. Schumpeter argues that the relevant problem is how capitalism creates and destroys these structures (Metcalfe, 1998).

Schumpeter's conception of creative destruction overturns the idea that price competition is the only component of the market behaviour of entrepreneurs. In fact, it is not that kind of competition which counts, but the competition from the new commodity, the new technology, the new source of supply and
the new type of organization. Instead of marginal changes, fundamental upheavals are brought about by process and product innovations of existing firms and potential competitors. Restrictive practices of monopolists and large firms are to be judged against the background of the perennial gale of creative destruction, rather than in the context of stationary development. The potential threat of process and product innovation reduces the scope and importance of restrictive practices that aim to guarantee the monopolist or big firm a quiet life. If however the profits are used to counterattack, restrictive practices may help to deepen the process of creative destruction and, therefore, the dynamic effects of capitalism (Reisman, 2004).

The process of creative destruction as described by Schumpeter has been experienced again since the 1980s in the United States, Japan and Western Europe and since the 1990s in China and India as well. On the basis of new technologies many old firms, structures and professions have been swept away and new industrial organizations and labour relations have emerged. In particular, the application of information technology and the Internet with the dramatic decrease in transaction costs of communication is leading to major changes of a quantitative and qualitative nature in both the private and public sector of the economy. On the one hand, ‘external’ growth of already large firms which take over others is a feature of modern capitalism; on the other hand, every day new small firms are established, often created by former executives of existing (and long-lived) companies.

This extensive discussion of the process of creative destruction illustrates Schumpeter's strong emphasis on the supply side of the economy. It would be an interesting question to study the impact of the process of creative destruction on employment. My guess would be that, on balance, the process of creative destruction is more creative than destructive, not only with regard to employment but also concerning broader perspectives of growth and welfare. This may be one of the reasons why Schumpeter's work has had a lasting and ever-increasing influence on economic theory.

Bibliography

Creative destruction refers to the incessant product and process innovation mechanism by which new production units replace outdated ones. This restructuring process permeates major aspects of macroeconomic performance, not only long-run growth but also economic fluctuations, structural adjustment and the functioning of factor markets. Over the long run, the process of creative destruction accounts for over 50 per cent of productivity growth. At business cycle frequency, restructuring typically declines during recessions, and this add a significant cost to downturns. Obstacles to the process of creative destruction can have severe short- and long-run macroeconomic consequences.

Article

Creative destruction refers to the incessant product and process innovation mechanism by which new production units replace outdated ones. It was coined by Joseph Schumpeter (1942), who considered it 'the essential fact about capitalism'.

The process of Schumpeterian creative destruction (restructuring) permeates major aspects of macroeconomic performance, not only long-run growth but also economic fluctuations, structural adjustment and the functioning of factor markets.

At the microeconomic level, restructuring is characterized by countless decisions to create and destroy production arrangements. These decisions are often complex, involving multiple parties as well as strategic and technological considerations. The efficiency of those decisions not only depends on
managerial talent but also hinges on the existence of sound institutions that provide a proper transactional framework. Failure along this dimension can have severe macroeconomic consequences once it interacts with the process of creative destruction (see Caballero and Hammour, 1994; 1996a; 1996b; 1996c; 1998a; 1998b; 2005). Some of these limitations are natural, as they derive from the sheer complexity of these transactions. Others are man-made, with their origins ranging from ill-conceived economic ideas to the achievement of higher human goals, such as the inalienability of human capital. In moderate amounts, these institutional limitations give rise to business cycle patterns such as those observed in the most developed and flexible economies. They can help explain perennial macroeconomic issues such as the cyclical behaviour of unemployment, investment and wages. In higher doses, by limiting the economy’s ability to tap new technological opportunities and adapt to a changing environment, institutional failure can result in dysfunctional factor markets, resource misallocation, economic stagnation, and exposure to deep crises.

Given the nature of this short piece, I will skip any discussion of models, and refer the reader to Caballero (2006) for a review of the models behind the previous paragraph, and to Aghion and Howitt (1998) for an exhaustive survey of Schumpeterian growth models. Instead, I focus on reviewing recent empirical evidence on different aspects of the process of creative destruction.

Recent evidence on the pace of creative destruction

There is abundant recent empirical evidence supporting the Schumpeterian view that the process of creative destruction is a major phenomenon at the core of economic growth in market economies. The most commonly used empirical proxies for the intensity of the process of creative destruction are those of factor reallocation and, in particular, job flows. Davis, Haltiwanger and Schuh (1996) (henceforth DHS) offered the clearest peek into this process by documenting and characterizing the large magnitude of job flows within US manufacturing. They defined job creation (destruction) as the positive (negative) net employment change at the establishment level from one period to the next. Using these definitions, they concluded that over ten per cent of the jobs that exist at any point in time did not exist a year before or will not exist a year later. That is, over ten per cent of existing jobs are destroyed each year and about the same amount is created within the same year. Following the work by DHS for the United States, many authors have constructed more or less comparable measures of job flows for a variety of countries and episodes. Although there are important differences across them, there are some common findings. In particular, job creation and destruction flows are large, ongoing and persistent. Moreover, most job flows take place within rather than between narrowly defined sectors of the economy.

Given the magnitude of these flows and that they take place mostly within narrowly defined sectors, the presumption is strong that they are an integral part of the process by which an economy upgrades its technology. Foster, Haltiwanger and Krizan (2001) provide empirical support for this presumption. They decompose changes in industry-level productivity into within-plant and reallocation (between-plant) components, and conclude that the latter – the most closely related to the creative destruction component – accounts for over 50 per cent of the ten-year productivity growth in the US manufacturing sector between 1977 and 1987. Moreover, in further decompositions they document that entry and exit account for half of this contribution: exiting plants have lower productivity than continuing plants. New plants,
on the other hand, experience a learning and selection period through which they gradually catch up with incumbents. Other studies of US manufacturing based on somewhat different methodologies (see Baily, Hulten and Campbell, 1992; Bartelsman and Dhrymes, 1994) concur with the conclusion that reallocation accounts for a major component of within-industry productivity growth. Bartelsman, Haltwanger and Scarpetta (2004) provide further evidence along these lines for a sample of 24 countries and two-digit industries over the 1990s.

Recent evidence on the cyclical features of creative destruction

At the business cycle frequency, sharp liquidations (rises in job destruction) constitute the most noted impact of contractions on creative destruction. In contrast, job creation is substantially less volatile and mildly pro-cyclical. There is an extensive literature that, extrapolating from the spikes in liquidations (recently measured in job flows but long noticed in other contexts), finds that recessions are times of increased reallocation. In fact, this has been a source of controversy among economists at least since the pre-Keynesian ‘liquidationist’ theses of such economists as Hayek, Schumpeter, and Robbins. These economists saw in the process of liquidation and reallocation of factors of production the main function of recessions. In the words of Schumpeter (1934, p. 16): ‘depressions are not simply evils, which we might attempt to suppress, but … forms of something which has to be done, namely, adjustment to … change.’

In Caballero and Hammour (2005) we turned the liquidationist view upside down. While we sided with Schumpeter and others on the view that increasing the pace of restructuring of the economy is likely to be beneficial, we provided evidence that, contrary to conventional wisdom, restructuring falls rather than rises during contractions. Since the rise in liquidations during recessions is not accompanied by a contemporaneous increase in creation, implicit in the increased-reallocation view is the idea that increased destruction is followed by a surge in creation during the recovery phase of the cyclical downturn. This presumption is the only possible outcome in a representative firm economy, as the representative firm must replace each job it destroys during a recession by creating a new job during the ensuing recovery. However, once one considers a heterogeneous productive structure that experiences ongoing creative destruction, other scenarios are possible. The cumulative effect of a recession on overall restructuring may be positive, zero, or even negative, depending not only on how the economy contracts but also on how it recovers. Thus, the relation between recessions and economic restructuring requires one to examine the effect of a recession on aggregate separations not only at impact, but cumulatively throughout the recession-recovery episode. We explored this issue using quarterly US manufacturing gross job flows and employment data for the 1972–93 period, and found that, along the recovery path, job destruction declines and falls below average for a significant amount of time, more than offsetting its initial peak. On the other hand, job creation recovers, but it does not exceed its average level by any significant extent to offset its initial decline. As a result, our evidence indicates that, on average, recessions depress restructuring.

Similarly, in Caballero and Hammour (2001) we approached the question of the pace of restructuring over the cycle from the perspective of corporate assets. Studying the aggregate patterns of merger and acquisition (M&A) activity and its institutional underpinnings, we reached a conclusion that also
amounts to a rejection of the liquidationist perspective. Essentially, a liquidationist perspective in this context would consider fire sales during sharp liquidity contractions as the occasion for intense restructuring of corporate assets. The evidence points, on the contrary, to briskly expansionary periods characterized by high stock market valuations and abundant liquidity as the occasion for intense M&A activity.

Recent evidence on institutional impediments to creative destruction and their cost

For all practical purposes, some product or process innovation is taking place at every instant in time. Absent obstacles to adjustment, continuous innovation would entail infinite rates of restructuring. What are these obstacles to adjustment? The bulk of it is technological – adjustment consumes resources – but (over-) regulation and other man-made institutional impediments are also a source of depressed restructuring.

While few economists would object to the hypothesis that labour market regulation hinders the process of creative destruction, its empirical support is limited. In Caballero et al. (2004) we revisited this hypothesis using a sectoral panel for 60 countries. We found that job security provisions – measured by variables such as grounds for dismissal protection, protection regarding dismissal procedures, notice and severance payments, and protection of employment in the constitution – hamper the creative destruction process, especially in countries where regulations are likely to be enforced. Moving from the 20th to the 80th percentile in job security cuts the annual speed of adjustment to shocks by a third. By impairing worker movements from less to more productive units, effective labour protection reduces aggregate output and slows down economic growth. We estimated that moving from the 20th to the 80th percentile of job security lowers annual productivity growth by as much as 1.7 per cent.

Similarly, the idea that well-functioning financial institutions and markets are important factors behind economic growth is an old one. The process of creative destruction is likely to be a chief factor behind this link. In Caballero, Hoshi and Kashyap (2006) we analysed the decade-long Japanese slowdown of the 1990s and early 2000s. The starting point of our analysis is the well-known observation that many large Japanese banks would have been out of business had regulators forced them to recognize all their loan losses. Because of this, the banks kept many zombie firms alive by rolling over loans that they knew would not be collected (evergreening). Thus, the normal competitive outcome whereby the zombies would shed workers and lose market share was thwarted. Using an extensive data-set, we documented that roughly 30 per cent of firms were on life support from the banks in 2002 and about 15 per cent of assets resided in these firms. The main idea in our article is that the counterpart to the congestion created by the zombies is a reduction in profits for potential and more productive entrants, which discourages their entry. We found clear evidence of such a pattern in firm-level data and of the corresponding reduced restructuring in sectoral data.

Bertrand, Schoar and Thesmar (2004) further drive home the point that problems in the banking sector can have grave consequences for the health of the restructuring process. They use a differences-in-differences approach on firm-level data for the period 1977–99 to analyse the impact of the banking reforms of the mid-1980s on firm and bank behaviour. These reforms eliminated government interference in bank lending decisions, eliminated subsidized bank loans, and allowed French banks to compete more freely in the credit market. They find that, after the reforms, firms' exit rates and asset reallocation rise, and are more correlated with performances.
International competition is an important source of creative destruction. Trefler (2004) concludes that there are significant productivity and reallocation effects from trade openness, even in industrialized economies. To reach this conclusion, Trefler takes advantage of the Canada–US Free Trade Agreement (FTA) to study the effects of a reciprocal trade agreement on Canada. He finds that, for industries that experienced the deepest Canadian tariff reductions, the contraction of low-productivity plants reduced employment by 12 per cent while raising industry-level labour productivity by 15 per cent. Moreover, he finds that at least half of this increase is related to exit and/or contraction of low-productivity plants. Finally, for industries that experienced the largest US tariff reductions, plant-level labour productivity soared by 14 per cent. Consistent with this evidence, Bernard, Jensen and Schott (2006) find that in the United States productivity growth is fastest in industries where trade costs (barriers) have declined the most.

Domestic deregulation of goods markets can have similar effects. For example, Olley and Pakes (1996) find that deregulation in the US telecommunications industry increased productivity predominantly through factor reallocation towards more productive plants rather than through intra-plant productivity gains. More broadly, Klapper, Laeven and Rajan (2004) study the effect of entry regulation on firm behaviour in a sample including firm-level data from countries of western and eastern Europe. Their findings support the notion that regulation affects entry: ‘naturally high-entry’ industries have relatively lower entry in countries that have higher entry regulations. Moreover, both the growth rate and share of high-entry industries are depressed in countries with more stringent barriers to entry. Finally, Fishman and Sarria-Allende (2004) extend the Klapper, Laeven and Rajan study to countries outside Europe and include both industry- and firm-level data from the UNIDO and WorldScope databases, and reach similar conclusions.

Final remarks

Evidence and models coincide in their conclusion that the process of creative destruction is an integral part of economic growth and fluctuations. Obstacles to this process can have severe short- and long-run macroeconomic consequences.

The concept of a general purpose credit card originated in 1949, when Frank McNamara dined in a New York restaurant and discovered that he could not pay for his meal (Evans and Schmalensee, 1999). By the 1980s credit cards had become ubiquitous, and they remain a popular form of payment in most economies. Banks offer cards, setting terms such as interest rates and annual fees. Transactions are handled by networks such as Visa and MasterCard, which emerged in the 1970s as joint member associations. Early research examining the market typically focused on the retail level, while more recent work has tended to focus on the network level, mirroring a shift in policy concerns in the 1980s. In its early years the US retail credit card market was characterized by extreme interest rate ‘stickiness’ – credit card rates remained virtually constant over time, regardless of economy-wide changes in interest rates. Credit card issuers also appear to have earned super-normal profits during the same period. This presents a puzzle in an industry displaying many classic characteristics of a perfectly competitive market (Ausubel, 1991). Ausubel suggests a variety of explanations for this puzzle, including the possibility that credit card borrowers do not fully anticipate the degree to which they will use the cards. Ausubel's research spurred a wave of subsequent work proposing explanations for interest rate stickiness. Mester (1994) and Brito and Hartley (1995) provide theoretical explanations for interest rate stickiness based on asymmetric information or consumer transaction costs. Calem and Mester (1995) provide empirical evidence that consumer search and switching costs might explain interest rate stickiness. A complementary explanation for interest rate stickiness is that state-level interest rate ceilings during the 1980s facilitated tacit collusion among card issuers, leading to greater-than-normal interest rate stability (Knittel and Stango, 2003). By the early 1990s interest rates had become much more flexible as credit card issuers switched to...
variable interest rates. By most accounts, the market also became more competitive during this time. One explanation for the change is technological progress that allowed more efficient credit scoring by large nationally marketed card issuers, creating a truly national market that fostered aggressive competition. Other explanations include the threat of interest rate regulation and the entry of new issuers. At the network level, the key economic issue is that payment card systems like MasterCard and Visa are two-sided markets: they have to attract cardholders to get merchants and merchants to get cardholders. Diners Club did this in 1950 by initially giving away cards to consumers and charging merchants seven per cent of their bill. These days, consumers obtain rewards for using their cards. This structure of pricing has raised the concern of some policymakers. In their view, retailers pay too much to accept credit cards, costs that end up being covered by consumers who do not use credit cards (by way of higher retail prices). Card associations sustain such a price structure through the setting of an interchange fee, which determines how much the merchant's bank must pay the cardholder's bank for each card transaction. A high interchange fee results in a high merchant fee and a low (or negative) fee for cardholders.

The issue of how much to charge each type of user is a common one in other two-sided markets. Magazines and newspapers decide how much to charge readers versus advertisers, and shopping malls decide how much to charge shoppers versus shops. The interest of policymakers in credit cards has spurred research in two-sided markets more generally. Baxter (1983) provides an early analysis of interchange fees (see Rochet, 2003, for a survey). His key insight is that efficiency calls for card transactions whenever the joint benefits to the consumer and merchant of using the card exceed the joint costs of doing so. In the absence of an interchange fee, each type of user will face only the private costs and benefits of cards. A payment from the merchant's bank (acquirer) to the cardholder's bank (issuer) via the interchange fee can align the private incentive to use cards with the social incentive. This provides a justification for setting an interchange fee, but does not imply that card associations will set it at the right level.

One reason a card association might set the interchange fee too high is that acquirers may pass through a larger proportion of interchange fees into merchant fees than issuers pass back to cardholders (in the form of lower fees or higher rewards). Then associations will want to pass revenues to the issuing side, via high interchange fees, where they are competed away less aggressively. A second possible reason is that, if merchants accept cards to attract customers from each other, their private willingness to accept cards includes the surplus their customers get from using cards. As a result, cardholder surplus is over-represented, and card associations tend to charge merchants too much and cardholders too little. Although these theoretical possibilities highlight possible divergences between privately and socially optimal interchange fees, they provide no basis for the cost-based regulation of interchange fees.

credit cycle

P. Bridel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

It was with the post-First World War attempts to integrate marginalist value and monetary theory that theorists started pondering the possible (in Hayek's words) ‘incorporation of cyclical phenomena into the system of economic equilibrium theory’. Hayek's own ‘intertemporal equilibrium’ approach overturned the traditional view of cycles as temporary deviations from long-period equilibrium conditions. But the publication of Keynes's *General Theory* redirected research efforts towards the determination of output at a point in time. Since the late 1960s, with the search for ‘microfoundations for macroeconomics’, this line of thought has been back on the theoretical agenda.

Article

Prior to Keynes's *General Theory*, the resolution of the question why, in capitalist economies, aggregate variables undergo repeated fluctuations about the trend was regarded by economists as a main challenge for the profession. What was then called business (or trade) cycle theory grew quite independently from the classical and subsequently neoclassical corpus of price theory. In fact, for all economists, a clear-cut distinction existed between the long-run forces at work in an economy – the subject of a rigorous value and distribution theory – and the more or less ad hoc explanations of the short-run oscillations around such an (equilibrium) centre of gravity. Of course, from Ricardo and Thornton down the 19th century to Overstone and Mill, money and credit played a substantial, but independent, part in these exogenous
explanations of the business cycle. Along the same line, the founding fathers of marginalism (in particular Walras, Marshall and Jevons) failed to coordinate, even in a remotely satisfactory way, money and trade cycle with their then novel price theory.

Following Wicksell's and Mises's lead, it is only with the post-First World War attempts to integrate marginalist value and monetary theory that theorists started pondering the possible ‘incorporation of cyclical phenomena into the system of economic equilibrium theory’ (Hayek, 1929, p. 33n.). The rediscovery of Tooke's (1844) income approach to the quantity theory of money is probably one of the earliest stepping-stones in the development of credit-cycle theories. This line of thought suggests that the explanation of money prices should start not from the quantity of money but from nominal income. Though another way of writing a Marshallian cash balance equation, Wicksell's (1898, p. 44) or Hawtrey's (1913, p. 6) emphasis on the ‘aggregate of money income’, on how it varies, is expanded or held, is a crucial turning-point on the road towards an analysis in terms of income, saving and investment. This shift of emphasis, together with the simultaneous progress in monetary theory proper (notably the development of a comprehensive and integrated monetary theory of interest), the 1914–18 inflationary episode and the post-war cyclical upheavals provided in the 1920s and 1930s the right intellectual stimulus for credit-cycle theories to grow and multiply.

Explicitly or implicitly, to tackle this issue, Continental economists (for example, Mises, Cassel, Hayek, Schumpeter and Aftalion), members of the Cambridge School then dominating in England (Keynes, Robertson, Pigou, Hawtrey), Fisher and Mitchell in the United States all used the common analytical framework established jointly by Walras, Menger, Marshall and Jevons. This is made up of two basic (though familiar) propositions: on the one hand, there is an inverse relation between the volume of investment and the rate of interest (that is, a downward-sloping investment demand curve) and, on the other, despite short-run ‘frictions’, the interest rate is assumed to be sensitive enough to divergences between investment decisions and full employment saving.

The central theme of this argument (first expressed with great clarity in Wicksell's cumulative process) is that the market rate of interest oscillates in the short run around a natural rate of interest determined in the long run by the supply of and the demand for capital as a stock, which, in turn, guarantees the equality between planned investment and full employment saving. Once this logic is understood, it then emerges that the entire development of interwar trade-cycle theories took place within the second proposition outlined above; namely, that, in the long run, the interest rate is assumed to be sensitive enough to divergences between investment decisions and full employment saving. Hence, since the twin concepts of an interest-elastic demand curve for investment and natural rate of interest were never called into question, the orgy of debates that took place in the 1920s and 1930s was conducted in terms of an analysis of various short-run forces which temporarily keep at bay the long-run forces of saving and investment.

These forces are, of course, of multiple nature. Of particular interest to interwar economists, and one of the essential features of business cycle, with its recurrence of upswings and downswings, is a credit cycle, an alternation of credit expansion and credit contraction. But it was assumed neither that an alternation of prosperity and depression would not exist in a barter economy (or in a purely specie system) nor that cycles could be viewed as functions of monetary factors only.

In fact, and thanks to their common capital theory, none of the leading interwar credit cycle theorists fell into either of these traps. Even Hawtrey who, with remarkable consistency kept claiming that business cycles are a purely monetary phenomenon, had clearly in mind a Wicksell-like cumulative process.
credit cycle: The New Palgrave Dictionary of Economics

derived from Marshall's oral tradition in monetary theory. This common theoretical background and a deep interest in a then fast-developing monetary theory make similarities between credit cycle theorists sufficiently pronounced to entitle us to speak of a single monetary theory [of the cycle], the votaries of which disagree on one issue only: whether bank-loan rates act primarily on ‘durable capital’ [Keynes, Robertson, Hayek] or via the stocks of wholesalers [Hawtrey]. (Schumpeter, 1954, p. 1121)

In 1913, Hawtrey was amongst the first to provide a detailed analysis of the financial working of the cumulative process in an Anglo-Saxon environment. However, even if his theory usefully describes the ways in which money and credit behave in the cycle, the main weakness of his contribution is, of course, its almost exclusive emphasis on dealers' stocks in the course of a credit cycle. If Hawtrey does not deny altogether that a credit expansion/contraction has an influence on the volume of investment, he holds it however to be unimportant when compared with the direct influence on the wholesalers' stocks. He then logically disputes the existence of forced saving on the very ground of this availability of stocks and fails completely to link his credit cycle theory with the dominant Marshallian capital theory. Such a model led Hawtrey not only to give Bank Rate the crucial part to play in any counter-cyclical policy but also to consider its fluctuations as the only explanation of cyclical fluctuations. To sketch British interwar depressions as almost exclusively functions of Bank Rate (itself a function of Britain's absorption of gold) is a rather bold simplification Hawtrey was never quite ready to abandon.

If the theoretical apparatus underlying the Treatise on Money proceeds from the same logic, Keynes's fundamental equations introduce, however, a number of very sophisticated and new variations on the basic credit-cycle theme. In particular, causes of credit cycles are of non-monetary nature (they result from fluctuations in the rate of investment relative to the rate of saving), the influence of Bank Rate on investment is not limited ‘to one particular kind of investments, namely, investments by dealers in liquid goods [stocks]’ (Keynes, 1930, vol. 1, p. 173), the cumulative process includes a theory of the demand for money beyond the traditional income motive (that is, an early version of liquidity preference), and, in the short run, there is no longer a direct relation between the quantity of money/credit and the price level: monetary or credit changes do not foster ipso facto a forced/abortive saving process. Despite the higher degree of sophistication shown in the Treatise, in a classic chapter on the modus operandi of the Bank Rate, Keynes displays bold confidence in this mechanism to smooth any credit cycle, to fill the gap between saving and investment and to correct all temporary monetary divergences from the long-run full employment equilibrium. However, Keynes's disaffection with the forced saving doctrine and the purely static nature of his fundamental equations drew sharp criticisms from Robertson and Hayek. Though from different standpoints, they both considered Keynes's credit cycle analysis as no more than an attempt to spell out the appropriate banking policy which could maintain a monetary equilibrium. In particular, Keynes's version of the credit cycle lacked, for the former, a proper sequential stability analysis and, for the latter, an explicit integration with capital theory.

Along lines very similar to Keynes's and, up to the late 1920s, in close cooperation with him, Robertson worked out a detailed sequential analysis of the interdependence of real and monetary magnitudes during the cycle. But clearly, for him, the cycle results from over-investment, this tendency to over-invest being a typical feature of decentralized economies stemming from the repercussions on the volume of investment of its gestation period. However, the largest part of Robertson's professional
output was devoted to studying the monetary or credit symptoms of such economic fluctuations, that is, how banks may respond to an increased demand for credit during expansion. This led Robertson to a redefinition of the concept of saving in a monetary economy and to the rôle of this new concept in the cycle. This approach was linked with a sequential analysis of the lagged adjustments of output to monetary flows. In the ‘forced saving’ debate, central to all credit cycle theories, and contrary to Hayek who considered it as the villain of the piece, Robertson saw that phenomenon as only a relatively minor component of his theory, the factors at the root to his ‘credit inflation’ being the real cause of this expansion. Dragged among others by Keynes into endless discussions in the realm of monetary and interest theory, Robertson never managed however to offer an articulate and full-blown version of his theory of industrial fluctuations. In particular, the problem of the alteration in the structure of production, a question forming the core of Hayek's cycle theory, never received more than passing comment.

Grounded of course in the Austrian tradition and Wicksell's cumulative process (first extended by Mises, 1912, and Cassel, 1918), the distortion of the production time structure is absolutely central to Hayek's monetary cycle theory. The divergence between ‘natural’ and market rates of interest is linked by Hayek to the variability in forced saving and considered as the cause of cyclical fluctuations. Hayek's ‘additional credit’ theory places the cause of this gap between these two rates upon newly created money. The increase in loan capital resulting from a ‘trailing market rate’ makes investment surpass voluntary saving: a cumulative expansion results. Such an increase in investment alters the relative prices of capital and consumer goods in favour of the former. The increased output of capital goods distorts the production time structure. At a later stage, higher factor incomes drive up the demand for consumption goods, which through increased withdrawals from bank accounts will raise the market rate of interest and, finally, make some investment unprofitable. Then, the turnabout that takes place in the cycle brings a change in the other direction in the production structure, this time in favour of consumer goods. Clearly, crises are caused by over-investment, that is, by a decline in the desire to purchase the flow of capital goods coming on the market. The reversal of the process initiated by credit inflation does take place (as in most credit cycle theories) whenever the market rate catches up with prices; and since, sooner or later, banks run up against the limits set to their lending by their reserves, this process cannot be explosive (Fisher, 1911, also noticed, at least in his earliest writings, this stabilizing influence of the banking system).

Hayek's credit cycle theory thus marks a real break with what had come before. The theory of money is no longer a theory of the value of money ‘in general’ because relative prices may be changed by monetary influences and the Wicksellian full-employment assumption is dropped. The specific task of the trade cycle theorist is, for Hayek, to analyse short-period positions of the economy ‘in successive moments of time’ (1941, p. 23). The adoption of such an ‘intertemporal equilibrium’ approach to cycles (conceptually not different from modern temporary equilibrium) marks not only a crucial methodological turning point, but also the swan song of credit cycle theories.

On the one hand, this new method of ‘intertemporal equilibrium’ heralds the abandonment of the traditional framework in which cycles (defined as short-run disequilibria) are seen as temporary deviations from long-period equilibrium conditions determined by systematic and persistent forces at work in decentralized economies. In the present case, the ‘natural’ rate of interest determined in the long run by the supply of and the demand for capital is no longer the norm towards which the system is tending. It is in fact a property of such an ‘intertemporal equilibrium’ that not only will the price of the
same commodity be different at different points in time but also that the stock of capital will not yield a uniform ‘natural’ rate of interest on its supply-price.

On the other, the publication of Keynes's *General Theory* redirected research efforts away from this question into the problem of the determination of output at a point in time. It is only since the late 1960s, with the search for ‘microfoundations for macroeconomics’, and the subsequent advent of rational expectations and non-Walrasian equilibria, that this line of thought has been back on the theoretical agenda. However, given the extreme complexity of the problem and the relative crudeness of models still in their infancy, progress has so far been very modest.

Credit rationing – a situation in which lenders are unwilling to advance additional funds to borrowers at the prevailing market interest rate – is now widely recognized as a problem arising because of information and control limitations in financial markets. This article reviews various motivations behind research on credit rationing, traces the history of theoretical efforts to explain how this phenomenon can persist in equilibrium, and reviews recent empirical research on its prevalence and effects. In the process, credit rationing is shown to be simply an extreme case of the more general problem of capital market misallocation.

Article
Broadly speaking, ‘credit rationing’ refers to any situation in which lenders are unwilling to advance additional funds to a borrower even at a higher interest rate. In the words of Jaffee and Modigliani (1969, pp. 850–1), ‘credit rationing [is] a situation in which the demand for commercial loans exceeds the supply of these loans at the commercial loan rate quoted by the banks’. Key to this definition is that changes in the interest rate cannot be used to clear excess demand for loans in the market. In essence, this definition treats credit rationing as a supply side phenomenon, with the lender's supply function becoming perfectly price inelastic at some point.
If the projects that are being funded by the loan are not scalable, however, then a distinction must be
made between a situation in which a lender eventually restricts the size of loan it will provide to any individual borrower and one in which ‘rationed’ borrowers are denied credit altogether. This phenomenon arises in circumstances in which lending is not scalable. Stiglitz and Weiss (1981, pp. 394–5) therefore define credit rationing as follows:

We reserve the term credit rationing for circumstances in which either (a) among loan applicants who appear to be identical some receive a loan and others do not, and the rejected applicants would not receive a loan even if they offered to pay a higher interest rate; or (b) there are identifiable groups of individuals in the population who, with a given supply of credit, are unable to obtain loans at any interest rate, even though with a larger supply of credit, they would.

According to this definition, lenders fully fund some borrowers but deny loans to others despite the fact that the latter are identical in the lender's eyes to those who receive loans. Thus, there are two working definitions of credit rationing in the literature. The first focuses on situations in which increases in the interest rate cannot clear excess demand in the loan market, whether this excess demand reflects a single borrower (who would like a larger loan amount) or many. Under this definition, rationing would exist if every potential borrower received a loan but a smaller one than that desired at the equilibrium interest rate. The second definition – the Stiglitz–Weiss definition – restricts its attention to situations in which some borrowers are completely rationed out of the market, even though they would be willing to pay an interest rate higher than that prevailing in the market. Both of these definitions focus on the supply side of the market. One could argue, however, that it is useful to think of non-price rationing as any phenomenon that limits the amount of funding used by firms such that firms are not able to use the price mechanism to successfully bid for additional funds, whether this is caused by supply-side constraints (as under the narrow definitions of credit rationing described above) or by other distortions in credit markets (related, for example, to regulation). This would allow a broader definition of ‘credit rationing’ in which regulatory constraints, rather than just informational problems, lead to non-price allocations of credit.

**Why care about credit rationing?**

Early interest in credit rationing was driven in part by questions about the role that credit rationing might play in transmitting the macroeconomic effects of monetary policy, which was related to research on the so-called ‘availability doctrine’ in the 1950s and 60s (Scott, 1957). To the extent that monetary policy operates through a ‘credit channel’ (in which contractionary policy affects the economy through a decline in the supply of funds available for banks to lend), and to the extent that changes in the terms of lending include not only changes in loan pricing but also changes in the quantities of credit available to borrowers, credit rationing may play an important role in the transmission of monetary policy’s effects on the economy (Blinder and Stiglitz, 1983). In addition to the cyclical effects of rationing in credit markets related to monetary policy, development economists, especially Ronald McKinnon (1973), argued that a different credit rationing problem is more relevant for the long-term growth prospects of developing countries. High inflation, high zero-
interest reserve requirements, government-mandated loan allocations to favoured borrowers, and interest rate ceilings on loans or deposits in developing economies (a combination which McKinnon termed ‘financial repression’) subjected many developing countries' banking systems to an extreme form of regulation-induced credit rationing. High reserves, high inflation, and interest ceilings on deposits meant that banks were rationed in the deposit market, and thus had few funds to lend, while lending mandates and loan interest-rate ceilings meant that what funds were available to lend were often rationed by restrictions on who could bid for those funds.

Additionally, George Akerlof (1970), in his path-breaking article on the role of adverse selection in preventing market development, drew attention at an early date to the possible effects of information problems in retarding the development of lending markets, particularly in developing countries. In an ideal world, in the absence of any government policies limiting beneficial lending, all borrowers with positive net present value projects would be able to obtain outside funding (whether through debt or equity instruments, or bank or non-bank sources of funds). But Akerlof showed that, if markets were unable to distinguish good risks from bad ones, lending might not be feasible. The failure to develop institutions capable of producing credible information about borrowers and using that information to screen applicants could, according to Akerlof, play an important role in financial underdevelopment.

Many development economists have come to recognize that the failure to properly allocate funds in the loan market – a broad phenomenon, within which credit rationing is a special and extreme case – can be an especially important potential impediment to growth in developing countries because of the relative absence of institutions in those countries that allow effective screening of borrowers (to mitigate adverse selection) or ongoing monitoring of borrowers’ actions (to mitigate moral hazard).

An additional motivation for an interest in credit rationing comes from the literature on bank fragility. Credit rationing can also apply to the market in which financial intermediaries raise their funds. Financial institutions go to great pains to attract and maintain deposits through (a) the structure of their contracts (which typically afford withdrawal options to depositors), (b) their long-term relationships with market monitors who track their progress, and (c) their established reputations for good management. But sometimes the market suddenly decides to ration credit to a particular bank or to the whole banking system; and when this happens the affected banks find it hard to attract and maintain deposits at any price. Thus, the literature on ‘bank runs’ as an historical phenomenon can be thought of as a literature on credit rationing in the markets in which financial institutions raise their funds. Depositors that decide to participate in a bank run ration credit to their bank in the sense that the decision to withdraw is a quantity, not a price, decision. They are simply unwilling to leave their money in the bank.

Finally, much of the current research on discrimination in credit markets is driven by evidence that black and Hispanic minority loan applicants are denied more frequently than comparable whites (for example, Munnell et al., 1996; Cavalluzzo and Cavalluzzo, 1998; Cavalluzzo and Wolken, 2005). Of course, this begs the question of why borrowers are denied loans in the first place, rather than simply priced according to their risk. In other words, understanding why there are differences in denial rates across groups necessarily entails exploring why rationing (loan denial) occurs.

The development of credit rationing theory

Early views on credit rationing
The earliest discussions of credit rationing viewed it as a non-equilibrium phenomenon, arising either because of exogenous interest rate rigidities (for example, interest rate ceilings or usury laws) or because of a lack of competition in the loan market (Scott, 1957). Soon authors made a distinction between temporary credit rationing, in which market interest rates are slow to adjust to exogenous shocks such as changes in the lender's cost of funds or borrower demand, and 'equilibrium' credit rationing, which persists after the market has fully adjusted to these shocks. Clearly the more interesting and difficult to explain phenomenon is equilibrium credit rationing.

Hodgman (1960) was the first to try to explain how credit rationing can persist in a rational, equilibrium framework. In this model, lenders evaluate potential borrowers on the basis of the loan's expected return–expected loss ratio. In addition, it is assumed to there is a maximum repayment that the borrower can credibly promise, which effectively limits how much the lender will offer the borrower regardless of the interest rate: eventually the expected losses become too great relative to the expected return. This model was much debated in the ensuing years. In particular, Miller (1962) argued that Hodgman's analysis could be made consistent with rational expectations between the borrower and lender by incorporating bankruptcy costs that would be incurred by the lender upon the borrower's default. The real significance of the Hodgman article, however, was that it established as an important theoretical goal the objective of explaining how credit rationing could persist as an equilibrium phenomenon.

Freimer and Gordon (1965) resolved many of the issues regarding the structure of the Hodgman and Miller models by showing that credit rationing can occur with a risk-neutral lender if the borrower has a fixed-sized funding need. But this was done assuming an exogenous interest rate. Jaffee and Modigliani (1969) completed the picture by endogenizing the equilibrium interest rate by modelling both the supply and demand sides of the market. Credit rationing in their model, however, is the direct result of an exogenous assumption that borrowers within a given group must be charged the same interest rate, even though the lender can distinguish differences among them.

This early work was important in that it firmly established the idea that credit rationing could be a persistent equilibrium phenomenon. Ultimately, however, the solutions proposed relied on very restrictive assumptions about agent preferences or the contracts they could employ. More satisfactory explanations of credit rationing had to wait for the information economics revolution of the 1970s.

**Modern credit rationing theory**

Akerlof's (1970) pioneering article on adverse selection was motivated in part by the desire to explain extreme cases of credit rationing (the absence of a credit market), but Jaffee and Russell (1976) provide the first explicit asymmetric information rationale for credit rationing in the general sense. In their model, lenders cannot distinguish *ex ante* between high- and low-quality borrowers (that is, those who will repay their loans and those who will default). Contracts are written to determine the size of the loan offered and the interest rate. As in the Rothschild–Stiglitz (1976) insurance framework, low-quality borrowers must accept the contract that is preferred by the high-quality borrowers, lest they be identified as the deadbeats they are. Although a market-clearing interest rate/loan amount combination does exist, high-quality borrowers prefer a contract that entails a slightly lower interest rate with a reduced loan amount. As a result, the pooling outcome entails credit rationing. The primary problem with this model
is that the ‘equilibrium’ is not stable, in that unsustainable separating contracts dominate the pooling outcome.

In 1981, Joseph Stiglitz and Andrew Weiss published what has become the canonical model of credit rationing, because it was the first model that fully endogenized contract choices with a stable, rationing equilibrium. In the Stiglitz–Weiss framework, credit rationing occurs because the lender's expected return is not monotonically increasing in the interest rate. Instead, adverse selection or moral hazard problems eventually cause the lender's expected return to decline as the interest rate rises.

In the adverse selection version of the model, borrowers and lenders are both risk neutral. Borrowers are characterized by their projects, which are assumed to have the same expected returns but differ from one another in their risk. Specifically, borrower projects differ on the basis of mean-preserving spreads (Rothschild and Stiglitz, 1970). These projects are also assumed to require a fixed investment (that is, they are indivisible) and borrowers have a fixed amount of internal equity that they can invest in the project. Limited liability upon default means that the lender's payoff is a concave function of the project's return, while the borrower's profit function is convex.

These assumptions imply that, at any given interest rate, a subset of the least risky borrowers will drop out of the market, choosing instead to forgo their projects. In essence, the borrower's limited liability means that he reaps all of the project's gain (beyond the cost of debt service) when its return is high, but loses his collateral (his paid-in capital invested in the project, if any) only when the project's return is low. For low-risk projects, however, the potential upside gains are small. If those low-risk borrowers are pooled with high-risk borrowers, they will face higher than warranted interest rates. Low-risk borrowers will increasingly withdraw from the market as interest rates rise; as rates rise, borrowers with low-risk projects are better off withdrawing from the market and simply consuming their endowments rather than agreeing to invest and pay a high interest rate. As a result, increases in the interest rate cause more and more good borrowers to drop out of the market, lowering the average creditworthiness of the lender's remaining applicant pool. The size of the adverse selection premium faced by low-risk borrowers (the amount of interest low-risk borrowers have to pay in excess of what their project risks warrant) becomes larger with each interest rate rise because the interest rate must compensate for the default risk of an ever-worsening pool of borrowers.

Thus, increases in the interest rate affect lender returns in two ways. The first is the direct effect that a higher interest rate raises the lender's return (for a given pool of borrowers). Rising interest rates, however, also have the indirect effect of lowering the average quality of the lender's applicant pool, thereby lowering the lender's expected return from any given loan. Eventually, this secondary, adverse selection effect may outweigh the first interest rate effect, causing lender profits to decline as the interest rate rises.

Once the non-monotonicity of the lender's return in the interest rate is established, the possibility of credit rationing follows immediately. Profit-maximizing lenders will never voluntarily choose to raise the interest rate beyond where the adverse selection effect dominates. If excess demand exists in the market at this rate, credit rationing will be the equilibrium.

Paradoxically, in this model the very best credit risks do not seek funding because they do not find it worthwhile. This may seem odd, but it is important to remember that these borrowers are not rationed. Instead, they voluntarily drop out of the market because the cost of being pooled with higher-risk borrowers is too great. The rationed borrowers are the higher-risk borrowers who stay in the market and request funding.
Alternatively, Stigliz and Weiss show how changes in the interest rate may also affect the borrower’s choice of project, so that moral hazard in project choice (sometimes referred to as ‘asset substitution’ in the finance literature) can be another reason that the lender’s expected return is non-monotonic in the interest rate. Suppose that the borrower is able to choose among projects with different risk profiles. If, at a given interest rate, the borrower is indifferent between two projects, Stiglitz and Weiss show that an increase in the interest rate will cause the borrower to prefer the project that has the higher probability of default. Of course, the lender prefers the safer project. Thus (with slightly more restrictive distributional assumptions than in the adverse selection case), increases in the interest rate once again can eventually lower the lender’s expected return, leading to credit rationing.

Models of credit rationing need not posit rationing for all borrowers. Realistically, some borrowers (certain firms for which information control problems are particularly acute) may be subject to rationing while other borrowers are not. Borrowers not subject to rationing may be able to avoid rationing because their prospects are more observable, or because their behaviour is more controllable.

**Bank runs as credit rationing**

The theoretical literature on credit rationing in the deposit market (bank runs) has some features that distinguish it from the literature on credit rationing in the loan market. The ultimate causes of deposit market rationing can be similar to, or very different from, the causes of loan market rationing. As discussed above, loan market rationing can reflect either information and incentive problems in the loan market or exogenous regulations. In the case of the deposit market, rationing can result either from incentive and information problems relating to the depositor–bank relationship or from exogenous liquidity needs of depositors.

With respect to the former, under some circumstances a bank run may reflect a loss of confidence in the market value of the bank’s asset portfolio and changes in bank behaviour that attend such a loss. If the value of the portfolio falls sufficiently, and if the information and incentive problems are sufficiently severe, the perceived risk of losses in the bank can prompt depositors to ask for their money back because depositors have reason to be risk-intolerant (that is, to be unwilling to leave their money in a bank that has too high a level of risk). An example of such a model is Calomiris and Kahn (1991). Here the depositor withdraws funds in bad states of the world because doing so is necessary to prevent the banker from abusing his control over the bank’s portfolio.

An alternative cause of credit rationing in the deposit market is a shock to the liquidity needs of depositors, which forces depositors to demand their funds from their banks irrespective of the portfolio performance of the banks. Diamond and Dybvig (1983) is an example of a model of this phenomenon. Bank depositor runs are but one specific example of how financial intermediaries may be credit rationed due to creditor risk intolerance and/or liquidity shocks. During the 1998 Russian financial crisis, for example, it was widely reported that many emerging market hedge funds dumped their holdings of risky securities of all kinds in a scramble to reduce their risks and thus re-establish the high-quality credit ratings needed to retain their debtors. Intermediaries were also scrambling to accumulate liquidity, as many of their claimants needed to withdraw funds to meet other obligations related to the financial market upheaval.
Credit rationing as a problem of information and control (as it was modelled by Jaffee and Russell, 1976, and Stiglitz and Weiss, 1981) is properly seen as an extreme case of the more general phenomenon of capital market misallocation, which includes cases where capital is misallocated (due to adverse selection and moral hazard) without any rationing occurring. It is important to recognize that, from the standpoint of either cyclical concerns about the transmission of monetary policy or developmental concerns about the efficiency of the allocation of capital, the important phenomenon is not rationing per se but rather the extent to which the market fails to allocate resources efficiently. Even a market that never suffers from credit rationing can be highly inefficient in its allocation of capital. In that sense, credit rationing may be somewhat beside the point. Indeed, the corporate finance literature is full of examples of models of market imperfections involving moral hazard and adverse selection in which credit is misallocated, and in which positive net present-value projects are not funded or negative net present-value projects are funded.

In some cases, firms may even be priced out of the market for funds entirely, so that they avoid funding profitable investments. For example, Jensen and Meckling (1976) show that the potential for asset substitution at the expense of creditors can make it much more costly for firms to access debt markets. Indeed, asset substitution can make it prohibitively expensive to issue debt. Note that this is not a case of credit rationing as defined by Stiglitz and Weiss, since suppliers are not refusing credit. Rather, the high asset substitution premium that firms would be charged if they sought credit can result in a decision by the firm not to fund a positive net present-value investment. Similarly, Myers and Majluf (1984) show that because of adverse selection problems – which are particularly acute in the public equity market – some firms may decide to avoid issuing equity to fund a positive net present-value investment. Here, again, a firm is not being rationed by suppliers, but is unwilling to seek financing because of its prohibitive pricing.

As the literature on capital market misallocations and credit rationing developed in the late 1970s and early 1980s, critics pointed out some limiting circumstances in which capital markets did not have a tendency to underfund positive net present-value projects. For example, both adverse selection and moral hazard problems can be overcome by sufficient collateral. By placing collateral at risk, a firm could signal its high quality, or commit itself not to abuse creditors by undertaking excessive risk (see Bester, 1985). Of course, collateral is not always available, nor is it costless to place collateral at risk. In the case of a limited liability enterprise, the firm's net worth limits its available collateral. Firms that can finance themselves from internal funds and limited amounts of low-risk debt can avoid the adverse selection and moral hazard costs associated with external finance, but young, growing firms tend to be in need of substantial amounts of external finance, far in excess of their accumulated net worth. If borrowers use all of their available ‘collateral’, then, on the margin, collateral cannot mitigate adverse selection or moral hazard problems.

In the consumer context, it is also important to recognize that the moral hazard and adverse selection problems that arise in corporate lending may differ in importance across the various areas of consumer lending. For example, moral hazard may be limited in the context of mortgage lending where actions destructive to the lender's interest are likely to harm the homeowner as well (consider inadequate protection against the risk of fire, for example). Furthermore, the modern use of credit scores and loan-
to-value ratios may make mortgage lenders more knowledgeable about an applicant’s true credit risk than the applicant himself, particularly if that applicant has significant equity invested in the house and lacks experience in the credit market (Calomiris, Kahn and Longhofer, 1994). Under such circumstances, the implications of adverse selection models (which depend on the superiority of the information of the borrower about his type) may be irrelevant, or even reversed. On the other hand, in the context of uncollateralized credit card borrowing based only on past credit records, unobservably high-risk borrowers (those who know that they are about to have major medical costs, lose their job, or become divorced) may have strong incentives to borrow, implying the possibility for severe adverse selection.

How is credit rationing measured empirically?

Although credit rationing is a widely discussed phenomenon, there is a surprising paucity of evidence confirming its existence. The key problem is that, while the concept of a credit-rationed borrower is easy to understand in theory, under each of the various models of credit rationing discussed above it is extremely difficult to measure ‘excess demand’ of individual borrowers or the similitude of borrowers’ creditworthiness.

Indirect methods

Jaffee and Modigliani (1969) attempt to infer the presence of credit rationing by measuring the proportion of new commercial loans originated at the prevailing prime rate and/or with very large loan sizes. The intuition they use is that prime and/or large borrowers have the lowest risk and are therefore the least likely to be rationed. As a result, a larger proportion of loans will go to these low-risk borrowers when credit rationing is severe. Jaffee and Modigliani use this proxy to see how market factors affect the prevalence of credit rationing. Of particular interest is their result that increases in the average commercial loan rate are associated with higher levels of rationing, which seems to confirm the appropriateness of their proxy for credit rationing.

Other authors have attempted to measure whether commercial loan rates are ‘sticky’ in response to changes in open-market interest rates. The idea here is that in most credit rationing models there is an implicit cap above which lenders will ration credit. As open-market rates rise, this cap is more likely to become binding, meaning that commercial loan rates will not fully respond to changes in open-market rates. Following this approach, a number of authors, including Goldfeld (1966) and Jaffee (1971), have found that commercial loan rates are, in fact, slow to adjust to changes in open-market rates, and offer this as evidence in support of credit rationing.

Berger and Udell (1992), however, provide convincing evidence that, although commercial-loan rate stickiness does occur, it does so in a fashion that is inconsistent with information-based credit rationing models. In particular, they find that nearly half of the observed loan rate stickiness occurs for loans made to borrowers who are exploiting a previously contracted bank loan commitment. Such borrowers are precluded from rationing by contract. Furthermore, they show that the fraction of loans made under commitment actually decreases during times of credit market tightness, exactly the opposite of what one would expect should credit rationing be an important phenomenon.
Direct methods

Other authors have attempted to directly measure credit rationing using survey data to identify ‘rationed’ borrowers. For example, Cox and Jappelli (1990) and Chakravarty and Scott (1999) use data from the Survey of Consumer Finances (SCF) in which households are directly asked whether they recently have been denied credit or been unable to obtain as much credit as they requested. Although these articles purport to measure how some outside factor affects the likelihood of being rationed, it is not clear that borrowers who self-report being denied credit have, in fact, been ‘rationed’ in the Stiglitz–Weiss meaning of the term. After all, their denial of credit could simply reflect a failure to properly select into the right risk class in order to be approved, or the fact that the borrower was simply uncreditworthy at any interest rate.

With regard to business lending, Cressy (1996) uses a sample of new businesses that opened accounts with a major British bank to ascertain whether credit rationing affects the likelihood of business survival. He concludes that firms self-select for finance based on the entrepreneur’s human capital, implying that no credit rationing is occurring.

One strand of the empirical literature on credit rationing, broadly defined, focuses on whether differential mortgage loan denial rates between white and minority borrowers constitutes evidence of discrimination (a much cited reference is Munnell et al., 1996; Ross and Yinger, 2002, provide an excellent review of this literature). Although the discrimination literature does not specifically focus on the question of whether borrowers are credit rationed, any conclusion that one group is denied loans at a greater rate than others after creditworthiness is controlled for would imply that a form of credit rationing is occurring. This ‘rationing’, however, is distinct from that in Stiglitz–Weiss because the borrowers are not observably identical, and the underlying cause of ‘rationing’ is either lender preferences (Becker, 1971) or some form of statistical discrimination (Calomiris, Kahn and Longhofer, 1994; Longhofer and Peters, 2005).

Evidence on ‘intermediary rationing’

In contrast to the limited evidence of traditional borrower credit rationing, there is a significant body of evidence supporting the idea that financial institutions are rationed by their depositors. In recent years, a large literature has developed examining the determinants of deposit withdrawal from individual banks, and a parallel literature has developed on systemic banking panics. These articles find that in circumstances where the condition of banks is perceived to have deteriorated, depositors withdraw funds rather than simply demand a higher interest rate on deposits (Calomiris and Mason, 2003; Calomiris and Wilson, 2004). The links between bank characteristics and deposit withdrawals observed in these and other similar studies suggest that deposit rationing is related to information and incentive problems, rather than just liquidity shocks to depositors, although such shocks may still play a role.

Final thoughts

It is worth noting that improvements in underwriting processes may have dramatically altered the
practical impact of credit rationing in recent years. The use of risk-based pricing in consumer lending, including credit card loans and mortgages, has become widespread, reflecting the increased ability of lenders to distinguish between borrowers with different risk profiles (see, for example, Edelberg, 2003; Chomsisengphet and Pennington-Cross, 2006). The same is true for commercial credit markets, in which instruments such as junk bonds, senior-subordinated securitization issues, and the like serve to provide financial market access to broader classes of instruments, borrowers and risks. As a result, ‘sorting’ among borrowers overall has increased, and today there is likely much less diversity in pools of ‘observably identical’ borrowers than there was when Stiglitz and Weiss first developed their model. While this suggests that in some markets credit rationing is a very different and perhaps less important phenomenon today than it once was, an important potential role remains for credit rationing, particularly as it pertains to financial allocations in emerging markets, the pricing of particularly opaque segments of the lending markets of developed economies, and the ways in which financial institutions may be rationed in response to shocks to their portfolios.

crime and the city

Yves Zenou
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Crime is unevenly distributed across space and tends to be concentrated in poor areas. Recent theoretical advances show that social interactions and peer effects can explain this pattern because of contagion effects and social multipliers. An individual is more likely to commit crime if his or her peers commit crime than if they do not. Recent empirical findings suggest that, indeed, social interactions and networks are key to understand criminal behaviour in cities.

Keywords

Article

Crime is defined as an act committed in violation of a law forbidding it and for which punishment is imposed upon conviction. Crime is, however, not evenly distributed across space as it tends to be concentrated in specific areas where people are generally poor and uneducated. In both the United States and Europe, the typical urban pattern is that large cities have higher crime rates than smaller cities, and poor, largely minority neighbourhoods experience higher crime rates than more affluent white neighbourhoods (Raphael and Sills, 2005). According to the United Nations Interregional Crime and Justice Research Institute, (see Alvazzi del Frate, 1997), the percentage of population who are victims of burglary in urban areas with more than 100,000 inhabitants over a five-year period (between 1992 and 1996) is: 16 for Western Europe, 24 for North America, 20 for South America, 18 for Eastern Europe, 13 for Asia and 38 for Africa. Another typical pattern common to both the United States and Europe is that ethnic minorities are overrepresented in criminal activities. In the United States, the proportion of 20–29-year-old black men directly in trouble with the law (in jail or prison or on probation or parole)
reached 23 per cent in 1989 (Freeman, 1999). There is, however, one notable difference. Since the mid-1980s, crime has declined in the United States but increased in Europe, especially in large urban areas (Blumstein and Wallman, 2000).

**Theories**

In the standard crime model (Becker, 1968), each individual has to implement a cost–benefit analysis in order to choose between becoming a criminal and participating in the labour market. The cost is the severity of punishment, which obviously depends on the probability of being arrested. The benefit consists in the proceeds from crime. If crime is localized, then criminals will trade off a lower probability of being arrested (since, in some areas, a host of criminals are active and the number of policemen is not sufficient) against lower proceeds from crime (more criminals also imply less booty).

In this context, Sah (1991) examines the influence of the social environment on individuals’ perceptions of the probability of arrest. Indeed, people develop their ideas about the relative benefits and costs of crime based on the observations they make every day. If a person lives in an area with a high crime rate, and particularly if the criminals are seen to be relatively successful, then that person is more likely to engage in criminal activity. The main result of this paper is that individuals in some areas tend to commit more crime than the Beckerian model would predict because of the gap between the perceived and the real cost of committing crime, which leads to a lower sense of impunity based on the information provided by their criminal friends.

Another approach (Verdier and Zenou, 2004) proposes that distance to jobs plays a role in crime behaviour and provides a unified explanation for why blacks commit more crime, are located in poorer neighbourhoods and receive lower wages than whites. The mechanism is as follows. If everybody believes that blacks are more prone to crime than whites, even if there is no basis for this, then blacks are offered lower wages and, as a result, locate further away from jobs. Because distant residence implies more tiredness and higher commuting costs, the black–white wage gap is widened further. Blacks have thus a lower opportunity cost of committing crime (lower outside option) and become indeed more criminal than whites. The loop is closed and the beliefs are self-fulfilling.

Whereas the standard Beckerian approach focuses on individual behaviour, Glaeser, Sacerdote, and Scheinkman (1996) stress the role of peers and social interactions in criminal activities, especially in urban areas because of the high variance in crime rates. Two types of individuals are assumed: those who, as in the standard model, base their crime decision on a cost–benefit analysis, and those who only imitate their neighbours. Because of these social interactions, the benefits from crime are greater than in the Beckerian model. Moreover, if these interactions are localized (as is usually the case), then it becomes easy to explain very high levels of crime in some areas of the city. Indeed, if there are already a lot of criminals in a particular location, then crime becomes ‘contagious’ by spreading like a virus and amplifies the number of criminals in this location. There are social multiplier effects through a feedback loop: negative social behaviour such as crime leads to more negative social behaviour.

Calvó-Armengol and Zenou (2004), and Ballester, Calvó-Armengol and Zenou (2004) propose a model along these lines but represent social interactions in terms of a social network of criminal friends. People in a network not only imitate but also influence each other. Here, the cost of committing crime is reduced thanks to the network of friends. Indeed, delinquents learn from other criminals belonging to the
same network how to commit crime in a more efficient way by sharing the know-how about the ‘technology’ of crime. They show that the influence of peers on the individual’s criminal activity depends on his or her position in the network, and each agent’s criminal effort is proportional to his or her Bonacich centrality measure (see Bonacich, 1987). For a given network, the Bonacich network centrality counts, for each agent, the total number of direct and indirect paths of any length in the network stemming from this agent. Such paths are weighted by a geometrically decaying factor (with path length). In other words, the ‘location’ of each individual in a network of friends, as measured by the Bonacich centrality measure, is a key determinant of his or her criminal activity.

As a result, in a spatial or social context, an efficient policy aiming at reducing crime would not be, as in the Beckerian model, to increase at random the cost of committing crime, but rather to target criminals according to their location in the urban or social space. Ballester, Calvó-Armengol and Zenou (2004) propose a policy that consists in finding and getting rid of the key player, that is, the criminal who, once removed, leads to the highest aggregate crime reduction. They show that the key player is not necessarily the most active criminal (that is, the one with the highest Bonacich centrality). Indeed, removing a criminal from a network has both a direct and an indirect effect. The direct effect is that fewer criminals contribute to the aggregate crime level. The indirect effect is that the network topology is modified, and the remaining criminals adopt different crime efforts. The key player is the one with the highest overall effect.

**Empirical studies**

One of the first tests of the Becker model was undertaken by Ehrlich (1973), who used as explanatory variables the imprisonment rate and the average sentence for the crime in question. More recently, the focus has been on urban or social problems because this is particularly fruitful for understanding personal and property crime as opposed to white-collar crime. Cullen and Levitt (1999), using data for 137 US cities from 1976 to 1993, explore the relationship between crime and urban flight (that is, the flight of the white population from city centres to suburbs). They find that each additional reported crime in city centre is associated with a net decline of about one resident. Causality runs from rising crime rates to city depopulation. Pursuing this area of research, Glaeser and Sacerdote (1999) provide three reasons for higher crime rates in big cities. They report that 27 per cent of the difference between urban and rural crime rates in the United States is due to higher pecuniary benefits for crime in cities, 20 per cent to a lower probability of arrest and recognition in cities, and the remaining 45–60 per cent to the observable characteristics of individuals. This last number can be explained by a positive covariance across agents’ decisions about crime, so that the variance of crime rate is higher than the variance predicted by local conditions. This implies that social interactions should matter, especially in cities.

Case and Katz (1991) were among the first to investigate this last issue. Using data from the 1989 NBER survey of youths living in low-income Boston neighbourhoods, they find that the behaviours of neighbourhood peers appear to substantially affect youth behaviours in a manner suggestive of contagion models of neighbourhood effects. The direct effect of moving a youth with given family and personal characteristics to a neighbourhood where 10 per cent more of the youths are involved in crime than in his or her initial neighbourhood is to raise the probability the youth will become involved in crime by 2.3 per cent.
Glaeser, Sacerdote and Scheinkman (1996) find that, across crimes, crime committed by younger people has higher degrees of social interaction, while, across cities, for serious crimes in general and for larceny and auto theft in particular, the degree of social interactions is larger in those communities where families are less intact, that is, have more female-headed households. Ludwig, Duncan and Hirschfield (2001) and Kling, Ludwig and Katz (2005) explore this last result by using data from the Moving to Opportunity (MTO) experiment that assigned a total of 638 families from high-poverty Baltimore neighbourhoods into three ‘treatment groups’: (a) Experimental group families receive housing subsidies, counselling and search assistance to move to private-market housing in low-poverty census tracts; (b) Section 8-only comparison group families receive private-market housing subsidies with no programme constraints on relocation choices; and (c) a Control group receives no special assistance under MTO. They show that relocating families from high- to low-poverty neighbourhoods reduces juvenile arrests for violent offences by 30 to 50 per cent of the arrest rate for control groups. This also suggests very strong social interactions in crime behaviours.

Using a very detailed data-set of friendship networks in the United States from the National Longitudinal Survey of Adolescent Health (AddHealth), Calvó-Armengol, Patacchini and Zenou (2005) test the main results of Ballester, Calvó-Armengol and Zenou (2004). Contrary to the standard approach, here peer effects are conceived not as an average intra-group externality that affects identically all the members of a given group, but as a collection of dyadic bilateral relationships, which constitutes a social network. The position and thus the centrality of each individual are thus crucial to understand criminal behaviour. Calvó-Armengol, Patacchini and Zenou (2005) show that, after observable individual characteristics and unobservable network specific factors are controlled for, the individual's position in a network (as measured by his or her Bonacich centrality) is a key determinant of his or her level of criminal activity. A standard deviation increase in the Bonacich centrality increases the level of individual delinquency by 45 per cent of one standard deviation.

cross-cultural experiments

Rob Boyd
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Experiments conducted in student populations suggest that people are not money maximizers, but also seem to have social preferences. To determine whether these social preferences are culturally variable, a group of economists and anthropologists undertook a series of economic experiments in a wide range of non-Western, small scale societies. Results in these societies were highly variable, and in some of them strikingly different from experiments in student populations. Variation in behaviour was correlated with societal characteristics, but not individual attributes. Finally, variation in punishment across societies predicted variation in cooperation across societies.

Keywords

Article

A large number of well-replicated results using a wide variety of experimental games are inconsistent with the assumption that people are money maximizers. Instead, people's behaviour is consistent with choices based on social preferences in which people place a positive value on fairness, reciprocity, or equity (see Camerer, 2003, for a review). For example, subjects typically make significant positive contributions in the public goods games, reject positive offers in the ultimatum game, and impose costly punishment in the third-party punishment game (see, Camerer, ch. 2, for descriptions of these games.) In some games these results are insensitive to framing and whether behaviour is anonymous to the experimenter (‘double blind’).

These experiments are open to two qualitatively different interpretations: It could be that pro-social behaviours like cooperation in the public goods game and punishment in the third-party punishment game reflect human nature. Cooperation in the public goods game could result from universal cognitive systems that cause people everywhere to behave as if all acts have reputational consequences, even when facts suggest no one will know what they have done. Punishment in the third-party punishment game could result from a pan-human motivational system that causes people to prefer outcomes that are fair or mutually beneficial, and to derive satisfaction from punishing unfair behaviour. However, with few exceptions experimental subjects have been university students in urbanized, industrial societies. Thus, it also could be that observed pro-social behaviour results from culturally evolved beliefs and values that are specific to such social environments. It is obviously of great importance to determine which of these two interpretations is correct.

To answer this question, a team of anthropologists and economists performed two rounds of experimental games in a wide range of cultural environments. The first round (Henrich et al., 2004; 2005) comprised a diverse group of 15 societies including peoples like the Aché and Hadza who live in nomadic foraging bands, the Achuar and Au who live in small villages and mix hunting and horticulture, Mongol and Sangu pastoralists, and sedentary Shona farmers in Zimbabwe. The ultimatum game was performed in all 15 societies, and the public goods game and the dictator game were performed in different subsets. The second round (Henrich et al., 2006) included a similar and overlapping range of 15 societies. Based on experience in the first round, experimental protocols were improved and standardized, and a greater effort was made to collect standardized data on individual characteristics. During the second round the ultimatum, dictator, and third-party punishment games were performed in all 15 societies. In addition complete strategies for second players in the ultimatum game and punishers in the third-party punishment game were elicited using the strategy method.
These experiments reveal a number of interesting results. Behaviour in non-Western populations can be quite different from that of Western university subjects. Figure 1 shows the distribution of ultimatum game offers in the first round of experiments. The Pittsburgh data taken from Roth et al. (1991) are typical for university populations — the modal offer is 50 per cent but many subjects make somewhat lower offers. Behaviour in other populations can be very different. For example, modal offers are much lower among two lowland tropical forest groups; the Achuar and the Machiguenga are quite low. Interestingly, these very low offers were usually accepted, behaviour much closer to the predictions of money maximization than the behaviour of Western university subjects. Non-western populations also exhibited novel behaviours not seen in university populations. Figure 2 shows the rejection probabilities for different ultimatum game offers. Notice that in several populations increasing offer level above 50 per cent increased the rate of rejections, a phenomenon not observed among student subjects.

Figure 1
Ultimatum game offer. Note: A bubble plot showing the distribution of ultimatum game offers for each group. The diameter of the circle at each location along each row represents the proportion of the sample that made a particular offer. The right edge of the lightly shaded horizontal grey bar is the mean offer for that group. In the Machiguenga row, for example, the mode is 0.15, the secondary mode is 0.25, and the mean is 0.26. Source: Henrich et al. (2005).
Ultimatum game rejection rates. 

Note: The diameter of the black circles is proportional to the fraction of offers that would have been rejected in the ultimatum game during the second round of experiments plotted as a function of the offer as a percentage of the maximum offer. For scale, note that the Gusii and Maragoli rejected all offers of zero. Notice that in all societies offering 50% of the stake minimizes the probability of rejection, but that in a number of societies increasing offers above 50% increases the rate of rejection. 

Source: Henrich et al. (2006).
2. Behavioural differences are correlated with group characteristics but not individual characteristics. The ethnographers who performed most of these experiments have studied
these groups for many years and have detailed data on subjects about income, wealth, education, market contact, and a variety of other factors. None of these factors was significantly correlated with ultimatum game offers within social groups in first round, or offers or rejections in the second round. Because measures of wealth, income, and so on are not comparable across groups, these measures could not be aggregated to derive group characteristics. However, during the first round, ethnographers who were blind to the results ranked each of the groups along five dimensions: extent of cooperation in subsistence, degree of market contact, amount of privacy, amount of anonymity, and social complexity. We also had comparable data on settlement size. It turned out that market contact, settlement size, and social complexity were all highly correlated, so these were collapsed into a single variable labelled ‘aggregate market contact’. Multiple linear regression showed that increasing aggregate market contact and cooperation in subsistence significantly predicted increased ultimatum game offers, and together the two variables accounted for more than half of the variance among groups in average offers.

3. Variation in punishment predicts variation in altruism across societies. In the third-party punishment game, an individual, the ‘punisher’ observes a dictator game and can punish the dictator at a cost to him or herself. The average minimum offer acceptable to the punisher in this game provides a measure of the level of punishment in that society. As is shown in Figure 3, this measure of punishment also predicts the level of altruism measured by dictator offers in the ordinary dictator game.

Figure 3
Mean minimum acceptable offer, third-party punishment game. Note: The mean offer in the dictator game for a society plotted against the mean value of the minimum acceptable offer in the third-party punishment game. The different symbols indicate continents. The size of each symbol is proportional to the number of DG pairs at each site. The dotted line gives the weighted regression line, with continental controls of mean dictator game offers against mean minimum acceptable offer in the third-party punishment game. Source: Henrich et al. (2006).
Taken together these results indicate that pro-social behaviour in economic experiments does not result from an invariant property of our species, and instead suggest that there are significant cultural differences between societies. The fact that ultimatum game behaviour is predicted by the average level of cooperation and average level of market contact further indicates that these cultural differences are not arbitrary, but may reflect economic, ecological and social differences between societies. However, the lack of correlation between individual characteristics and individual behaviour indicates that the differences between societies are not likely to be explained as the simple aggregation of individual experiences. Instead, it is more plausible that cultures evolve over time in response to the average conditions which they face, and that individual behaviour is, in turn, shaped by these cultural differences.

‘Crowding out’ refers to all the things which can go wrong when debt-financed fiscal policy is used to affect output. While the initial focus was on the slope of the LM curve, ‘crowding out’ now refers to a multiplicity of channels through which expansionary fiscal policy may in the end have little, no or even negative effects on output.

Article
‘Crowding out’ refers to all the things which can go wrong when debt-financed fiscal policy is used to affect output.
A first line of argument questions whether fiscal policy has any effect at all on spending. Changes in the pattern of taxation which keep the pattern of spending unaffected do not affect the intertemporal budget constraint of the private economy and thus may have little effect on private spending. This argument, known as the ‘Ricardian equivalence’ of debt and taxation, holds only if taxes are lump sum (Barro, 1974). Some taxes which induce strong intertemporal substitution, such as an investment tax credit for firms, will have stronger effects if they are temporary; for most others, such as income taxes, changes in the intertemporal pattern may have only a small effect on the pattern of spending.
The Ricardian equivalence argument is not settled empirically and its validity surely depends on the circumstances. A change in the intertemporal taxation of assets such as land or housing, leaving the
crowding out: The New Palgrave Dictionary of Economics

present value of taxes the same, will have little effect on their market value, thus on private spending. An explicitly temporary income tax increase may have little effect on spending while the anticipation of prolonged deficits may lead taxpayers to ignore the eventual increase in tax liabilities. Evidence from specific episodes, such as the 1968 temporary tax surcharge in the United States, suggests partial offset at best.

Changes in the pattern of government spending obviously have real effects. But here again, various forms of direct crowding out may be at work. Public spending may substitute perfectly or imperfectly for private spending, so that changes in public spending may be directly offset, fully or partially, by consumers or firms. Even if public spending is on public goods, the effect will depend on whether the change in spending is thought to be permanent or transitory. Permanent changes, financed by a permanent increase in taxes, will, as a first approximation, lead to a proportional decrease in private spending, with no effect on total spending. Temporary changes in spending, associated with a temporary increase in taxes, lead to a smaller reduction in private spending and thus to an increase in total spending. In summary, one should not expect any change in taxation or government spending to have a one-for-one effect on aggregate demand. An eclectic reading of the discussion above may be that only sustained decreases in income taxation, or the use of taxes that induce strong intertemporal substitution, or temporary increases in spending, can reliably be used to boost aggregate demand. The focus in what follows will be on these forms of fiscal expansion.

Crowding out at full employment

Not every increase in aggregate demand translates into an increase in output. This is clearly the case if the economy is already at full employment (I use ‘full employment’ to mean employment when unemployment is equal to its natural rate). While tracing the effects of fiscal expansion at full employment is of limited empirical interest, except perhaps as a description of war efforts, it is useful for what follows. If labour supply is inelastic, output is fixed and any increase in aggregate demand must be offset by an increase in interest rates, leaving output unchanged. In the case of an increase in public spending, private spending will decrease; in the case of a decrease in income taxation, private spending will in the end be the same, but its composition will change as the share of interest sensitive components decreases. (If labour supply can vary, the story is more complicated. See, for example, Baxter and King, 1993, for an analysis of changes in government spending in an otherwise standard RBC model.)

This is just the beginning of the story, however. Over time, changes in capital and debt lead to further effects on output. The decrease in investment in response to higher interest rates leads to a decline in capital accumulation and output, reducing the supply of goods. If fiscal expansion is associated with sustained deficits, the increase in debt further increases private wealth and private spending at given interest rates, further increasing interest rates and accelerating the decline in capital accumulation (see, for example, Blanchard, 1985, for a characterization of these dynamic effects in an economy with finite horizon consumers). How strong is this negative effect of debt on capital accumulation likely to be? One of the crucial links in this mechanism is the effect of government debt on interest rates; empirical evidence, both across countries and from the last two centuries, shows surprisingly little relation between the two. This probably reflects, however, more the difficulty of identifying and controlling for other factors than the absence of an effect of debt and deficits on interest rates.
Worse can happen. It may be that the fiscal programme becomes unsustaina
ble. There is no reason to worry about a fiscal programme in which debt grows temporarily faster than the interest rate. But there is reason to worry when there is a positive probability that, even under the most optimistic assumptions, debt will have to grow for ever faster than the interest rate. When this is the case, it implies that the government can meet its interest payments on existing debt only by borrowing more and more. What happens then may depend on the circumstances. Bond holders may start anticipating repudiation of government debt and require a risk premium on the debt, further accelerating deficits and the growth of the debt. If they instead anticipate repudiation through inflation, they will require a higher nominal rate and compensation for inflation risk in the form of a premium on all nominal debt, private and public. What is sure is that there will be increased uncertainty in financial markets and that this will further contribute to decreases in output and in welfare. The historical record suggests that it takes very large deficits and debt levels before the market perceives them as potentially unsustainable. England was able in the 19th century to build debt-to-GDP ratios close to 200 per cent without apparent trouble. Some European countries are currently running high deficits while already having debt-to-GDP ratios in excess of 100 per cent, without any evidence of a risk premium on government debt. The threshold seems lower for Latin American economies. But even if one excludes this worst-case scenario, fiscal expansion can clearly have adverse effects on output at full employment. The relevant issue, however, is whether the same dangers are present when fiscal expansion is implemented to reduce unemployment, which is presumably when it is most likely to be used.

Crowding out at less than full employment

The historical starting point of the crowding out discussion is the fixed price IS–LM model. In that model, a fiscal expansion raises aggregate demand and output. The pressure on interest rates does not come from the full employment constraint as before but from the increased demand for money from increased output. Thus the fiscal multiplier is smaller the lower the elasticity of money demand to interest rates, or the larger the elasticity of private spending to interest rates. Fiscal expansion crowds out the interest-sensitive components of private spending, but the multiplier effect on output is positive. As output and interest rates increase, it is quite possible for both investment and consumption to increase. But what happens when the model is extended to take into account dynamics, expectations and so on? Can one overturn the initial result and get full crowding out or even negative multipliers? Even within the static IS–LM, one can in fact get zero or negative multipliers. This is the case, for example, if money demand from agents is higher than that from the government and the change in policy redistributes income from the government to agents. While this case is rather exotic, a much stronger case can be made if the economy is small, open, and with capital mobility and flexible exchange rates, as in the ‘Mundell–Fleming’ model. In this case, with the interest rate given from outside, and fixed money supply, money demand determines output; fiscal policy leads only to exchange rate appreciation. Exchange rate-sensitive components are now crowded out by fiscal expansion. The multiplier is equal to zero.

When dynamic effects are taken into account, other channels arise for crowding out. The analysis of these dynamic effects, with the dynamics of debt accumulation taken into account, was initially conducted under the maintained assumption of fixed prices and demand determination of output (Tobin and Buiter, 1976). Then, as debt was accumulating, private wealth and spending increased, leading to...
crowding out: The New Palgrave Dictionary of Economics

even larger effects of fiscal policy on output in the long run than in the short run. But the assumption of fixed prices, while debt and capital accumulation are allowed to proceed, is surely misleading; when prices are also allowed to adjust, the effects of fiscal policy become more complex, and crowding out more likely. This is because some of the full employment effects come back into prominence: if fiscal expansion is maintained even after the economy has reached full employment, then the perverse effects of higher interest rates on capital accumulation and full employment output come again into play. This is true even if deficits disappear before the economy returns to full employment; the economy inherits a larger level of debt, and thus must have higher interest rates and lower capital accumulation than it would otherwise have had. The fiscal expansion trades off a faster return to full employment for lower full-employment output.

Anticipations of these full employment effects are likely to feed back and modify the effects of fiscal policy at the start, when the economy is still at less than full employment. Anticipations of higher interest rates, perhaps also of higher distortions due to the higher taxes needed to service the debt, may dominate the direct effects of higher government spending on demand, and lead to an initial decrease rather than an initial increase in demand and output. Symmetrically, fiscal consolidation, to the extent that it implies lower interest rates and lower distortions in the future, may be expansionary. This is even more likely to be the case if fiscal consolidation decreases the risk of default on government debt, and thus decreases the risk of major economic disruptions. There is indeed some evidence that, when initial fiscal conditions are very bad, and the fiscal consolidation is large and credible, the net effect of consolidation may be expansionary (Giavazzi and Pagano, 1990).

Crowding out: an assessment

Should one conclude from this that fiscal policy is an unreliable macroeconomic tool, with small and sometimes negative effects on output? The answer is ‘no’. Fiscal policy is likely to partly crowd out some components of private spending, even in the best circumstances, but there is little reason to doubt that it can help the economy return to full employment. Ricardian equivalence and direct crowding out warn us that not any tax cut or spending increase will increase aggregate demand. But there is little question that temporary spending or sustained income tax cuts will do so. Results of full crowding out at less than full employment, such as the Mundell–Fleming result, are simply a reminder that the monetary-fiscal policy mix is important.

In all cases, monetary accommodation of the increased demand for money removes the negative or the zero multipliers. That fiscal expansion affects capital accumulation, and output adversely at full employment, and that unsustainable fiscal programmes may lead to crises of confidence, is a reminder that fiscal expansion should not be synonymous with steady increases in the debt-to-GDP ratio even after the economy has returned to full employment. This shows one of the difficulties associated with fiscal expansion: if done through tax cuts, it has to be expected to last long enough to affect private spending, but not so long as to lead to expectations of runaway deficits in the long run. The room for manoeuvre is, however, substantial. Some taxes, such as the investment tax credit, work best when temporary. These can be used, as they work in the short run and have few adverse implications for the long run.

cultural transmission

Alberto Bisin and Thierry Verdier
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The economic literature analyses cultural transmission as the result of interactions between purposeful socialization decisions inside the family (‘direct vertical socialization’) and indirect socialization processes like social imitation and learning (‘oblique and horizontal socialization’). This article reviews the main contribution of these models from theoretical and empirical perspectives. It presents the implications regarding the long-run population dynamics of cultural traits, and discusses the links with other approaches to cultural evolution in the social sciences as well as in evolutionary biology. Applications to economic problems are also briefly surveyed.

Keywords

altruism; cooperation; cultural transmission; evolutionary biology; evolutionary economics; genetic evolution; identity; imperfect empathy; inter-generational altruism; nature–nurture debate; religion, economics of; social interaction; social norms; socialization

Article

Preferences, beliefs, and norms that govern human behaviour are partly formed as the result of genetic evolution, and partly transmitted through generations and acquired by learning and other forms of social interaction. The transmission of preferences, beliefs and norms of behaviour which is the result of social interactions across and within generations is called cultural transmission. Cultural transmission is therefore distinct from, but interacts with, genetic evolution. Cultural transmission is an object of study of several social sciences, such as evolutionary anthropology, sociology, social psychology and economics, as well as of evolutionary biology. The theoretical contributions of Cavalli-Sforza and Feldman (1981) and Boyd and Richerson (1985), who apply models of evolutionary biology to the transmission of cultural traits, as well as the empirical study of cultural socialization in American schools by Coleman (1988), had a great multidisciplinary impact. Recently,
economists have also studied the determination and the dynamics of preferences, beliefs, norms and, more generally, cultural and cognitive attitudes. Cultural transmission arguably plays an important role in the determination of many fundamental preference traits, like discounting, risk aversion and altruism. It plays a central role in the formation of cultural traits and norms, like attitudes towards the family and fertility practices, and in the job market. It is, however, the pervasive evidence of the resilience of ethnic and religious traits across generations that motivates a large fraction of the theoretical and empirical literature on cultural transmission. For instance, the fast assimilation of immigrants into a 'melting pot', which many social scientists predicted until the 1960s (see, for example, Gleason, 1980, for a survey), simply did not materialize. Moreover, the persistence of ‘ethnic capital’ in second- and third-generation immigrants has been documented by Borjas (1992), and recently also by Fernandez and Fogli (2005) and Giuliano (2007) for norms of behaviour regarding, respectively, work and fertility practices and living arrangements. Orthodox Jewish communities in the United States constitute another example of the strong resilience of culture (see Mayer, 1979, and the discussion of a ‘cultural renaissance’ rather than the complete assimilation of Jewish communities in New York in the 1970s). Outside the United States, Basques, Catalans, Corsicans, and Irish Catholics in Europe, Quebecois in Canada, and Jews of the diaspora have all remained strongly attached to their languages and cultural traits even through the formation of political states which did not recognize their ethnic and religious diversity.

Models of cultural transmission have implications regarding the determinants of the persistence of cultural traits and more generally regarding the population dynamics of cultural traits. In the economic literature in particular, cultural transmission is modelled as the result of purposeful socialization decisions inside the family (‘direct vertical socialization’) as well as of indirect socialization processes like social imitation and learning (‘oblique and horizontal socialization’). Therefore, the persistence of cultural traits or, conversely, the cultural assimilation of minorities is determined by the costs and benefits of various family decisions pertaining to the socialization of children in specific socio-economic environments, which in turn determine the children's opportunities for social imitation and learning.

Evolutionary biology models

L. Cavalli-Sforza and M. Feldman are the first to formally study the transmission of cultural traits. Their formal models are adopted from evolutionary biology. In a baseline version of these models, they obtain a simple differential equation which describes the population dynamics of cultural traits. Consider the dynamics of a dichotomous cultural trait in the population; formally, a fraction $q^i$ of the population has trait $i$, and a fraction $q^j = 1 - q^i$ has trait $j$. Families are composed of one parent and a child, and hence reproduction is asexual. All children are born without defined preferences or cultural traits, and are each first exposed to their parent's trait, which they adopt with probability $d^i$. If a child from a family with trait $i$ is not directly socialized, which occurs with probability $1 - d^i$, he or she picks the trait of a role model chosen randomly in the population (that is, he or she picks trait $i$ with probability $q^i$ and trait $j$ with probability $1 - q^i$). Therefore, the probability that the child of parents of trait $i$ will also have trait $i$ is $\Pi^i = d^i + (1 - d^i)q^i$; while the probability that he or she will have trait $j$ is $\Pi^j = (1 - d^i)(1 - q^i)$. It follows that the dynamics of the fraction of the population with trait $i$, in the continuous time limit, are
characterized by:

\[ q^i = (d^i - d^j)q^j(1 - q^j) \]  

(1)

The dynamics that equation (1) describes implies that the distribution of cultural traits in the population converges to a degenerate distribution concentrated on trait \( i \) whenever \( d^i > d^j \) (and on trait \( j \) when \( d^i < d^j \)), while any initial distribution is stationary in the knife-edge case in which \( d^i = d^j \). This model therefore predicts the complete assimilation of the trait with weaker direct vertical socialization. Moreover, it predicts faster assimilation for smaller minorities. Both predictions are at odds with the documented strong resilience of cultural traits discussed above. Cavalli-Sforza and Feldman show how these extreme predictions can be relaxed by considering other effects like mutations, migrations and horizontal cultural transmission among peers. Boyd and Richerson (1985) in turn extend the analysis of Cavalli-Sforza and Feldman (1981) by considering forms of direct vertical socialization called *frequency dependent* biased transmission, which depend on the distribution of the population by cultural trait.

Formally, they allow \( d^i \) to be a function of \( q^i \).

Bisin and Verdier (2001a) study the same differential equation for the population dynamics of cultural traits, with the objective of characterizing the conditions which give rise to culturally heterogeneous stationary distributions, that is, limit population with a positive fraction of either cultural trait, \( 0 < q^i < 1 \). They show that the crucial determinant of the composition of the stationary distribution consists in whether the socio-economic environment (oblique socialization) acts as a substitute or as a complement to direct vertical socialization. More precisely, when direct vertical socialization and oblique transmission are *cultural substitutes*, parents by definition socialize their children less the more widely dominant are their cultural traits in the population. In such a case, \( d^i(q^i) \) is a strictly decreasing function in \( q^i \), and in the long run a non-degenerate stable stationary distribution exists. It is characterized by a \( q^i \) such that the direct vertical socialization of the two cultural types are equalized (that is, \( d^i(q^i) = d^j(1 - q^j) \)). Intuitively, when family and society are substitutes in the transmission mechanism, in fact families socialize children more intensely whenever the set of cultural traits they wish to transmit is common only to a minority of the population. Conversely, families which belong to a cultural majority spend fewer resources directly socializing their children, since their children adopt or imitate with high probability the predominant cultural trait in society at large, which is the one their parents desire for them. *Cultural substitutability* tends to preserve cultural heterogeneity in the population because in this case minorities directly socialize their children more than majorities. The other typical situation is the opposite one in which direct vertical transmission is a *cultural complement* to oblique transmission; that is, when parents socialize their children more intensely the more widely dominant their cultural trait is in the population. In such a case, \( d^i(q^i) \) is a strictly increasing function in \( q^i \) and in the long run the dynamics converges to a culturally homogeneous cultural population (with
either $q^i = 0$ or $q^i = 1$ depending on the initial distribution).

Economic models of cultural transmission

Economic models of cultural transmission induce testable restrictions on the form of the function $d^i(q^i)$. In their baseline specification, for instance, Bisin and Verdier (2001a) assume that parents are altruistic towards their children and hence might want to socialize them to a specific cultural model if they think this will increase their children's welfare. If we let $V_{ij}$ denote the utility to a type $i$ parent of a type $j$ child, $i, j \in \{a, b\}$, the formal assumption is

$$
\text{forall } i, j \text{ with } i \neq j, V^i_{ij} > V^j_{ji}
$$

This assumption, called imperfect empathy, can be interpreted as a form of myopic or paternalistic altruism. Parents are aware of the different traits children can adopt and are able to anticipate the socio-economic choices a child with trait $i$ will make in his or her lifetime. However, parents can evaluate these choices only through the filter of their own subjective evaluations and cannot ‘perfectly empathize’ with their children. As a consequence of imperfect empathy, parents, while altruistic, tend to prefer children with their own cultural trait and hence attempt to socialize them to this trait. (Some justifications of imperfect empathy from an evolutionary perspective are provided by Bisin and Verdier, 2001b. The assumption can be relaxed, as for example in Sáez-Martí and Sjogren, 2005.) Assume socialization is costly and let costs be denoted by $C(d^i)$. Parents of type $i$ then choose $d^i$ to maximize:

$$
- C(d^i) + (\Pi^i V^i_{ii} + \Pi^i V^i_{ij})
$$

Under standard assumptions, the solution to this problem provides a continuous map $d^i = d(q^i, \Delta V^i)$, where $\Delta V^i = V^i_{ii} - V^i_{ij}$ is the subjective utility gain of having a child with trait $i$. It reflects the degree of
cultural intolerance’ of type \( i \)'s parents with respect to cultural deviations from their own trait. Given imperfect empathy on the part of parents, \( \Delta V^i > 0 \). The dynamics of the fraction of the population with cultural trait \( i \) is then determined by equation (1) evaluated at \( d^i(q^i) = d(q^i, \Delta V^i) \). It is straightforward to demonstrate that this class of socialization mechanisms generates cultural substitutability and therefore the preservation of cultural heterogeneity. Other micro-founded specifications and examples are provided in Bisin and Verdier (2001a), some of which illustrate the contrary possibility of cultural complementarity and the tendency of cultural homogenization over time.

**Direct socialization mechanisms and socio-economic interactions**

Several specific choices contribute to direct family socialization and hence to cultural transmission. Prominent examples are education decision, family location decisions, and marriage choices. While education choices have been studied by Cohen-Zada (2004), and marriage choices by Bisin and Verdier (2000), the literature has to date shown little interest in the socialization effects of location choices, for instance, the socialization effects of urban agglomeration by ethnic or religious trait.

The simple analysis of the economic model of cultural transmission of Bisin and Verdier depends crucially on the assumption that the utility to a type \( i \) parent of a type \( j \) child, \( V_{ij} \) is independent of the distribution of the population by cultural trait, that is, independent of \( q^i \). Many interesting analyses of cultural transmission require this assumption to be relaxed. In many instances the adoption of the cultural trait of the majority in fact favours children, for example in the labour market; a typical example is language adoption. In this case altruistic parents, even if paternalistic, might favour (or discourage less intensely) the cultural assimilation of their children. If we allow for interesting socio-economic effects interacting with the socialization choices of parents, the basic cultural transmission model of Bisin and Verdier has been applied to several different environments and cultural traits and social norms of behaviour, from preferences for social status (Bisin and Verdier, 1998) to corruption (Hauk and Sáez-Martí, 2002), hold-up problems (Olcina and Penarrubia, 2004), development and social capital (François, 2002), inter-generational altruism (Jellal and Wolff, 2002), labour market discrimination (Sáez-Martí and Zenou, 2005), globalization and cultural identities (Olivier, Thoenig and Verdier, 2005), and work ethics (Bisin and Verdier, 2005).

**Empirical analysis of cultural transmission models**

While an interesting literature has documented the relevance of cultural factors in several socio-economic choices, much less is known about cultural transmission per se. Nonetheless, several important questions are beginning to be answered. First of all, several important correlations have been documented in sociology, in particular with regard to the role of marriage in socialization (see, for instance, Hayes and Pittelkow, 1993; Ozorak, 1989; Heaton, 1986). The literature in economics has instead concentrated more specifically on the direct empirical validation of the economic approach to cultural transmission surveyed above, thereby estimating the relative importance of direct and oblique socialization for different specific traits and the prevalence of cultural substitution or complementarity in specific socio-economic environments. Patacchini and Zenou (2004) find evidence of cultural
complementarity in education in the United Kingdom. Cohen-Zada (2004) finds instead for the United States that the demand for private religious schooling decreases with the share of the religious minority in the population, in accord with cultural substitution. Fernandez, Fogli and Olivetti (2004) find evidence of an important role for mothers in the transmission to their sons of attitudes favouring the participation of women in the labour force and acquisition of higher education. Finally, Bisin, Topa and Verdier (2004a), using the General Social Survey data for the United States over the period 1972–96, estimate for religious traits the structural parameters of the model of marriage and child socialization in Bisin and Verdier (2000). They find that observed intermarriage and socialization rates are consistent with Protestants, Catholics and Jews having a strong preference for children who identify with their own religious beliefs, and taking costly decisions to influence their children's religious beliefs. The estimated ‘relative intolerance’ parameters are high and asymmetric across religious traits, suggesting an interestingly rich representation of ‘cultural distance’.

**Genetic and cultural evolution**

Cultural transmission possibly has a role also in the determination of fundamental preference parameters, such as time discounting, risk aversion, altruism, and interdependent preferences. Purely evolutionary models have been complemented by alternative models of cultural transmission and genetic and cultural co-evolution. The wealth of different approaches proposed is best exemplified by the study of preferences for cooperation. The observation that humans often adhere to collectively beneficial actions which are not in their private interest (or which are not rationalizable as strategic equilibria) has led to a theoretical literature explaining how psychological ‘preferences for cooperation’ can be sustained in the context of genetic and/or cultural evolution (this is called the puzzle of pro-sociality by Gintis, 2003a). For instance, in the context of the Prisoner’s Dilemma, Becker and Madrigal (1995) exploit the ability of habits to induce preferences; Guttman (2003), Stark (1995), and Bisin, Topa and Verdier (2004b) show how cooperation can be sustained by different modes of cultural evolution; Gintis (2003b) shows that a general capacity to internalize fitness-enhancing norms of behaviour can be genetically adaptive, and hence that cooperation can also be internalized by ‘hitchhiking’ on this general capacity.

The empirical evidence on the nature–nurture debate (see Ceci and Williams, 1999, for a review) has not yet been systematically taken to the point of distinguishing the genetic from the cultural factors in the determination of fundamental preference parameters. Similarly, the empirical evidence distinguishing the different cultural transmission models of fundamental preference traits is almost non-existent. The only exception is by Jellal and Wolff (2002), who study the implication of the pattern of inter vivos transfers within the family in France for the transmission of inter-generational altruism. They argue that the evidence is more consistent with a cultural transmission model such as that of Bisin and Verdier (2001a) rather than with a ‘demonstration effect’ model, as in Stark (1995), where parents take care of their elders in order to elicit similar behaviour in their children.

culture and economics

Raquel Fernández
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Modern neoclassical economics has, until recently, ignored the potential role of culture in explaining variation in economic outcomes, largely because of the difficulty in rigorously separating the effects of culture from those of institutions and traditional economic variables. This article selectively reviews some recent attempts to empirically identify the effects of culture on economic outcomes and to answer the question, ‘does culture matter and, if so, how much?’ Open theoretical and empirical questions are discussed, including the relationship between culture and institutions.

Keywords

agency problems; assortative matching; cultural assimilation; culture and economics; endogenous preferences; epidemiology; fertility; human capital; institutions; instrumental variables; international migration; multiple equilibria; occupational selection; religion; social norms; technology; trust; women's work and wages; beliefs; identity; preference transmission

Article

Economic decisions are made within a social context; as Aristotle reminds us, man is a social animal. The relevance of this statement to economics, however, is far from clear. In what ways, if any, do we need to consider the social nature of man in order to study economic questions? This article attempts to provide a partial answer to this question.

Traditionally, economists seek to explain differences in economic outcomes by studying how agents, with given preferences and beliefs, react to changes in the policy environment, institutions and technology. At a deeper level than the taste for apples versus oranges, however, few would deny that preferences and beliefs must be, to some extent, endogenous. Our level of trust in others, the determinants of status in society, our beliefs about the correct trade-off between efficiency and equity, or the ‘proper’ roles for men and women, are all examples of beliefs or preferences that have differed
across societies and over time. These beliefs and preferences impact on individual behaviour and how society allocates scarce resources. At the individual level they help determine whether a woman participates in the formal labour market and the career she follows, the extent to which racism is tolerated, or the degree of assortative matching on wealth in marriages. At a collective level, they help determine, for example, the range and depth of the welfare state, the legality of slavery, or the proportion of the budget that is dedicated to foreign aid.

Although at some general level few may disagree that preferences, beliefs, or values of the type discussed above are endogenous (and may therefore differ across societies), whether they have a quantitatively significant impact on economic outcomes is another matter. Do differences in beliefs and preferences that vary systematically across groups of individuals separated by space (either geographic or social) or time – what I shall henceforth term culture – play an important role in explaining differences in outcomes? (For the purposes of this article, I will not give a more rigorous definition of culture than the abbreviated one here. See Elster, 1989, for a discussion of social norms and culture and Manski, 2000, for a discussion of peer effects and social interactions.) Modern economics (as opposed to sociology or anthropology) has largely been, until recently, reluctant to investigate this question. Although in principle there is nothing non-standard about positing preference/belief heterogeneity among individuals to explain differences in outcomes, the Stigler–Becker dictum *de gustibus non est disputandum* (Stigler and Becker, 1977) and its assertion that ‘no scientific behavior has been illuminated by assumptions of differences in taste’ has cast a long shadow in economics. Thus, the main challenge faced by those who believe that culture might matter has been to find a convincing way to show that culture can be studied rigorously and, in particular, that it is possible to separate the influence of culture from institutions and standard economic variables. In this sense, running, say, cross-country regressions on variables that one suspects reflect cultural attitudes (for example, different savings patterns may reflect attitudes towards thrift) to study the effect of culture has long (and correctly) been considered unsatisfactory. Despite one's best efforts to control for differences in countries’ economic environments, identifying the residual with culture is ultimately unconvincing. It is difficult, if not impossible, to summarize the economic environment faced by agents with a few aggregate variables. Thus, there are bound to be omitted variables and problems of endogeneity, which are all further confounded by mismeasurement.

Hence, despite a long history of writers on the relationship between culture and economics (which includes Marx, Weber, Gramsci, Polanyi, Banfield and, more recently, Putnam and Landes, among others), modern neoclassical economics has been by and large silent on the topic of culture and only in recent years have economists started to think seriously again about how culture may help explain economic phenomena. In this article I will selectively review some recent attempts to empirically identify the effects of culture on important economic outcomes and to answer the question, ‘does culture matter?’ Answering this question affirmatively naturally leads one to explore the propagation mechanisms of culture, to theorize about the relationship between institutions and culture, and to investigate the dynamic of culture – all topics that I will briefly touch upon at the end.

**Empirical evidence on culture**

In this section I examine some of the recent evidence on the importance of culture for economic
outcomes. For expository ease, I have divided the empirical evidence into that which uses survey data, evidence based on immigrants or their descendants (what I call the ‘epidemiological approach’), and historical case studies. There is also a small body of experimental work that, by showing that across societies there exist marked differences in how individuals play games such as the ultimatum, public good or dictator game, has also shed light on the relationship between culture and economics (see, for example, Henrich et al., 2001).

Survey-based evidence

Perhaps the most natural approach to doing empirical work on culture consists in using the beliefs expressed by individuals in surveys (for instance, the World Value Surveys) on a variety of issues as expressions of culture and correlating them with economic outcomes. This approach, however, must overcome the problem of reverse causality. That is, differences in beliefs may be solely a consequence of different economic and institutional environments. Hence, the use of instrumental variables is required in order to identify causality. Overall, this has been difficult to achieve.

As shown by Guiso, Sapienza and Zingales (2003), the intensity of religious beliefs and religious denomination are correlated with a variety of individual attitudes such as trust in others, government’s role, views of working women and the importance of thrift. Guiso, Sapienza and Zingales (2006) show that these attitudes, aggregated at the country level, are correlated with cross-country aggregate outcomes (for example, savings, redistributive versus regressive taxation, and trade). In order to ensure that the reverse causality is not at play, the attitudes are instrumented, usually by the religious composition in the country. This work is suggestive but there are several concerns associated with it. In addition to questions about omitted variables, it is not clear that religious composition is a valid instrument since it may also help explain the aggregate outcome through other channels. (Indeed, the coefficients on the instrumental variable results tend to look very high relative to the ones obtained by ordinary least squares. Running regressions at the individual outcome level would be more convincing, but opinion surveys unfortunately tend not to have high-quality economic data (the World Value Survey, for example, classifies income levels into ten categories). Recent work by Guiso, Sapienza and Zingales (2005) on the relationship between trust and trade, instead instruments trust with the genetic distance between indigenous populations. This seems a promising avenue of research.

Tabellini (2005) takes a significant step towards overcoming some of the weaknesses discussed above. To study whether culture affects economic development across European regions, he also aggregates (at the regional level) individual responses from the World Value Surveys to questions about trust, respect and the link between individual effort and economic success. The scope for omitted variables is reduced by focusing on within-country variation in Europe (by including country fixed effects). The attitudes are then instrumented with historical variables, such as regional literacy rates at the end of the 19th century and indicators of political institutions in the period from 1600 to 1850. The author finds that the proxies for culture are quantitatively significant determinants of per capita GDP levels and growth rates across regions. It is possible of course that the instruments are not valid. For example, they could affect output directly via sectoral composition or public investment. The paper contains a good discussion of these and other alternative hypotheses.
A very different approach to relying on opinion data is to examine the economic outcomes of immigrants or their descendants. This is reminiscent of the epidemiology literature that, in order to attempt to identify the contribution of the environment broadly defined (namely, physical and cultural) relative to genes in disease, studies various health outcomes for immigrants and compares them to outcomes for natives (see, for example, the classic study by Marmot et al., 1975).

To understand the strengths and weaknesses of such an approach, suppose that the level of, say, heart disease differs markedly between two countries (the source and host countries). If heart disease in immigrants converges to that of natives in the host country, the difference between the two countries is unlikely to be driven by genetics and instead results from the environment. Failure to find convergence, on the other hand, does not imply the opposite. There are many reasons why the environment may be solely responsible and still sustain differential levels of heart disease. For example, cultural assimilation may occur slowly (for instance, if immigrants maintain the same dietary patterns as in the source country), or living in the source country at a young age may confer some degree of immunity, or selection into immigration may be correlated with a particular health outcome.

The epidemiological strategy in economics has its own set of problems. In particular, it is important to recognize that immigrants may be subject to many shocks (language difficulties, worse employment opportunities, greater uncertainty and so forth) which cause them to deviate from their traditional behaviour. Culture, furthermore, is socially constructed: to be replicated, the behaviour may require the incentives—rewards and punishments – provided by a larger social body such as a neighbourhood, school, or ethnic network. Furthermore, immigrants are unlikely to be a representative sample of their home-country's population. Their beliefs, preferences, and unobserved differences in their economic circumstances may differ significantly from the country average. Lastly, the exposure of immigrants (or their descendants) to a different culture from the one prevalent in their country of heritage presumably weakens the latter's impact on their behaviour. Note that all the factors mentioned above introduce a bias towards finding culture to be insignificant. Thus, on the whole, comparisons of behaviour or outcomes across different immigrant groups are a very demanding test of the importance of culture. In epidemiology, when differences across groups remain, one must be careful not to conclude that genetics is determinative when the underlying cause may be cultural; in economics, when significant differences are not observed, one must be careful not to rule out cultural forces.

In economics, the paper by Carroll, Rhee and Rhee (1994) is the first that, to my knowledge, follows an approach similar to the one described above. The authors are interested in exploring whether cross-country differences in savings rates may be culturally driven. Using individual-level data on immigrants to Canada, they estimate individual consumption levels as a function of permanent income (as captured by labour and asset income), the interaction of this variable with demographic variables, some measures of wealth, and finally the interaction of a region of origin dummy (and years since arrival to Canada) with their measure of permanent income. If there exist different cultural attitudes towards savings, and if this attitude is maintained in immigrants, then one should observe different propensities across immigrants, by region of origin, to consume out of permanent income (that is, the regional dummies should be significantly different from one another). The authors find that the saving patterns of immigrants do not vary significantly by region of origin. Recent immigrants as a whole save less than native-born Canadians, but there is no statistically significant difference in behaviour across immigrant
There are several weaknesses in the data-set used in the study above that may bias it against finding results that show a significant impact of culture. Wealth, for example, is not well measured. In particular, as only South East Asia's saving rate differed markedly from those of other regions in the immigrant population (31 per cent relative to 18–20 per cent across the remaining regions), the small number of immigrants from this group in the sample limits the power of the test. Note also that, if the motivation to save more stems from the desire to provide one's child with greater status via a larger bequest, the incentive to do this may be much less marked in a society in which savings are generally low or in which status stems from consumption behaviour.

Fernández and Fogli (2005; 2006) use a similar, but arguably less problematic, methodology by studying second-generation Americans in order to investigate the quantitative importance of culture. Their research focuses on the fertility and work behaviour of married second-generation American women (that is, women who were born in the United States but whose parents were born elsewhere). The use of second-generation immigrants attenuates the problems associated with the first generation's adjustment to a foreign setting (for example, language difficulties) and even some selection problems are less likely to play a role for the second generation. On the other hand, second-generation individuals have been more exposed to the new culture, and that will tend to diminish the role of culture from the country of heritage. Our hypothesis is that attitudes towards woman's 'proper' role in society and towards ideal family size are culturally different across countries and that this culture is likely to be transmitted intergenerationally and show up in systematic differences in female labour force participation (LFP) and fertility, even if individuals were raised in the United States.

In our 2005 paper, the challenge was how to best capture the attitudes towards women and family size in the parents’ country of origin. We chose not to use country dummies (as in Carroll, Rhee and Rhee, 1994) but to instead examine whether past values of economic variables in the country of origin that should reflect this culture – in particular, past values of female LFP and total fertility rates (TFR) – are able to play a quantitatively significant role in explaining differences in outcomes across second-generation women in the United States. Our argument is that these economic variables reflect the institutions (for example, markets, legal framework, minimum wages and so on), the strictly economic environment (demand and supply, transportation costs, access to day care, for example), as well as the preferences and beliefs (that is, the culture) of individuals in the country making decisions at that time. If these variables are able to explain the behaviour of women who, by virtue of living in the USA and in a different time period, face different institutions and economic variables, then solely the cultural component of these variables should affect their choices. This is a more demanding test that is superior to the ‘black box’ approach of using country dummies which leaves open the question of what it is about the country that matters to outcomes.

In individual level regressions, we find that our cultural proxies – past values of female LFP and TFR – help explain both how much second-generation American women work and their fertility. As our data-set – the 1970 US Census – does not allow us to control for family factors such as parental wealth, income, and education, we include the woman's education, her spouse's education, and total personal income (as well as location, age, and so on) in our regressions. By including these variables, the coefficient on the cultural proxy only captures the direct effect of culture rather than its full direct and indirect effects (for example, a woman who wants engage in market work is more likely to invest in education and hence, by controlling for education, we are eliminating the effect of culture on this
variable), but this is preferable to not controlling for differences in parental background, other than
culture, that may affect women's work and fertility outcomes. We find that the cultural proxies still
matter even after including these additional variables. Furthermore, the cultural proxies are
quantitatively significant: a one standard-deviation increase in the corresponding cultural proxy is
associated with approximately an eight per cent increase in hours worked per week and about a 14 per
cent increase in the number of children. The forces of assimilation means that these numbers should be
taken, if anything, as a downward biased estimate of the true power of culture in the original setting (that
is, in the country of ancestry).
We also examine the most compelling alternative economic explanation for our results, namely, the
hypothesis that these are driven by unobserved human capital. We do this by showing that the results are
robust to the inclusion of the country of ancestry's level of per capita GDP in various years and to the
years of education of immigrants (by country of ancestry) in 1940 (this remains the case when Hanushek
and Kimko's (2000) measures of education quality in the parents’ country of origin are included). We
also demonstrate that the work cultural proxy does not have explanatory power in a Mincer wage
regression which it would be expected to have if it captured unobserved human capital. Lastly, we show
that the work cultural proxy is insignificant in explaining how much married second-generation
American men work whereas the fertility cultural proxy retains its explanatory power. (If the work
cultural proxy had a negative effect on how much these men work, that might indicate a substitution
effect. In our regressions, the coefficient is basically zero and insignificant.) This is important because it
implies that there does not exist some omitted economic variable at the parental country-of-origin level
that affects the productivity of both men and women and that helps explain how much they work.
The methods used in Fernández and Fogli (2005) could be profitably extended to examine other issues,
such as entrepreneurship or savings behaviour. It might also be interesting to elaborate upon the recent
approach by Algan and Cahuc (2006) that attempts to combine survey evidence with the
epidemiological approach in order to study the effects of culture on cross-country labour market
outcomes. Although this work is too preliminary to discuss in depth, using the attitudes of, say, second-
generation Americans to instrument for the attitudes of individuals in the home country seems cleaner
than relying on variation in religious denominations. As usual, the question will be whether there is
some omitted background economic variable correlated with the country of origin (particularly given the
quality of the survey data-sets) that could be driving the results, but it seems a promising avenue of
research (see also the interesting work on culture and migrants within regions in Italy by Ichino and
Maggi, 2000. As shown recently in Fernández (2007a) using the World Value Survey, the attitudes of
individuals in the country of ancestry towards women's market work and housework have explanatory
power for the work outcomes of second-generation American women in 1970.

Historical case studies

The analysis of historical episodes in which changes in either culture or environment yield ‘natural
experiments’ is likely to add richness and depth to our understanding of culture and the economy. Greif’s
1994 paper is probably the best-known work in economics that makes the link between culture and
institutional development. In brief, Greif argues that cultural beliefs (collectivist versus individualist) are
reflected in the different ways in which in the 11th century Genoese traders and Maghrebi traders set up
their trading institutions. Both groups of merchants required agents to conduct their business overseas, and in both cases there was an agency problem as the overseas agent might be tempted to cheat the merchant. Maghrebi traders set up ‘horizontal’ relations in which merchants served as agents for traders and vice versa. Information was shared among merchants/traders and an agent who was dishonest with one merchant could expect to be shunned by other merchants. The Genoese, on the other hand, set up ‘vertical’ relationships in which individuals specialized as merchants or agents. Information was not shared among merchants. This led the Genoese to set up more formal enforcement institutions. The two different responses, argues Greif, then had important consequences once trading opportunities were expanded in previously inaccessible areas. The Maghrebi expanded trade using other Maghrebi agents whereas the Genoese were able to establish agency relations with non-Genoese, leading to very different economic development paths thereafter (see also Greif’s, 2005, recent book on the topic).

Another compelling example is provided by Botticini and Eckstein (2005) who present the thesis that an ‘exogenous’ cultural change gave rise to the pattern of Jewish occupational selection that we see to this day. They argue that with the destruction of the Temple in Jerusalem in 70 ce, the Pharisees became the dominant religious group and transformed Judaism from a religion based on sacrifices to one whose main rule required each male to read and to teach his sons the Torah. This reform was implemented in places where most Jews were farmers who would not gain anything from investing in education. When urbanization expanded many centuries later, Jews had a comparative advantage in the skilled occupations demanded in the new urban centres. Thus, culture – the religious requirement of reading skills for other than human capital reasons – gave rise to the pattern of Jewish occupational selection seen since the ninth century.

**Theories of culture**

Is it necessary to modify the standard economic model in order to incorporate culture? The answer definitely is ‘no’. What appear to be societal differences in preferences may only be choice of equilibrium strategies in a game with multiple equilibria and standard preferences. This is in fact the most common way to think about the role of culture in economics, and is fully in keeping with our working definition of culture as systematic differences (across groups) in preferences or beliefs. Here the heterogeneity lies in the expectations (beliefs) over the strategies that will be played in equilibrium. Hence differences in culture can be identified with, for example, which equilibrium we play in a static game (for example, do we drive on the right- or left-hand side of the road) or the degree of cooperation (‘trust’) sustained in a repeated Prisoner’s Dilemma game.

Within the ‘culture as multiple equilibria’ literature, I find particularly interesting the research that attempts to generate behaviour that looks like social norms (such as determinants of status). Take, for example, a dynamic matching model in which individuals who differ in wealth choose a partner with whom to match and obtain utility from joint consumption and the utility of their child. As shown in Mailath and Postlewaite (2003), in addition to an equilibrium in which there is assortative matching on wealth, there may also be an equilibrium with imperfectly assortative matching that depends also on non-economic characteristics such as whether one has blue eyes. In this equilibrium, blue eyes matter not because of their intrinsic value, but simply because the matching rule allocates, for the same wealth level, a wealthier partner to individuals with blue eyes. Thus, a woman would be willing to match with a man with blue eyes and slightly lower wealth than another man without blue eyes, because although she
obtains lower joint consumption, there is a 50 per cent chance that her child would inherit blue eyes and hence a better match and higher consumption in the future. To an outside observer, it might therefore appear that in this society people had an intrinsic preference for blue eyes, although this inference would be incorrect.

Although the example above is interesting, its explanation for a particular social norm seems incomplete and intuitively less than compelling. The preference for blue eyes or light skin may perhaps initially come about as a choice among many equilibria and involve solely a calculation about the trade-off between one's own consumption and that of one's child (though that too seems doubtful and is more likely the result of a history in which these traits are correlated with higher status). Over the longer run, however, one may conjecture that what sustains these equilibria – what makes these cultural traits less fragile to perturbations – is that these calculations are embodied in the individual and in society as preferences and beliefs about the inherent superiority/desirability of such features. People come to prefer blue eyes; people become racist. Thus, what is missing more generally in the theory of culture is an analysis of how preferences and beliefs (about things other than equilibrium strategies) themselves evolve.

The hypothesis that certain features of culture (those that have greater depth than driving on the left or the right side of the street) become part of preferences and beliefs implies that they cannot be discarded easily simply because they are no longer useful or beneficial, though over time this will certainly lessen their appeal. In this way, the operation of culture may be clearest to perceive when it no longer serves any useful societal purpose or particular group interest but nonetheless, at least for some time, persists – for example, religious prohibition on eating pork. (One reason speculated for this prohibition is that consumption of undercooked pork is linked to trichinosis. It is now known that this problem can be eliminated, however, by thoroughly cooking the meat.) In the context of the matching example above, individuals may eventually be willing to match with lower wealth people with blue eyes because this matching rule is incorporated into preferences/beliefs over what type of mate is intrinsically better even if the benefit derived by passing this trait on to their offspring is no longer substantial (say, because family size falls and decreases the payoff from the inheritable trait relative to the decrease in immediate joint consumption).

So far, we have discussed differences in culture as systematic differences in preferences and beliefs without distinguishing much between the two. This is not accidental, since, in general, the distinction between preferences and beliefs for our purposes is rather fuzzy. Even for simple preferences such as the trade-off between apples and oranges, what one knows (or believes) about the nutritional contents of the two may affect how one ‘feels’ about them, as may any other mental associations (for example, whether one is considered more exotic, how they were grown and so forth). In general, there are few pure (or naive) preferences – what one thinks or believes influences how one feels (and the same may be true vice versa. See Damasio, 1995, for an interesting exposition of evidence in favour of the hypothesis that emotions affect – and in fact are necessary for – the ability to think well). This is not to deny that people have some inherent tastes (for example, it is believed that human beings have a taste for fat, probably because of the evolutionary advantage associated with an inclination to eat meat in an environment in which protein and iron were not easily obtained).

For more complex questions the above is even more likely to be true. Consider, for example, the large increase in female labour force participation in the 20th century. Is it that woman's disutility from market work decreased or that her beliefs about the meaning or consequences of her working that changed over
time? The dichotomy between the two alternatives does not seem very useful in this case. If the focus is on understanding why actions change over time, then using standard preferences and modelling the evolution of beliefs as giving rise to changes in expected payoffs may be the more useful strategy (the latter is the approach taken by Fernández, 2007b, who shows that a model of the evolution of female LFP as an intergenerational learning process does a good job of replicating a century of US female LFP data). If instead one wished to understand the utility from a given action, particularly one in which identity is concerned, then incorporating cultural beliefs into preferences may be a better route (see, for instance, Akerlof and Kranton, 2000). For example, wearing a dress or having a woman as a boss may decrease a man's utility, independently of any expectations of future consequences, simply because it makes him feel (culturally) less masculine.

Culture and institutions

As seen previously, the main challenge faced by most empirical work on culture is to convincingly isolate its effects from the incentives provided by traditional economic variables and institutions. This should not be taken to mean that culture and institutions are independent variables. Indeed, one way to think about institutions is as congealed culture: that is, which institutions are set up and how these evolve depends not only on the problems faced by society (or by a particular group in society) at a particular moment in time but also the beliefs/preferences – the culture – that are prevalent. As elaborated on in our earlier discussion of Greif (1994), cultural beliefs (collectivist versus individualist), for example, were reflected in the different ways in which in the 11th century Genoese traders and Maghrebi traders set up their trading institutions, leading to very different economic development paths thereafter. My hypothesis is that the reverse causality is also likely to hold: that is, not only does culture affect institutions but also institutions affect the dynamic evolution of culture. In this sense, work that attempts to establish whether institutions or culture are the most important determinants of economic development seems misconceived (see Fernández, 2007c, for a theoretical analysis of the dynamic dependency of culture and institutions; also Bowles, 1998, for a review of some of the theoretical and empirical evidence on the effect of markets on culture).

Concluding remarks

The rigorous study of culture and economics is in its infancy. We would like to understand, for example, how culture propagates and evolves. In particular, what is the relative importance of family versus other institutions as cultural transmission mechanisms for different beliefs or in different environments? To what extent is cultural transmission purposeful, that is, optimizing on the part of an individual or her parents (as in Bisin and Verdier, 2000) or for a social group, and to what extent is it involuntary? (Fernández, Fogli and Olivetti, 2004, show that whether a man's mother worked while he was growing up is correlated with whether his wife works, even after controlling for a whole series of socioeconomic variables. They interpret this as preference transmission, but whether it is voluntary – optimizing – or simply by example is an open question.) When and why does culture change abruptly whereas at other times it proceeds glacially?

The relationship between technology and culture also needs to be investigated. How does technology
influence culture and how does culture shape technological change? Some papers (for instance, Greenwood and Guner, 2005; Greenwood, Seshadri and Yorukoglu, 2002) argue that sexual norms and female LFP changed because of changes in technology. These papers ignore, among other things, the endogeneity of demand for new technology. Despite the convenient simplification of treating technology as a primitive, it too is endogenous. The extent to which societies put resources into developing technology that ‘liberates’ individuals from household work, for example, depends on things such as whether slavery is available or whether women expect to work in the market or at home. Put differently, both the relative price of market versus household labour and the elasticity of labour supply depend on the institutions (for example, slavery) and expected division of labour (for example, clearly differentiated gender roles) that are in place. The opposite is also true – the extent to which one can substitute capital for labour, whether at work or at home, helps determine which institutions are viable and may determine the pace and ease with which beliefs or preferences change.

From a theoretical perspective, the endogeneity of preferences and beliefs raises difficult questions for welfare. How should we evaluate policies once we recognize that preferences can change? While this is indeed a vexing and problematic question for welfare economics, recognizing that man is a social animal that is (perhaps uniquely) capable of reflecting upon, and hence changing, his preferences and beliefs greatly enriches our view of ourselves and the world and within it the potential role of economic discourse. In the words of A.O. Hirschman, ‘de valoribus est disputandum’.

Cunningham, William (1849–1919)

O. Kurer
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Cunningham, W.; economic history; English Historical School; imperialism; Marshall, A.; protectionism

Article
A member of the English Historical School, Cunningham was educated at the Universities of Edinburgh and Cambridge. He held various posts as lecturer at Cambridge and was elected Fellow of Trinity College in 1891. From 1891 to 1897 he was Tooke Professor of Statistics of King's College London. In addition, he pursued a religious career. He was ordained in 1874 and rose to be Archdeacon of Ely (1907–19).

Cunningham was one of the most important pioneers in economic history. His Growth of English Industry and Commerce (1882) was the first textbook in the field, widely used for several decades and an important foundation on which English economic history was to be constructed, and he relentlessly fought for the recognition and establishment of economic history as an independent discipline. Cunningham became increasingly hostile towards economic theory. He felt that its assumptions about human behaviour and the institutional framework were leading to insufficiently complete analyses and were blatantly unrealistic for most periods in history. In 1892 he started the English Methodenstreit by attacking Marshall for constructing economic history from general principles instead of empirical data. The debate was partly the result of his personal and professional antagonism towards Marshall and his wish to apply economics to politics.

Cunningham shifted from an internationalist and free trader to a nationalist and protectionist, making the preservation and strengthening of the nation-state his most weighty political and economic objective. By the time of the fiscal controversy in 1903 he fully endorsed the tariff reform movement and subscribed to imperialism, with the great empire securing peace and order.

Cunynghame, Henry Hardinge (1848–1935)

J.K. Whitaker

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Cunynghame, Henry Hardinge; demand; supply curve

Article

Soldier, lawyer, civil servant, polymath and amateur economist, Sir Henry Cunynghame was born of distinguished forebears on 8 July 1848 at Penshurst. He died at Eastbourne on 3 May 1935, having been knighted in 1908. In 1870 he entered St John's College, Cambridge, to study law, throwing over a promising military career. There he became a favourite of Alfred Marshall and was infected by an enthusiasm for 'geometrical political economy', a topic on which he was eventually to publish one of his many books (1904). There too he invented for Marshall a machine (now lost) for drawing a grid of rectangular hyperbolae (Guillebaud, 1961, Vol. II, pp. 37–8).

Called to the Bar in 1875, Cunynghame had a varied career in law and government, but always retained his interest in economics. He occasionally lectured on the subject (his Notes on Exchange Value (1880) were printed for one such course) and in the later 1880s belonged to the economic discussion group which met at the Hampstead home of Henry Ramée Beeton. (P.H. Wicksteed, G.B. Shaw, H.S. Foxwell and F.Y. Edgeworth were among the regulars.) There he presented a paper (1888) defending Marshall's supply curve against Wicksteed's criticisms. The analysis of external effects in production and consumption, his most significant theoretical contribution, first appeared here, the arguments being amplified, but not much clarified, in Cunynghame (1892). His other notable contribution, the use of back-to-back demand–supply diagrams to analyse markets linked by trade, appeared in Cunynghame (1903). The 1904 book, although lively and praised by J.M. Keynes, added little and, indeed, rather compounded earlier ambiguities by a certain flabbiness of thought. Cunynghame's last economic publication (1912) was a valedictory address on methodology. For further biographical detail see Keynes (1935) and Ward and Spencer (1938). Consult also letters by Marshall (reproduced in Pigou, 1925, pp. 447–52; Guillebaud, 1961, Vol. II, pp. 809–13) and Edgeworth's review (1905) of Cunynghame (1904).

currency boards

Federico Sturzenegger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Currency boards are exchange rate arrangements in which the exchange rate is fixed to an anchor currency and central banks just buy and sell domestic currency at this exchange rate. We review the advantages and disadvantages of currency boards. While some of the alleged benefits of currency boards have diminished hand in hand with a reduction in inflation rates in most countries since the mid-1990s, currency boards may remain an attractive option for certain countries.

Article

A currency board is defined as an exchange rate arrangement in which the exchange rate is fixed to an anchor currency and the central bank operates with a simple rule that precludes the monetary authorities from issuing money unless they obtain an equivalent amount of international assets to back it. From a practical point of view this means that the central bank has no independent monetary policy and that it creates or contracts the money supply only as the result of its interventions in the foreign exchange market. If there is excess demand for domestic currency capital will flow in (probably in response to an increase in interest rates) and the central bank, by acquiring these flows, will expand the money supply. If there is excess supply of domestic currency, the central bank will take in this excess supply by giving away international assets, thus contracting the money supply. In some cases this rule is implemented by forcing the central bank to have full backing of domestic base money with international reserves. In some cases a currency board does not require a one-to-one backing of the monetary base, but it still
currency boards: The New Palgrave Dictionary of Economics

Precludes the conduct on an independent monetary policy beyond very strict limits. In fact, a currency board also differs from a typical peg in its commitment to the system, which is usually enshrined in law and in the Central Bank charter.

As of July 2006 the exchange rate arrangement classification published by the International Monetary Fund (IMF) identifies 13 countries with currency boards. Of these, six correspond to countries in the Eastern Caribbean Currency Union (Antigua and Barbuda, Dominica, Grenada, St Kitts and Nevis, St Lucia and St Vincent and the Grenadines), plus seven others: Bosnia and Herzegovina, Brunei Darussalam, Bulgaria, China-Hong Kong SAR, Djibouti, Estonia and Lithuania. Because all these countries are relatively small, currency boards are placed in a relatively unpopular category amongst potential exchange rate regimes.

There are two main reasons why countries have typically used currency boards. In some cases the currency board is more attractive than a common currency. For example, for the Eastern Caribbean countries mentioned above it seems relatively obvious they should use the US dollar as currency to maximize the benefits from a stable exchange rate arrangement with their almost sole trading partner. However, the currency board allows them to keep the exchange rate credibly fixed without giving up the seigniorage revenue of domestic currency. In other cases countries have resorted to a currency board as a way out of monetary and inflation chaos. Argentina's currency board experience in the 1990s and Bulgaria's currency board are appropriate examples. Even though, as we will see below, the evidence points to large trade benefits of currency boards, it is typically assumed that the main benefit of currency boards is as a tool to fight inflation.

The interest in and excitement about currency boards reflects both the need that countries have faced to solve either of the two problems mentioned above – currency integration without seigniorage cost and exiting from a high inflation situation – and the assessment made at the time of whether a currency board is the most efficient way to reach those objectives. Recent years have been unkind to currency boards on both counts. While the use of a currency board as a replacement for a common currency remains a valid motive, its effect as an anti-inflation device has become less relevant as inflation rates fell throughout the 1990s. In 2007 most countries exhibit single-digit inflation rates, and only a handful of exotic cases appear to have a monetary policy that is out of control. The high-inflation history of yesteryear has been critical to this improvement by fostering much stronger fiscal policies and monetary policies that are much freer from political pressures (both when central banks are independent and when they are not) and increasingly within an inflation targeting framework. As inflation has decreased, so have the benefits of a currency board, thus making it a relatively less attractive proposition.

Furthermore, while before the demise of Argentina's currency board in early 2002 no currency board had been forced to end, the fact that Argentina's currency board came to an end in the midst of a major crisis (after enduring a long period of high interest rates) raised some questions as to how much credibility the regime actually bought. As a result, many countries have opted to jump directly all the way to dollarization (for example, El Salvador and Ecuador) or to pursue integration into a currency union (Slovenia) thus making currency boards lose ground even to alternative ‘harder’ exchange-rate commitments.

In spite of the recent drop in interest in this specific regime, nothing precludes a rise in interest again in the future, so a discussion of the specifics of currency boards remains useful. The best way to organize the discussion is to present the advantages of a currency board, then move to the disadvantages, and then attempt a synthesis.
Advantages of a currency board

The main advantage that is ascribed to a currency board is the credibility gains that it allows, helping deliver lower inflation and better fiscal results. The argument is simple: a currency board represents a strong commitment that if broken can have a large and costly effect on expectations. Because politicians fear this loss of credibility, the currency board, while in place, lowers inflation expectations and inflation itself and should provide the incentives for an improvement in fiscal behaviour. These predictions have been broadly borne out. On the inflation front Ghosh, Gulde and Wolf (1998), drawing on a data-set for all IMF countries between 1970 and 1996, found that countries with currency boards delivered an inflation rate that was about four per cent lower, a sizable effect. This result has held up in later work (see for example Levy-Yeyati and Sturzenegger, 2001; and Kuttner and Posen, 2001). The record on fiscal discipline is also relatively favourable. Ghosh, Gulde and Wolf (1998) and Culp, Hanke and Miller (1999) find that countries on currency boards tend to run tighter fiscal policies. Fatas and Rose (2000) also find that currency boards are associated with fiscal restraint (though, somewhat surprisingly, this restraint does not carry on to dollarized economies or those operating within the context of a common currency). Anecdotal evidence also seems to point in the same direction. In 2001, as Argentina's currency board was under fire, fiscal authorities implemented large budget adjustments in an attempt to strengthen the system.

Currency boards may also have an effect on trade as a result of the stability it induces on the exchange rate, an effect similar to the one that has been identified for countries that adopt a common currency with other countries. This exercise is specifically undertaken in Frankel and Rose (2002), who find that the effect of a currency board is a more than tripling of trade (in fact they find that the trade effects for currency boards and common currencies are statistically indistinguishable). Thus the trade motive for a currency board seems to be important. Added to the benefits of saving on seigniorage, it explains why currency boards may remain an attractive option for some small countries.

Disadvantages of a currency board

Four main arguments have been advanced against currency boards. First, the fact that it precludes monetary authorities from running an independent monetary policy and that the exchange rate cannot adjust in response to real shocks; second, that it may ‘hide’ underlying problems, leading to larger crises down the road; third, that it stimulates large currency mismatches in the portfolio structures of government and the private sector; and fourth, that it limits the ability of the central bank to act as a lender of last resort, thus hindering the possibility of developing a locally based financial sector. The debate has focused mostly on whether alternative mechanisms and policies within the context of the currency board are available to deal with these problems. Let us review each of them briefly.

On the loss of monetary/exchange rate policy, the question is how relevant a loss this it. It can be argued that the idea of a currency board is indeed to limit the scope for an independent monetary policy, which had otherwise proven unable to contain high inflation. To the extent that inflation and fiscal policy improve, not much may be lost relative to the situation in which monetary policy merely induced inflation without any particular benefit in terms of macroeconomic stabilization. Thus, assessing
currency boards: The New Palgrave Dictionary of Economics

whether this is a cost requires us to evaluate what the counterfactual is. Proponents of currency boards could argue that only countries where monetary policy serves no purpose choose currency boards as a commitment device.

Of course, if monetary policy were possible, the costs of doing without it may turn out to be particularly costly for currency boards. The case of Argentina helps illustrate why this should be so. Argentina had established a currency board with the dollar to quell inflation expectations in the early 1990s. Like any other emerging country, it was hurt by the rush out of emerging markets following Russia's default in 1998. This rush strongly appreciated the dollar, making Argentina's currency stronger exactly when the country needed it to weaken. The fact that currency boards require a strong anchor currency and that capital flows may strengthen these currencies when there is turmoil in emerging countries – thus moving the exchange rate exactly in the opposite direction to the one the country would have otherwise chosen – poses a problem for currency boards during periods of high turbulence in international financial markets.

Of course, as much as in the optimal currency area debate, how costly the loss of the monetary instrument is depends on the availability of alternative adjustment mechanisms: fiscal transfers, remittances, labour market mobility, or internal price flexibility, which may all operate as substitutes for the loss of monetary policy (the effectiveness of these alternative mechanisms may explain the different fates of Hong Kong's and Argentina's currency boards). Fiscal policy can also be used as a stabilizer that may substitute for the lack of exchange or monetary policy, though the ability of countries to use it seems relatively limited, particularly for those countries that opted for a currency board as a result of their poor fiscal policies. Some evidence for the fact that the lack of monetary policy may hurt is provided by Levy-Yeyati and Sturzenegger (2001), who compare the growth performance of hard pegs generally (including currency boards) with other regimes. They find that hard pegs trail floating regimes in growth performance (though not by more than pegs or intermediate regimes). However, this allows us to conclude that, in the end, the lack of policy responses may have a detrimental effect on overall economic performance.

The fact that currency boards may delay an adjustment has also been a cause of concern. Aizenman and Glick (2005) and Kuttner and Posen (2001) have both found that the harder and longer the peg, the larger are the depreciations upon exiting. This is to be expected, because the stronger the commitment, the fixed exchange rate spell will be typically longer, and only under more unfavourable conditions will the peg be abandoned, suggesting that an earlier adjustment may have been beneficial. This conclusion, however, should be treated with care because it fails to take into account the fact that this stringency also helps avoid many exits that later on would have turned out to be unnecessary.

The same caution should be used when evaluating the tendency of currency boards to foster the evolution of mismatches in government and private sector debt structures. The basic idea is that as long as the currency board holds countries develop a tendency to ‘dollarize’ their financial sectors (see Catao and Terrones, 2000), with banks piling foreign currency deposits on their liability side, firms borrowing in dollars abroad and governments issuing debt in dollars. This is a problem because the asset side of these borrowers is in most cases linked mostly to the local economy, and thus, whether denominated in foreign currency or not, subject to currency risk in the event of a devaluation. This mismatch, however, is a double-edged sword. On the one hand it increases the commitment of the authorities to the peg (and this is why sometimes it is encouraged by the authorities as an additional credibility booster), but on the other it may also trigger large capital outflows in anticipation of a crisis. In the presence of large mismatches, agents would correctly anticipate a devaluation to produce a costly crisis, thus accelerating
the run and the likelihood that the currency will sink. How these two factors play out during a crisis depends on the specifics of each individual country. Finally, a currency board limits the ability of the central bank to operate as lender of last resort, particularly in the event of a bank run. This has been suggested as an explanation of why countries with currency boards quickly develop an international based banking system (typically with local institutions bought by foreign banks) which is better insured against runs at any specific location. Proponents of currency boards have suggested several alternatives to replace the central bank's function as lender of last resort with other mechanisms. Among these are the possibility of the government operating as lender of last resort, potentially by borrowing in dollars in times of need; the setting up of insurance schemes by which financial institutions buy in advance the access to funds in the context of a systemic liquidity run (these schemes were implemented by Mexico and Argentina); tighter capital and liquidity requirements on the banking sector; and the piling up of ‘extra reserves’ as far as possible. The first of these mechanisms is doubtful, as the government may have limited access to financing when it faces a crisis, and the others entail a cost. However, it may be said that some of these schemes have been implemented and used successfully. Specifically, Argentina used its contingent credit line with private banks during its 2001 crisis and banks honoured their pledge at the time.

Where does this leave us?

The conclusion is then that, as much as with currency unions, there seems to be a strong trade motive to set up a currency board. In fact, for a fiscally sound small country with the ability to conduct fiscal policy with some flexibility a currency board may be superior to a common currency as it allows the country to retain the seigniorage on its money stock. For larger middle-income countries a currency board has been pursued more as a way of improving credibility than anything else. While currency boards seem to have delivered, the Argentina case also suggests that their role in improving credibility cannot be taken fully for granted. If a currency board is implemented in times of easy access to international financial markets, fiscal discipline may be sidestepped and a fiscal and currency crisis may still occur at the end of the day. Additionally, policymakers should ask themselves if it makes sense to buy the credibility through a peg, or to buy it the hard way, day by day, implementing reasonable fiscal policies while maintaining some degree of flexibility in monetary policy. The successful experience since the mid-1990s of many countries with managed floating regimes and inflation targeting seems to point to this direction. If this trend continues, currency boards may become even rarer in the future.

currency competition

Stacey L. Schreft
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Currency competition’ means the virtually free entry of private-sector firms into the issuance of a currency. Such competition no longer exists, but interest in it revived in the 1970s as high inflation was attributed by some to governments’ incentives to overissue their currencies to generate additional seigniorage. Competition was advocated as a potential remedy because it was thought to give issuers an incentive to protect the value of their currencies by limiting issuance.

Article

‘Currency competition’ refers to the free, or virtually free, entry of private-sector firms into the issuance of a circulating medium of exchange in lieu of a government monopoly on currency issue. Although there is little analytical basis for focusing on the private issuance of securities that circulate at the expense of those that do not, that is exactly the approach of the literature on currency competition and thus of this article.
The best real-world examples of currency competition come from periods, some lasting more than a century, in which countries allowed banks to operate relatively free from regulation. This freedom allowed, among other things, banks to issue paper notes. Shuler (1992) identified 66 countries as having free banking for some period in the 19th and 20th centuries, and all of them reportedly had multiple private-sector note issuers.
Today, there is no true private note issuance. Any privately issued notes are issued by banks that operate as agents of their respective central banks. Shuler (1992) attributed the demise of privately issued notes to several factors. One factor was a shift in attitudes about the need for and proper role of central banks.
The view took hold that currency issuance could be destabilizing if left to the private sector, and governments nationalized currency issuance in their central banks. This was the case in England, for example, where the Currency School came to dominate and the Bank Act of 1844 eliminated private note issuance. Another major factor leading to government monopolies over currency issuance was the First World War and governments' need for additional sources of revenue. The ability to issue currency directly became very appealing.

By the 1970s, governments' monopoly on currency creation was raising its own concerns. These government issuers had an incentive to overissue to generate additional seigniorage revenue. When inflation began rising in the 1970s, some blamed this incentive to overproduce and called for denationalization of currency issuance. Friedrich Hayek (1990) was perhaps the most prominent proponent of a return to currency competition. Hayek argued, in the terms of today, that an equilibrium could exist with competitive issuance and that it would likely dominate the equilibrium arising when the government monopolizes currency issuance. The logic was that the demand for a privately issued currency depends in part on the currency's quality because such currencies are distinguishable. The more units of a currency supplied, the lower is the currency's value in exchange and thus its perceived quality and the public's demand for it. Competition would thus give issuers an incentive to protect the value of their currencies by not overissuing.

In considering what currency competition might look like, economists rediscovered the free banking periods, and a literature arose studying them. The first wave of that literature consisted of historical studies of free banking and private note issuance, although there were also a few theoretical models. Later, in the 1990s, the potential for new electronic means of payment, such as stored value and digital currencies for the Internet, led to another generation of research on currency competition, this time primarily theoretical.

Most discussions of currency competition, whether from a theoretical or an historical perspective, failed to distinguish inside money from outside money. Hellwig's work (1985) was an exception. Inside money is a claim that obligates its issuer to redeem or exchange the money for some specified monetary or non-monetary object. Failure to do so, perhaps because of insufficient reserves held against the money, can result in a failure to fulfill that obligation and ultimately bankruptcy. The value of a privately issued inside money depends in part, then, on the likelihood of the issuer fulfilling its claim, and only in part on the value of using the money in exchange. Outside money is not a claim against the issuer or anyone else. The issuer makes no promise to redeem its currency at any time for anything of value. The value of a privately issued outside money derives solely from its value in exchange.

The experience in the US free banking era (1837–63) is an example of the importance of the claim that backs an inside money. Bank notes issued in the free banking era were supposed to be fully backed to guarantee the issuer's ability to redeem them, but often they were not. In some cases, no backing was held. Bank note reporters kept track of the financial condition of issuers and of the prices at which notes were trading. Weber (2002) found that notes traded for one another at flexible exchange rates that often depended in part on the extent to which the notes were backed. When the public became aware that an issuer's notes lacked backing, the notes stopped circulating.

The distinction between inside and outside money is important for studying currency competition. Competition in outside note issuance is likely to divert fewer resources from consumption and production than competition in inside note issuance because there is no need to hold reserves against the outside notes. However, without reserves to back outside money, the money is likely to be overissu
because of its near-zero marginal cost of production. Thus, the welfare gain from avoiding overissuing with an inside money must be balanced against the welfare loss from holding full or fractional reserves against such money.

Historical experience with outside money has almost always involved a single, government-issued fiat currency. The existing theoretical literature suggests why privately issued outside money is virtually never observed. In many different economic environments, economists have shown that there can be no equilibrium with competitive issuance of outside money if issuers cannot make binding commitments about the volume of notes they will issue. Taub (1985) and Bryant (1981) showed this in an overlapping-generations model. Ritter (1995) did so in a search model of money. In all cases, the argument is as follows, and similar to Hayek's. If issuing new money is costless, issuers cannot make binding commitments, and money has some positive value, then any private agent that issues notes will issue an unlimited quantity, driving the inflation rate to infinity and the real value of the money to zero. Rational agents would anticipate this ultimate outcome and be unwilling to hold the money at any earlier date. The inability to make binding commitments, coupled with a time inconsistency problem, is a key feature of this argument because issuers always want to believe they will constrain their note issuance, but when they need to they never have the incentive to do so.

A few models have gotten around this result. Klein (1974), for example, provided an early argument based on reputation formation for the existence of equilibria with free entry into private issuance. He argues that the monies of different issuers can be distinguishable by quality, so they can circulate at flexible exchange rates with one another. His discussion, however, blurs the distinction between inside and outside money.

In another example, Martin and Schreft (2006) showed that privately issued outside money can be valued if agents believe that all notes issued up to some threshold will be valued, but additional notes will be worthless. These beliefs create a discontinuity in the value of the marginal unit of currency. Because the value of a marginal unit of currency reaches zero for some finite supply, the limit argument no longer applies. Martin and Schreft derived their existence result in both an overlapping generations and a search-theoretic environment, though it should hold in any environment in which fiat currency could be valued. Interestingly, welfare is not necessarily greater with competitive issuance than with monopoly issuance and depends on the environment considered. In the search environment, neither competitive issuers nor a monopolist achieve the efficient quantity of money in the long run. In the overlapping-generations environment, the efficient allocation is achieved in finitely many periods if agents incur a cost of becoming money issuers. A monopoly issuer might achieve as desirable an allocation, but only if its actions are sufficiently constrained by agents' beliefs.

In contrast, the historical experience with inside money has involved multiple inside monies that are all convertible into some single dominant outside money. A modern literature on privately issued inside notes, largely attributable to Wallace and others, has considered this case. Cavalcanti and Wallace (1999a; 1999b) studied a search-theoretic model with an exogenously given and indivisible outside money and inside money issued by private agents known as banks. To get the private money to be valued, they assumed that issuers who do not accept a note when presented with one face a stiff punishment: they lose the ability to issue notes and revert to autarky. This assumption is reminiscent of the redemption requirements of successful systems for private inside currency issuance, like the Suffolk Banking System that operated in New England in the early 1800s. The authors found that, if the stock of outside money is sufficiently small, then the optimal mechanism has private notes issued and also
currency competition: The New Palgrave Dictionary of Economics

redeemed on demand. Additionally, expected utility is greater in economies with inside money than only outside money because the set of implementable allocations is larger. In the United States, at least, it is claimed that little currently prohibits private-sector issuance of outside currency in either paper or digital form. The laws prohibiting it have either expired or been repealed. It will be interesting to see if a resurgence of private issuance occurs.

Abstract

Currency crises have occurred frequently in the post-war era. In this article we review the literature on the causes and consequences of currency crises. First-generation models attribute a central role to fiscal policy as a fundamental determinant of crises. Second-generation models emphasize the possibility of self-fulfilling speculative attacks and multiple equilibria. Third-generation models stress how financial fragility can lead to currency crises.

Article

There have been many currency crises during the post-war era (see Kaminsky and Reinhart, 1999). A currency crisis is an episode in which the exchange rate depreciates substantially during a short period of time. There is an extensive literature on the causes and consequences of a currency crisis in a country with a fixed or heavily managed exchange rate. The models in this literature are often categorized as first-, second- or third-generation.

In first-generation models the collapse of a fixed exchange rate regime is caused by unsustainable fiscal policy. The classic first-generation models are those of Krugman (1979) and Flood and Garber (1984). These models are related to earlier work by Henderson and Salant (1978) on speculative attacks in the gold market. Important extensions of these early models incorporate consumer optimization and the government’s intertemporal budget constraint into the analysis (see Obstfeld, 1986; Calvo, 1987; Drazen...
currency crises models: The New Palgrave Dictionary of Economics

In a fixed exchange rate regime a government must fix the money supply in accordance with the fixed exchange rate. This requirement severely limits the government’s ability to raise seigniorage revenue. A hallmark of first-generation models is that the government runs a persistent primary deficit. This deficit implies that the government must either deplete assets, such as foreign reserves, or borrow to finance the deficit. It is infeasible for the government to borrow or deplete reserves indefinitely. Therefore, in the absence of fiscal reforms, the government must eventually finance the deficit by printing money to raise seigniorage revenue. Since printing money is inconsistent with keeping the exchange rate fixed, first-generation models predict that the regime must collapse. The precise timing of its collapse depends on the details of the model.

The key ingredients of a first-generation model are its assumptions regarding purchasing power parity (PPP), the government budget constraint, the timing of deficits, the money demand function, the government’s rule for abandoning the fixed exchange rate, and the post-crisis monetary policy. In the simplest first-generation models there is a single good whose domestic currency price is \( P_t \) and whose foreign currency price is 1. Let \( S_t \) denote the nominal exchange rate. PPP implies \( P_t = S_t \). Suppose for simplicity that the government has a constant ongoing primary deficit, \( \delta \). It finances this deficit by reducing its stock of foreign reserves, \( f_t \), which can either evolve as a smooth function of time or jump discontinuously. In the former case, \( f_t \) evolves according to \( \dot{f}_t = r f_t - \delta + \dot{M}_t / S_t \), where \( r \) is the real interest rate, \( M_t \) is the monetary base, and a dot over a variable denotes its derivative with respect to time. When foreign reserves change discontinuously, \( \Delta f_t = \Delta (M_t / S_t) \). When \( \delta > rf_0 \) interest income from foreign assets will not be sufficient to finance the deficit.

To illustrate the key properties of first-generation models, we make three simplifying assumptions. First, money demand takes the Cagan (1956) form, \( \dot{M}_t = \theta \exp[-\eta(r + \pi_t)] \), where \( \theta > 0 \) and \( \pi_t = \dot{P}_t / P_t \) is the inflation rate. Second, the government abandons the fixed exchange rate regime when its foreign reserves are exhausted. Third, as soon as foreign reserves are exhausted, the government prints money at a constant rate \( \mu \) to fully finance its deficit.

These assumptions imply that after the crisis the level of real balances, \( m_t = M_t / P_t \), is constant and equal to \( \overline{m} = \theta \exp[-\eta(r + \mu)] \). The post-crisis government budget constraint reduces to \( \delta = \mu \overline{m} \). This equation determines \( \mu \). Let \( t^* \) denote the date at which foreign reserves are exhausted and the government abandons the fixed exchange rate regime. PPP implies \( S_{t^*} = P_{t^*} = \overline{M} / \overline{m} \), where \( \overline{M} \) is the monetary base the instant after date \( t^* \). Under perfect foresight the exchange rate cannot jump discontinuously at \( t^* \) since such a jump would imply the presence of arbitrage opportunities. Given that the exchange rate must be a continuous function of time at \( t^* \), \( \Delta f_{t^*} = \overline{m} - m \). This is why the literature refers to \( t^* \) as the date of the speculative attack. Prior to the crisis real balances are given by \( m = \theta \exp(-\eta r) \). Therefore, at date \( t^* \) there is a sudden drop in real money demand from \( m \) to \( \overline{m} \) implying that reserves drop discontinuously to zero at time \( t^* \): \( \Delta f_{t^*} = \overline{m} - m \). This is why the literature refers to \( t^* \) as the date of the speculative attack. Prior to the crisis the government’s reserves fall at the rate \( \dot{f}_t = rf_t - \delta \). The budget constraint implies that \( t^* = \ln \{ (\delta - r(m - \overline{m}) / (\delta - rf_0) ) / r \} \). While the collapse of the fixed exchange rate regime is
currency crises models: The New Palgrave Dictionary of Economics

inevitable, it does not generally occur at time zero unless $m - \bar{m} > f 0$.

A shortcoming of this type of first-generation model is that the timing of the speculative attack is deterministic and the exchange rate does not depreciate at the time of the attack. These shortcomings can be remedied by introducing shocks into the model, as in Flood and Garber (1984).

Early first-generation models predict that ongoing fiscal deficits, rising debt levels, or falling reserves precede the collapse of a fixed exchange rate regime. This prediction is inconsistent with the 1997 Asian currency crisis. This inconsistency led many observers to dismiss fiscal explanations of this crisis. However, Corsetti, Pesenti and Roubini (1999), Burnside, Eichenbaum and Rebelo (2001a), and Lahiri and Végh (2003) show that bad news about prospective deficits can trigger a currency crisis. Under these circumstances a currency crisis will not be preceded by persistent fiscal deficits, rising debt levels, or falling reserves. These models assume that agents receive news that the banking sector is failing and that banks will be bailed out by the government. The government plans to finance, at least in part, the bank bailout by printing money beginning at some time in future. Burnside, Eichenbaum and Rebelo (2001a) show that a currency crisis will occur before the government actually starts to print money. Therefore, in their model, a currency crisis is not preceded by movements in standard macroeconomic fundamentals, such as fiscal deficits and money growth. Burnside, Eichenbaum and Rebelo argue that their model accounts for the main characteristics of the Asian currency crisis.

This explanation of the Asian currency crisis stresses the link between future deficits and current movements in the exchange rate. This link is also stressed by Corsetti and Mackowiak (2006), Daniel (2001), and Dupor (2000), who use the fiscal theory of the price level to argue that prices and exchange rates jump in response to news about future deficits.

In first-generation models the government follows an exogenous rule to decide when to abandon the fixed exchange rate regime. In second-generation models the government maximizes an explicit objective function (see, for example, Obstfeld, 1994; 1996). This maximization problem dictates if and when the government will abandon the fixed exchange rate regime. Second-generation models generally exhibit multiple equilibria so that speculative attacks can occur because of self-fulfilling expectations. In Obstfeld's models (1994; 1996) the central bank minimizes a quadratic loss function that depends on inflation and on the deviation of output from its natural rate (see Barro and Gordon, 1983, for a discussion of this type of loss function). The level of output is determined by an expectations-augmented Phillips curve. The government decides whether to keep the exchange rate fixed or not. Suppose agents expect the currency to devalue and inflation to ensue. If the government does not devalue then inflation will be unexpectedly low. As a consequence output will be below its natural rate. Therefore the government pays a high price, in terms of lost output, in order to defend the currency. If the costs associated with devaluing (lost reputation or inflation volatility) are sufficiently low, the government will rationalize agents’ expectations. In contrast, if agents expect the exchange rate to remain fixed, it can be optimal for the government to validate agents’ expectations if the output gains from an unexpected devaluation are not too large. Depending on the costs and benefits of the government's actions, and on agents’ expectations, there can be more than one equilibrium. See Jeanne (2000) for a detailed survey of second-generation models.

Morris and Shin (1998) provide an important critique of models with self-fulfilling speculative attacks. They emphasize that standard second-generation models assume that fundamentals are common knowledge. Morris and Shin demonstrate that introducing a small amount of noise into agents’ signals
about fundamentals will lead to a unique equilibrium. Many currency crises coincide with crises in the financial sector (Diaz-Alejandro, 1985; Kaminsky and Reinhart, 1999). This observation has motivated a literature that emphasizes the role of the financial sector in causing currency crises and propagating their effects. These third-generation models emphasize the balance-sheet effects associated with devaluations. The basic idea is that banks and firms in emerging market countries have explicit currency mismatches on their balance sheets because they borrow in foreign currency and lend in local currency. Banks and firms face credit risk because their income is related to the production of non-traded goods whose price, evaluated in foreign currency, falls after devaluations. Banks and firms are also exposed to liquidity shocks because they finance long-term projects with short-term borrowing. Eichengreen and Hausmann (1999) argue that currency mismatches are an inherent feature of emerging markets. In contrast, authors such as McKinnon and Pill (1996) and Burnside, Eichenbaum and Rebelo (2001b) argue that, in the presence of government guarantees, it is optimal for banks and firms to expose themselves to currency risk.

Different third-generation models explore various mechanisms through which balance-sheet exposures may lead to a currency and banking crisis. In Burnside, Eichenbaum and Rebelo (2004) government guarantees lead to the possibility of self-fulfilling speculative attacks. In Chang and Velasco (2001) liquidity exposure leads to the possibility of a Diamond and Dybvig (1983) style bank run. In Caballero and Krishnamurthy (2001) firms face a liquidity problem because they finance risky long-term projects with foreign loans but have access to limited amounts of internationally accepted collateral.

An important policy question is: what is the optimal nature of interest rate policy during and after a currency crisis? There has been relatively little formal work on this topic. Christiano, Braggion and Roldos (2006) take an important first step in this direction. They argue that it is optimal to raise interest rates during a currency crisis and to lower them immediately thereafter. Studying optimal monetary policy in different models of currency crises remains an important area for future research.

currency crises

Graciela Laura Kaminsky
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article describes models and empirical evidence on currency crises. The evidence from developed and developing countries indicates that crises are of different varieties. It also shows that crises do not occur in economies with sound fundamentals, with vulnerabilities far more widespread and profound in emerging economies. Vulnerabilities are associated with fiscal problems, loss of competitiveness and a deteriorating current account, external debt unsustainability, or problems in the financial sector – especially banks. Interestingly, those crises associated with bank fragility are the costliest in terms of output losses and loss of access to international capital markets.

Keywords

Article

A currency crisis occurs when investors flee from a currency en masse out of fear that it might be devalued. Currency crises are episodes characterized by sudden depreciations of the domestic currency, large losses of foreign exchange reserves of the central bank, and (or) sharp hikes in domestic interest rates.

There have been numerous currency crises since 1980. The so-called debt crisis erupted in 1982 following Mexico's default and devaluation in August. This crisis spread rapidly to all Latin American countries, and by the time it was over, most Latin American countries had devalued their currencies and defaulted on their foreign debts. The debt crisis was followed by a decade of negative growth and isolation from international capital markets. The output costs of this crisis were so large that the 1980s
currency crises: The New Palgrave Dictionary of Economics

became known as the ‘lost decade’ for Latin America. Crises are not just emerging-market phenomena. The 1990s opened with crises in industrial Europe – the European Monetary System (EMS) crises of 1992 and 1993. By the end of these crises, in the summer of 1993, the lira and the sterling had been driven from the Exchange Rate Mechanism (ERM); Finland, Norway, and Sweden had abandoned their unofficial peg to the European Currency Unit (ECU); the Spanish peseta, the Portuguese escudo and the Irish punt had devalued; and Europe's central bank governors and finance ministers had widened the ERM's intervention margins to ±15 per cent from ±2.25 per cent. Only then did the currency market stabilize.

Crises are hardy perennials. Within one year of the EMS crises, a currency crisis exploded in Mexico, with currency jitters spreading around the Latin American region. In 1997, it was Asia's turn. A new episode of currency turbulences started in July of that year with the depreciation of the Thai baht. Within a few days the crisis had spread to Indonesia, Korea, Malaysia and the Philippines. Turmoil in the foreign exchange market heightened in 1998 with the Russian default and devaluation in August. The Russian crisis spread around the world with speculative attacks in economies as far apart as South Africa, Brazil and Hong Kong. Currency crises have continued to erupt in the new millennium, with Argentina's crisis in December 2001 including the largest foreign-debt default in history.

The numerous financial crises that have ravaged emerging markets as well as mature economies have fuelled a continuous interest in developing models to explain why speculative attacks occur. Models are even catalogued into three generations. The first-generation models focus on the fiscal and monetary causes of crises. These models were mostly developed to explain the crises in Latin America in the 1960s and 1970s. In these models, unsustainable money-financed fiscal deficits lead to a persistent loss of international reserves and ultimately to a currency crash (see, for example, Krugman, 1979).

The second-generation models aim at explaining the EMS crises of the early 1990s. These models focus on explaining why currency crises tend to happen in the midst of unemployment and loss of competitiveness. To explain these links, governments are modelled facing two targets: reducing inflation and keeping economic activity close to a given target. Fixed exchange rates may help in achieving the first goal but at the cost of a loss of competitiveness and a recession. With sticky prices, devaluations restore competitiveness and help in the elimination of unemployment, thus prompting the authorities to abandon the peg during recessions. Importantly, in this setting of counter-cyclical policies, the possibility of self-fulfilling crises becomes important, with even sustainable pegs being attacked and frequently broken (see, for example, Obstfeld, 1994).

The next wave of currency crises, the Mexican crisis in 1994 and the Asian crisis in 1997, fuelled a new variety of models – also known as third-generation models – which focus on moral hazard and imperfect information. The emphasis here has been on ‘excessive’ booms and busts in international lending and asset price bubbles. These models also link currency and banking crises, sometimes known as the ‘twin crises’ (Kaminsky and Reinhart, 1999). For example, Diaz-Alejandro (1985) and Velasco (1987) model difficulties in the banking sector as giving rise to a balance of payments crisis, arguing that, if central banks finance the bail-out of troubled financial institutions by printing money, we have the classical story of a currency crash prompted by excessive money creation. Within the same theme, McKinnon and Pill (1995) examines the role of capital flows in an economy with an unregulated banking sector with deposit insurance and moral hazard problems of the banks. Capital inflows in such an environment can lead to over-lending cycles with consumption booms, real exchange rate appreciations, exaggerated current account deficits, and booms (and later busts) in stocks and property markets. Importantly, the
excess lending during the boom makes banks more prone to a crisis when a recession unfolds. In turn, the fragile banking sector makes the task of defending the peg by hiking domestic interest rates more difficult and may lead to the eventual collapse of the domestic currency. Following the crisis in Argentina in 2001, the links between debt sustainability, sovereign defaults, and currency crises again attracted the attention of the economics profession. Finally, currency crises have also been linked to the erratic behaviour of international capital markets. For example, Calvo (1998) has brought to general attention the possibility of liquidity crises in emerging markets due to sudden reversals in capital flows, in large part triggered by developments in the world financial centres.

To summarize, all models suggest that currency crises erupt in fragile economies. Importantly, the three generations of models conclude that vulnerabilities come in different varieties. Still, the first attempts to study the vulnerabilities that precede crises have adopted ‘the one size fits all’ approach (see, for example, Frankel and Rose, 1996; and Kaminsky, 1998). That is, the regressions estimated to predict crises include all possible indicators of vulnerability. These indicators include those related to sovereign defaults, such as high foreign debt levels, or indicators related to fiscal crises, such as government deficits, or even indicators related to crises of financial excesses, such as stock and real estate market booms and busts. In all cases, researchers impose the same functional form on all observations. When some indicators are not robustly linked to all crises, they tend to be discarded even when they may be of key importance for a subgroup of crises. Naturally, these methods leave many crises unpredicted and, furthermore, cannot capture the evolving nature of currency crises.

The next step in the empirical analysis of crises should be centred on whether crises are of different varieties. The first attempt in this direction is in Kaminsky (2006). In this article, a different methodology is used to allow for ex ante unknown varieties of currency crises. To identify the possible multiple varieties of crises, regression tree analysis is applied. This technique allows us to search for an unknown number of varieties of crises and of tranquil times using multiple indicators. This technique was also applied to growth by Durlauf and Johnson (1995).

Interestingly, this method catalogues crises into six classes:

1. 1. **Crises with current account problems.** This variety is characterized by just one type of vulnerability, that of loss of competitiveness, that is, real exchange rate appreciations.
2. 2. **Crises of financial excesses.** The fragilities are associated with booms in financial markets. In particular, they are identified as crises that are preceded by the acceleration in the growth rate of domestic credit and other monetary aggregates.
3. 3. **Crises of sovereign debt problems.** These crises are characterized by fragilities associated with ‘unsustainable’ foreign debt.
4. 4. **Crises with fiscal deficits.** This variety is just related to expansionary fiscal policy.
5. 5. **Sudden-stop crises.** This type of crisis is only associated with reversals in capital flows triggered by sharp hikes in world interest rates, with no domestic vulnerabilities.
6. 6. **Self-fulfilling crises.** This class of crises is not associated with any evident vulnerability, domestic or external.

These estimations allow us to answer four important questions about crises.
1. **Do crises occur in countries with sound fundamentals?** Even though this estimation allows for the identification of self-fulfilling crises (crises in economies with sound fundamentals), the results indicate that basically all crises are preceded by domestic or external vulnerabilities. Only four per cent of the crises are unrelated to economic fragilities.

2. **How important are sudden reversals in capital flows in triggering crises?** While many have stressed that the erratic behaviour of international capital markets is the main culprit in emerging market currency crises, only two per cent of the crises in developing countries are just triggered by sudden-stop problems. While sudden-stop problems do occur, the reversals in capital flows mostly occur in the midst of multiple domestic vulnerabilities (see, Calvo, Izquierdo and Talvi, 2004).

3. **Are crises different in emerging economies?** Crises in emerging markets are preceded by far more domestic vulnerabilities than those in industrial countries. Overall, 86 per cent of the crises in emerging economies are crises with multiple domestic vulnerabilities, while economic fragility characterizes only 50 per cent of the crises in mature markets.

4. **Are some crises more costly than others?** It is a well-established fact that financial crises impose substantial costs on society. Many economists have emphasized the output losses associated with crises. But these are not the only costs of crises. In the aftermath of crises, most countries lose access to international capital markets, losing the ability to reduce the effect of adverse income shocks by borrowing in international capital markets. In most cases, countries have to run current account surpluses to pay back their debt. Finally, the magnitude of the speculative attack is itself important. For example, large depreciations may cause adverse balance sheet effects on firms and governments when their liabilities are denominated in foreign currencies. **Crises of financial excesses**, those also associated with banking crises – twin crisis episodes – are the costliest. Not only does the domestic currency depreciate the most, but also output losses are higher and the reversal of the current account deficit is attained via a dramatic fall in imports. In the aftermath of these crises, exports fail to grow even though the depreciations in this type of crises are massive. This evidence suggests that countries are even unable to attract trade credits to finance exports when their economies are mired in financial problems. In contrast, **self-fulfilling crises** and **sudden-stop crises** (but with no domestic vulnerabilities) have no adverse effects on the economies. Output (relative to trend) is unchanged or continues to grow in the aftermath of crises with no observed domestic fragility. In these crises, booming exports are at the heart of the recovery of the current account.

Currency unions (also known as monetary unions) are groups of countries that share a single money. Currency unions are unusual, since most countries have their own currency. For instance, the United States, Japan and the United Kingdom all have their own monies. But a reasonable number of countries participate in currency unions, and their importance is growing. In May 2005, 52 of the 184 IMF members participated in currency unions.

Currency unions present and past

Currency unions commonly come about when a small or poor country unilaterally adopts the money of a larger, richer ‘anchor’ country. For instance, a number of countries currently use the US dollar, including Panama, El Salvador, Ecuador, and a number of smaller countries and dependencies in the...
Caribbean and Pacific. Swaziland, Lesotho and Namibia all use the South African rand. Both the Australian and New Zealand dollars are used by a number of countries in the Pacific; Liechtenstein uses the Swiss franc; and so forth. In the past, a number of countries have used the currency of their colonizer; over 50 countries and dependencies have used the British pound sterling at one time or another. Cases like this are known as official dollarization (unofficial dollarization occurs when the currency of a foreign country circulates widely but is not formally the national currency). In such cases, the small country essentially relinquishes its right to sovereign monetary policy. It loses its ability to independently influence its exchange and interest rates; these are determined by the anchor country, typically on the basis of the interests of the anchor.

There are also a number of multilateral currency unions between countries of more or less equal size and wealth. For instance, the East Caribbean dollar circulates in Anguilla, Antigua and Barbuda, Dominica, Grenada, Montserrat, Saint Kitts and Nevis, Saint Lucia, and Saint Vincent and the Grenadines. The Central Bank of the West African States circulates the Communauté française d'Afrique (CFA) franc in Benin, Burkina Faso, Côte d'Ivoire, Guinea-Bissau, Mali, Niger, Senegal, and Togo. The Bank of the Central African States circulates a slightly different CFA franc in Cameroon, the Central African Republic, Chad, Republic of Congo, Equatorial Guinea, and Gabon.

The largest and most important currency union is the Economic and Monetary Union of the European Union (EMU). EMU technically began on 1 January 1999, although the euro was physically introduced only three years later. Twelve countries are formally members of EMU: Austria, Belgium, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, the Netherlands, Portugal, and Spain. (A number of smaller European territories and French dependencies also use the euro.) These countries jointly determine monetary policy for EMU through the international European Central Bank. The number of members in EMU is expected to grow with time, especially as countries that acceded to the European Union in 2004 become eligible for EMU entry. However, both Sweden and Denmark have rejected membership in referenda, and the euro remains unpopular in the UK.

While a number of currency unions currently exist, many have not survived. The Latin Monetary Union began in 1865 when France, Belgium, Italy and Switzerland (later joined by Greece, Romania, and others) adopted common regulations for their individual currencies to encourage the free international flow of money. This essentially amounted to a commitment to mint silver and gold coins to uniform specifications, but without other restrictions on monetary policy. The union effectively ended with the onset of the First World War. The war also ended the Scandinavian Monetary Union which Denmark, Norway, and Sweden began in 1873. The economic union between Belgium and Luxembourg that began in 1921 has been absorbed into EMU. Multilateral currency unions in East Africa, Central Africa, West Africa, South Asia, South-East Asia, and the Caribbean have also disappeared.

**Theory: why should countries enter currency union?**

Historically, most countries have had their own moneys. There seems to be a tight connection between national identity and national money; a country's money is a potent symbol of sovereignty. Still, some countries have entered into currency union. Why? Economists have theorized about the potential economic benefits of currency union which can, in certain circumstances, overwhelm the perceived political costs.

Like all other monetary regimes, currency unions are fully compatible with Robert Mundell's (1968)
currency unions: The New Palgrave Dictionary of Economics

celebrated ‘Trilemma’ or ‘Incompatible Trinity’. A country would like its monetary regime to deliver three desirable goals that turn out to be mutually exclusive: domestic monetary sovereignty, capital mobility, and exchange rate stability. Currently, large rich countries like the United States, Japan and the UK have domestic monetary sovereignty and open capital markets but have floating exchange rates. By way of contrast, members of a currency union essentially relinquish the first objective (monetary independence) in exchange for the latter benefits (capital mobility and stable exchange rates). Indeed, some economists think of currency unions as simply extreme forms of fixed exchange rates, with all the associated pros and cons. Countries inside currency union receive more microeconomic benefits than they would from a fixed exchange rate, since sharing a single money leads to deeper integration of real and financial markets. On the other hand, a country can devalue or float the exchange rate more easily than it can leave a currency union. Still, this is an unsatisfying theoretical approach the issue of currency unions. It does not address to the vital question: what is the optimal size of a currency union? If the right size for a currency union is not necessarily the country, how should we tackle the problem?

The theoretical analysis of currency unions began with a seminal paper by Mundell (1961). Mundell’s analysis answered the question: what is the appropriate domain for a currency? Mundell briefly argued there are advantages to regions that use a common money. In particular, currency union facilitates international trade; a single medium of exchange reduces transactions costs, as does a common unit of account. However, a common currency can also cause problems in the dual presence of asymmetric shocks and nominal rigidities (in prices and wages). Suppose demand shifts from Western to Eastern goods. The increase in demand for Western output results in inflationary pressures there, while East goes into recession. Mundell argued that, if unemployed labour could move freely from East to relieve inflationary pressures in West, the two problems could be resolved simultaneously. However, in the absence of labour mobility, the asymmetric shock could be better handled by allowing the Western currency to appreciate. But in order for this to happen, both East and West must have their own monies! Mundell concluded that the optimal currency area was the area within which labour is mobile; regions of labour mobility should have their own currencies.

Two other classic contributions to the theory of optimal currency areas are worthy of note. McKinnon (1963) examined the effects of country size on currency unions; he concluded that smaller countries tend to be more open and have fewer nominal rigidities, making them better candidates for currency union. Kenen (1969) considered the effects of the economy’s degree of diversification, and argued that more diversification resulted in fewer asymmetric shocks, and accordingly fewer benefits from national monetary policy.

The key focus of Mundell's theoretical optimum currency area framework – the adjustment to asymmetric shocks – has stood the test of time well. The ability of a region to respond to such shocks is viewed as a critical part of a sustainable and desirable currency union. Still, hardly anyone now takes the narrow specifics of Mundell's original article seriously. In particular, Mundell's conclusion that the optimum currency area is a region of labour mobility is no longer widely believed. The problem of asymmetric business cycles that Mundell described is intrinsically a problem of … business cycles. The costs of shifting labour are high almost everywhere in the world, which is why labour moves only slowly, even within countries with relatively flexible labour markets like the United States. Accordingly, most economists are uncomfortable thinking that labour could or should shift in response to the shocks and propagation mechanisms that cause business cycles. After all, the nominal rigidities that are responsible for business cycles do not last for ever. Thus, Mundell's idea of labour mobility is no longer
currency unions: The New Palgrave Dictionary of Economics

viewed as a viable adjustment mechanism. (This conclusion is tempered if one believes that real shocks cause business cycles without nominal rigidities.)

Still, there are other ways to share the risks of, or adjust to, asymmetric shocks, and much of the relevant work has incorporated these other mechanisms. Mundell originally ignored capital mobility. But private capital markets can, in principle, spread shocks internationally if investors diversify across regions or sectors. However, more attention has been paid to the public sector, since a federal system of taxes and transfers may be an efficient way to spread risks across regions. To continue with the East and West example, a progressive federal tax structure reduces inflationary Western pressures, and allows benefits to be paid to the unemployed in the East. Both regions suffer less macroeconomic volatility with such automatic stabilizers in place. The most controversial adjustment mechanism is counter-cyclical fiscal policy. In response to an asymmetric shock, regions that are free and capable of deploying discretionary fiscal policy can use changes in taxes and government spending to respond to asymmetric shocks, even within the monetary confines of a currency union. More generally, mechanisms to handle asymmetric shocks are still an integral part of the theory of currency unions.

Mundell originally thought the great benefit of currency union was the facilitation of trade since money is a convenience that lowers transactions costs. But suppose that countries produce moneys of different qualities. Argentina has gone through five currencies since 1970; high Argentine inflation results in a low convenience value for Argentine money. Suppose Argentina decides to give up on a national money altogether and enter into a currency union with a foreign producer of higher-quality money: the United States, say. Argentina will surely experience different shocks from the United States, and these shocks have to be handled. Perhaps then Argentina should enter a currency union with a country with more similar shocks? The problem is that the most obvious contender, Brazil, also has a history of monetary incompetence. The larger point is that a low-quality domestic monetary authority increases a country's willingness to enter currency union, as does the availability of high-quality foreign money. Alesina and Barro (2002) provide an elegant model that incorporates such features. In their model, countries enter currency unions with neighbours in order to facilitate trade, so long as the neighbours possess monetary institutions of quality. Lower inflation and reduced transactions costs of trade provide gains, while the inability to respond to idiosyncratic asymmetric shocks generates losses.

Empirics: what do we know in practice about currency unions?

During the run-up to EMU, a considerable empirical literature developed that quantified different aspects of optimal currency areas. Much attention was paid to estimating the synchronization of business cycles for potential EMU candidates; Bayoumi and Eichengreen (1992) was the first important paper. The tradition has since been generalized to more countries by Alesina, Barro and Tenreyro (2002), who characterized co-movements in prices as well as output. Frankel and Rose (1998) showed that the intensity of trade had a strong positive effect on business cycle synchronization; that is, the optimum currency area criteria are jointly endogenous. If currency union lowers the transactions costs of trade and thus leads to an increase in trade, it may also thereby reduce the asymmetries in business cycles; areas that do not look like currency unions ex ante may do so ex post. Bayoumi and Eichengreen (1998) successfully link optimum currency area criteria (principally the asymmetry of business cycle shocks) to exchange rate volatility and intervention, and show that a number of features of the optimum currency
currency unions: The New Palgrave Dictionary of Economics

area theory appear in practice, even for countries not in currency unions.

Somewhat curiously, little work was done to analyse actual currency unions until around 2000. This is probably because the currency unions that preceded EMU consisted mostly of small or poor countries, which were viewed as irrelevant for EMU. But this gap in the literature implicitly allowed economists to focus their attention on the costs of currency union, which tend to be macroeconomic in nature (resulting from the absence of national monetary policy as a tool to stabilize business cycles). As Mundell clearly pointed out, there are also benefits from a currency union, mostly microeconomic in nature. Fewer monies mean lower transactions costs for trade, and thus higher welfare. An unresolved issue of importance is the size of the benefits that stem from currency union. There is evidence that currency unions have been associated with increased trade in goods, though its size is much disputed. Using data on pre-EMU currency unions (such as the CFA franc zone), Rose (2000) first estimated the effect of currency union on trade, and found it to result in an implausibly high tripling of trade. This finding and the intrinsic interest of EMU have resulted in a literature that has almost universally found smaller estimates, which are yet of considerable economic size. Rose and Stanley (2005) provide a quantitative survey that concludes that currency union increases trade by between 30 and 90 per cent. Engel and Rose (2002) examine other macroeconomic aspects of pre-EMU currency unions, and find that currency union members are more integrated than countries with their own monies, but less integrated than regions within a single country. Edwards and Magendzo (2003) compare inflation, output growth and output volatility in countries inside currency unions and those outside them, and find that currency unions have lower inflation and higher output volatility than countries with their own currencies.

Areas of ignorance

The impact of currency union on financial markets is not something that is currently well understood. Yet this is an area of great interest, since currency union might result in deeper financial integration – or it might not. It is clearly of concern to the British government, which has made the financial effects one of its five tests for EMU entry (see HM Treasury, 2003).

More generally, Europe's experiment with currency union is still young. It is simply too early to know whether EMU has resulted in substantial changes in the real economy, financial or labour markets, or political economy. As the data trickles in, most expect a continuing reassessment of currency unions in theory and especially practice.

Abstract

At Harvard in the early 1930s Currie pioneered a monetary diagnosis of the 1929–32 collapse and placed blame on the Federal Reserve Board. As a prominent New Dealer at the Fed during 1934–9 he urged contra-cyclical monetary and fiscal activism. During 1939–45 he worked in Washington as President Roosevelt's economic adviser. After heading a World Bank mission to Colombia in 1949 he spent 40 years advising on national development there. He emphasized urban housing as a leading sector, based on an innovative housing finance system, and extended Allyn Young's ideas on macroeconomic increasing returns and endogenous growth.

Article

Lauchlin Currie was born on 8 October 1902 in West Dublin, Nova Scotia, and died in Bogotá, Colombia, on 23 December 1993 after an unusually long and varied career as an academic economist and top-level policy adviser. After two years at St Francis Xavier University, Nova Scotia, 1920–2, he moved to the London School of Economics (LSE), where his teachers included Edwin Cannan, Hugh Dalton, A. L. Bowley, R. H. Tawney and Harold Laski. In 1925 he obtained his BsC and moved to Harvard, where the chief inspiration for his Ph.D. thesis, ‘Bank Assets and Banking Theory’ (January 1931), was Allyn Abbott Young. However, when Young moved to the LSE in 1927 his formal supervisor was John H. Williams.

He remained at Harvard until 1934 as teaching assistant to Williams, Ralph Hawtrey and Joseph
Schumpeter. His Ph.D. thesis attacked the ‘commercial loan’ or ‘needs of trade’ theory of banking by showing that it was not only unsound in theory but had been more honoured in the breach than the observance – until its disastrous influence on monetary policy in the late 1920s and early 1930s.  

In a January 1932 memorandum, Currie, Harry Dexter White and Paul Theodore Ellsworth presented a radical anti-depression programme (see Laidler and Sandilands, 2002). In keeping with their explanation of the contraction as due to a collapsing money supply, they urged vigorous open-market operations and deficit spending financed by money creation. This memorandum was part of an early Harvard influence (through Young, Hawtrey, Williams and Currie; see Laidler, 1999) on what had been claimed as a unique Chicago monetary tradition.

In Currie (1933a) he showed the hopeless confusion that resulted from the ambiguity of the word ‘credit’. He stressed control over the quantity of money (defined as cash plus demand deposits, for which there had been no estimates until Currie published a series in 1934) rather than the quantity or quality of credit or loans. He also computed the first estimate of the income velocity of money in the United States (Currie, 1933b), with an explanation of its cyclical variations.

His ‘The Failure of Monetary Policy to Prevent the Depression of 1929–32’ (1934a) fully anticipated Milton Friedman and Anna Schwartz's (1963) diagnosis of this period. He argued that apart from the stock market there were none of the traditional signs of a boom in the 1920s. Tight monetary policies had been ineffectual in checking the rise in stock prices but only too effective in contributing to the decline in building activity and the pressure on foreign countries that preceded the Depression. He also demonstrated the perverse elasticity of money in the business cycle due to differences in reserve requirements for different classes of bank and bank deposit (1934b). In the face of the banks' reserve losses in 1929–32 and their abhorrence of heavy indebtedness to the reserve banks, the administration's policy was ‘one of almost complete passivity and quiescence’, so the self-generating forces of the Depression continued unchecked.

In 1934 Jacob Viner recruited him to the ‘freshman brain trust’ at the US Treasury where he developed a blueprint for a system of 100 per cent reserves against demand deposits, to break the link between the lending and the creation of money and to strengthen central bank control (see Phillips, 1995). Later that year Marriner Eccles, the new governor of the Federal Reserve Board, hired Currie as his top adviser, from 1934 to 1939. (Many of his memoranda to Eccles are published in Sandilands, 2004.)

At the Fed Currie drafted what became the 1935 Banking Act that gave the Fed increased powers to raise reserve requirements. In 1936–7 these powers were used, ‘as a precautionary measure’, to reduce the huge build-up of banks' excess reserves. This has been widely blamed for the sharp recession of 1937–8, a view Currie consistently rejected (1938). Instead, he invoked his newly constructed ‘net federal income-creating expenditure series’ (1935; and see Sweezy, 1972) to show the strategic role of fiscal policy in complementing monetary policy to revive an acutely depressed economy. In November 1937 he had a four-hour meeting with President Roosevelt to explain that the recession was due to sharp fiscal contraction and that balancing the budget was not the way to restore business confidence. He insisted on the need for better coordination of monetary and fiscal policy. In May 1939 the rationale for this was explained in theoretical and statistical detail by Currie and Alvin Hansen (respectively ‘Mr Inside’ and ‘Mr Outside’, according to Tobin, 1976), in joint testimony before the Temporary National Economic Committee.

From 1939 to 1945, Currie was President Roosevelt's special adviser on economic affairs in the White
House. He was also in charge of lend-lease to China, 1941–3, and ran the Foreign Economic Administration, 1943–4. In early 1945 he headed a tripartite (United States, British and French) mission to Bern to persuade the Swiss to freeze Nazi bank balances and stop shipments of German supplies through Switzerland to the Italian front. He was also closely involved in loan negotiations with British and Soviet allies and in preparations for the 1944 Bretton Woods conference (staged primarily by his friend Harry White).

After the war it was alleged by Elizabeth Bentley, an ex-Soviet agent, that Currie and White had participated in Soviet espionage. Though she had never met them herself, she claimed they had passed information to other Washington economists who were abetting her own espionage, and that they probably knew this. White and Currie were heavily involved in official wartime cooperation with the Soviets, but Bentley put a sinister interpretation on these activities. They appeared together before the House Committee on Un-American Activities in August 1948 to rebut Bentley's charges. Their testimony satisfied the Committee at that time, though the strain contributed to the fatal heart attack that White suffered three days after the hearing.

No charges were laid against Currie, and in 1949 he headed a major World Bank survey of Colombia. In 1950 the Colombians invited him to return to Bogotá, where he remained for most of the next 40 years as a top presidential adviser. He has been falsely accused of fleeing the United States to avoid charges of disloyalty. In fact in December 1952 he was a witness before a grand jury in New York investigating Owen Lattimore's role in the famous Amerasia case that involved the publication of secret State Department documents by that magazine, though his next visit to the United States was not until 1961 when he had a meeting in the White House with Walt Rostow, then President Kennedy's National Security Adviser, to discuss a development plan for Colombia.

By that time Currie had assumed Colombian citizenship (personally conferred on him by President Alberto Lleras in 1958), partly because in 1954 the US government had refused to renew his passport, ostensibly because he was only a naturalized US citizen and was now residing abroad. However, the reality was probably connected with the then secret ‘Venona’ project that had deciphered wartime Soviet cables that mentioned Currie. The related cases of Currie and White are discussed in Sandilands (2000) and Boughton and Sandilands (2003), where it is shown that the evidence against them is far from conclusive. After reading the latter paper, Major-General Julius Kobyakov, deputy director of the KGB's American desk in the late 1980s, wrote to the present writer on 22 December 2003 to confirm our conclusions. After extensive archival research on Soviet intelligence in the 1930s and 1940s he found that there was nothing in [Currie's] file to suggest that he had ever wittingly collaborated with the Soviet intelligence… However, in the spirit of machismo, many people claimed that we had an ‘agent’ in the White House. Among the members of my profession there is a sacramental question: ‘Does he know that he is our agent?’ There is very strong indication that neither Currie nor White knew that.

There were two breaks to Currie's advisory and academic work in Colombia: during a military dictatorship, 1953–8, he retired to develop a prize-winning herd of Holstein cattle; and from 1966 to 1971 he was a professor at Michigan State (1966), Simon Fraser (1967–8 and 1969–71), Glasgow (1968–9), and Oxford (1969) universities. He returned permanently to Colombia in 1971 at the behest of
President Misael Pastrana to prepare a national plan of development known as the Plan of the Four Strategies, with a focus on urban housing and export diversification. The plan was implemented and the institutions that were established in support of the plan played a major role in accelerating Colombia's urbanization.

He remained as chief economist at the National Planning Department for ten years, 1971–81, followed by 12 years at the Colombian Institute of Savings and Housing until his death in 1993. There he defended the unique index-linked housing finance system (based on ‘units of constant purchasing power’ for both savers and borrowers) that he had established in 1972. The system thus continued to boost Colombia's growth rate and urban employment opportunities year by year. Currie was also a top adviser on urban planning, and played a major part in the first United Nations Habitat conference in Vancouver in 1976. His ‘cities-within-the-city’ urban design and financing proposals (including the public recapture of land's socially created ‘valorización’, or ‘uneared land value increments’, as cities grow) were elaborated in *Taming the Megalopolis* (1976). To the time of his death he was a regular teacher at the National University of Colombia, Javeriana University, and the University of the Andes, and continued to publish widely (a comprehensive bibliography is in Sandilands, 1990, reviewed by Charles Kindleberger, 1991). His writings and policy advice were heavily influenced by his old Harvard mentor, Allyn Young. Notable is his posthumous (1997) paper that offers a unique macroeconomic interpretation of Youngian increasing returns and the endogenous nature of self-sustaining growth.

cyclical markups

Julio J. Rotemberg

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article first shows that countercyclical variations in the ratios of prices to marginal cost (markups) can cause pro-cyclical fluctuations in the demand for labour at a given real wage and thus induce fluctuations in economic activity that look like business cycles. It then discusses methods for measuring cyclical movements in markups and shows that several types of evidence suggest that these are counter-cyclical. Lastly, it discusses economic mechanisms that can explain these counter-cyclical markup movements.

Keywords

Cobb–Douglas functions; cyclical markups; elasticity; imperfect competition; increasing returns; inventory investment; labour productivity; labour supply; leisure; limit pricing; real business cycles; sticky prices; wealth effects

Article

Firms that have increasing returns to scale, that produce differentiated products, or that are part of a small oligopoly can generally be expected to set a price above marginal cost. In so far as a firm's ratio of price to marginal cost is larger than one, there is no particular reason to suppose that this ratio, or markup, will stay constant when overall economic conditions change. Indeed, different models of imperfect competition have different predictions concerning how this markup should vary as aggregate income and activity expands and contracts. Thus, an analysis of whether markups rise when aggregate activity rises or whether they rise when aggregate activity declines provides a useful lens for determining which theories of firm behaviour have more validity.

Markup variations are also of central importance for macroeconomics. One of the central questions for macroeconomics is why the economy expands and contracts at cyclical frequencies in the first place, and cyclical movements in markups are potentially an important nexus that allows such fluctuations to occur.
When a single firm (or industry) raises the ratio of its price to its marginal cost, one expects its relative price to rise so that the quantity it sells falls. However, when every firm in the economy tries to raise its price relative to its marginal cost, relative prices need not be affected. When every firm raises its markup two important consequences follow. The first is that real marginal cost, which can be defined as nominal marginal cost divided by the typical price charged by firms, must fall. Thus, the question of whether markups are countercyclical is the same as the question of whether real marginal costs are procyclical. The second consequence of all firms varying their markups at the same time is that the aggregate demand for labour changes. To see this, notice that nominal marginal cost is equal to the nominal wage divided by the marginal product of labour. Thus, a generalized increase in markups means that prices must rise relative to nominal wages if employment is to remain at a level that keeps the marginal product of labour constant. Alternatively, firms are willing to pay the same real wage only if the marginal product of labour rises, and this requires that employment fall if labour is subject to diminishing returns. In either way of seeing this change, the demand for labour at any given wage falls.

The role of markup changes in economic fluctuations

The capacity of markup changes to generate changes in aggregate labour demand is important because several pieces of evidence suggest that short-run business fluctuations are the result of changes in the demand for labour. That the willingness of firms to hire labour at any given real wage increases in economic expansions is suggested first of all by the tendency of real wages to increase when the economy expands. As shown by Bils (1985), this tendency is particularly strong when one looks at the wages of individuals (as opposed to looking at average wages paid to all workers). Moreover, as emphasized by Bils (1987), firms tend to use more overtime hours in economic booms, and firms are legally obliged to pay higher hourly wages for these overtime hours. When combined with the procyclicality of real wages, other pieces of evidence also suggest that labour demand is higher in booms. In booms, both the unemployment rate and the fraction of the unemployed who have been unemployed for longer than five weeks tend to be lower (both of which suggest that finding jobs is easier) and that the number of help-wanted advertisements is larger (suggesting that it is more difficult for firms to find workers even as they pay them higher wages). The real business cycle literature stresses a different source of labour demand movements: namely, exogenous changes in the productivity of the typical firm. This hypothesis has the advantage that it explains in a straightforward fashion why labour productivity is somewhat pro-cyclical. However, as discussed below, movements in markups lead to pro-cyclical productivity under a variety of plausible assumptions. In this regard, a clear advantage of the view that markup movements are responsible for important labour demand movements is that labour productivity and real wages rise together with output when output increases appear to be due to non-technological factors such as increases in military spending, expansionary monetary policy or reductions in the price of oil. (Evidence of these conditional correlations of productivity and output can be found in Hall, 1988.) Relative to markup variations, exogenous short-run changes in technical progress have another disadvantage as sources of cyclical fluctuations. This is that technical progress not only increases the willingness of firms to hire workers but also reduces the willingness of workers to work at any given wage. These contractionary movements in labour supply are the result of ‘wealth effects’: technical
progress makes people richer and thus induces them to consume both more goods and more leisure. These effects are particularly large if technical progress is somewhat permanent, as tends to be true with actual examples of such progress. These reductions in labour supply imply that shocks to technical progress have only small expansionary effects on employment. By contrast, reductions in markups induce only modest wealth effects, so employment responds more strongly to the resulting increases in labour demand. These conceptual benefits of countercyclical markups raise the question of whether markups do indeed rise in economic contractions and fall in booms. To discuss this, it is worth starting with the case where the value added production function takes the Cobb–Douglas form. With capital essentially fixed in the short run, this implies that aggregate value added $Y$ is equal to the labour input $H$ to the power $\alpha$. The marginal product of labour is then equal to $\alpha$ times the average product of labor $Y/H$. The ratio of marginal cost to price is then the wage divided by both the marginal product of labour and the price, so that it is proportional to the labour share in value added (or unit labour cost) $WH/PY$.

**Measuring markup variations**

If aggregate data are used, the labour share in value added is not a very cyclical variable. Labour productivity $Y/H$ tends to rise mildly in expansions, as does the average real wage – though the size of these effects depends on how one measures economic expansions. Because cyclical productivity changes are slightly larger than the corresponding average changes in real wages, the labour share has a modest tendency to fall in expansions. If the labour share were seen as equal to the inverse of the markup (as implied by the Cobb–Douglas assumptions), markups would be pro-cyclical and actually dampen cyclical fluctuations.

As suggested in the survey by Rotemberg and Woodford (1999), this Cobb–Douglas case is a good baseline, but a number of corrections to the resulting measure of the markup immediately suggest themselves, and these tend to make measured markups more counter-cyclical. The first of these is that, as already alluded to above, what matters for marginal cost is not the average wage but the marginal wage for an additional hour of work. The average wage is dragged down in booms by the absorption into employment of many relatively low-wage workers who are not employed in recessions. If these workers are less productive, their wage per effective unit of labour input may actually be relatively large. Whatever the case, individual workers who remain employed do see their wages rise more substantially, as emphasized by Bils (1987). Admittedly, these wage increases are concentrated among workers who change jobs, and the increases in the ‘straight-time’ wages of people who stay in the same job are more modest. The marginal hour of work, on the other hand, is more likely to be an overtime hour in booms, and this is probably the most important reason for believing that the marginal hour of labour is more expensive then.

It also seems important to correct the way the Cobb–Douglas approach measures the marginal product of labour. According to this functional form, the marginal product of labour is simply proportional to the average product of labour. Given that the average product of labour actually rises slightly in booms, this functional form essentially requires that the economy become ‘more productive’ in booms, perhaps as a result of increased technical progress. The tendency of labour productivity to be pro-cyclical can be interpreted in two rather different ways,
both of which have a direct bearing on calculations of the cyclical properties of the marginal product of labour. The first is that firms are subject to increasing returns to scale. The simplest functional form that captures this supposes that there are fixed costs, that is, that some of their inputs are ‘overhead’ inputs that are required to produce even a minuscule positive quantity of output for sale. Suppose for example, that \( \tilde{H} \) units of labour are overhead units so that output continues to be given by the Cobb–Douglas form but is now proportional to \( (H - \tilde{H}) \) to the power \( \alpha \). The marginal product of labour is then proportional to the ratio \( \gamma / (H - \tilde{H}) \). In booms, the percentage increase in \( H - \tilde{H} \) obviously exceeds the percentage by which \( \gamma \) rises so that \( \gamma / (H - \tilde{H}) \) falls by more than \( Y/H \). This means that for \( \tilde{H} \) sufficiently large, the marginal product of labour falls, marginal costs rise and measured markups fall. Assuming that some of the labour input takes this overhead form can thus easily lead to the inference that markups are indeed counter-cyclical.

A second possible reason for the observation that the average product of labour is pro-cyclical is that firms do not fully utilize all their labour in recessions. They ‘hoard’ labour to avoid having to incur hiring and training costs when economic activity recovers. This raises two important questions. The first is whether workers produce something else other than measured output when they are being hoarded. The second is whether the firm needs to pay them less when their GDP-producing effort is lower. Given that real wages are only slightly pro-cyclical, it is probably more realistic to suppose that the cost of an hour of labour services to the firm is the same whether the worker incurs effort (and produces) or not. Particularly if the workers are not producing much unmeasured output in recessions, this implies that marginal cost in recessions is considerably smaller than is implied by \( WH/PY \). Real marginal cost is more pro-cyclical than \( WH/PY \) and markups are more counter-cyclical. One attractive feature of this explanation for pro-cyclical labour productivity is that it is very compatible with the idea that markups are counter-cyclical. Firms are willing to keep workers idle in recessions even though marginal cost is extremely low precisely because they are keeping their prices high relative to marginal cost.

There are two additional types of evidence suggesting that markups are relatively low in booms and high in recessions. The first comes from the behaviour of intermediate inputs relative to final goods. A crude view of materials is that these are used in fixed proportions relative to the gross output of final goods. However, Basu (1995) shows that the ratio of materials to final goods tends to rise when the economy expands. If the material intensity of output is a choice variable, the ratio of marginal cost to price must also equal the real price of materials divided by the marginal product of materials. It is reasonable to suppose with Basu (1995) that the marginal product of materials diminishes as the level of materials inputs rises. With constant returns, the increase in the ratio of materials to output in booms thus implies that real marginal cost is pro-cyclical even if the price of materials relative to final output were constant. In fact, Murphy, Shleifer and Vishny (1989) show that that prices of more processed goods tend to fall relative to prices of less processed goods in economic expansions, and this too indicates a tendency of price to fall relative to marginal cost during booms.

The second additional source of evidence comes from the behaviour of inventories. Inventories rise in booms but, as stressed by Bils and Kahn (2000), they rise by less in percentage terms than sales. At the same time, long-run growth in sales does tend to be associated with equiproportionate increases in inventories in the industries they consider. In addition, they discuss cross-sectional evidence that shows that, within industries, the inventory–sales ratios of products with large sales are not smaller than the inventory–sales ratios for products with low sales. This suggests that there is something special about the
cyclical markups: The New Palgrave Dictionary of Economics

decline in inventory–sales ratios that is observed in booms. It suggests, in particular, that conditions in booms lead firms to economize on inventory holding. As Bils and Kahn (2000) argue, the evidence seems most consistent with the idea that firms keep their inventories relatively low in booms because real marginal cost is relatively high.

Theories of cyclical markup variations

A considerable body of evidence, then, seems consistent with counter-cyclical markups, and suggests that countercyclical markups might be central to aggregate fluctuations because they rationalize the changes in employment that characterize such fluctuations. The question that remains is why markups should vary cyclically. There are basically five types of models that explain these movements in markups. These are: models of variable demand elasticity, models of variable entry, models of sticky prices, models of investment in market share and models of implicit collusion.

In a monopolistically competitive setting, markups are equal to the elasticity of demand over the the elasticity of demand minus 1. Increases in the elasticity of demand thus lower markups (towards the competitive level of 1) and could thus be a source of business expansions. This still leaves the question of why the elasticity of demand facing the typical firm should vary over time. One possibility is that the proportion of demand that comes from highly elastic customers rises in booms. Gali (1994) obtains such composition effects under the supposition that investment is more price sensitive than consumption. Ravn, Schmidt-Rohe and Uribe (2004) obtain a related effect by supposing that people have formed a ‘habit’ for at least a fraction of past purchases, and the elasticity of demand for these habitual purchases is negligible relative to the elasticity of demand for non-habitual ones. As consumption rises in economic expansions, more of the purchases are non-habitual so that the elasticity of demand is higher and markups have to be correspondingly lower.

Devereux, Head and Lapham (1996) show that changes in demand induced, for example, by changes in government purchases lead new firms to enter existing industries. Entry of new firms is indeed quite pro-cyclical. Such entry can, in turn, make each firm’s perceived elasticity of demand higher (because they fear more competitors). Thus variable entry can be seen as a reason for changes in elasticities that lead to counter-cyclical markups. Even if the expansion in the number of firms that takes place in booms is seen as too small for this effect to be large, the potential for increases in entry may lead incumbents to keep their prices low to avert the creation of an even larger number of new firms. This limit pricing might also be able to rationalize counter-cyclical markups.

Sticky prices, which are widely assumed in new Keynesian macroeconomics, probably provide the most straightforward model of counter-cyclical markups. Firms that keep their prices constant when demand increases (as a result of expansionary government policy, for example) will generally see their marginal costs rise both because of diminishing returns and because of increases in the costs of factor inputs. Thus, keeping their prices relatively constant will lead them to have lower markups. The argument that sticky prices derive their influence on the economy from their consequences for variable markups is presented in more detail in Kimball (1995).

If customers who have already purchased a good have relatively inelastic demand, keeping price low is like an investment activity for the firm. It encourages new customers (those whose demand is elastic) to become addicted. Changes in economic conditions can lead firms to desire to either increase or decrease

these investments. Increases in interest rates in particular might lead firms to wish to reduce these investments, at least temporarily. Chevalier and Scharfstein (1996) provide evidence that the cash condition of firms plays a large role in these investments as well. They show that recessions have a disproportionate effect on the pricing of cash-strapped firms, who turn out to be more eager to raise prices and thereby reduce their investment in market share.

Lastly, Rotemberg and Saloner (1986) have emphasized that high prices may be more difficult to sustain for implicitly collusive oligopolists in economic expansions. When current sales are high, each firm perceives a greater benefit from undercutting the implicit agreement because it can thereby secure even higher sales. To prevent this, the oligopolists must lower their markups of price relative to marginal cost. Some cross-sectional evidence suggests that markups are indeed more counter-cyclical in more concentrated sectors, as a theory that applies only to implicitly collusive oligopolists suggests. As shown by Rotemberg and Woodford (1992), the model can be embedded in a general equilibrium structure so that increases in government purchases raise output together with real wages. The increased rate of interest induced by additional government purchases lowers the present value of the future benefits from cooperation. It thus forces oligopolies to be less ambitious in the profits that they seek from current prices, so that markups fall and labour demand rises.

British fiscal economist and prominent Labour politician, Hugh Dalton was a student of A.C. Pigou and J.M. Keynes. His main professional interest was in the use of taxation as an instrument for the redistribution of income and wealth, an interest inspired by Pigou's teaching and by his revulsion at the contrast between the sufferings inflicted on younger generations by the First World War and the material gains of those who financed or profited from the war itself. (Dalton spent four years on military service in France and Italy and lost several close friends, including the poet Rupert Brooke.) His main contribution was to investigate the properties of a modification of Bernoulli's formula $\frac{dW}{dx}$ = $\frac{c}{x}$, where $w$ = economic welfare and $x$ = income but in which equal increases in welfare should correspond to more than proportionate increases in income, a condition satisfied by Dalton's formula $\frac{dW}{dx} = \frac{dx}{x^2}$ so that $W = c - 1/x$ where $c$ is a constant. Using this formula he concluded that economic welfare would be improved by transfers from rich to poor (Dalton, 1935), a proposition that has excited the interest of 'modern' public finance theorists of the neo-utilitarian school (see Fishburn and Willig, 1984). He elaborated his ideas in several works including his highly successful standard text *Principles of Public Finance* and in his lectures as Reader in Economics at the London School of Economics (1923–36). There he was responsible for teaching and for recommending Lionel Robbins to be Professor of Economics, a typical example of his desire not only to 'corrupt the young' (as he termed it) but also to promote the interests even of those with whom he disagreed.

Dalton combined teaching with a political career throughout the 1920s and 1930s, rising to political eminence as a member of Churchill's coalition government during the Second World War. As Minister of Economic Warfare he was responsible for setting up the famous sabotage team, the Special Operations Executive (SOE). Later as President of the Board of Trade he formulated plans for post-war distribution of industry designed to prevent mass unemployment. In the Attlee Labour government of
1945 he reached the pinnacle of his political career as Chancellor of the Exchequer, one of his first acts being to nationalize the Bank of England. His famous attempt to drive down interest rates through a cheap money policy in order to float off an issue of Treasury stock at 2.5 per cent is a classic example of the failure of even an experienced and able economist to understand that, other than in the short run, governments can control either the price or the supply of bonds but not both.

Dantzig, George B. (1914–2005)

Richard W. Cottle, B. Curtis Eaves and Mukund N. Thapa

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

George Dantzig is known as ‘father of linear programming’ and ‘inventor of the simplex method’. This biographical sketch traces the high points of George Dantzig's professional life and scholarly achievements. The discussion covers his graduate student years, his wartime service at the US Air Force's Statistical Control Division, his post-war creativity while serving as a mathematical advisor at the US Air Force Comptroller's Office and as a research mathematician at the RAND Corporation, his distinguished career in academia – at UC Berkeley and later at Stanford University – and finally as an emeritus professor of operations research.

Article

George Dantzig is known as the ‘father of linear programming’ and the ‘inventor of the simplex method’. Employed at the Pentagon (the US government's defence establishment) in 1947 and motivated to ‘mechanize’ programming in large time-staged planning problems, George Dantzig gave a general statement of what is now known as a linear program, and invented an algorithm, the simplex method, for solving such optimization problems. By the force of Dantzig's theory, algorithms, practice, and professional interaction, linear programming flourished. Linear programming has had an impact on economics, engineering, statistics, finance, transportation, manufacturing, management, and
mathematics and computer science, among other fields. The list of industrial activities whose practice is affected by linear programming is very long.

Over the subsequent half century, Dantzig remained a major contributor to the subject of linear programming as researcher, practitioner, teacher, mentor, and leader. The impact of linear programming and extensions on theory, business, medicine, government, the military, all in the broadest sense, is now hard to overstate. In the words of the editors of the Society for Industrial and Applied Mathematics: ‘In terms of widespread application, Dantzig’s algorithm is one of the most successful of all time: linear programming dominates the world of industry, where economic survival depends on the ability to optimize within budgetary and other constraints …’ (quoted in Dongarra and Sullivan, 2000).

There were some significant contributions to what became linear programming prior to Dantzig’s work. In their time, however, these results were not applied, linked together, or continued. In fact, they were nearly lost, perhaps because the prevailing historical setting was not favourable. As these contributions have been recognized, they have been drawn into the history of linear programming.

A linear program defined

In mathematical terms, a linear program is most simply stated as the problem of minimizing a multivariate linear function constrained by linear inequalities. Dantzig’s first formulation of a linear program was the equivalent problem of minimizing a linear function over non-negative variables constrained by linear (material balance) equations. In matrix notation such a linear program is:

$$\text{Minimize } c^T x = zLP(A, b, c): \quad \text{subject to } Ax = b, \ x \geq 0.$$ 

Here the given data are the $m \times n$ matrix $A$ and vectors $b$ and $c$; the unknowns to be determined are the objective scalar value $z$ and the decision-variable vector $x$. The simplex method solves a linear program in a comprehensive sense; in particular, no conditions are imposed on the data $(A, b, c)$. Dantzig assessed a linear program as the simplest optimization model with broad applicability.

The study, solution, and application of linear programs constitute the subject of linear programming. The use of the words ‘programming’ and ‘program’ has changed somewhat over time. The original idea was that ‘programming’ is the activity of deciding now upon a plan, called a program, for some system that would be executed later in time. The same meaning was subsequently adopted in computer programming where the system is a computer. (See linear programming.)

Early life and education

George Bernard Dantzig was born to Tobias Dantzig and his wife, Anja Ourisson, in Portland Oregon, on 8 November 1914. Tobias, a housepainter and pedlar in his early years in the United States, later held professional positions at John Hopkins University (1919–20) and the University of Maryland (1927–46) where he chaired the mathematics department from 1930 to 1941. He is best known for his book
In 1936, George Dantzig both received an A.B. in Mathematics and Physics at the University of Maryland and married Anne Shmuner (1917–2006), who at age 19 received an A.B. in French at Maryland. In 1938 Dantzig received an MA in Mathematics at the University of Michigan; he was a Horace Rackham Scholar. In 1937–39 Dantzig worked at the U.S. Bureau of Labor Statistics as a junior statistician. Inspired by a paper of J. Neyman on which he had been assigned to report, Dantzig wrote to Neyman, then at University College London, asking if he could study under his supervision. Neyman relocated to the University of California at Berkeley, and Dantzig became his student in 1939. As is now folklore, one day Dantzig arrived late for one of Neyman's theoretical statistics classes and proceeded to copy two problems from the blackboard. In a few weeks time, with some effort, Dantzig solved the problems and submitted his homework, whereupon it was tossed onto a large pile of papers on Neyman's desk. Early one Sunday morning, about two weeks later, George and Anne were awakened by a pounding on their apartment door. There was Neyman waving George's homework. As it turned out, the assumed homework problems were, in fact, important unsolved problems. Furthermore, Neyman continued, these solutions, suitably presented, would suffice for George's Ph.D. dissertation. A. Wald independently obtained one of the same results, and the work was eventually published jointly in Dantzig and Wald (1951). Before Dantzig could complete his degree, Pearl Harbor was attacked, and he took leave of absence to work at the U.S. Air Force Comptroller's Office.

Dantzig in Washington, DC, 1941–52

At the outbreak of the Second World War, Dantzig began working at the War Department, again as a junior statistician. By the war's end, he was in charge of the Combat Analysis Branch of the Statistical Control Division of the United States Air Force. His office collected and consolidated data with hand-operated mechanical desk calculators about sorties flown, tons of bombs dropped, planes lost, personnel attrition rates, and so on. By end of the war, Dantzig had a personnel force of 300 reporting to him. In 1946 Dantzig returned to Berkeley for one semester to defend his thesis and complete his minor thesis in dimension theory. Throughout his life, Dantzig acknowledged a great debt to J. Neyman, his mentor. Dantzig nonetheless turned down a position in mathematics at UC Berkeley for the greater financial security of a position at the Pentagon. There he undertook the challenge to 'mechanize' the planning process. War planning required coordination of an entire nation and yet was executed with desk calculators; the need for mechanization was clear. To this end, a group in the Air Force was organized under the name Project SCOOP (Scientific Computation of Optimum Programs) and headed by M.K. Wood. Dantzig was a principal. Two movements suggested that progress was possible: Leontief's (1936) work and the emergence of the computer; indeed, Project SCOOP arranged for Pentagon support of computer development (see Dantzig, 1947).

In early 1947, Dantzig formulated the general statement of a linear program. In June of that year he learned from T.C. Koopmans, who had been studying transportation problems (Koopmans, 1947) that economists had no algorithm for solving a linear program. By July Dantzig had designed the simplex method, a name suggested by Leo Hurwicz (see simplex method for solving linear programs). Experiments with the simplex method in the following year at the Pentagon were encouraging. Linear programs were also solved with the simplex method at the National Bureau of Standards (NBS) in
coordination with SCOOP. At NBS a ‘large one’, the diet problem, was undertaken by J. Laderman. It
had been studied earlier by Stigler (1945). The question was: what selection of 77 foods produces a diet
meeting nine nutritional criteria at the least cost? The problem was solved by the simplex method with
five statistical clerks using desk calculators. According to (Dantzig 1963), ‘approximately 120 man-days
were required to obtain a solution’. The simplex method was gaining acceptance. Air Force applications
of linear programming in years following included contract bidding, crew training, deployment
scheduling, maintenance cycles, personnel assignments, and airlift logistics.

From special cases as a triangular model to the general algorithm, the simplex method was first
implemented on a computer in 1949 by M. Mantalbano (NBS) on an IBM 602-A, in 1950 by C. Diehm
on the SEAC, in 1951 by A. Orden (Air Force) and A. Hoffman (NBS) on the SEAC, and in 1952 by the
Air Force for the Univac. The next generation of codes, circa 1952–56, which achieved commercial
quality, was developed by W. Orchard-Hays at the RAND Corporation on a sequence of IBM machines.

For the matrix $A$ of LP $(A, b, c)$ of size 200 by 1000, linear programs could be solved in five hours
(Orchard-Hays, 1954). In years following, there was a flood of computer implementations, both by
commercial vendors and in research institutions. As of 2006, linear programs where both $m$ and $n$
exceed hundreds of thousands are routinely solved in hours by the simplex method on personal
computers.

After describing and testing the simplex method, Dantzig had an audience with J. von Neumann at
Princeton in 1947. Among world-class mathematicians, von Neumann had the broadest interests.

Dantzig began his explanation of linear programming with the 30-minute version when von Neumann
snapped ‘Get to the point’. Dantzig began again, this time with his one-minute version. Von Neumann
responded, ‘Oh, that!’ He envisioned an analogy with matrix games as developed in von Neumann and
Morgenstern (1944). Extrapolating from what he knew about duality in matrix games, von Neumann
expounded on what was to become known as duality in linear programming. As a by-product of the
meeting, it was evident that any matrix game problem could be solved by a linear program. Volume VI
of John von Neumann: Collected Works contains his previously uncirculated manuscript dated 15–16
November 1947 on duality in linear programming (von Neumann, 1947). The following January,
Dantzig (1948a) wrote ‘A Theorem on Linear Inequalities’. This memorandum clarified his
understanding of von Neumann's duality monologue. Von Neumann's (1947) paper is regarded as the
earliest on this subject; Dantzig's memorandum is the second. A.W. Tucker, also at Princeton, took an
interest in the relationship of linear programming and game theory and involved his students, D. Gale
and H.W. Kuhn. These three subsequently wrote the definitive account of duality in linear programming
(Gale, Kuhn and Tucker, 1951).

**First linear programming conference, 1949**

Koopmans organized a conference on ‘linear programming’ and economics in Chicago at the Cowles
Commission for Research in Economics in 1949. Koopmans and others (including Dantzig) edited the
conference proceedings volume *Activity Analysis of Production and Allocation* (1951). Dantzig's work
was the focus of the proceedings; of the 25 papers, Dantzig co-authored a paper with M.K. Wood and
authored four others, including the two leading papers which developed linear programming for
time-staged planning. Earlier versions of these two papers appeared in *Econometrica* (1949). Four of the 20
contributors to these proceedings – K.J. Arrow, T.C. Koopmans, P.A. Samuelson, and H.A. Simon – were later to win Nobel Prizes. Hundreds of books on, or inspired by, linear programming followed over the years. Four of note are Dorfman, Samuelson and Solow (1958), Arrow, Hurwicz and Uzawa (1958), Dantzig (1963), and Schrijver (1986). The terminology ‘linear programming’ was not in regular use at the time of this conference; Koopmans had suggested it to Dantzig (1948b) in lieu of expressions like ‘programming in a linear structure’. Even so, Koopmans (1951) observed, ‘To many economists the term linearity is associated with narrowness, restrictiveness, and inflexibility of hypotheses’. R. Dorfman, at the Pentagon with Dantzig, had suggested the broader expression of ‘mathematical programming’.

Nonlinear programming, 1950

Following the early successes of linear programming, there was a natural inclination to generalize the model, the algorithm, and duality to results beyond linear functions to a next layer of difficulty such as differentiable, convex, quadratic, or polynomial functions. This body of research has become known as ‘nonlinear programming’. As for optimality conditions and duality, the paper ‘Nonlinear Programming’ of Kuhn and Tucker (1951) was pivotal at the time: their investigation proceeded through the Lagrangian function and saddle points thereof with the duality in linear programming as a target. The Lagrangian had been used in equality-constrained optimization, and results obtained there were less general. Kuhn and Tucker cited the fundamental paper of John (1948), which includes inequality constraints. Some 25 years later, the master's thesis of Karush (1939) came to light in the mathematical programming community; Karush, as far as is known, was the first to lay down optimality conditions for a nonlinear (inequality constrained) program. Rockafellar (1970) carried the convex duality analysis to a new level. As for nonlinear programming algorithms, tens, and eventually hundreds, were forthcoming, many using ideas from the simplex method in one way or another.

Dantzig at RAND, 1952–60

Reorganization of the Air Force preceded Dantzig's taking a position at the RAND Corporation in Santa Monica, California, as a research mathematician. Awareness of the power of linear programming set the scene for a second growth. For the next few years most theoretical development of linear programming took place at RAND and Princeton. Dantzig's book *Linear Programming and Extensions* (1963) records his own (and collaborative) contributions during this period.

Transportation and network optimization problems

The war years has seen interest in optimal transportation research. Historically significant papers from this period include Hitchcock (1941), Kantorovich (1942), Koopmans (1947; 1949), Kantorovich and Gavurin (1949), and Flood (1956). Flood, through M. Shiffman, had come upon the Kantorovich papers on translocation and transportation; however, linear programming launched the general analysis of optimal transportation. Dantzig made several contributions here, starting with Dantzig (1951). Dantzig,
Fulkerson and Johnson (1954) is a seminal work on the travelling salesman problem. Others are Dantzig and Fulkerson (1954) on tanker routing, and Dantzig and Fulkerson (1955) on maximizing flow through a network. For networks with non-negative arc distances, Dantzig (1960a) stated an algorithm for shortest distances. Dijkstra (1959) produced similar results at about the same time. *Flows in Networks* by the RAND Corporation's Ford and Fulkerson (1962) was then the definitive work on the subject.

### Large-scale methods and decomposition

Dantzig and Orchard-Hays (1954) described the ‘revised simplex method’ as a more efficient version of the simplex method. As linear programming was applied to more applications and with a broader scope, including time and alternate scenarios, the size of linear programs that needed to be solved continued to grow. Dantzig was among the first to observe that large linear programs typically had two convenient features: sparsity and structure. Sparsity refers to the fact that a very small percentage, often less than one hundredth of one per cent, of the $A$ data matrix is non-zero. Structure refers to the fact that the non-zeros typically occur in an orderly pattern of submatrices of $A$. Dantzig (1955a) wrote the first paper on methods for large-scale linear programs addressing upper bounds, block triangular systems, and secondary constraints. Building on the Dantzig, Orden and Wolfe (1955) paper on generalized linear program, Dantzig and Wolfe (1960) devised a generalization of the simplex method, called the *decomposition principle*, for certain structured large-scale linear programs, wherein the problem is decomposed allowing for use for what is now called distributed computation.

### Quadratic programming

A most natural first extension of a linear program is a quadratic program, that is, a linear program except that the objective is a quadratic function such as $x^TQx + q^Tx$. A convex quadratic program is one with a convex objective function to be minimized. Following the success of linear programming, there was a proliferation of studies on convex quadratic programming and associated algorithms.

### Convex programming

Convex programming is also a natural extension of linear programming. Here a convex function is minimized over a convex region; the latter is specified by convex inequality constraints. If the feasible region is bounded, the convex program can be approximated as close as desired by a linear program, and one can improve the approximation as the simplex method runs. A special case of a convex program is one having linear inequality constraints and a *separable* objective function, that is, a function that is the sum of univariate convex functions. Charnes and Lemke (1954) and Dantzig (1956) solved such problems with linear programming approximations.

### Stochastic programming with recourse

Linear programming offered a breakthrough for mathematical approximation and solution of planning problems. Dantzig knew that to move to the next level of approximation of planning, an accommodation...
of uncertainty and of discrete variables was needed; he made inroads on each. Linear programming has been extended in a number of directions to incorporate uncertainty. An elementary example is a linear program where the costs \( c = (c_1, c_2, \ldots, c_n) \) are random variables and the desire is to minimize the expected value. In this case the problem is solved as the linear program where the costs are simply taken as their expected value. More interesting is the Markowitz (1956) portfolio selection where quadratic programming is used to obtain at least a desired level of expected return while minimizing risk.

Dantzig's early work on stochastic programming was stimulated by his work with A.R. Ferguson on the assignment of aircraft to routes, where a deterministic formulation proved insufficient, and so uncertain demand needed to be considered (Ferguson and Dantzig, 1955). Subsequently, Dantzig (1955b) applied linear programming to solve multistage decision problems sequenced amidst uncertainty; this topic is often referred to as stochastic programming with recourse. Such a multistage problem concerns the optimization of a sequence of decisions in time where each decision depends on random events which in turn are dependent on previous decisions. The vision in this paper was truly extraordinary, and has been reprinted as one of the ten most influential papers in management science since the mid-1950s in Hopp (2004).

Integer programming and cuts

An integer program is a linear program except that some, or all, of the variables \( x_1, x_2, \ldots, x_n \) are required to take on integer values, as in \( x_i = 0, 1, 2, \ldots \). Dantzig, Fulkerson and Johnson (1954) took the first steps towards obtaining integer solutions for a large problem with the simplex method. They addressed an instance of the travelling salesman problem: find the shortest route, by car, through major cities of the 48 states and Washington, DC. Let a directed network represent the available roads and let costs represent distances. The variables are flows on each link of the network. Constrain for one unit of flow into each capital, constrain for one unit of flow out of each capital, constrain for conservation of flow at other nodes, and find the minimum cost flow. The linear programming solutions here, which yield flows of 0 or 1, are deficient as a solution for the travelling salesman problem in that isolated loops of flow may occur. To combat such loops, Dantzig et al. sequentially and dynamically (as the simplex method was stopped and continued) introduced additional constraints, called cuts, which would prohibit those loops which had occurred in a solution of the expanding linear program, without constraining out desired solutions. The concept of a cut or cutting planes was so conceived. In addition, this study revealed the inherent difficulty of the travelling salesman problem. Over the following decades, aspects of this matter would grow to become a major issue in applied mathematics. There is a vast difference between linear constraints and linear inequality constraints (both with unconstrained variables); there is an even larger difference between real variables and integer variables. Subsequently, Gomory (1958), at Princeton, began the design of several general purpose cutting plane algorithms for solving integer programs, and gave proofs for finite convergence. These algorithms did not work well for a reason not understood at the time namely, that general integer programs are inherently hard to solve.

Other edge path descent algorithms

By 1955 the simplex method was regarded as the algorithm for solving linear programs. Indeed, the
simplex method inspired dozens of related fundamental ideas for algorithms, and hundreds of variations. In particular, there was steady research on variations of edge path descent algorithms, that is, those which accept the simplex method strategy but strive to improve upon it. One target was to reduce computation time by reducing the number of pivots and the work per pivot. Example contributions include: the dual simplex method of Lemke (1954), the parametric method of Orchard-Hays (1954), the primal-dual method of Dantzig, Ford and Fulkerson (1956) and the parametric objective method of Gass and Saaty (1955). In a slightly different direction were the column generation and the decomposition method of Dantzig and Wolfe (1960; 1961). Essentially all of these variants of the simplex method have proved valuable for various specialized tasks related to linear programs, and sometimes nonlinear programs. For nonlinear programs the main ideas of the simplex method have been adopted; here one can think of solving linear or quadratic programs that are approaching the nonlinear program. It is interesting to note that as late as the early 1970s an eminent speaker of a plenary session of a national mathematical programming conference said that the simplex method was the best algorithm for linear programming and that it always would be; the statement was accepted, without objection.

Problem reduction

The mathematical subject of computational complexity aims to categorize problems by their solution difficulty. Several of Dantzig's papers (1957; 1960b; 1968) contributed to the foundation of this subject. A basic technique of computational complexity is the reduction of one class of problems to another. For the reduction of discrete problems, Dantzig focused on problems in mixed binary form, MBP, and the related relaxed form RMBP obtained by replacing binary constraints with corresponding interval constraints. MBP(A, b, c) is a linear program LP(A, b, c) plus the discrete constraints \( x_i = 0, 1 \) for \( i = 1, ..., k \) for some \( k \leq n \). RMBP(A, b, c) is the linear program LP(A, b, c) plus the linear inequalities \( 0 \leq x_i \leq 1 \) for \( i = 1, ..., k \). For emphasis, MBP(A, b, c) is not a linear program whereas RMBP(A, b, c) is.

A few problem classes of form MBP can be solved as the corresponding linear program RMBP; that is if \((x, z)\) is an extreme point solution, as the simplex method would generate, of RMBP, then \((x, z)\) is a solution to MBP. Problem classes MBP which can be so solved by RMBP include the assignment problem, shortest route problems with non-negative distances, and the tanker scheduling problem. Other problems, such as the empty container problem, most scheduling problems, fixed charge problems, and travelling salesman problems, do not permit such solution; nevertheless, the corresponding RMBP can be most helpful in solving or approximately solving MBP. As time and theory have revealed, general problems of type MBP are difficult to solve.

Let \( C^* \) be the convex hull of all feasible solutions of MBP and let \( C \) be the set of all solutions of RMBP. Then \( C^* \) is a subset of \( C \), and all extreme points of \( C^* \) are extreme points of \( C \); the issue is, however, that there are extreme points of \( C \) that are not in \( C^* \). Note that, if there is but one binary variable, then MBP can be solved as two linear programs, one with \( x_1 = 0 \) and one with \( x_1 = 1 \); but for general \( k \), this scheme requires the solution of an exponential number \( 2^k \) of linear programs. For reducing problems to the MBP form, Dantzig (1960b) illustrated a number of examples such as: (a) dichotomies, (b) discrete variables, (c) piecewise linear objective functions, (d) conditional constraints, and (e) the fixed charge problem.
Towards the end of the 1950s, the mathematical programming community became aware of three relevant works from the past. The first two are pertinent to the simplex method and the third relevant to the formulation of real problems as linear programs. Fourier (1826) had also written on the idea of descending from vertex to adjacent vertex in the polyhedron defined by linear inequalities for minimizing a linear error over linear inequalities. De la Vallée Poussin (1911), independently of Fourier's work, made a similar suggestion and gave two examples. There appears to have been no follow-up on their suggestions. Also, neither Fourier nor de la Vallée Poussin described his ideas fully enough to reveal any awareness of degeneracy considerations and corresponding non-convergence possibilities, much less any procedures for coping with the matter. Made aware of Kantorovich's transportation papers by Flood (1956), Koopmans (1960) corresponded with Kantorovich. In due course, an English translation of Kantorovich's remarkable 1939 paper was made available to the West as ‘Mathematical Methods of Organizing and Planning Production’ (Kantorovich, 1960). Therein Kantorovich had formulated a collection of problems as what we now call linear programs. These problems were: machine utilization, production planning, scrap management, refinery scheduling, fuel utilization, construction planning, and arable land distribution. Using the Minkowski separation theorem, Kantorovich proved in this work that optimal multipliers exist. He suggested some ideas based on ‘resolving multipliers’ (essentially dual variables, or marginal costs) towards an algorithm, but none has emerged following this line of thought. According to Dantzig (1963), ‘Kantorovich should be credited with being the first to recognize that certain important broad classes of production problems had well-defined mathematical structures which, he believed, were amenable to practical numerical evaluation and could be numerically solved’. But although Koopmans (1960) argued that, with a suitable transformation, one of Kantorovich's problems had the generality of Dantzig's linear program, Koopmans's conclusion was not justified as the argument did not and could not cover the possibilities of infeasibility and an unbounded objective, a point made by Charnes and Cooper (1962). Koopmans's argument notwithstanding, the statement of a general linear program belongs to Dantzig.

Dantzig returns to UC Berkeley, 1960- 66

Dantzig left RAND to become a professor in the industrial engineering department at the University of California at Berkeley. There, that year, he established the Operations Research Center. Operations research (OR) was a term that emerged in the Second World War to describe the activity of studying an operation (process, system, and so on) with mathematical methods with the intent of improving performance. In 1963 Dantzig completed his classic Linear Programming and Extensions. The book was based on his research which began at the Pentagon and continued through RAND and UC Berkeley. By the time Dantzig left UC Berkeley in 1966, he had produced 11 Ph.D. students, and written about 25 research papers on the theory and practice of linear programming and extensions (integer, nonlinear, stochastic, and so on). As a mentor of Ph.D. students, Dantzig was among the very best. Within a course or two he could bring students to the frontier on some aspect of linear programming. His new book offered a full perspective of linear programming right up to 1963. Dantzig supplied the time, inspiration, guidance, knowledge, and example that students needed. He lived and breathed research.
Interest in the study of linear and nonlinear complementarity problems, as such, began in the early 1960s. Dantzig's second student, Cottle (1964), wrote on this topic, and his work was extended in Cottle and Dantzig (1968). Problems in this category can be viewed as abstractions of optimality conditions or of (economic or physical) equilibrium conditions. In a complementarity problem, one has a mapping $W$ of $\mathbb{R}^N$ into itself and seeks a solution $z$ of the conditions $W(z) \geq 0, \ z \geq 0, \ z^T W(z) = 0$. In the linear complementarity problem, the mapping would be of the form $W(z) = Mz + q$. The linear complementarity problem is related to the minimization of $z^T (Mz + q)$ subject to the constraints $Mz + q \geq 0$ and $z \geq 0$. This would be easy enough to solve as a quadratic program, if the objective function were convex. However, the excitement arose from the fact that the problem could be solved, effectively, in the absence of convexity. From the classic paper of Lemke (1965) followed the computation of points in the core of a balanced game and the computation of economic equilibria (Scarf, 1967; 1973), the computation of fixed points with piecewise linear homotopies (Eaves, 1972), and the computation with differentiable functions (Smale, 1976).

Dantzig at Stanford University, 1966–96

Dantzig joined the Stanford faculty in 1966, half-time in the inter-departmental Operations Research Program and half-time in Computer Science. In 1967 the OR Program became the Department of Operations Research in the School of Engineering; this is where Dantzig conducted his work. He was away for two years: in 1973–74 at the International Institute for Applied Systems Analysis in Austria, and in 1978–79 at the Center for Advanced Study in the Behavioral Sciences on the Stanford campus. In 1973 he was appointed to the C.A. Criley Professorship in Transportation Science. While at Stanford, Dantzig produced 41 Ph.D. students and published about 115 research papers on the theory and applications of mathematical programming. Dantzig's Ph.D. progeny, if Berkeley and Stanford graduates and subsequent generations are counted, as of 2006 exceeded 200. Dantzig had long felt that the development of good software was key to widespread usage of linear programming in industry. This vision led him to create the Systems Optimization Laboratory (SOL) at Stanford for research and development of numerical algorithms for mathematical programming. Under the SOL banner were the PILOT and planning under uncertainty programs (see Dantzig et al., 1973; Gill et al., 2007).

Stochastic programming with recourse, continued, 1989–2005

Cognizant of the potentially enormous size of multi-stage stochastic linear programs, Dantzig and Madansky (1961) suggested the incorporation of statistical sampling of uncertainties together with approximating time-staged models to solve the full problem. Following this avenue some 30 years later, Dantzig and Glynn (1990) brought together decomposition, Monte Carlo sampling, and multiprocessing to solve time-staged linear programs (see also Infanger, 1991; Dantzig and Infanger, 1992). In a series of papers, importance sampling was used to estimate second-stage costs and Benders cuts. Portfolio optimization and electric power planning were among the applications envisioned; the latter problems, with 39 uncertain parameters leading to 15 million scenarios, were solved to high accuracy with a confidence level of 95 per cent; in equivalent deterministic form, such problems would have more than
four billion constraints. However, Dantzig, to the end, regarded stochastic linear programming as a major unresolved problem.

Computational complexity, 1972–2006

Since its inception, the question of the number of steps required by the simplex method for a given linear program has been of interest. In the 1970s the field of ‘computational complexity’ emerged; a theory of problem difficulty which draws a sharp distinction between categories of problems that could be solved in polynomial time (number of steps) in the size of their data, and those which could not. How did linear programming fit into this scheme? Klee and Minty (1972) produced a worst case example of a simple linear program on which the simplex method takes an exponential number of iterations. But the expected number of pivots of the simplex method over a random selection of problems was shown to be polynomial in \((m, n)\) (Smale, 1983). This raised the question: could a linear program be solved in polynomial time? Khachiyan (1979) defined a polynomial time algorithm for linear programs based on a sequence of convergent ellipsoids; however, unexpectedly according to computational complexity, the algorithm was very slow, and certainly no competitor of the simplex method. Later, Karmarkar (1984) gave a polynomial time interior point algorithm for linear programs which was claimed to be superior to the simplex method in the sense of solving linear programs much faster on a computer; the method required the linear program to be expressed in a special form with an optimal objective value of zero and viewed each iterate as being at the centre of a polyhedron in a different coordinate system. The method typically required considerably fewer iterations than the simplex method, but each iteration required significantly more computations. The method was patented by AT&T and published as a theoretical result. There was considerable secrecy associated with the particulars of its implementation; and, thus, no independent verification was possible regarding its claimed superiority in computational speed over the simplex method. It was later shown to be equivalent under the same special form to the logarithmic barrier method, a method traceable back to Frisch (1955) and Fiacco and McCormick (1968). The logarithmic barrier method, however, could be applied to a linear program in standard form. The logarithmic barrier method was in the public domain and so allowed researchers to focus on computational improvements. Today, it is known that there are problems for which the logarithmic barrier method is superior to the simplex method; notable are those very large problems for which \(A^T\) is sparse. For a survey of interior point methods, see Todd (1996). It is also interesting to note that most practical interior-point algorithms include an option to move the \(\varepsilon\) -optimal interior point solution to the nearest extreme point, a procedure requiring a significant number of simplex-type pivots. A technique to do this was proposed by Dantzig (1963, ch. 6, exercise 11). As of 2006, the simplex method (and various realizations thereof) remains the algorithm of choice for the majority of linear programs.

Dantzig in retirement, 1996–2005

Dantzig was retired from Stanford in stages, each firmly resisted. He was formally retired from the regular faculty at age 65 in 1980, but was recalled until age 82 in 1996. Until that year he remained as active as formal members of the faculty. After that he met at home with all who wished to consult him: students, colleagues, and strangers. Whenever presented with an idea, Dantzig would respond, as
always, with something of value. Until around 2001 he continued to travel and present papers. At his
90th birthday celebration, he attended a full day of presentations followed by a banquet and additional
talks. He was full of energy, enthusiasm, keen observations, and wit. Dantzig's mind was razor-sharp up
to the end.
In retirement, Dantzig's principal project was the writing of a multi-volume book on linear programming
and extensions. Dantzig had always felt that software was a key element that would contribute to the
success of linear programming usage. He wanted to write another book on linear programming that
incorporated software to aid students in learning both the theory and the practice of linear programming,
and in particular in learning how to implement the simplex method and other algorithms for commercial
use. In 1985 he invited M.N. Thapa to coauthor such a book. As work on the book progressed, it became
apparent to the authors that the amount of material required a really huge book. One volume became
two, and two became four. In the end only two volumes were completed (Dantzig and Thapa, (1997;
2003). Dantzig continued to be fascinated by interior point methods; von Neumann's and Karmarkar's
algorithms were reanalysed and included in the second volume. According to M. Thapa, Dantzig never
tired of editing and re-editing to improve proofs and readability. He would say: 'it is like polishing a
stone; the more you polish it, the more it will shine.' Dantzig also continued his work with G. Infanger
on planning under uncertainty. In addition to their research together, Dantzig and Infanger consulted on
financial portfolio design. They intended to edit a collection of papers (including work of their own) on
planning under uncertainty. Dantzig was convinced that the way to get further exposure for, and research
into, planning under uncertainty was to set up an institute; to no avail, he tried at Stanford, tried at EPRI,
and finally tried to create a stand-alone non-profit organization. In addition to these projects, Dantzig
reworked the text of a science fiction novel he had begun in 1980.

Dantzig's honours

In 1975 L.V. Kantorovich and T.C. Koopmans received the Nobel Prize in Economics for ‘their
contributions to the theory of optimum allocation of resources’. Both mentioned Dantzig in their Nobel
Lectures. That Dantzig did not participate in this prize came as a great shock and disappointment to
those familiar with his contributions. Himself aside, Dantzig regarded Leontief, Kantorovich, von
Neumann, and Koopmans as the principal early contributors to linear programming.
Dantzig, the man, and his contributions have nevertheless been honoured extensively. His honours
include distinguished memberships, prizes, honorary doctorates, and dedications. He was elected to
membership in the National Academy of Sciences, the National Academy of Arts and Sciences, and the
National Academy of Engineering. He was a fellow of the Econometric Society, the Institute of
Mathematical Statistics, the Association for the Advancement of Science, the Operations Research
Society, IEEE, and the Omega Rho Society. He was awarded the War Department Exceptional Civilian
Service Medal, the National Medal of Science, the John von Neumann Theory Prize, the NAS Award in
Applied Mathematics and Numerical Analysis, the Harvey Prize (Technion), the Silver Medal of
Operational Research Society (England), the Adolph Coors American Ingenuity Award, the Special
Recognition Award of Mathematical Programming Society (MPS), the Harold Pender Award, and the
Harold Lardner Memorial Prize (Canada). He received honorary doctorates from the Israel Institute of
Technology (Technion), University of Linköping (Sweden), University of Maryland, Yale University,
Université Catholique de Louvain (Belgium), Columbia University, the University of Zurich, and

Carnegie-Mellon University. Dantzig was also honoured as the dedicatee of a symposium of MPS, in two volumes of Mathematical Programming, in the first issue of the Journal of Optimization of the Society for Industrial and Applied Mathematics (SIAM), with the joint MPS-SIAM Dantzig Prize, and with the INFORMS Dantzig Prize for students. In 2006, a fellowship in his name was established in the Department of Management Science and Engineering at Stanford University.

Empirical economists often filter data prior to analysis to remove features that are a nuisance from the point of view of their theoretical models. Examples include trends and seasonals. This article describes how data filters work and the rationale that lies behind them. It focuses on the Baxter–King and Hodrick–Prescott filters, which are popular for measuring business cycles.

Keywords
ARIMA models; band-pass filters; Baxter–King filter; business cycle measurement; Cramer's representation theorem; data filters; deterministic linear trends; Gaussian log likelihood; generalized method of moments; Granger causation; high-pass filters; Hodrick–Prescott filter; impulse response function; rational-expectations business-cycle models; seasonal adjustment; seasonal fluctuations; shocks; spurious cycle problem; stochastic general equilibrium models; stochastic trends; trend reversion; vector autoregressions

Article
Economic models are by definition incomplete representations of reality. Modellers typically abstract from many features of the data in order to focus on one or more components of interest. Similarly, when confronting data, empirical economists must somehow isolate features of interest and eliminate elements that are a nuisance from the point of view of the theoretical models they are studying. Data filters are sometimes used to do that.

For example, Figure 1 portrays the natural logarithm of US GDP. Its dominant feature is sustained growth, but business cycle modellers often abstract from this feature in order to concentrate on the transient ups and downs. To relate business cycle models to data, empirical macroeconomists frequently filter the data prior to analysis to remove the growth component. Until the 1980s, the most common way to do that was to estimate and subtract a deterministic linear trend. Linear de-trending is conceptually unattractive, however, because it presupposes that all shocks are neutral in the long run. While some disturbances – such as those to monetary policy – probably are neutral in the long run, others probably are not. For instance, a technical innovation is likely to remain relevant for production until it is superseded by another, later technical innovation.

Figure 1
The desire to model permanent shocks in macroeconomic time series led to the development of a variety of stochastic de-trending methods. For example, Beveridge and Nelson (1981) define a stochastic trend in terms of the level to which a time series is expected to converge in the long run. Blanchard and Quah (1989) adopt a more structural approach, enforcing identifying restrictions in a vector autoregression that separate permanent shocks that drive long-run movements from the transitory disturbances which account for cyclical fluctuations.

Another popular way to measure business cycles involves application of band-pass and high-pass filters. Engle (1974) was one of the first to introduce band-pass filters to economics. In the business cycle literature, the work of Hodrick and Prescott (1997) and Baxter and King (1999) has been especially influential. Figure 2 illustrates measures of the business cycle that emerge from the Baxter–King and Hodrick–Prescott filters.

Figure 2
In this article, I describe how data filters work and explain the theoretical rationale that lies behind them. I focus on the problem of measuring business cycles because that is one of the principal areas of application. Many of the issues that arise in this context are also relevant for discussions of seasonal adjustment. For a review of that literature, see Fok, Franses and Paap (2006).

How data filters work

The starting point is the Cramer representation theorem. Cramer's theorem states that a covariance stationary random variable \( x_t \) can be expressed as

\[
x_t - \mu_x = \int_{-\pi}^{\pi} \exp(i\omega t) dZ_x(\omega),
\]

(1)

where \( \mu_x \) is the mean, \( t \) indexes time, \( i = \sqrt{-1} \), \( \omega \) represents frequency, and \( dZ_x(\omega) \) is a mean zero, complex-valued random variable that is continuous in \( \omega \). The complex variate \( dZ_x(\omega) \) is uncorrelated across frequencies, and at a given frequency its variance is proportional to the spectral density \( f_{xx}(\omega) \). If we integrate the spectrum across frequencies, we get the variance of \( x_t \),

\[
\sigma_x^2 = \int_{-\pi}^{\pi} f_{xx}(\omega) d\omega.
\]

(2)

This theorem provides a basis for decomposing \( x_t \) and its variance by frequency. It is perfectly sensible to speak of long- and short-run variation by identifying the long run with low-frequency components and the short run with high-frequency oscillations. High frequency means that many complete cycles occur within a given time span, while low frequency means the opposite.

Baxter and King (1999) define a business cycle in terms of the periodic components \( dZ_x(\omega) \). They partition \( x_t \) into three pieces: a trend, a cycle, and irregular fluctuations. Inspired by the NBER business cycle chronology, they say the business cycle consists of periodic components whose frequencies lie between 1.5 and 8 years per cycle. Those whose cycle length is longer than 8 years are identified with the trend, and the remainder are consigned to the irregular component.

The units for \( \omega \) are radians per unit time. A more intuitive measure of frequency is units of time per cycle, which is given by the transformation \( \lambda = 2\pi / \omega \). Often we work with quarterly data. To find the \( \omega \) corresponding to a cycle length of 1.5 years, just set \( \lambda = 6 \) quarters per cycle and solve for \( \omega = 2\pi / 6 = \pi / 3 \). Similarly, the frequency corresponding to a cycle length of 8 years is \( \omega = 2\pi / 32 = \pi / 16 \). Baxter and King define the interval \([\pi / 16, \pi / 3]\) as 'business cycle frequencies'. The interval \([0,\pi / 16]\) corresponds to the trend, and \([\pi / 3, \pi ]\) defines irregular fluctuations. One nice feature of the Baxter–King filter is that it can be easily adjusted to accommodate data sampled
monthly or annually, just be resetting $\omega_j$ and $\omega_h$.

To extract the business cycle component, we need to weigh the components $dZ_t(\omega)$ in accordance with Baxter and King's definition and integrate across frequencies,

$$x_t^B = \int_{-\pi}^{\pi} B(\omega) \exp(i\omega t) dZ_t(\omega),$$

(3)

where

$$B(\omega) = 1 \text{ for } \omega \in \left[ \pi / 16, \pi / 3 \right] \text{ or } \left[ -\pi / 3, -\pi / 16 \right], = 0 \text{ otherwise.}$$

(4)

In technical jargon, $B(\omega)$ is an example of a ‘band-pass’ filter: the filter passes periodic components that lie within a pre-specified frequency band and eliminates everything else. The Baxter–King filter suppresses all fluctuations that are too long or short to be classified as part of the business cycle and allows the remaining elements to pass through without alteration.

Many economists are more comfortable working in time domain, and for that purpose it is helpful to express the cyclical component as a two-sided moving average,

$$x_t^B = \sum_{j=-\infty}^{\infty} \beta_j (x_{t+j} - \mu x).$$

(5)

The lag coefficients can be found by solving

$$\beta_j = \frac{1}{2\pi} \int_{-\pi}^{\pi} B(\omega) \exp(i\omega j) d\omega.$$  

(6)

The solution is

$$\beta_0 = \frac{\omega_h - \omega_i}{\pi},$$

$$\beta_j = \frac{\sin(\omega_h j) - \sin(\omega_i j)}{\pi j} \text{ for } j \neq 0.$$
Notice that an ideal band-pass filter cannot be implemented in actual data samples because it involves infinitely many leads and lags. In practice, economists approximate $x_t^{g}$ with finite-order moving averages,

$$x_t^{g} = \sum_{j=-n}^{n} \hat{\beta}_j(x_{t+j} - \mu x).$$

(Baxter and King (1999) and Christiano and Fitzgerald (2003) analyse how to choose the lag weights $\hat{\beta}_j$ in order to best approximate the ideal measure for a given $n$.

For real-time applications, the two-sided nature of the filter is a drawback because the current output of the filter depends on future values of $x_{t+j}$, which are not yet available. Kaiser and Maravall (2001) address this problem by supplementing the filter with an auxiliary forecasting model such as a vector autoregression or univariate ARIMA model, replacing future $x_{t+j}$ with forecasted values. This substantially reduces the approximation error near the end of samples.

That the filter is two-sided is also relevant for models that require careful attention to the timing of information. Economic hypotheses can often be formulated as a statement that some variable $z_t$ should be uncorrelated with any variable known in period $t$ or earlier. These hypotheses can be examined by testing for absence of Granger causation from a collection of potential predictors to $z_t$. The output of a two-sided filter should never be included among those predictors, however, for that would put information about present and future conditions on the right-hand side of the regression and bias the test towards a false finding of Granger causation. Similar comments apply to the choice of instruments in generalized-method-of-moments problems. For applications like these, one-sided filters are needed in order to respect the integrity of the information flow.

While Baxter and King favour a three-part decomposition, other economists prefer a two-part classification in which the highest frequencies also count as part of the business cycle. The trend component is still defined in terms of fluctuations lasting more than eight years, but the cyclical component now consists of all oscillations lasting eight years or less. To construct this measure, we define a new filter $H(\omega)$ such that

$$H(\omega) = 1 \text{ for } \omega \in [\pi / 16, \pi] \text{ or } [-\pi, -\pi / 16], = 0 \text{ otherwise.}$$

This is known as a 'high-pass' filter because it passes all components at frequencies higher than some pre-specified value and eliminates everything else. If we use this filter in the Cramer representation, we can extract a new measure of the business cycle by computing

$$x_t^{H} = \int_{-\pi}^{\pi} H(\omega) \exp(i\omega t) dX(\omega).$$

Once again, this corresponds to a two-sided, infinite-order moving average of the original series $x_t$. 

Data filters: The New Palgrave Dictionary of Economics

\[ x_t^H = \sum_{j=-\infty}^{\infty} Y_j (x_{t+j} - \mu x), \]

(11)

with lag coefficients \( Y_0 = 1 - \omega_j \pi \) and \( Y_j = -\sin(\omega_j \pi) / \pi j \). As before, this involves infinitely many leads and lags, so an approximation is needed to make it work. The approximation results of Baxter and King (1999) and Christiano and Fitzgerald (2003) apply here as well.

Hodrick and Prescott (1997) also seek a two-part decomposition of \( x_t \). They proceed heuristically, identifying the trend \( \tau_t \) and the cycle \( c_t \) by minimizing the variance of the cycle subject to a penalty for variation in the second difference of the trend,

\[ \min_{\{\tau, \phi\}} \left\{ \sum_{t=-\infty}^{\infty} \left[ (x_t - \tau_t)^2 + \phi (\tau_{t+1} - 2\tau_t + \tau_{t-1})^2 \right] \right\}, \]

(12)

The Lagrange multiplier \( \phi \) controls the smoothness of the trend component. After experimenting with US data, Hodrick and Prescott set \( \phi = 1600 \), a choice still used in most macroeconomic applications involving quarterly data. After differentiating (12) with respect to \( \tau_t \) and rearranging the first-order condition, one finds that \( c_t \) can be expressed as an infinite-order, two-sided moving average of \( x_t \),

\[ c_t = HP(L)x_t = \frac{\Phi(1-L)^2(1-L^{-1})^2}{1 + \Phi(1-L)^2(1-L^{-1})^2} x_t, \]

(13)

where \( L \) is the lag operator. Although Hodrick and Prescott's derivation is heuristic, King and Rebelo (1993) demonstrate that \( HP(L) \) can be interpreted rigorously as an approximation to a high-pass filter with a cut-off frequency of eight years per cycle. The close connection between the two filters is also apparent in Figure 2, which shows that high-pass and Hodrick–Prescott filtered GDP are highly correlated.

Data filters for measuring of business cycles?

While data filters are very popular, there is some controversy about whether they represent appealing definitions of the business cycle. For one, there is a disconnect between the theory and macroeconomic applications, for the theory applies to stationary random processes and applications involve non-stationary variables. This is not critical, however, because the time-domain filters \( \beta(L), \gamma(L), \) and \( HP(L) \) all embed difference operators, so business cycle components are stationary even if \( x_t \) has a unit root.

A more fundamental criticism concerns the fact that the Baxter–King definition represents a deterministic vision of the business cycle. According to a theorem of Szego, Kolmogorov, and Krein, the prediction error variance can be expressed as

\[ \sigma^2_{\hat{e}} = 2\pi \exp \left[ \frac{1}{2\pi} \int_{-\pi}^{\pi} \log f_{B\hat{C}}(\omega) \, d\omega \right], \]

where \( f_{B\hat{C}} \) is the spectral density of the filtered series.
where \( f_{BC}(\omega) \) is the spectrum for the business-cycle component (see Granger and Newbold 1986, pp. 135-6). For an ideal band-pass filter, the spectrum of \( x^B_t \) is

\[
 f_{BC}(\omega) = |B(\omega)|^2 f_{xX}(\omega).
\]

Since \( B(\omega) = 0 \) outside of business cycle frequencies, it follows that \( f_{BC}(\omega) = 0 \) on a measurable interval of frequencies. But then eq. (14) implies \( \sigma^2_s = 0 \), which means that \( x^B_t \) is perfectly predictable from its own past. The same is true of measures based on ideal high-pass filters. A variable that is perfectly predictable based on its own history is said to be ‘linearly deterministic’. Thus, according to the Baxter–King definition, the business cycle is linearly deterministic.

In practice, of course, measured cycles are not perfectly predictable because actual filters only approximate the ideal. But this means that innovations in measured cycles are due solely to approximation errors in the filter, not to something intrinsic in the concept. The better the approximation, the closer the measures are to determinism.

How to square this deterministic vision with stochastic general equilibrium models is not obvious. Engle (1974), Sims (1993) and Hansen and Sargent (1993) suggest one rationale. They were interested in estimating models that are well specified at some frequencies but mis-specified at others. Engle studied linear regressions and showed how to adjust for this when calculating standard errors and other test statistics. He also developed methods for diagnosing mis-specification on particular frequency bands.

Sims (1993) and Hansen and Sargent (1993) are interested in fitting a rational-expectations model of the business cycle to data that contain seasonal fluctuations. They imagine that the model abstracted from seasonal features, as is common in practice, and they wonder whether estimates could be improved by filtering the data with a narrow band-pass filter centred on seasonal frequencies. They find that seasonal filtering does help, because otherwise parameters governing business cycle features would be distorted to fit unmodelled seasonal fluctuations. Filtering out the seasonals lets the business cycle parameters fit business cycle features.

Business cycle modellers also frequently abstract from trends, and Hansen and Sargent conjectured that the same rationale would apply to trend filtering. Cogley (2001) studies this conjecture but finds disappointing results. The double-filtering strategy common in business cycle research (which applies the filter to both the data and the model) has no effect on periodic terms in a Gaussian log likelihood, so it is irrelevant for estimation. The seasonal analogy (which filters the data but not the model) also fails, but for a different reason. The key assumption underlying the work of Engle, Sims, and Hansen and Sargent is that specification errors are confined to a narrow frequency band whose location is known a priori. That is true of the seasonal problem but not of the trend problem. Contrary to intuition, trend-specification errors spread throughout the frequency domain and are not quarantined to low frequencies. That difference explains why the promising results on seasonality do not carry over to trend filtering.

Finally, some economists question whether filter-based measures capture an important feature of business cycles. Beveridge and Nelson (1981) believe that trend reversion is a defining characteristic of the business cycle. They say that expected growth should be higher than average at the trough of a recession because agents can look forward to a period of catching up to compensate for past output losses. By the same token, expected growth should be lower than average at the peak of an expansion. Cochrane (1994) confirms that this is a feature of US business cycles by studying a vector autoregression for consumption and GDP.

Cogley and Nason (1995) consider what would happen if \( x_t \) were a random walk with drift. For a random walk, expected growth is constant regardless of whether the level is a local maximum or minimum. Because it lacks the catching-up feature, many economists would say that a random walk is acyclical. Nevertheless, when the Hodrick–Prescott filter is applied to a random walk, a large and persistent cycle emerges. Thus the Hodrick–Prescott filter can create a business cycle even if no trend reversion is present in the original data. Cogley and Nason call this a spurious cycle. Furthermore, the problem is not unique to the Hodrick–Prescott filter; Benati (2001), Murray (2003) and Osborn (1995) document similar results for band-pass filters and for other approximations to high-pass filters.

Conclusion
Christiano and Fitzgerald remark that data filters are not for everyone. They are certainly convenient for constructing rough and ready measures of the business cycle, and they produce nice pictures when applied to US data. But some economists worry about the spurious cycle problem, especially in applications to business cycle models where the existence and properties of business cycles are points to be established. In much of that literature, attention has shifted away from replicating properties of filtered data to matching the shape of impulse response functions.

data mining

Clinton A. Greene
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Data mining is defined by presenting an example contrasting the role of specification search in economics to its role in experimental science. Historical references are provided, along with a short review of contemporary proposals to remedy sources of and problems with data mining.

Keywords

data mining; model selection; regression analysis; specification problems in econometrics

Article

‘Data mining’ and the older word ‘fishing’ are pejorative terms for illusory or distorted statistical inference from an empirical regression model, where the distortion results from explorations of various models in a single sample of data. This process usually involves adding or dropping variables, but may involve exploring a variety of alternative nonlinear functional forms or data subsamples. Data mining properly applies as a derogatory term only when exploratory results are used for inference within the sample used in exploration. But the term is sometimes used to refer to the exploratory process itself, as economists emphasize inference over data exploration, and even use inference to discuss exploratory activities. Some take data mining to be a more serious offence when there is conscious effort to manipulate, although data mining will distort results regardless of intent.

Importance and history

Some economists consider data mining to be pervasive in applied work. But the portion subscribing to this view is unclear, since those who do so understandably retreat from applied work into economic or econometric theory. Leamer and Leonard (1983, p. 306) give voice to the view that collective data mining renders standard inference meaningless, and hence in general ‘statistical analyses are either
greatly discounted or completely ignored’. This stance may have reached a peak in the late 1970s, fuelled by an explosion in the volume of regression studies. But contemporary suspicion is still quite common. Kennedy (2003, pp. 82–3) characterizes the ‘average economic regression’ as perpetrating some of the worst data mining practices.

The issue was known to the originators of econometrics. Ragnar Frisch (1934) advocated methods to deal with the data mining issue which were applied into the 1950s, then neglected for two decades and reincarnated in modern form by Leamer (1983). Because Frisch found that differing but reasonable specifications could yield disparate results, he came to believe attempts at formal inference were illegitimate. Malinvaud (1966, chs. 1 and 2) provides a wonderful exposition of Frisch’s methods and of why Frisch’s stance was replaced by contemporary textbook assumptions. Even Haavelmo’s (1944, ch. 7, sect. 17) founding statement of the contemporary inferential approach discusses data mining.

Econometrics textbooks quite properly warn against data mining, yet it is difficult to avoid and is pervasive in published work. This places the new practitioner in a difficult position. It is helpful to be armed with an understanding of the consequences of data mining and why data mining is difficult to avoid. Econometrics in the contemporary sense began when we decided that economic data could be treated as equivalent to sampling from an uncontrolled experiment (Haavelmo, 1944), borrowing from R. A. Fisher’s methods for experimental data. The following illustration clarifies these issues.

An illustration

Suppose two students of the economy live in parallel universes. Both are interested in a variable $y$, believing the most important determinant of this variable $y$ to be another variable $x_1$, but also supposing that variables $x_2$ and $x_3$ may be relevant. Their initial data-sets are identical, and they propose to model $y$ via a linear regression model. Both start out assuming that the errors of the model ($\varepsilon$) are independent and normally distributed with constant variance. Thus they propose the model

$$y = b_1 x_1 + b_2 x_2 + b_3 x_3 + \varepsilon,$$

where the coefficients ‘$b_i$’ are to be estimated.

The first student lives in a universe in which he can generate more data via experiments. The second student must wait passively for the passage of time before she can see more data; data generated by events she does not control. Thus, the first student is confident of his science, while the second student is in the actual universe of economics.

Now suppose that in their initial regression results for the coefficient on $x_1$ they find the sign is the opposite of what they expected. As in standard practice they take this to imply that they have omitted an important variable. After fiddling with their specifications they find that adding a variable $x_4$ yields a more sensible coefficient estimate for the variable $x_1$. Suppose also they find that, for the coefficients on $x_2$ and $x_3$, the null hypothesis for coefficients of zero would be accepted individually (leaving the other variable coefficient unrestricted, as in a t-test). But suppose they find the joint hypothesis ($b_2 = b_3 = 0$) would be rejected. They find the fit of the regression is penalized least by dropping the variable $x_3$ and do so. They have used a process of specification search to arrive at a model for $y$ as a function of $x_1, x_2$ and $x_4$.

The first student takes the results to his professor. The professor commends the effort to learn from the

world, but corrects the student on one point. He notes that, although the estimated standard error for the coefficient on $x_3$ included zero, it also included (we will suppose) five, and if this coefficient is truly so far from zero then (given expected variation in $x_3$) the variable $x_3$ would have appreciable effects. So the professor tells him to run another experiment designed so that the resulting data-set is large enough (and so standard errors of coefficient estimates are small enough) to usefully distinguish between large and small values of $b_3$. The student does so, and publishes the results with the statistics and standard critical values treated as valid ‘tests’. This is not data mining.

Now the second student takes her results to her professor. This professor says the first regression result (employing $x_1$, $x_2$ and $x_3$) can be treated as possibly generating test statistics drawn from standard distributions. However, in the final model ($x_1$, $x_2$ and $x_4$) some of the t-statistics were created by design. Since one ‘fished’ or fiddled with variables included in the model until the coefficient on $x_1$ had the correct sign, the t-statistic was drawn from a distribution such that there was 100 per cent probability it would have the ‘correct’ sign. Likewise the student explored specifications until the t-statistic for the coefficient on $x_2$ appeared to be significant. This implies for the final specification that within the interval bounded by the standard critical values (approximately plus or minus 2) the probability of the t-statistic for $b_2$ falling within this standard range must actually be zero, hardly a standard t-distribution. This process of modifying the model and re-estimating it using the same sample used to suggest those modifications will also affect in an unknown manner the distribution of other test statistics, even those that were not direct objects of exploration and design. These are data mined results.

Note that the two professors agree that something was potentially learned in the exploratory stage. Both students could use data exploration to reveal aspects of the first sample, but the results of exploration over this same sample could not then provide a formal test. As in any legitimate science, the first professor views taking inspiration from observation to be a process separate from confirmation or testing. The second student also hopes to have learned something from the sample, but her professor objects to treating the statistics resulting from this exploration as providing a test. The second student treated each regression as though it was a separate experiment, but regressions and their associated statistics are mere calculations that organize the data. Also note that, when these students took the initial estimate of $b_1$ as having the ‘wrong sign’, they were applying strong prior beliefs which led them to place little weight upon this empirical result. Bayesian inference provides a formal treatment of such priors.

The second student continues the consultation with her professor. The professor says these first results are not publishable because economists are interested in inference, and all she has shown is that the first model did not make sense. The professor may advise that she should first have chosen a successful regression model from the empirical literature, modifying it only slightly if at all. If the student is alert, she will notice the data available to her is identical to that in the literature, except for a few more recent observations.

So this alert student will go back to her professor and tell him she already knows the regression results will be the same as those already published, except to the extent the new data observations have some effect when averaged with the old. The test statistics will not have the usual distributions; instead, the distributions are a function of the previous results and the portion of new observations relative to those used in the previously published results. The student has discovered that, to the extent data-sets overlap, taking guidance from the regressions of other researchers is collective data mining, even if one runs only
one regression oneself. Thus collective data mining is pervasive, and the meaning of published test statistics is unclear. Only if each data-set is entirely distinct can one learn from the work of others while preserving known statistic distributions.

Contemporary practice and remedies

Three partial remedies for data mining are practised in the current literature. One is to insist upon seeing all the possible regression results a reasonable researcher might propose, supplementing imperfect ‘tests’ with a range of results. This is most associated with Leamer (1983), but we have already mentioned the earlier work of Frisch. Current practice is moving towards this approach, more often presenting multiple specifications.

A second remedy is inspired by noting that it is possible to calculate probabilities for statistics resulting from specification search, if the process begins with a model including a set of variables large enough that the true model is reasonably assumed nested within, and respecification deletes and does not add variables. An example is the general-to-specific approach. This approach is now common when specifying lag-lengths of time-series models, but in other contexts is controversial. The statistical consequences of such an approach fall under the heading of ‘pretest’ estimators discussed in most econometrics textbooks, but the best introductory discussion is found in Campos, Ericsson and Hendry (2005, Introduction, sects. 3.3–3.4). Interestingly, Hoover and Perez (1999) show that when pretest distributions are not accounted for this second remedy leads to an acceptable level of distortion.

A third remedy reserves some of the available data for ‘out-of-sample’ tests. Here one engages in specification search in one portion of the data and then tests in the reserved portion. We place ‘out-of-sample’ in quotes because this is not confirmation in a new sample. This response cannot avoid collective data mining because it is likely that among many projects the more satisfactory reserved-sample results will be selected for publication, if not by individual authors then through the collective filter of journal referees. But this remedy is useful to the individual researcher.

The first two remedies focus on data exploration, and only the third remedy adds the key scientific step of confirmation in separate data. Followers of the second remedy such as David Hendry and others of the ‘London School’ are often accused of data mining. Yet they have been the strongest proponents and practitioners of the third remedy, which provides the legitimate test in separate data, even inventing new out-of-sample tests such as for forecast encompassing. A good introduction to the second and third remedies is found in Charemza and Deadman (1997).

As noted in our discussion of the third remedy, universal adoption of these remedies cannot avoid collective data mining. Collective data mining would be avoided if upon accepting a paper the journal offered an explicit or implicit contract to accept a follow-up study. Formal and precise testing would be performed in the subsequent study employing only data not available for the initial paper. This is yet to be practised by any journal, so as a result the methodological issues remain troublesome, leaving room for vague and inconsistent norms across referees and journals. New practitioners must develop their own approaches to navigating these norms and practices, while deciding how to preserve their own sense of integrity.

Davanzati, Bernardo (1529–1606)

Peter Groenewegen

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

barter; Davanzati, B.; division of labour; foreign exchange markets; money; paradox of value; quantity theory of money; scarcity

Article

Merchant, classical scholar, translator and economist, Davanzati was born in Florence where, apart from a period of residence in Lyon as a merchant, he worked until his death. His contributions to economics are contained in Notizia dei cambi (1582) which explains the operation of the foreign exchanges, and Lezione delle Monete (1588), translated into English in 1696 as A Discourse Upon Coin presumably because of its relevance to the recoinage controversies. Besides these economic writings, Davanzati produced a history of the English Reformation (1602) and a translation of Tacitus (1637) frequently described as a masterpiece of Italian literature.

Davanzati's observations on the foreign exchanges present a detailed discussion of the origins and practice of this art classified by him as the third type of mercantile transaction, the others being barter (goods for goods) and trade (goods for money). The analysis demonstrates how exchange rates fluctuate between gold points according to the supply and demand of bills, the gold points being determined by a risk premium, transport costs and interest lost while the funds are in transit. His illustration of a foreign exchange transaction by bills of exchange involving six parties residing in Lyon and Florence (1582, pp. 62–8) has been argued by De Roover (1963, p. 113) to be so instructive that, had it been more thoroughly studied by historians and economists, ‘fewer blunders in the history of banking’ would have been made.

Davanzati's lecture on coin is one of the earliest presentations of the metallist view of the origin and nature of money. He stresses the advantages of money over barter in facilitating both the division of labour and trade of ‘superfluities’ between cities and nations. In the metallist tradition, money is defined as ‘Gold, Silver, or Copper, coin'd by Publick Authority at pleasure, and by the consent of Nations, made the Price and Measure of Things’ (1588, p. 12). Non-metallic and non-convertible money can only be made acceptable to the public through coercion. Money is therefore a human convention and its
intrinsic value is small relative to its value as means of exchange. To explain this value, Davanzati presents an early quantity theory which relates the value of stocks of commodities to the world's money stock. Although he is aware of the importance of monetary circulation (he compares it to the importance of the circulation of blood in the animal body), he does not develop a concept of its velocity. The lecture on money concludes with a forceful critique of the practice of debasing the coinage, based on analysing its consequences and illustrated with many examples of the practice. Davanzati argues that this 'evil' can be avoided only by making 'Money pass according to its Intrinsick Value' (1588, p. 24). Davanzati's lecture has also been noted because of its hints at the so-called 'paradox of value' and its references to elements of scarcity and usefulness in the determination of commodity prices. This and other aspects of his work were noted by Galiani (1750). Earlier his views appear to have been well received by Locke who owned, annotated and may even have inspired the Toland translation (Harrison and Laslett, 1965, p. 120).

Davenant, Charles (1656-1714)

Peter Groenewegen
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Davenant, C.; King, G.; King–Davenant law of demand; mercantilism; political arithmetic; recoinage debates; tax administration

Article

Economist and administrator. Born in London, eldest son of William Davenant, the playwright and Poet Laureate, he was educated at Cheam School, Surrey, and entered Balliol College, Oxford, in 1671, going down in 1673 without a degree to take over the management of his father's theatre. In 1675 he wrote a tragedy, *Circe* (Davenant, 1677), but the theatre gained him little financial success. He also obtained an LLD from Cambridge in 1675 and practised law for a short period. From 1678 to 1689 he was Commissioner of Excise. He sat as MP for St Ives from 1685 to 1688 and represented Great Bedwin in the Tory interest following the elections of 1698 and 1700. The financial consequences of his loss of office as Excise Commissioner in 1689 and unsuccessful attempts in 1692 and 1694 to obtain other positions in the revenue service appear to have inspired a career as pamphleteer, starting in 1695. Until 1702, when he again obtained preferment by being appointed Secretary to the Commission for negotiating the union between England and Scotland, he produced a steady flow of political and economic writings dealing with aspects of taxation, public debt, monetary and trade questions, foreign policy and criticisms of Whig policy in general. In June 1703 he obtained the post of Inspector-General of Exports and Imports in the Customs Office, a position he retained till his death in 1714. Most of his political and commercial writings were collected by C.E. Whitworth (1771) but two manuscript works on money and credit (Davenant, 1695b and 1696) were not published till 1942 (Evans, 1942).

Davenant's position in the history of economics rests on a variety of contributions. Initially, his work was largely depicted as typically that of an 'adherent of the mercantile theory' (Hughes, 1894, p. 483), but 'Tory free trader' (Ashley, 1900, p. 269) better describes his pronouncements on foreign trade policy as he particularly advocated the removal of trade restrictions, such as those affecting woollen exports, which benefited the landed interest by raising land values (Davenant, 1695a, pp. 16–17; 1697, pp. 98–
Davenant, Charles (1656–1714) : The New Palgrave Dictionary of Economics

104). His free trade position is not unambiguous. Although Davenant's remark that 'Trade is by its nature free, finds its own channel, and best directeth its own course.' (1697, p. 98) is often quoted, the contradictory view that 'it is the prudence of a state to see that [its] industry, and stock, be not diverted from things profitable to the whole, and turned upon objects unprofitable, and perhaps dangerous to the public' (1697, p. 107) is less frequently noticed. Schumpeter's (1954, p. 196, n.4, and p. 242) depiction of Davenant's work as 'comprehensive quasi-system' emphasizing the interdependence of economic activity is also rather difficult to sustain, though it is possible to quote isolated remarks from Davenant's works in support. For example, Davenant's statement that 'all trades have a mutual dependence one upon the other, and one begets another, and the loss of one frequently loses half the rest' (1697, p. 97) cannot really be described as the general theoretical proposition it appears to be. Its only use is to provide a basis for some special pleading on behalf of the East India trade. Waddell's conclusion (1958, p. 288) that Davenant was a person neither of 'exceptional ability, nor of any great strength of character' and 'a competent publicist' rather than 'an original thinker' or 'practical man of affairs' seems a more appropriate assessment from an examination of his economic writings.

Davenant's plea for the importance of 'political arithmetic' or 'the art of reasoning by figures, upon things relating to government' (1698, p. 128) provides a further claim to fame, partly because it made more readily available the fairly sophisticated national income and expenditure estimates of his friend Gregory King (1696). Most of Davenant's political arithmetic application relates to taxation and estimating the gains from trade in terms of bullion, but he himself also made a useful contribution to the collection of international trade data as part of his duties as Inspector-General of Exports and Imports. The precise details of Davenant's association with Gregory King are not fully known, but their names are also linked in another famous 'statistical' exercise, the so-called King–Davenant law of demand, first noted by Thornton (1802) and Lauderdale (1804), and later extensively discussed by Jevons (1871, pp. 154–8), who on the evidence available to him cautiously attributed to Davenant the data on which the law is based (but see Barnett, 1936, pp. 6–7). However, apart from providing these data, Davenant himself characteristically drew no such analytical conclusions from this information (1698, Part II, pp. 224–5; see Creedy, 1986, for a detailed discussion).

Davenant's contributions to the recoinage debates (1695b; 1696) are less well known because they were not included in Whitworth (1771). Full recoinage was not necessary in Davenant's view when the inferior (because clipped or worn) coins were still usefully employed in small retail transactions. In addition, the detrimental effects on the exchange rate and commodity prices of the deterioration of currency were greatly exaggerated. The rise in prices, Davenant argues, could be attributed to a great many other causes; the depreciated exchange rate was more easily explained by the substantial overseas remittances induced by the European war and was therefore better remedied by floating a public loan in Holland. Although in these essays, Davenant's exposition is not always complete, Evans (1942, p. vi) regards them as containing 'all the essential elements of the analysis of money and credit' and integrating 'the entire problem of currency and public finance'. Finally, Davenant's contributions to tax administration need to be recognized. They have been described as 'translating into principles, and trying to provide a reasonable justification for the practices that the more methodical and innovating officials (such as Pepys at the Navy Office and Admiralty, and Downing and Lowndes at the Treasury …) were adopting and enforcing’ and that in these matters of administrative thinking, unlike his economics, 'Davenant's viewpoint steadily became [dominant] in the course of the next century or so’ (Hume, 1974, p.477). His
writings also remain a useful source for much information on trade and finance over the final decades of
the Stuart monarchy.

Davenport, Herbert Joseph (1861–1931)

Warren J. Samuels

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

absolutist value theory; American Economic Association; Davenport, H. J.; positive economics; relativistic price theory; supply and demand; Veblen, T.

Article

Davenport was born on 10 August 1861, in Wilmington, Vermont, and died on 16 June 1931, in New York City. He commenced a professorial career at the age of 41 after having been a land speculator (initially successful, but wiped out in the Panic of 1893) and high school teacher and principal. His academic work was at the University of South Dakota, Harvard Law School, Leipzig, Paris and Chicago (Ph.D., 1898). He taught at Chicago (1902–8), Missouri (1908–16) and Cornell (1916–29). He was President of the American Economic Association in 1920.

A leading, albeit somewhat iconoclastic, economic theorist of his day, he contributed to the reformulation of microeconomics from absolutist value theory to relativistic price theory. He stressed that, while there were real forces at work in the economy, identifying them as human desires and productive capacities, price itself reflected nothing more fundamental than a temporary equation of demand and supply. Prices are not determined by the margins but at the margins. Recognizing the limits imposed by a resultant superficiality and simultaneity of determination, he felt that economists qua economists need not inquire into the formation of desires or institutions but should study the pecuniary logic of phenomena from the standpoint of price in a society dominated by the private and acquisitive point of view. His economics focused on entrepreneurial opportunity-cost adjustments and encompassed a non-normative distribution theory based directly on price theory.

While differing from his close friend Thorstein Veblen on certain substantive issues, Davenport's work nonetheless reflected the impact of Veblen's critiques of traditional theory and of the actual market economy. Emphasizing positive economics and rejecting apologetics (economic theory was not to be the monopoly of reactionaries), Davenport was willing to recognize that the search for private gain did not always conduce to social welfare, but this conclusion was not to be considered a part of economic science per se.

Davidson, David (1854–1942)

C.G. Uhr
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Böhm-Bawerk, E. von; capital gains taxation; capital theory; consumption taxation; Davidson, D.; progressive taxation; taxation of income; taxation of wealth; Wicksell, J. G. K.

Article
Born into a Jewish merchant family in Stockholm, Davidson studied law and economics at Uppsala University from 1871, became a docent in 1878, professor extraordinarius from 1880 to 1889, and then professor ordinarius for 30 years until he retired in 1919. Frequently called on to serve on parliamentary committees from 1891 to 1931, Davidson's influence was strongly felt on Sweden's monetary and tax policies, for instance the 'gold exclusion policy' of 1916–24.

In 1899 Davidson launched Sweden's first economic journal, *Ekonomisk Tidskrift*, to which he contributed almost all his work over 40 years as its owner and editor (in 1965 it was renamed *The Swedish Journal of Economics* and issued in English). This journal greatly stimulated economic research in Sweden with numerous contributions from, among others, Wicksell, Cassel, Lindahl, Myrdal and Ohlin.

Unlike Wicksell and Cassel, who published their works in German (later translated into English), all of Davidson's writings are in Swedish, none of them translated. This, and the fact that his work – five tracts 1878–89, over 200 articles in his journal on a variety of subjects, plus chapters in several government reports – was never systematized in treatise form, accounts for his contributions to economics having been known, until recently, only to Scandinavian academics.

In his dissertation, *Bidrag till läran om de ekonomiska lagarna för kapitalbildningen* (A Contribution to the Theory of Capital Formation), Davidson anticipated Böhm-Bawerk's *Positive Theory of Capital* (1884). To Davidson, capital was generated in the main by the unequal distribution of income. To the wealthy, increases in present goods have small and declining utility relative to that of future goods. The latter are obtained in greater quantity, variety and value by investing savings for a return – interest – in production of capital goods which, indirectly, increase productivity. This perspective inverts the first of Böhm-Bawerk's famous ‘three grounds’ for interest, and transforms the third to a marginal productivity...
theory of waiting. In his later work Davidson adopted the substance of Wicksell's amendments and reconstruction of Böhm-Bawerk's capital theory. Davidson's monetary theory is best understood from his response in articles of 1908–25 to his friend Wicksell's path-breaking work in this area. *Inter alia*, Davidson criticized Wicksell's monetary norm of price level stability as inappropriate in conditions of 'commodity shortage'. Eventually, by 1925 Wicksell was moved to amend his norm to accommodate Davidson's critique (Uhr, 1960, chs 10 and 11).

In his early tract *Om beskattningsnormen vid inkomstskatten* (A Taxation Norm for the Income Tax, 1889), Davidson urged the replacement of Sweden's several property taxes and most of its excises by a progressive income tax with a uniquely broad base. It base was to include 'the citizen's potential consumption power' by levying the tax (a) on any increment in his net worth accrued (*whether realized or not*) between the end and the beginning of the tax year; and (b) also on his actual consumption spending during the year. Net worth increments accrue to a person as the value of his assets increases over that of his liabilities, due to savings, capital gains, bequests, and so on. Such gains confer potential consumption power, which should be taxed along with actual consumption spending out of income. Over the years, aware of difficulties his proposed tax base would encounter as it called for annual balance sheet and income–consumption statements, Davidson conceded some simplifications on the tax declarations, and to taxing capital gains only when realized by the sale of value-appreciated assets. He also agreed that the tax rates levied on net worth increments would have to be lower than the rates levied on consumption expenditures.

These concessions notwithstanding, Sweden's parliament in its first comprehensive income tax of 1910 adopted only one part of Davidson's proposal. It passed a progressive tax on income as usually defined (rather than on consumption spending as such), and added to it a second title, a tax on net worth increments at rates substantially lower than on income. Largely due to Davidson, this combination of an income and a net worth increments tax has remained a standard feature in Sweden's tax system since 1910.

De Finetti was born in Innsbruck, Austria, and died in Rome. After a degree in mathematics at Milan University, he chose practical activities rather than an academic career, and worked at the Istituto Centrale di Statistica (1927–31) and then at the Assicurazioni Generali (1931–46). Only later did he turn to an academic career and win a chair in financial mathematics at Trieste University (1939); from 1954 to 1961 he held the chair in the same subject at the University of Rome and from 1961 to 1976 the chair of calculus of probabilities at the same university. He was a member of the Accademia Nazionale dei Lincei and Fellow of the International Institute of Mathematical Statistics.

De Finetti's fame rests on his contributions to probability and to decision theory, but he also worked in descriptive statistics, mathematics and economics.

Together with Ramsey and Savage, de Finetti is one of the founders of the subjectivist approach to probability theory. The first illustrations (in non-technical terms) of his conception are in (1930a) and (1931b). He considers probability as a purely subjective entity ‘as it is conceived by all of us in everyday life’. The probability that a person attributes to the occurrence of an event is nothing more or less than the measure of the person's degree of confidence (hope, fear, …) in this event actually taking place. This can be interpreted as the amount (say, 0.72) that the person deems it fair to pay (or receive) in order to receive (or pay) the amount 1 if the event in question occurs. The mathematical theory was presented in his 1935 lectures at the Institut Poincaré (1937); see also (1970) and (1972).

De Finetti also introduced the important concept of exchangeability in probability (1929; 1930b; 1937; 1938) and proved the theorem on exchangeable variables named after him. Exchangeability is a weaker concept than independence and has been receiving increasing attention in probability theory (in fact, the natural assumption for a Bayesian is not independence, but exchangeability). In his 1935 Poincaré lectures (1937) he also treated the relations between the subjectivist point of view and the concept of...
exchangeability, which in his vision are at the basis of sound inductive reasoning and behaviour and, hence, of (statistical) decision theory (1959; 1961). It goes without saying that his position on the subject of statistical inference is fundamentally Bayesian.

In descriptive statistics he adhered to the functional concept according to which a statistic is an index selected on the basis of the single case (the aspects that one wants to stress, the aim of the statistical investigation, and so on); in (1931a) he stressed the importance of means which have the property of being associative.

Among his mathematical contributions the (1949) paper is especially interesting for economists. Here de Finetti investigates the conditions under which a concave function can be associated with a given ‘convex stratification’ (that is, a one-parameter family of convex sets, one interior to the other as the parameter varies). The author also discusses the conditions for a quasi-concave function to be transformed into a concave one by means of an increasing function. This paper started the literature on the ‘concavification’ of quasi-concave functions. As the author pointed out, these investigations also bear on consumer theory – where the convex stratification is the indifference map and the associated function is the utility function.

De Finetti also wrote on economic problems, where he stressed the importance of rigorous reasoning and verification, and emphasized the idea that the scope of economics, freed from the tangle of individual and corporative interests, should always and only be that of realizing a collective optimum (in Pareto's sense) inspired by criteria of equity (1969). An important initiative of his for the diffusion and correct application of mathematical and econometric methods in economics was the annual CIME (Centro Internazionale Matematico Estivo) seminar that he organized from 1965 to 1975; this enabled young Italian economists to benefit from courses given by Frisch, Koopmans, Malinvaud, Morishima, Zellner, to mention only a few of the lecturers.

Article

Life

Gerard Debreu, the son of a Calais lace manufacturer, was born on 4 July 1921. He took his baccalauréat in 1939, just before the outbreak of the Second World War. Instead of entering university, he then began an improvised mathematics curriculum in Ambert and, later, in Grenoble. In 1941 he was admitted to the École normale supérieure, where he studied with Henri Cartan and the Bourbaki group. After D-Day he enlisted in the French Army, and served in Algeria and Germany. Returning to his studies, he completed the agrégation de mathématiques in early 1946. While pursuing his mathematical studies in Paris, he was captivated by Maurice Allais's (1943) exposition of the Walrasian general equilibrium analysis, which became the central pillar of his research programme. It was the flip of a coin which determined that he, rather than Edmond Malinvaud, would receive a travelling fellowship from the Rockefeller Foundation.
This funded a year at Harvard, Berkeley and the Cowles Commission at Chicago, followed by studies at
Uppsala and, with Ragnar Frisch, in Oslo. Debreu returned to Chicago and the Cowles Commission, and
moved with it to Yale in 1955 with his wife of ten years and his nine- and five-year-old daughters. A
year at the Center for Advanced Study in the Behavioral Sciences at Stanford gave the Debreu family a
taste for California, and in 1962 Debreu accepted a position at the University of California at Berkeley.
There he remained until his retirement. Debreu became a US citizen in 1975, having been deeply moved
by America's response to the Watergate affair.

Gerard Debreu received numerous honours and awards. He was a Fellow of the American Academy of
Chevalier de la Légion d'honneur (1976), a member of the National Academy of Sciences (1977), a
Distinguished Fellow of the American Economic Association (1982) and its president in 1990, a Foreign
Associate of the French Académie des sciences (1984) and a Fellow of the American Association for the
Advancement of Science (1984). He was awarded honorary degrees from, among many, the University
of Bonn, Université de Lausanne, Northwestern University, Université des sciences sociales de
Toulouse, and Yale University. Most prominent of all, in 1983 he was the recipient of the Bank of
Sweden Prize in Economic Sciences in Memory of Alfred Nobel.

The elegance of Gerard Debreu's work was reflected in his personal style. He was also a competitive
bridge player, and perhaps his first publication was a monograph on the game. In contrast to his revealed
preference for the spare prose and clean, elegant arguments of the Theory of Value (1959) was his love
interview, ‘is in his style, subtlety and taste. I prize conciseness very much, and that is certainly
something that you cannot accuse Proust of. His compulsion, as you know, eventually killed him. I'll try
to escape that fate.’ Debreu was reserved in person, but displayed a quick and subtle wit. I remember his
beginning a lecture on the computation of economic equilibrium with the observation that the existence
of equilibrium had been established and that now Herbert Scarf has taught us how to compute the zeros
of the excess demand function. It only remains, he said, for the econometricians to estimate it, and we
would be done. Gerard Debreu died in Paris on New Year's Eve 2004. His ashes were placed in a niche
in the Père Lachaise cemetery, the final resting place of many of France's most eminent artists and
intellectuals, including Marcel Proust.

Work

The influence of Gerard Debreu's work can be seen throughout contemporary economics, but his
research output was largely confined to general equilibrium theory and its requirements.

The existence of competitive equilibrium

Gerard Debreu's broad fame in the economics community is due to his work on the existence of
competitive equilibrium. The complexity of simultaneous price and quantity determination in multiple
markets of related and unrelated goods stands in stark contrast to the cutting power of the simple
Marshallian scissors of supply and demand in a market with a single good. It is certainly not obvious
that a multi-market equilibrium should exist. The existence problem, open since the publication of Léon
Walras's Éléments d'économie politique pure (1874), was first given a broad and general treatment by

Arrow and Debreu (1954a). As Arrow tells the story, in earlier work on the problem, he and Debreu had each made a mistake for which the other had a solution. It was suggested that they collude, and the outcome was displayed at the remarkable 1952 Winter Meeting of the Econometric Society in Chicago where both the Arrow and Debreu's paper (1954a) and McKenzie's (1954) paper were presented. The Arrow and Debreu 'private ownership economy' is today the standard reference for a general competitive model. McKenzie's treatment of technology is somewhat more special, although the two models are not directly comparable. The method of proof is to introduce a fictitious agent, a Walrasian auctioneer, whose role is to choose prices. Then the entire problem sets up like a non-cooperative game, with the added wrinkle that feasible strategies for one player may depend upon the choices of the others. Fortunately, Debreu (1952) had already established the existence of a kind of Nash equilibrium for these games, which he called a ‘social equilibrium’. This approach to the existence of equilibrium is quite different from the approach through the excess demand correspondence, which was already developed in 1954 and appears in Debreu's (1959) essential masterwork, the Theory of Value. The social equilibrium approach is particularly well-suited to economies in which it is difficult to get one's hands on excess demand directly, such as economies with externalities, public sector decision-making, non-convexities, and incomplete and intransitive preferences.

**Welfare economics**

The central question of economic analysis, the workings of the invisible hand, is formulated today as the achievement (or not) of an optimal allocation of resources. The characterization of optimality by means of marginal rates of substitution was first completed by Oscar Lange (1942). This characterization, however, is unsatisfactory for several reasons, including the facts that marginal rates of substitution may fail to exist for otherwise unremarkable preference orders, the treatment of corners is complicated, and the corresponding second-order conditions are sufficient only for local optimality. At about the same time on two different American coasts, Kenneth Arrow (1952) and Gerard Debreu (1951) proposed an alternative analysis of the relationship between equilibrium and optimality, making use of convexity assumptions and, in particular, the separating hyperplane theorem instead of the calculus. Debreu (1954b) extended his geometric analysis from finite dimensional vector spaces to linear topological vector spaces, that is, from finite to an infinite number of commodities. This advance is important for such diverse topics as financial markets, uncertainty, dynamic modelling and commodity differentiation. The first half of Debreu (1951) establishes the classical welfare theorems, relying only on convexity and topological assumptions on preferences. The second half of the paper introduces the coefficient of resource utilization, a measure of deadweight loss. Debreu (1954a) applied this measure to the deadweight loss associated with tax-subsidy schemes, a measure that has been implemented empirically by Farrell (1957) and Whalley (1976) to study productive efficiency and the deadweight loss of alternative tax schemes. A comparison of the Debreu coefficient with other measures of deadweight loss, including that of his contemporary M. Boiteux at the École normale supérieure, can be found in Diewert (1981).

**The theory of value**
Debreu's *Theory of Value* (1959) is not simply about the existence and optimality of equilibrium. It is a statement of method that has profoundly changed the way economics is practised. For this alone it is among the most original books of 20th-century economic thought. Most economists identify Debreu with mathematics, manipulating formulas and proving theorems. But for Debreu this, although pleasurable, was the easy part of economic theory. He once told me that it was harder to be an economist than a mathematician. A mathematician had to be correct and elegant; but an economist had to be all that and also interesting. The power of a model lies in the economist's ability to interpret with it, and this is the point of all the ‘elegance’ and clarity in Debreu's exposition. In the preface, he writes (1959, p. x), ‘Allegiance to rigor dictates the axiomatic form of the analysis where the theory, in the strict sense, is logically entirely disconnected from its interpretations. … Such a dichotomy reveals all the assumptions and the logical structure of the analysis.’ Debreu taught that the separation of logical analysis from interpretation is crucial to good theory. The logic of market equilibrium is independent of what commodities actually are, except in so far as what they are may suggest additional structure on the primitives of the equilibrium model. This is most clearly demonstrated in Chapter 7. Here Debreu reinterprets the model by appending to the description of commodities the state of nature in which it is available. The use of Arrow's (1953) contingent commodities ‘allows one to obtain a theory of uncertainty free from any probability concept and formally identical with the theory of certainty developed in the preceding chapters’ (1959, p. 98). Three pages later, Debreu observes that the convexity assumptions required by the theoretical analysis could be understood as risk aversion. And although Debreu stops here, it is not a big step to observe that natural preference models, like Savage's subjective expected utility model, lead to an additive structure for preferences that may have implications for the nature of equilibrium.

**Large economies and the core**

Competitive equilibrium requires prices, and prices in turn already require a sophisticated set of market institutions. Nonetheless, ‘general’ is a key word in the phrase general competitive equilibrium. The principle behind the abstract treatment of market equilibrium is that the workings of supply and demand are more or less the same whether the market under discussion is a modern financial market in London or New York or a village market of farmers and petty traders in India or East Africa. This is quite a claim. Support for this idea comes from the fact that the Walrasian outcome from markets with quoted prices can also be supported by a seemingly more fundamental equilibrium concept that makes no mention of prices at all: the core.

The core comes from F. Y. Edgeworth's *Mathematical Psychics* (1881), in which the contract curve is first introduced, and which, remarkably, undertakes a limit analysis of the economy with two types of traders and two goods. Edgeworth showed that the set of core allocations shrinks to the set of competitive equilibria as the number of agents becomes large. Debreu and Scarf (1963) pick up this question and quickly dispatch it for replica economies, which are generalizations of the large population structures Edgeworth studied. Immediately thereafter came Aumann's (1964) equivalence theorem for the core and equilibrium set of an economy with a continuum of agents, which, among other things, launched the subject of economies described by a measure space of agents. These developments are important because perfect competition is most naturally expressed as a large economy (large number of agents) phenomenon, and because empirical descriptions of large markets may be best described by
distributions on the space of agent characteristics.

Smooth economies

It is often said that Gerard Debreu took the calculus out of economics with his topological equilibrium analysis of the 1950s and early 1960s. If so, it returned with a vengeance in his 1970 and 1972 papers on economies with differentiable excess demand. It has been clear since the Edgeworth box that economies with multiple equilibria are inescapable, a fundamental indeterminacy of the analysis. One can easily construct exchange economies with a continuum of equilibria. But how far does it extend? Is this the norm or are these economies pathological? In a path-breaking series of papers Debreu drew the line between normal and bizarre. He demonstrated that if individual demand is differentiable, then the ‘generic’ case is one in which there are only a finite number of isolated equilibria; that is, equilibria are locally unique. ‘Economies with a Finite Set of Equilibria’, his 1970 paper, is particularly striking in its simplicity. Once it is determined that an economy is regular, the main result follows from the inverse function theorem – surely a result known to anyone who has taken a multivariate calculus course. Only the deeper fact that regularity is generic requires more advanced tools such as Sard's theorem. Again, Debreu's intuition was geometric. In lectures this was explained with a simple diagram. Subsequent work has used the tools of differential topology to uncover the deeper structure of the equilibrium manifold, the graph of the equilibrium correspondence. These tools are also of fundamental importance for economies with incomplete markets. With incomplete markets and financial assets rather than real assets, indeterminacy is no longer unusual, and this is of critical importance for applications to macroeconomics and finance. Some of this work is surveyed in the monographs of Balasko (1988) and Mas-Colell (1985).

Excess demand

It is important to ask of any theory, ‘what can it say?’ That is, what kinds of predictions will the theory make, and what patterns in data will contradict the theory? In general equilibrium theory this question was first asked by Sonnenschein (1972) in the following way: in exchange economies, the market excess demand function satisfies the restrictions of continuity, homogeneity and Walras's Law. This and a boundary condition is enough to prove the existence of equilibrium prices. Sonnenschein asked if excess demand functions had any additional structure beyond these three requirements. Sonnenschein (1972), Mantel (1974) and Debreu (1974), with an important extension by (Mas-Colell, 1977), showed that the answer is ‘no’. Any function defined for strictly positive prices and satisfying these three conditions is identical up to boundary behaviour with an excess demand function for an exchange economy containing no more agents than goods, each agent with continuous, strictly convex and monotonic preferences. Thus the hypothesis of utility maximization in exchange economies, with no additional assumptions about agents’ characteristics, will place few restrictions on comparative static results or on the nature of the equilibrium price set. These results are often incorrectly interpreted to mean that general equilibrium theory is empty, that it predicts nothing. This is entirely incorrect. General equilibrium theory is not so much a theory as a theoretical framework within which theories can be built by making explicit assumptions about the
nature of tastes, technologies and endowments. To say that the framework does not limit market behaviour without any assumptions about its primitive objects is to say that the framework is maximally expressive. Its power to predict market behaviour comes from assumptions about the population of agents participating in the market. The so-called ‘anything goes’ theorems simply imply that more results will require more assumptions about the preferences and endowments of agents. It had been Debreu's hope that restrictions on the distributions of agents’ characteristics would lead to interesting conclusions: but progress has been slow.

Other contributions

Debreu has produced seminal papers in areas of economic theory other than general equilibrium analysis. Which preference orders have a continuous utility representation? This question is answered by (1954c). Which preferences have additive separable representations? Debreu's (1958) answer to this very difficult question is topological in nature, and quite distinct from the algebraic answers found in the mathematical psychology literature.

Debreu was exceptional in the classroom and in seminar. His lectures were crystalline, elegantly shaped, and parsimonious. Often they were too clear; we students left the class convinced we understood, only to discover on problem sets how subtle were the arguments that had seemed so obvious on the blackboard. Debreu's expository writings, especially his Nobel Address (1984), are required for everyone with a serious interest in contemporary economics.

Conclusion

It is impossible to imagine modern economics without the scholarship of Gerard Debreu. Debreu, Kenneth Arrow and a few others who solved the big open questions of general equilibrium theory in the 1950s had an impact that reached far beyond the confines of formal competitive analysis. They were responsible for making formal modelling a requirement for serious economic analysis of any kind. Formal modelling is not merely a theoretical discourse; the availability of formal models requires a means for the models to confront data. Modern econometrics is inconceivable without the idea of formal modelling as a strategy of enquiry. It is not by accident that, just as the general equilibrium theory was taking off at the Cowles Commission in the 1950s, so too was modern econometrics. The contributions of the ‘mathematical economists’ launched a revolution that has touched on every area of economic practice.

decentralization

E. Malinvaud

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Central planning is inefficient because it lacks incentives and is poorly informed. Complete decentralization risks being inequitable and also inefficient because markets are incomplete and public goods may be neglected. Intermediate systems can overcome these difficulties to the extent that planning mechanisms can mimic the market system while avoiding its deficiencies, public goods can be successfully delivered at the local level, and incentives to report and behave faithfully and to avoid free riding can be secured.

Keywords

autonomy; central planning; competitive equilibrium; decentralization; decomposability; free rider problem; Hayek, F.; incentive compatibility; incentives; information; non-economic motivation; Lange, O.; Malinvaud, E.; misreporting; Pareto efficiency; principal and agent; private information; prospective indices; public goods; resource allocation mechanisms; social choice; socialism; Mises, L. von

Article

The main question to be answered by the theory of resource allocation, or by the theory of economic organization, concerns the performances of alternative systems characterized by different degrees of centralization of decision taking. A fully centralized system runs the risk of being inefficient because it does not create proper economic incentives and the centre is poorly informed. A pure market system with its high degree of decentralization runs the risk of bringing inequitable results and being inefficient because markets can never be complete, externalities exist and public wants tend to be neglected. Can these risks be avoided within the two opposite extremes of pure centralization or full decentralization? Can intermediate systems better resolve the difficulties? And if so, how?

Basic to the discussion are two features: the nature of the information held by various agents, and the incentives that should lead them to behave in conformity with collective requirements. These features
and the issue of decentralization do not only appear for full economic systems, which this entry will consider, but also for the internal organization of firms or communities. They are stylized in the principal–agent problem: which rules should determine how to share the proceeds of an activity between the principal owner and his better-informed agent? (Ross, 1973; Grossman and Hart, 1983).

For the clarification of the complex issues involved, theory starts from a model of the conditions of economic activity. It makes assumptions such that, independently of economic organization, there exists a best outcome, or at least a set of ‘optimal’ outcomes. It then asks how well alternative forms of organization succeed in finding, implementing or at least approaching this best outcome or set of optimal outcomes.

By so doing, the theory discussed here neglects two related questions: how to determine what should be considered as ‘the best’ outcome in a society with many individuals, and which non-economic considerations interfere with the issue of decentralization? The theory of social choice shows the fundamental difficulty of the first question (Arrow, 1951), which is avoided when optimality is identified with Pareto efficiency. As for the second, philosophers may find in human nature or in the aims pursued by human societies reasons that favour some organization, beyond its economic performance; in particular, the right of individuals to autonomy appears fundamental in Western culture and is an important justification of decentralization, and even of the market system for such economists as Hayek (1944).

**Formal concepts and preliminaries**

The following conceptual apparatus, although not yet common, is well suited to the purpose (see Hurwicz, 1960; Mount and Reiter, 1974).

An *economic environment* is defined by a set of commodities and their possible uses, by a list of agents and their characteristics (technology, endowments, preferences, and so on), and by an initial information structure (what each agent knows). The feasible set of economic environments defines ‘the economy’. An important property of an economy is its higher or lower degree of *decomposability*, which concerns agents’ characteristics and the information structure. The highest decomposability is assumed in competitive equilibrium theory, where all consumption is private, no external effect exists and a *private information structure* prevails (each agent perfectly knows its own characteristics and the situation on all markets, but nothing else). But models with public goods, for instance, usually admit some decomposability, which matters for the validity of the results.

An *optimality correspondence* $P: E \rightarrow A$ defines which vectors of actions simultaneously taken by the various agents are optimal when the economic environment is $e$, i.e. optimal vectors belong to $P(e)$ (clearly, $E$ is the set of feasible $e$, that is ‘the economy’, while $A$ is the set of feasible vectors $a$, each one of them defining the actions taken by all the agents). For instance $P(e)$ may be the set of Pareto efficient vectors. But in the theory discussed here, it is often more narrowly defined so as to take equity considerations into account: a social utility function may have to be maximized or a rule on the consumers ‘income distribution’ satisfied.

A *resource allocation mechanism* $f: E \rightarrow \mathcal{A}$ should select one $a = f(e)$ for each environment $e$ (in some cases $f$ may be multivalued, i.e. become a correspondence). The best formalized mechanism is the competitive equilibrium of a ‘private ownership economy’. A study of decentralization requires a careful
specification of the mechanism, which is typically viewed as operating in two stages: first, an iterative exchange of messages, usually between the agents and a centre, resulting in a message correspondence \( g : E \to M \) (the message \( m = g(e) \) specifies what information about \( e \) has been collected at the centre), second an outcome function \( h : M \to A \). For instance, the competitive mechanism is often specified as resulting from the tâtonnement process, in which an auctioneer learns which demands and supplies are announced at various proposed vectors of prices, and searches for the equilibrium prices; once these prices are found, the outcome function gives the equilibrium exchanges, hence productions and consumptions.

The performances of alternative mechanisms of course concern the final result: one must know whether the outcome \( f(e) \) belongs to the optimal set \( P(e) \) for all environments in \( E \), or at least for a precise subset of \( E \), and how close it is to \( P(e) \) otherwise. But interesting performances also concern intermediate features of the mechanism, which usually is iterative. At step \( t \) the previously collected message \( m_{t-1} \) is enriched according to \( m_t = g_t(m_{t-1}, e) \) and, if necessary, the process could end by \( a = h_t(m_t) \). In a finite procedure it does end at \( T \) with \( m = m_T \) and \( h(m) = h_T(m_T) \); but most mechanisms assume an infinite sequence of \( m_t \) for \( t = 1, 2 \ldots \) ad infinitum. One must then know whether and how \( h_t(m_t) \) approaches \( P(e) \), monotonically or otherwise. Since the transmission of information is costly, the nature and size of the message space \( M_t \) to which \( m_t \) belongs are also important characteristics (Mount and Reiter, 1974).

**The planning problem**

Early in this century many economists objected to socialist planning programmes that could not be implemented, because they unrealistically assumed that a central administration could have the knowledge and computing power required for an efficient control of economic activity. The leading figure was L. von Mises (1920 in particular); but Hayek (1935) was first to emphasize the problems raised by the decentralization of information. Socialist economists answered that decentralized mechanisms could operate, either mimicking the market system while being free of its deficiencies (Lange, 1936) or using different well conceived modes of information gathering (Taylor, 1929). The debate was, in the interwar years, the subject of the ‘economic theory of socialism’. (For a well-documented survey, see Bergson, 1948.)

The problem was again taken up during the 1960s, in particular because the logic of efficient planning was discussed in Eastern and Western Europe (Arrow and Hurwicz, 1960; Kornai, 1967; Malinvaud, 1967; Heal, 1973). Many planning procedures were rigorously studied as resource allocation mechanisms. Their definition implied an iterative exchange of information between a Central Planning Board and firms, sometimes also representative consumers. The additional messages provided by the function \( g_t \) at step \( t \) then consisted of prospective indices announced by the Board, for instance prices for the various commodities, and replies called proposals sent to the Board by firms and other agents, for instance preferred techniques of production and their input requirements, or supplies and demands. In this discussion it is common to distinguish between price-guided procedures, in which the Board announces price vectors, and other procedures, in which quantity indices or targets worked out at the centre play a more or less important role. The nature and properties of the environment are then found to
be crucial for the determination of the relative performances of alternative procedures, in particular of price-guided against quantity-guided procedures (Weitzman, 1974).

The analytical study of various procedures usually assumes that decentralized agents exactly follow specified rules for the determination of their proposals and so faithfully reveal part of their private information. Some procedures are then found to be efficient and to permit achievement of distributive objectives. But efficiency is typically easier precisely in those environments that are also favourable to the efficiency of free competition. Besides the possibility of incorrect reporting, the main difficulty concerning the relevance of this literature is to know whether its models provide an approximate representation of procedures that are actually used, or at least administratively feasible. Manove (1976) has made this claim for his representation of Soviet planning.

The public good problem

The most relevant field of application may very well be the theory of public goods. Decisions concerning the provision of public services and their financing cannot be fully decentralized; but the knowledge required is dispersed and must be gathered in a proper way. Hence even the positive theory of public goods was often formulated along lines that look like those of planning procedures (Malinvaud, 1971). The same remark applies to decisions concerning public projects with large fixed costs, even if their output is privately consumed.

Considered as a planning procedure, the search for the best decision is often viewed as involving ‘prospective indices’ that define amounts of service to be provided, ask for corresponding individual marginal utilities and look whether the sum of the latter would cover the cost of additional service. This is compatible with the dual arrangement for private goods, prices being announced, supplies and demands being the replies. The procedure is then quantity-guided for public goods and price-guided for private goods (Drèze and Vallée Poussin, 1971).

The collective consumption of many types of public goods is not really national but limited to local communities (primary education, city transports, and so on). Administrative science sees the decentralization issue as being to know at which level should decisions be taken: at the national level, so as to distribute fairly these services among communities, or at the local level, so as to permit better adaptation to local needs and wishes. Economists do not seem to have contributed to this issue; their discussion of local public goods assumes full administrative decentralization (Tiebout, 1956).

Incentive compatibility

The study of a decentralized system has to consider whether the actual reports and behaviour of individual agents do not deviate from what they are supposed to report and do; in case of deviations, how are the performances of the system affected? The problem is serious: once the rules of organization and decisions are known, individual agents may benefit from misreporting their private information or from behaving in a way that, although deviant, does not clearly appear to be so. In other words, they may act as players in a game, rather than as members of a team, and this may be more or less detrimental for the optimality of the final result.

The problem has long been known for organizations in which some agents do not individually benefit
from what is achieved and therefore lack the incentive to do their best. Monopolistic or other non-competitive behaviour is often interpreted as a breach of the normal rules of resource allocation. In the theory of public good the ‘free rider problem’ occurs as soon as some individuals, having a high marginal utility for the public good, would benefit from hiding this fact so as to contribute little to the financing of the good. Study of the problem has been active during the past two decades (Green and Laffont, 1979). The fundamental difficulty has been exhibited by such results as the following one: in the classical model of an exchange economy with a finite number of consumers, no procedure can be found that would necessarily lead to a Pareto efficient result in which individuals, acting as players in a non-cooperative game, would faithfully report (Hurwicz, 1972). However, misreporting may not prevent a procedure from eventually leading to an optimum, as was proved in a number of cases. Experiments moreover show that the game-theoretic approach to the incentive problem may be misleading because it neglects non-economic motivations that individuals may find for accepting a team-like behaviour and therefore for faithfully reporting (Smith, 1980).

decision theory in econometrics

Keisuke Hirano
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The decision-theoretic approach to statistics and econometrics explicitly specifies a set of models under consideration, a set of actions that can be taken, and a loss function that quantifies the value to the decision-maker of applying a particular action when a particular model holds. Decision rules, or procedures, map data into actions, and can be ordered according to their Bayes, minmax, or minmax regret risks. Large sample approximations can be used to approximate complicated decision problems with simpler ones that are easier to solve. Some examples of applications of decision theory in econometrics are discussed.

J.; search models; semiparametric models; statistical decision theory; time series models; treatment assignment; white noise

Article

The decision-theoretic approach to statistics and econometrics explicitly specifies a set of models under consideration, a set of actions available to the analyst, and a loss function (or, equivalently, a utility function) that quantifies the value to the decision-maker of applying a particular action when a particular model holds. Decision rules, or procedures, map data into actions, and can be evaluated on the basis of their expected loss.

Abraham Wald, in a series of papers beginning with Wald (1939) and culminating in the monograph (Wald, 1950), developed statistical decision theory as an extension of the Neyman–Pearson theory of
testing. It has since played a major role in statistical theory for point estimation, hypothesis testing, and forecasting, especially in the construction of ‘optimal’ procedures. Some textbooks such as Ferguson (1967) and Berger (1985) emphasize statistical decision theory as a foundation for statistics. But the decision theory framework is sufficiently flexible that it can be used for many empirical applications that do not fit neatly into the usual statistical set-ups. Some examples are discussed below.

Like the Neyman–Pearson theory, Wald's approach emphasizes evaluating the performance of a decision rule under various possible parameter values. There does not always exist a single rule that dominates all others uniformly over the parameter space, just as there does not always exist a uniformly most powerful test in the special case of hypothesis testing. Wald, who also made contributions to game theory, proposed to evaluate a procedure by its minmax risk – the worst-case expected loss over the parameter space. Savage (1951) discusses the minmax principle and suggests an alternative, the minmax-regret principle. Alternatively, one can place a probability measure on the parameter space, and evaluate rules by their weighted average (Bayes) risk.

Basic framework

In Wald's basic framework, we start with a set of actions $A$, and a parameter space $\Theta$, which characterizes the set of models under consideration. A loss function $L(\theta, a)$ gives the loss or disutility suffered from taking action $a \in A$ when the parameter is $\theta \in \Theta$. The decision maker observes some random variable $Z$, distributed according to a probability measure $P_\theta$ when $\theta$ is the ‘true’ parameter. Here, the parameter space $\Theta$ could be finite-dimensional (corresponding to a parametric family of distributions) or infinite-dimensional (corresponding to semiparametric and nonparametric models). The observed random variable $Z$ could be a vector, as for example in the situation of observing a random sample of size $n$ from some distribution. Often, the set of possible probability measures $\{P_\theta : \theta \in \Theta\}$ is called a statistical experiment.

A decision rule or procedure $d(z)$ maps observations on $Z$ into actions. In some cases, it is useful to allow for randomization over the actions. A randomized decision rule is a mapping from observations into probability measures over the action space. A simpler, usually equivalent formulation is to consider rules $\delta'(z, u)$ which are allowed to depend on the observed value $z$ and the value $u$ of a random variable $U$, distributed standard uniform independently of $Z$. The risk, or expected loss, of a decision rule $\delta$ under $\theta$ is defined as

$$R(\theta, \delta) = E_\theta[L(\theta, \delta(Z, U))] = \int_0^1 \int L(\theta, \delta(z, u)) dP_\theta(z) du.$$ 

A rule $\delta$ is admissible if there exists no other rule $\delta'$ with

$$R(\theta, \delta') \leq R(\theta, \delta), \ \forall \theta \in \Theta,$$
and

$$R(\theta, \delta') < (\theta, \delta) \text{for some } \theta.$$ 

**Ordering decision rules**

In general, there are many admissible decision rules, which may do well in different parts of the parameter space. Thus, while the admissibility criterion eliminates obviously inferior rules, it may not provide concrete guidance on how to ‘solve’ the decision problem. Additional criteria can help by providing a sharper partial ordering of decision rules.

One way to rank decision rules is to average their risk over the parameter space. Let $\Pi$ be a probability measure on $\Theta$. The *Bayes risk* of a decision rule $\delta$ is

$$r(\Pi, \delta) = \int R(\theta, \delta) d\Pi(\theta).$$

A rule is a *Bayes rule* if it minimizes this weighted average risk. Let the probabilities $P_\theta$ have densities $p_\theta$ with respect to some dominating measure, and let the prior $\Pi$ have density $\pi$. Typically, a Bayes rule can be implemented by choosing, for any given observed data $z$, the action that minimizes the posterior expected loss

$$\int L(\theta, a) d\Pi(\theta|z),$$

where $\Pi(\theta|z)$ is the posterior distribution with density

$$\pi(\theta|z) = \frac{\pi(\theta) p_\theta(z)}{\int p_\theta(z) d\Pi(\theta)}.$$
There is a close connection between the admissible rules and the Bayes rules. If the parameter set is finite, a Bayes rule for a prior that places positive probability on every element of \( \Theta \) is admissible. Furthermore, ‘complete class theorems’ give results in the opposite direction. In particular, if the parameter set is finite, any admissible rule is Bayes for some prior distribution. If \( \Theta \) is not finite, some care needs to be taken to make a precise statement of the relationship between the admissible and Bayes rules; see for example Ferguson (1967).

An alternative ordering is based on the worst-case risk \( \sup_{\theta \in \Theta} R(\theta, \delta) \). A \textit{minmax} rule \( \delta^m \) satisfies

\[
\sup_{\theta \in \Theta} R(\theta, \delta^m) = \inf_{\delta \in \Theta} \sup_{\theta \in \Theta} R(\theta, \delta).
\]

In general, a minmax rule need not be admissible.

A closely related criterion is the \textit{minmax regret} criterion. The regret loss of a rule is the difference between its loss and the loss of the best possible action under \( \Theta \):

\[
L_{r}(\theta, a) = L(\theta, a) - \inf_{a' \in A} L(\theta, a').
\]

We can then define regret risk as \( R_r(\Theta, \delta) = \mathbb{E}_\Theta (L_r(\Theta, \delta(Z, U))) \). The \textit{minmax regret rule} minimizes the worst-case regret risk. This rule was suggested by Savage (1951) as an alternative to the minmax criterion. He argued that in cases where the minmax criterion is unduly conservative, minmax regret rules can be reasonable.

Savage (1954) showed that a decision-maker who satisfied certain axioms of coherent behaviour would act as if she placed a prior on the parameter space and minimized posterior expected loss. Gilboa and Schmeidler (1989) showed that, under a different set of axioms, a decision-maker would follow the minmax principle.

Calculation of Bayes and minmax rules can be difficult in many applications. Bayesian posterior distributions can be calculated directly when the prior and likelihood have a conjugate form. One way to solve for a minmax rule is to guess the form of a ‘least favourable’ prior and solve for the associated Bayes rule. If the risk function of the Bayes rule is everywhere less than the Bayes risk, then the rule is minmax. A related method is to construct a least favourable sequence of prior distributions, and calculate the limit of the Bayes risks. If a particular rule has worst-case risk lower than the limit of Bayes risks, then the rule is minmax. Another useful technique for obtaining minmax rules makes use of invariance properties of the decision problem. If the model and loss are invariant with respect to a group of transformations, and that group satisfies a condition called amenability, then the best equivariant procedure is minmax by the Hunt–Stein theorem. These techniques are discussed in Ferguson (1967) and Berger (1985).
decision theory in econometrics: The New Palgrave Dictionary of Economics

If Bayes and minmax rules cannot be obtained analytically, computational methods can sometimes be useful. Recently developed simulation methods such as Markov chain Monte Carlo have greatly expanded the range of settings where Bayes rules can be numerically computed. Chamberlain (2000) develops algorithms for computing minmax rules, and applies them to an estimation problem for a dynamic panel data model.

Asymptotic statistical decision theory

Despite advances in computational methods, many statistical decision problems remain intractable. In such cases, large-sample approximations may be used to show that certain rules are approximately optimal. Le Cam (1972; 1986) proposed to approximate complex statistical decision problems by simpler ones, in which optimal decision rules can be calculated relatively easily. One then finds sequences of rules in the original problem that approach the optimal rule in the limiting version of the problem.

As an example, suppose we observe \( n \) i.i.d. draws from a distribution \( P_\theta \), where \( \theta \in \Theta \subset \mathbb{R}^k \) and the probability measures \( \{ P_\theta \} \) satisfy conventional regularity conditions with non-singular Fisher information \( I_\theta \). We can think of this as defining a sequence of experiments, where the \( n \)th experiment consists of observing an \( n \)-dimensional random vector distributed according to \( P_\theta \), the \( n \)-fold product of \( P_\theta \). Since, in the limit, \( \theta \) can be determined exactly, we fix a centring value \( \theta_0 \), and reparametrize the model in terms of local alternatives \( \theta_0 + h/\sqrt{n} \), for \( h \in \mathbb{R}^k \). This sequence of experiments has as its ‘limit experiment’ the experiment consisting of observing a single draw \( Z \sim N(h, I^{-1}_{\theta_0}) \), and we say that the original sequence of experiments satisfies local asymptotic normality (LAN). More precisely, according to an asymptotic representation theorem (see van der Vaart, 1991), for any sequence of procedures \( \delta_n \) in the original experiments that converge in distribution under every local parameter \( h \), these limit distributions are matched by the distributions associated with some randomized procedure \( \delta(Z) \) in the limit experiment. Thus, the limit experiment characterizes the set of attainable limit distributions of procedures in the original sequence of experiments. Solving the decision problem in the limit experiment leads to bounds on the best possible asymptotic behaviour of procedures in the original problem, and often suggests the form of asymptotically optimal procedures.

Le Cam's theory underlies the classic result that in regular parametric models, Bayes and maximum likelihood point estimators of \( \theta \) are ‘asymptotically efficient’. In the LAN limit experiment \( Z \sim N(h, I^{-1}_{\theta_0}) \), a natural estimator for the parameter \( h \) is \( \delta(Z) = Z \). This can be shown to be minmax and best equivariant for ‘bowl-shaped’ loss functions. Both the Bayes and MLE estimators in the original problem are matched asymptotically by this optimal estimator, so they are locally asymptotically minmax and best equivariant. The ideas have been extended to models with an infinite-dimensional parameter space (see Bickel et al. (1993) and van der Vaart, 1991, among others), to obtain semiparametric efficiency bounds for finite-dimensional sub-parameters. More recently, a body of work has developed limit experiment theory for nonparametric problems such as nonparametric regression and nonparametric density estimation (see Brown and Low, 1996, and Nussbaum, 1996, among others).
These results show that nonparametric regression and density estimation are asymptotically equivalent to a white-noise model with drift, for which a number of optimality results are available.

Applications in economics

Portfolio choice

A number of authors have used statistical decision theory to study portfolio allocation when the distribution of returns is uncertain. Some examples include Klein and Bawa (1976), Kandel and Stambaugh (1996), and Barberis (2000), who develop Bayes rules for portfolio choice problems.

Treatment choice

Another econometric application of statistical decision theory is to treatment assignment problems, in which a social planner wishes to assign individuals to different treatments (for example, different job training programmes) to maximize some measure of social welfare. Manski (2004) develops minmax-regret results for the treatment assignment problem, Dehejia (2005) develops Bayesian rules, and Hirano and Porter (2005) obtain asymptotic minmax regret-risk bounds and show that certain simple rules are optimal according to this criterion.

Model uncertainty and macroeconomic policy

Brainard (1967) studied a macroeconomic policy problem, in which a parameter describing the effect of a policy instrument on a macroeconomic outcome is not known with certainty but is given a distribution. The policymaker has a utility function over outcomes and chooses the policy that makes expected utility. More recently, a number of authors have continued this line of work, extending the analysis to more general forms of model uncertainty and developing both Bayesian and minmax solutions. Some examples include Hansen and Sargent (2001), Rudebusch (2001), Onatski and Stock (2002), Giannoni (2002), and Brock, Durlauf and West (2003).

Instrumental variables models

Decision-theoretic ideas underlie recent work on the linear instrumental variables model in econometrics. Chamberlain (2005) develops minmax optimal point estimators in the IV model using invariance arguments. Andrews, Moreira and Stock (2004) have developed tests in the IV model that are optimal under an invariance restriction, and Chioda and Jansson (2004) have developed optimal conditional tests.

Time series models

Asymptotic statistical decision theory has been useful in studying certain time series models which do
decision theory in econometrics: The New Palgrave Dictionary of Economics

not satisfy standard regularity conditions. Jeganathan (1995) shows that a number of models for econometric time series have limit experiments that are not of the standard LAN form, but are locally asymptotically mixed normal (LAMN) or locally asymptotically quadratic (LAQ). Ploberger (2004) obtains a complete class theorem for hypothesis tests in the LAQ case, which nests the LAMN and LAN cases.

Auction and search models

Some parametric auction and search models, in which the support of the data depends on some of the model parameters, do not satisfy the LAN regularity conditions. For such models, Hirano and Porter (2003) showed that the maximum likelihood point estimator is not generally optimal in the local asymptotic minmax sense, but that Bayes estimators are asymptotically efficient.

default and enforcement constraints

Fabrizio Perri
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article illustrates when limited enforcement of contracts induces enforcement constraints (limits to intertemporal exchange) or default (the breaking of intertemporal promises with the associated punishment), and sheds light on how enforcement policies should be related to the observed frequency of default. When limited enforcement is the only friction equilibrium default is never observed, yet tightening enforcement of contracts is socially beneficial. When limited enforcement coexists with other frictions, default occurs in equilibrium but tightening enforcement might be socially undesirable. The reason is that equilibrium default, although detrimental to intertemporal exchange, might lead to improved allocation of resources across states.

Keywords

Arrow–Debreu promises; default; enforcement constraints; intertemporal exchange; Lagrange multipliers; limited enforcement of contracts with default; limited enforcement of contracts without default; risk sharing

Article

Intertemporal exchange, that is the exchange of resources today for a promise of resources at a later date in a given state, is key for promoting economic efficiency. For example, to finance an investment, a government borrows capital abroad in exchange for a promise of repayment once the investment has paid off. Or, to finance consumption, an individual who loses her job borrows resources in exchange for the promise of repayment once she gets a new job. If the enforcement of promises is limited, the extent of intertemporal exchange can be reduced by so-called enforcement constraints and, under some conditions, default, that is, the breaking of promises, can arise. This article presents a simple general equilibrium set-up to analyse these issues and provide some direction for the design of enforcement policies. Key references for the theory of limited enforcement without default are Kehoe and Levine.
The set-up

The goal of this set-up is to capture the need for intertemporal exchange, as described in the examples above. There are two agents which live for two periods and consume a single good. Agent 1, the borrower, owns a technology such that, if $k$ units of the good are invested in period 1, $AK^\alpha$, $0 < \alpha < 1$, units are produced in period 2, where $A$ is a random variable realized in period 2, with positive support and distribution $F(A)$ known to both agents. Agent 2, the lender, is endowed with $e$ units of the consumption good in period 1. Consumption allocations of agent $i$ are consumption at date 1, $c_{i1}$ and the function $c_{i2}(A)$ which assigns period 2 consumption for each possible realization of $A$. Borrower's utility is given by

$$u(c_{11}) + \int u(c_{12}(A))dF(A)$$

where $u$ is a concave utility function satisfying Inada conditions. The lender has linear utility given by $c_{21} + \int c_{22}(A)dF(A)$. Linear utility implies that lender's equilibrium utility is constant across different market structures so that borrower's utility is the only statistic needed to Pareto-rank equilibria. In all the economies described below the following resource constraints hold

$$c_{11} + c_{21} + k = ec_{12}(A) + c_{22}(A) = AK^\alpha$$

for every $\mathcal{A}$

A frictionless benchmark

Assume agents can trade a complete set of Arrow–Debreu promises which are fully and costlessly enforceable. The budget constraints of the borrower are

$$c_{11} + k = \int p(A)dF(A)$$

(1)

$$c_{12}(A) = AK^\alpha - p(A)$$

(2)
where \( p(A) \) denotes the amount that the borrower promises to repay in state \( A \). Equilibrium allocations display complete risk sharing, that is, the ratio of marginal value of consumption of the two agents is constant across dates and states of the world. We denote with \( c^{AD} \) the constant, across dates and states, level of consumption of the borrower in this economy.

**Limited enforcement**

This section describes an economy denoted as ADLE (Arrow–Debreu Limited Enforcement) and shows that limited enforcement prevents full risk sharing, reduces investment and welfare. Assume that in period 2 the borrower can walk away from any promise made to the lender by suffering a default deadweight cost proportional to its output and equal to \( \delta A k^\alpha \) where \( \delta > 0 \) is a parameter that measures the strength of enforcement. This implies that any Arrow–Debreu promise \( p(A) > \delta A k^\alpha \) will not be honoured by the borrower and thus will not be purchased by the lender. Also, promises satisfying \( p(A) \leq \delta A k^\alpha \) will be fully honoured and priced as in the frictionless economy. So limited enforcement limits the use of state-contingent promises but does not induce default. A convenient way of capturing this, following Alvarez and Jermann (2000), is to assume that the borrower faces constraints on the sales of each promise so as to guarantee no default. These *enforcement* constraints have the form

\[
p(A) \leq \delta A k^\alpha \text{ for every } A
\]  

(3)

as the borrower can sell each promise only up to the point where the cost of keeping it is equal to the cost of defaulting on it. Equilibrium allocations can be characterized by substituting budget constraints (1) and (2) into the borrower's utility and taking first-order conditions with respect to \( k \) and \( p(A) \) subject to constraints (3). This yields

\[
u'(\epsilon_{11}) = \int [A \alpha k^\alpha - 1 u'(\epsilon_{12}(A)) + A \alpha k^\alpha - 1 \delta \mu(A)] dF(A)
\]

(4)

where

\[
\mu(A) = u'(\epsilon_{11}) - u'(\epsilon_{12}(A))
\]
are the Lagrange multipliers on the enforcement constraints. If the cost of default $\delta$ is sufficiently small and the distribution of $A$ is sufficiently spread out, $\ell_{11} = \ell(A) = \ell_{AD}$ is not a solution of (4) as enforcement constraints on the high $A$ promises would be violated. The solution is then characterized by a level of productivity $A^*$ such that for all $A > A^*$ enforcement constraints are binding and $\ell(A) = (1 - \delta)Ak^\alpha > \ell_{11}$. For $A \leq A^*$ enforcement constraints are not binding and $\ell(A) = \ell_{11} < \ell_{AD}$.

Complete risk sharing involves the borrower selling promises to repay in states with high $A$, in order to finance consumption today (when she has no output) and consumption tomorrow in states with low $A$. But if the distribution of $A$ is spread out, complete risk sharing calls for promises of a large transfer of resources from the borrower to the lender in the states with high $A$. When enforcement is limited ($\delta$ is low) the lender, in period 1, correctly anticipates that these transfers will not be made and buys a smaller amount of the promises. So, relative to complete risk sharing, the borrower has fewer resources in period 1 and in the period 2 states with low $A$, but consumes more in period 2 states high $A$. This allocation of consumption increases the marginal value of resources in period 1 relative to the expected marginal value of resources in period 2 and thus reduces $k$ relative to the full enforcement case. Finally, equilibria in economies with strong enforcement (high $\delta$) Pareto-dominate equilibria with weak enforcement (low $\delta$). To see this, note that, for the borrower, the equilibrium allocation in the weak enforcement economy is budget-feasible in the strong enforcement economy, so, if it is not chosen, it must yield her lower utility.

ADLE economies have been used extensively in a variety of applications such as asset pricing (Alvarez and Jermann, 2000), international business cycles (Kehoe and Perri, 2002) and consumption inequality (Krueger and Perri, 2006). All these studies show that limited enforcement prevents complete risk sharing, and for this reason it provides a much better fit with the data than standard Arrow–Debreu economies. This environment, though, cannot be used to understand equilibrium default (that is, the actual break of a promise and the suffering of the associated cost) as the trade in contingent promises makes incurring the default cost unnecessary. In order to understand when default arises and what its consequences are, the next section considers an economy in which contingent promises cannot be traded, either because markets are exogenously missing or because the borrower has private information about realizations of $A$.

**Limited enforcement and non-contingent promises**

The borrower finances consumption and investment only by selling a non-contingent promise $p$ which can be defaulted on in state $A$ by suffering the default cost $\delta Ak^\alpha$. Since the cost of repaying the promise does not vary with the state while the default cost is increasing with $A$, if there is equilibrium default it will happen in the low $A$ states. In particular, if the borrower invests $k$ and sells a promise $p$, she will default in all the states such that $A \leq \frac{p}{\delta k^\alpha}$.

As a consequence, the equilibrium price of the promise is given by
default and enforcement constraints: The New Palgrave Dictionary of Economics

\[ q(p, k) = 1 - F\left( \frac{p}{\delta k^\alpha} \right). \] (5)

The problem of the borrower is then

\[
\max_{p, k} u(q(p, k)p - k) + \int_0^{\frac{\nu}{\delta k^\alpha}} u((1 - \delta)A_k^\alpha) dF(A) + \int_0^\infty u(A_k^\alpha - p) dF(A).
\] (6)

The equilibrium is characterized by a couple \( p, k \) which solve (5) and (6). It can be immediately shown that equilibria in this economy are, generically, Pareto-inferior to equilibria in the corresponding ADLE economy. Also, for many parameter values equilibria in this set-up differ from those in the ADLE economy along two important dimensions: (a) there is a positive measure of states for which default occurs and (b) there is a positive measure of values for \( \delta \) for which welfare is decreasing in the strength of enforcement. As a simple example, consider the case in which \( A \) can take only two values: a high value \( A_h \) with probability \( \pi \) and a low value \( A_l \) with probability \( 1 - \pi \), with \( \pi > A_l / A_h \). In this case there is a range of values for \( \delta \) for which the equilibrium promise and capital satisfy

\[ \delta A_h k^\alpha < p < \delta A_l k^\alpha, \] (7)

so that default happens only when state \( A_l \) is realized and consequently \( q(p, k) = \pi \). Now consider the effect of a marginal reduction in \( \delta \). Equation (7) shows that, if the borrower kept \( k \) and \( p \) unchanged in response to the change in \( \delta \), default patterns, and hence \( q(p, k) \), would not change; however reducing \( \delta \) increases the returns of borrower in the default state so its utility would increase relative to the initial equilibrium. Here weakening enforcement allows the borrower to implicitly transfer, through default, more resources to the low \( A \) state and thus to achieve a better allocation of risk across states. In the ADLE economy this transfer was achieved through the Arrow–Debreu promises so default was not necessary. When promises cannot be made state-contingent, increasing payoffs in the default states is the only way of obtaining this transfer.

In this simple example weakening enforcement does not affect default frequency, but in more general set-ups it does and as a consequence increases equilibrium interest rates and hampers intertemporal
default and enforcement constraints: The New Palgrave Dictionary of Economics

exchange. This effect is detrimental for welfare. But the example above suggests that the detrimental effect can be offset by the positive effect of the better risk allocation across states. Note that this result does not rely on the two-state assumption, and it can be shown to hold, for example, also when $A$ is log-normally distributed.

Summary

Limiting contract enforcement in otherwise frictionless environments constrains intertemporal exchange and hampers risk sharing, investment and welfare, but does not induce default. When additional frictions, such as incomplete markets or private information, limit the span of tradable promises, then limited enforcement can play a positive role by inducing equilibrium default, which can be used as a (costly) way of providing better allocation of risk across states. The analysis sheds light on how enforcement policies should be related to the observed frequency of default. When limited enforcement is the only friction, default is never observed, yet tightening enforcement is socially beneficial. When limited enforcement coexists with other frictions, default happens in equilibrium but this does not necessarily mean that enforcement should be tightened. Indeed, tightening enforcement without ameliorating the additional friction might reduce default but also risk sharing and welfare.

Defence economics is a new field of economics. Its development and research agenda have reflected current events. Examples include the superpower arms race of the cold war, disarmament following the end of the cold war, international terrorism, peacekeeping and conflict. A brief history is presented; the field is defined and the facts of world military spending are outlined; the defence economics problem, namely, the need for difficult choices, is considered; and conflict and terrorism are used to illustrate some of the new developments in the field.

Article
Defence economics is a relatively new part of the discipline of economics. One of the first specialist contributions in the field was by C. Hitch and R. McKean, *The Economics of Defense in the Nuclear Age* (1960). This book applied basic economic principles of scarcity and choice to national security. It focused on the quantity of resources available for defence and the efficiency with which such resources were used by the military. For example, defence consumes scarce resources that are therefore not available for social welfare spending (for example, missiles versus education and health trade-offs).
Once resources are allocated to defence, military commanders have to use them efficiently, combining their limited quantities of arms, personnel and bases to ‘produce’ security and protection. Within such a military production function, there are opportunities for substitution. For example, capital (weapons) can replace (and have replaced) military personnel; imported arms can replace nationally produced weapons; and nuclear forces have replaced large standing armies. Defence economics is about the application of economic theory to defence-related issues.

The development of defence economics and its research agenda reflected current events. For example, during the cold war there was a focus on the superpower arms races, alliances (NATO and the Warsaw Pact), nuclear weapons and ‘mutually assured destruction’. The end of the cold war resulted in research into disarmament, the challenges of conversion and the availability of a peace dividend. Since the end of the cold war, the world remains a dangerous place with regional and ethnic conflicts (for example, Bosnia, Kosovo, Iraq), threats from international terrorism (for example, terrorist attacks on USA on 11 September 2001), rogue states and weapons of mass destruction (that is, biological, chemical and nuclear weapons). NATO has accepted new members (for example, former Warsaw Pact states) and has developed new missions, and the European Union has developed a European Security and Defence Policy. Changing threats and new technology require the armed forces and defence industries to adjust to change and new challenges. Peacekeeping has become a major mission for armed forces and is an example of the trend towards globalization.

The modern era of globalization involves more international transactions in goods, services, technology and factors of production, which brings new security challenges for both nation states and the international community. Defence firms have become international companies with international supply networks. Globalization also highlights the importance of international collective action to respond to new threats such as international terrorism and to maintain world peace (for example, through international peacekeeping missions under UN, NATO or EU control). But international collective action experiences the standard problems of burden-sharing and free riding.

This article outlines the development of defence economics; it defines the field and describes the ‘stylized facts’ of world military expenditure; the defence economics problem is considered; and a case study of conflict and terrorism illustrates some of the new developments in the field.

A brief history

Defence issues have existed throughout history as nations have been involved in armed conflict of various forms and durations (for example, the Hundred Years War). Great powers have used military force to dominate regions and parts of the world (for example, Alexander the Great; Roman legions; Genghis Khan; Ottoman Turks; Nazi Germany), with such powers rising and falling (Kennedy, 1988). Conflict has also been characterized by major technical changes ranging from bows and arrows to cannons and machine guns, from sailing ships to iron and steel warships and nuclear-powered vessels, from horse cavalry to tanks, from flag communications to radios and satellite communications and from balloons to aircraft, missiles, nuclear weapons and space systems. Historically, the economic base for conflict was first an agricultural society, then an industrial society followed by a knowledge economy. Some of the classical economists studied war and conflict (for example, Smith, Ricardo, Malthus, J. S. Mill: see Goodwin, 1991, ch. 2). For these economists, war departed from much of their conventional thinking: it involved chaos and disorder rather than market equilibrium, and it required government
action rather than private market behaviour. Yet it remains surprising that, with a long history of wars, including two world wars and the superpower arms race of the Cold War, relatively few economists have been attracted to the field. A review of the economics literature on conflict concludes that ‘We were surprised at the relative absence of applied economics studies of actual conflicts’ (Sandler and Hartley, 2003, p. xl). There are various possible explanations for the relative absence of economists studying war and conflict. These include data and security problems, the difficulty of applying conventional market analysis to the chaos and disequilibrium of conflict, a traditional reluctance to analyse the public sector (with defence assumed to be exogenous), and the feeling that defence and security issues are not as important as other social welfare issues, with war viewed as an immoral and unethical subject. Furthermore, security issues have not been as an attractive career path for economists (compared with issues such as inflation, unemployment, growth and developing countries), and conflicts are usually of short duration so that they offer only limited research prospects before peace returns to remove war-related problems (Goodwin, 1991, pp. 1–2).

Definitions

Defence economics studies all aspects of war and peace and embraces defence, disarmament and conversion. This definition includes studies of both conventional and non-conventional conflict such as civil wars, revolutions and terrorism. It involves studies of the armed forces and defence industries and the efficiency with which these sectors use scarce resources in providing defence output in the form of peace, protection and security. Reductions in defence spending (such as those following the end of the cold war) result in disarmament, which involves reallocating resources from the defence to the civilian sector. This raises questions about the impact of disarmament on the employment and unemployment of both military personnel and defence industry workers; the possibilities for converting military bases and arms industries to civil uses (the Biblical swords to ploughshares); and the role of public policies in assisting the transition and reallocation of resources.

The coverage of the subject is extensive and involves economic theory, empirical testing and policy-related issues, including applications of public choice analysis. Both defence and peace have distinctive economic characteristics in that they are public goods which are non-rival and non-excludable. There are large literatures dealing with the determinants of military expenditure, including economic theories of military alliances and arms races (that is, threats) and the impact of defence spending on economic growth and development. Armed forces are major buyers of both equipment (arms/weapons) and military personnel, and such procurement choices affect defence industries and both local and national labour markets. For example, government procurement of weapons involves choices between competition and preferential purchasing and between various types of contracts (for example, fixed-price, cost-plus), each with different implications for contractor efficiency and profitability. There is a related literature on industrial and alliance policies comparing the economics of supporting a national defence industrial base with alternative industrial policies such as international collaboration, licensed production or importing foreign equipment. Imports also involve the international arms trade, its economic impacts on both buyers and suppliers, and policy initiatives to regulate such trade. More generally, there is an extensive literature on arms control and disarmament, the adjustment costs of disarmament, the economics of conversion and the contribution of public policy to minimizing such
adjustment costs. Finally, there have been some new developments involving the application of economics to the study of conflict, civil wars, revolutions and terrorism (Brauer, 2003; Hegre and Sandler, 2002; Sandler and Hartley, 1995; 2007).

Defence economics became established in the 1960s with the publication of a number of pioneering contributions, mostly by US economists. These contributions applied economics to some novel areas and included economic models of alliances (Olson and Zeckhauser, 1966), the economics of arms races (Richardson, 1960; Schelling, 1966), the procurement of weapons and military personnel (Peck and Scherer, 1962; Oi, 1967), and the impact of military spending on economic development (Benoit, 1973). A further development confirming the emergence of defence economics as an accepted part of the discipline of economics was the launch in 1990 of a field journal, Defence Economics, later renamed Defence and Peace Economics (initially it was published four times per year, but in 2000 it was expanded to six issues per year).

Inevitably, defence economics generates controversy reflected in myths and emotion. Critics point to the ‘wastes’ of defence spending and its ‘crowding-out’ of ‘valuable’ civil expenditure. Classic examples include the sacrifice of schools and hospitals associated with major weapons projects such as modern combat aircraft and aircraft carriers (for example, the US F-22 aircraft and the European Typhoon). Peace economists are similarly critical of defence economics and military spending: they focus on peace topics such as disarmament and the maintenance of peace, arms control and international security, conflict analysis and management, and crises and war studies. Defence economists are not, however, ‘warmongers’: they are instead interested in understanding the economics of the military–industrial–political complex and all aspects of defence whereby a proper understanding of these issues will contribute to a more peaceful world. A starting point in showing how economists analyse defence is to review the ‘stylized facts’ of world military spending.

The stylized facts of world military spending

What is known about military spending, and where are the gaps in the data? Good quality data exist on world military spending, the world's armed forces and the arms trade. Cross-section and time-series data are available at the country level; some examples are shown in Table 1. The data on world military expenditure show aggregate spending by the USA accounting for 45 per cent of total world military spending and NATO accounting for some 70 per cent. Similarly, in 2004 the USA dominated defence R&D spending, accounting for some 75 per cent of the world total and 31 per cent of world arms exports.

*Sources: US DoS (2002); NATO (2005); OECD (2004); SIPRI (2005).*  

Table 1 shows examples of defence shares of GDP to illustrate the burdens of defence spending, especially for developing nations such as Eritrea, India and Pakistan (an arms race situation) and for the Middle East (a conflict region). Burundi and Sudan have defence burdens similar to or greater than those of the UK and Germany. Table 1 also shows other measures of the economic burdens of defence for the world's poorer nations (that is, nations which cannot feed, house or educate their populations and which have poor health records). Developing nations accounted for 70 per cent of the world total of 21.3 million military personnel, and such totals further show the importance of military manpower economics. Similarly, developing nations are major importers of arms, while the developed nations are the major arms exporters. Such data provide an introduction to some of the major themes of defence economics, namely, the determinants of military expenditure, arms races, alliances, the relationship between defence spending and economic development, the arms trade and the economics of military personnel.  

Micro-level data are more limited but there are some useful sources especially on defence contractors and defence industries. Table 2 provides examples of such micro-level data based on the 100 largest arms-producing companies (SIPRI, 2005) and employment in national defence industries (BICC, 2005).  

Again, these data are available on a cross-section and time-series basis, and the company data include total sales, total profits and aggregate employment. From Table 2 it can be seen that the USA has six of the world's top ten arms companies and that the American firms have a substantial scale advantage over their European rivals: the average size of a US firm from the top ten is almost twice the corresponding average of the European companies. These data are the basis for research questions about the determinants of firm size, the impact of economies of scale, scope and learning, and the determinants of performance in terms of labour productivity and profitability.  

Defence companies and industries

Major defence industries  Employment numbers, 2003 (‘000s)
Industrialized countries  4,710
Developing countries  2,769
NATO  3,452
EU  645
USA  2,700
China  2,100
Russia  780
France  240
UK  200

World total  7,479

Sources: BICC (2005); SIPRI (2005).

Table 2 also shows data on defence industry employment. The industrialized nations accounted for 63 per cent of total employment in the world's defence industries, with the developing countries accounting for the remaining 37 per cent. The USA, China and Russia have the largest defence industries by employment, accounting for 75 per cent of the world total. Overall, the world military–industrial complex employed almost 29 million personnel in the armed forces and defence industries, reinforcing its role as a major employer of labour, including some highly qualified R&D staff and other highly skilled workers. Such scarce labour has alternative uses in the civilian sector, raising questions as to whether defence spending 'crowds out' valuable civil investment and diverts scientific manpower from civil research projects.

Despite the available data, there remain significant gaps in our knowledge of the world's military sector. Typically, new defence projects are surrounded by secrecy; there are problems in identifying some defence goods (for example, dual use goods, such as civil airliners which can be used as military transport aircraft); there is a lack of good-quality data on defence R&D, including employment in defence R&D; and little is known about China, especially its defence R&D programmes (Hartley,
International comparisons of military expenditure data are also sensitive to the choice of exchange rate adjustments, with country rankings sensitive to the use of market exchange rates or purchasing power parity rates (SIPRI, 2005). At the firm and industry levels, analysis of the military business in terms of defence output, employment and profitability is complicated because the typical output comprises a mix of military and civil components, making it difficult to compare the performance of defence contractors and civil firms. Further gaps exist in our knowledge of the world regional distribution of military bases and defence plants, so that it is difficult to assess the economic dependence of various regions on defence spending. Little is known about defence industry supply chains both within countries and within the global economy. Finally, there is a need for more reliable data on the international trade (including illegal transactions) in small arms (these are often the main weapons used in many regional conflicts, such as in Bosnia).

The defence economics problem

This is the standard choice problem of economics, but applied to defence. Typically, following the end of the cold war defence budgets have been either constant or falling in real terms; and these limited budgets are faced with rising input costs of both capital and labour. Equipment costs have been rising by some ten per cent per annum in real terms, which means a long-run reduction in the numbers of weapons acquired for the armed forces (for example, the US Air Force’s original requirement for F-22 combat aircraft for 750 units was later reduced to some 180 aircraft). Similarly, with an all-volunteer force, the costs of military personnel have to rise faster than wage increases in the civil sector. This wage differential is required to attract and retain military personnel by compensating them for the net disadvantages of military life. Here, the military employment contract is unique in that armed forces personnel are subject to military discipline; they are required to deploy to any part of the world at short notice; they could remain overseas indefinitely; and some might never return (that is, death and injury are a feature of this contract). This combination of constant or falling defence budgets and rising input costs means that governments and defence policymakers cannot avoid the need for difficult choices in a world of uncertainty (that is, where the future is unknown and unknowable, and no one can accurately predict the future).

Faced with this defence choice problem, governments have adopted various solutions. They can adopt a policy of ‘equal misery’ whereby each of the services is subject to budget cuts (for example, reduced training, cancelling some new equipment projects and delaying others); or they can undertake a major revision of a nation’s defence commitments (for example, a defence review such as the UK’s 1998 Strategic Defence Review); or they can seek to improve efficiency in the armed forces and defence industries (for example, via a competitive equipment procurement policy and military outsourcing). Other policy options include joining a military alliance (such as NATO; EU) or avoiding the defence choice problem by increasing the defence budget (as in the USA since 11 September 2001); but then choices are needed between defence and social welfare spending.

Economics offers three broad policy principles for formulating an efficient defence policy, namely, final outputs, substitution and competition. Take first the principle of final outputs. Measuring defence output is notoriously difficult, but it can be expressed in such general terms as peace, security and threat reduction. The UK has solved the problem by committing (and funding) its armed forces to having the capacity to fight simultaneously three small to medium conflicts (for example, Bosnia, Kosovo, Sierra
Leone) or one large-scale conflict as part of an international coalition (for example, the Gulf War, Iraq).
This approach is a departure from the traditional focus on measuring inputs in terms of the numbers of
infantry regiments, warships, tanks and combat aircraft. Such a focus fails to address the key issue of the
contribution of these inputs to final defence output in the form of peace and protection. A focus on
inputs also fails to address the marginal contribution of each of the armed forces: what would be the
implications for defence output if, say, the air force were expanded by five to ten per cent, or the navy
was reduced by five to ten per cent?

The second economic principle is that of substitution. There are alternative methods of achieving
protection, each with different cost implications. Possible examples of partial substitutes include
reserves replacing regular personnel, civilians replacing regulars (for example, police in Northern
Ireland replacing army personnel), attack helicopters replacing tanks, ballistic and cruise missiles and
unmanned combat air vehicles replacing manned strike and bomber aircraft, air power replacing land
forces, and imported equipment replacing nationally produced equipment. Some of these substitutions
might alter the traditional monopoly property rights of each of the armed forces. For example, surface-to-
air missiles operated by the army might replace manned fighter aircraft operated by the air force, and
maritime anti-submarine aircraft operated by the air force might replace frigates supplied by the navy.

The third economic principle is that of competition as a means of achieving efficiency. Standard
economic theory predicts that, compared with monopoly, competition results in lower prices, higher
efficiency, and competitively determined profits and innovation in both products and industrial structure.

For equipment procurement, competition means allowing foreign firms to bid for national defence
contracts and awarding fixed-price contracts rather than cost-plus contracts; it also means ending any
‘cosy’ relationship between the defence ministry and its national champions and any preferential
purchasing and guaranteed home markets.

Competition can be extended to activities undertaken by the armed forces. Here, there is a public sector
monopoly problem whereby the armed forces have traditionally undertaken a range of activities ‘in
house’ without being subject to any rivalry. Military outsourcing allows private contractors to bid for
and undertake such activities. Examples include accommodation, catering, maintenance, repair, training,
transport and management tasks (for example, managing stores or depots and firing ranges). In some
cases, outsourcing involves private finance initiatives whereby the private sector finances the activity
(for example, new buildings or an aircrew simulator training facility) and then enters into a long-term
contract with the defence ministry to provide services to the armed forces in return for rental payments.

Another variant is a public–private partnership whereby the private sector finances an activity or asset in
return for rental payments from the defence ministry, but the contractor is allowed to sell any peacetime
spare capacity to other users (for example, tanker aircraft capacity which when not needed in peacetime
can be rented to other users).

Application of the policy guidelines to an efficient defence policy requires that individuals and groups in
the military–industrial–political complex are provided with sufficient incentives to behave efficiently.
There are the inevitable principal–agent problems where agents have considerable opportunities to
pursue their own interests which may conflict with those of their principals (for example, leading a quiet
life rather than bearing the costs of change). Individuals and groups in the armed forces and defence
ministries will be reluctant to apply the substitution principle if there are no personal or group incentives
and rewards for achieving efficient substitution (that is, interest groups can be barriers to change).

Compare the private sector, where there are market and institutional arrangements promoting efficiency
in the form of rivalry between suppliers, the profit motive and the capital market as a ‘policing and monitoring’ mechanism through the threats of takeover and bankruptcy. Such market arrangements are absent in the armed forces (and elsewhere in the public sector).

There is also the challenge of achieving ‘top level’ efficiency in defence provision. Economic theory solves this challenge as a standard optimization problem involving the maximization of a social welfare function subject to resource or budget constraints (where welfare is dependent on civil goods and security, with security provided by defence). Operationalizing this apparently simple optimization rule is much more difficult. Individual preferences for defence are subject to its public good characteristics and free riding problems and the continued difficulty of defining defence output. In democracies, society's preferences are usually expressed through voting at elections. However, elections are limited as a means of obtaining an accurate indication of society's preferences for defence and its willingness to pay. Elections occur infrequently; they are usually for a range of policies of which defence is only one element in the package (which includes policies on, for example, education, health, transport, the environment, foreign policy and taxation); and the ‘voting paradox’ shows the difficulty of deriving a society's preferences using the voting system. Nor do voters have reliable information on the output of defence spending.

Defence economics explains military spending using a demand model of the form:

\[
ME = M (P, Y, T, A, Pol, S, Z)
\]

where \(ME\)=real military spending; \(P\)=relative prices of military and civil goods and services; \(Y\)=real national income; \(T\)=threats in the form of the military expenditure of a rival nation (arms race models); \(A\)=membership of a military alliance and the real military expenditure of the allies (such as NATO); \(Pol\)=variable for the political composition of the government (for example, left- or right-wing, with the latter favouring ‘strong defences’); \(S\)=a variable representing the security and strategic environment (such as the end of the cold war; conflicts such as Korea, Vietnam, the Gulf War and Iraq); and \(Z\)=other relevant influences (for example, land mass to be protected). Estimation of the demand model usually proceeds without a price variable, mainly because most nations do not provide relative price data. This omission can be justified if the price of military goods and services has inflated at the same rate as civil goods and services; but such an assumption is not always realistic. A survey of empirical results is presented in Sandler and Hartley (1995; 2007).

Conflict and terrorism

The demand model for military expenditure recognized the relevance of threats such as terrorism and conflict as determinants of defence spending. Traditionally, conflict and terrorism have been the preserve of disciplines other than economics. For example, debates and decisions about war involve political, military, moral and legal judgements. But conflict has an economic dimension, namely, its costs. Wars are not costless: they can involve massive costs (for example, the Second World War). Economics has also made further contributions in analysing the causes of conflict and in identifying
potential targets during conflict (for example, the Second World War selection of aircraft factories, dams, submarine yards and oil fields as targets for Allied bombing raids on Germany). Economic models start by analysing conflict as the use of military force to achieve a reallocation of resources within and between nations (that is, civil wars and international conflict). Nations invade to capture or steal another nation's property rights over its resources (such as land, minerals, oil, population, water). Conflict has a distinctive feature: it destroys goods and factors of production, and it is easier to destroy than to create. In peacetime, civilian economies aim to create more goods and services through growth and expanding a nation's production possibility frontier. Conflict uses military force and destructive power to enable a nation to acquire resources from another state, so expanding its production boundary through military force (Vahabi, 2004).

Conflict and terrorism provide opportunities for applying game theory. They involve strategic behaviour, interactions and interdependence between adversaries ranging from small groups of terrorists, rebels and guerrillas to nation states. Strategic interaction means that conflict can be analysed as games of bluff, chicken and ‘tit-for-tat’ with first-mover advantage and possibilities of one-shot or repeated games. For example, first-mover advantage might indicate a pre-emptive strike (for example, Pearl Harbour in 1941; Kuwait in 1990). However, there are other, non-economic explanations of conflict. These include religion, ethnicity and grievance (for example, Germany after the First World War; the desire for a nation state (such as Palestine); the absence of democracy; and mistakes and misjudgement. The costs of war are a relatively neglected dimension of conflict. War involves both one-off and continuing costs. One-off costs are those of the actual conflict, while continuing costs are any post-conflict costs including those of occupation and peacekeeping. A further distinction is necessary between military and civilian costs. In principle, the military costs of conflict are the marginal resource costs arising from the conflict (that is, those costs which would not otherwise have been incurred). Examples include the costs of preparation and deployment prior to a conflict; the costs of the conflict, including the costs of basing forces overseas and the use of ammunition, missiles and equipment, including human capital and equipment losses in combat; the post-conflict occupation and peacekeeping missions and the costs of returning armed forces to their home nation.

There are further costs of conflict in the form of impacts on the civilian economies of the nations involved in the war. For example, the US and UK involvement in the Iraq war that began in 2003 had possible short- and long-term impacts for both economies. There were possible impacts on oil prices, share prices, the airline business, tourism, defence industries, private contractors, aggregate demand and future public spending plans. Further substantial costs were imposed on the Iraq economy in the form of deaths and injuries of military and civilian personnel, together with the damage and destruction of physical assets. Table 3 shows some examples of the costs of various conflicts for the UK and USA. The general point remains that wars are costly and require scarce resources which have alternative uses (that is, wars involve the sacrifice of hospitals, schools and social welfare programmes). Questions also arise as to whether the benefits of conflict exceed its costs.

### Costs of conflict

<td>357</td>
</tr>
<tr>
<td>World War II</td>
<td>1,175</td>
</tr>
</tbody>
</table>
Defence economists have also contributed to the analysis of terrorism using both choice-theoretic and game-theoretic models. Terrorism shows that non-conventional conflict is also costly. The attacks of 11 September 2001 on the USA resulted in almost 3,000 deaths and economic losses of $80 billion–90 billion (Barros, Kollisa and Sandler, 2005). Other terrorist-related costs include nations spending on homeland security measures, on terrorist-related intelligence, on security measures in airports, the lost time waiting at airports to clear security, the losses of liberty and freedoms and the war on terror (for example, in Afghanistan and Iraq).

Choice-theoretic models of terrorism apply standard consumer choice theory with terrorists maximizing a utility function subject to budget constraints. The utility function can be specific, such as a choice between attack modes, say, skyjackings and bombings, or more generally involve a choice between terrorist and peaceful activities. The approach offers some valuable insights into terrorist behaviour and possible policy solutions. The model shows that terrorist behaviour and activities can be influenced by governments acting to reduce terrorist funds (that is, an income effect), by changing relative prices (that is, promoting a substitution effect), and by efforts to change terrorist preferences towards more peaceful activities (for example, Northern Ireland). The substitution effect is an especially powerful insight showing that policies which increase the relative price of one attack mode, such as skyjackings, will encourage terrorists to substitute an alternative and lower-cost method of attack (for example, assassinations, bombings, or kidnappings: Frey and Luechinger, 2003; Anderton and Carter, 2005).
Conclusion

Defence economics is now established as a reputable sub-discipline of economics. It shows how economic theory and methods can be applied to the defence sector embracing the armed forces, defence industries and the political–institutional arrangements for making defence choices. But this is only the beginning. Massive opportunities remain for further research in the field. Changes in threats, new technology and continued budget constraints will require further adjustments in the armed forces and defence industries, and will generate a new set of research problems. Examples include space warfare, the economics of nuclear weapons policy, assessing the efficiency of armed forces, improving the efficiency of military alliances and developing more efficient approaches to international governance and international collective action.

de-industrialization, ‘premature’ de-industrialization and the Dutch Disease

José Gabriel Palma
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

OECD countries began de-industrializing in the late 1960s, while some high-income developing countries in East Asia entered this phase in the 1980s. Soon afterwards, some middle-income Latin American countries and South Africa also began to de-industrialize (‘prematurely’) after radical economic reforms, despite their level of income per capita being far lower than other countries which began to de-industrialize earlier. Since manufacturing is considered by many as the most effective engine of growth, it has been argued that de-industrialization could have significant negative long-term effects on growth, investment and employment, especially when done ‘prematurely’ or due to ‘Dutch disease’.

Article

One of the most notable stylized facts of the world economy since the late 1960s is the rapid decline in manufacturing employment in industrialized countries (a fall of about 25 million jobs). Although the structure of employment has changed substantially over the long-term course of economic development, changes of the scale and speed during this period constitute an unprecedented phenomenon – manufacturing employment in the European Union, for example, has fallen by more than a third. Manufacturing is an activity considered by many as the most effective engine of growth – either because it is a crucial driver of outward shifts of the production frontier, or due to its capacity to set in motion processes of cumulative causation based on increasing returns (for example, in Post Keynesian, structuralist and Schumpeterian thought). It has therefore been argued that a process of de-industrialization on this scale is likely to have significant negative long-term effects on growth (on both its rate and its sustainability), investment, and employment. This concern has been particularly pronounced in countries that experienced drastic de-industrialization following the discovery of mineral resources – a phenomenon that became known as the ‘Dutch Disease’. The key issue is the double-edged effect of a mineral discovery. On the one hand, it allows for an expansion of expenditure and employment; but on the other, it could easily lead to a contraction of the non-commodity tradable sector. This phenomenon was first analysed in the 1950s in relation to the mixed effects of sudden increases in mineral exports or in the price of wool for the Australian economy.

OECD countries began de-industrializing in the late 1960s, while some high-income developing countries in East Asia entered this phase in the late 1980s. Soon afterwards, some middle-income Latin American countries and South Africa also began to de-industrialize after radical economic reforms, despite their level of income per capita being far lower than other countries which began to de-industrialize earlier. This latter process has been labelled ‘premature’ de-industrialization (Palma, 2005), and should not be confused with the so-called ‘resource curse’ hypothesis, which refers to the poor macroeconomic performance of many mineral-exporting economies. The following tables (Tables 1 and 2) show the above-mentioned regional trends in the share of manufacturing in total employment and the share of manufacturing value added in GDP.

### The Four Sources of De-Industrialization

The first source of de-industrialization: an ‘inverted-U’ relationship between manufacturing employment and income per capita.

The most commonly used concept of de-industrialization emerges from an understanding of the relationship between manufacturing employment and income per capita as an ‘inverted-U’. De-industrialization is simply the drop in manufacturing employment occurring when countries reach a certain level of income per capita – that is, mature economies switching employment to specialized services as part of their ‘normal’ process of development. As such, de-industrialization could well have positive long-term growth effects. According to Rowthorn (1994), using data for 1990, this drop begins at US$12,000 (Figure 1).
Figure 1

Manufacturing employment (% of total)

Log of income per capita (1991 international $)

6.5  7  7.5  8  8.4  8.9  9.4  9.9  10.3
Although many other analyses are consistent with this hypothesis, Palma (2005) has suggested that de-industrialization has been a more complex phenomenon. He argues that, in addition to the ‘inverted-U’, there are three further processes at work.

One additional source of de-industrialization has been the remarkable collapse of the ‘inverted-U’ relationship over time. In essence, for high- and middle-income countries, the level of manufacturing employment associated with a given level of income per capita has been falling over time. In fact, the four better-known hypotheses originally developed to explain the ‘inverted-U’ relationship mentioned above are more relevant to this ‘second source’ of de-industrialization, as until the mid-1980s no country had reached the level of income corresponding to the turning point of the respective curve. These hypotheses are as follows:

- The fall in manufacturing employment is merely a statistical illusion caused primarily by the re-allocation of labour from manufacturing to services through contracting-out of activities such as transport, cleaning, design, security, catering, recruitment and data processing. This process could be the result of a further movement in a long line of progressive transformations aiming at enlarging the scope for specialization and the division of labour, or just a cost-cutting operation aimed, for example, at bypassing labour legislation.
- The fall in manufacturing employment results from a reduction in the income elasticity of demand for manufactures, particularly in high income countries.
- It is the consequence of higher productivity growth in manufacturing than in other sectors of the economy.
- It is the result of a new international division of labour (including ‘outsourcing’), which has a negative impact on manufacturing employment in industrialized countries, especially for non-skilled labour.

Although a detailed analysis of the role of each of these factors in de-industrialization is outside the scope of this article (see Rowthorn and Ramaswamy, 1999), it is important at least to add that the 1980s switch in ‘policy regime’ in OECD countries (broadly speaking, from post-war Keynesianism to demand-constraining monetarism) did also contribute to the huge 1980s drop in manufacturing employment. (For the 1980s debate on de-industrialization, see Singh, 1987.) The technological revolution that took off in the 1980s also played a major role (Pérez, 2002).

The third source of de-industrialization: changing income per capita corresponding to the turning point of the regression

This additional source of de-industrialization is also evident in Figure 2 (see also Figure 3). This concerns the remarkable leftwards movement in the turning point of the regressions during the 1980s. (Rowthorn and Wells, 1987, had discussed the possibility of the ‘inverted-U’ relationship peaking at a lower level of income per capita over time.) During the 1980s the income per capita at which the curve peaked fell by about half – from approximately $21,000 in 1980 to just over $10,000 in 1990 (in 1985 international US$). Until 1980 no country was located to the right of the turning point of the corresponding cross-section curve, but in the 1990 regression there were more than 30 countries beyond that critical point. However, during the 1990s this process was reversed, and by 2000 again no country was beyond that critical point.

Figure 2
Second source of de-industrialization: a declining relationship, 1960–2000. Notes: The range of the horizontal axis is the actual income range of the sample for 2000. The regressions are based on a sample of 105 countries. In all regressions in this and the following figures, all parameters are significant at the 1% level, and the adjusted $R^2$ are between 66% and 77%. All regressions pass the relevant diagnostic tests. Note that these regressions are simply a cross-sectional description of cross-country differences in manufacturing employment, when categorized by income per capita; hence they should not be interpreted in a ‘predicting’ way, because there are a number of difficulties with a curve estimated from a single cross-section – especially regarding the homogeneity restrictions that are required to hold. Source: Palma (2005), using ILO Databank and the Penn World Tables; this is the source for all figures other than Figure 8.
Figure 3
The changing nature of de-industrialization between the 1980s and the 1990s. Note: The range of the horizontal axis is the actual income range of the sample for 2000.
The changing shape of the curves is crucial to the understanding of the dynamic of the interrelationship between the three sources of de-industrialization discussed so far. Basically, as the arrows of Figure 3 indicate, during the 1980s there was a remarkable degree of de-industrialization in high-income countries; during the 1990s, by contrast, de-industrialization...
The fourth source of de-industrialization: the Dutch Disease

Finally, in several countries we can observe a further degree of de-industrialization. These countries experienced a fall in their manufacturing employment that was clearly greater than would have been expected, given the three sources of de-industrialization discussed above (Figure 4).

Figure 4
Fourth source of de-industrialization: cases of ‘overshooting’? Notes: Neth: The Netherlands; Bra: Brazil.
Rather than simple cases of ‘overshooting’, Palma (2005) identifies this phenomenon with a specific conceptualization of the Dutch Disease: in countries that have an export surge of commodities or services, or a major shift in economic policy, a unique additional degree of de-industrialization is typical (that is, additional to the three de-industrialization forces already discussed).

Originally, Dutch Disease had a narrow meaning – the appreciation of the real exchange rate resulting from a boom in commodity exports. (For an analysis of the macro-processes at work, see Corden and Neary, 1982; Ros, 2000.) Elsewhere, mostly in neoclassical models, it simply referred to the adverse terms of trade effect for tradables following a sudden shift in their production frontier. However, with time the meaning has widened to include all possible negative macroeconomic effects associated with the ‘resource curse’ hypothesis—for Woolcock, Pritchett and Isham (2001), for example, resource-rich countries are not very good at accumulating social capital. (See also Mehlum, Moene and Torvik, 2006; for a critical analysis of the ‘resource curse’ hypothesis, see DiJohn, 2007.)

The origins of this ‘disease’ lie in the fact that the relationship between manufacturing employment and per capita income tends to differ between those countries that generate a trade surplus in manufacturing and those that do not. Note that the ‘trade surplus in manufacturing’ group includes economies that find themselves in this position out of necessity as well as others due to growth policy. In the first case, given resource endowments force some countries to aim for a manufacturing surplus to finance inevitable trade deficits in commodities and/or services (for example, Japan and India). In the second, some resource-rich countries still try to achieve a trade surplus in manufacturing by implementing a growth policy based on a strong ‘industrialization agenda’ (for example, Finland, Malaysia and Vietnam).

Figure 5 shows the long-term changes between manufacturing employment and income per capita in the ‘trade surplus in manufacturing’ (mf) and in the ‘trade surplus in primary commodities or services’ (pc) groups of countries.

**Figure 5**
Changes in manufacturing employment and income per capita, 1960–2000. **Note:** An intercept dummy differentiates the two groups of countries.
Although the ‘pc’ countries tend to reach a lower level of industrialization at any given point in time, the ‘pc effect’ per se has not led to a higher degree of de-industrialization.
fact, if we take the highest point of the curves, in these four decades the share of manufacturing employment in both ‘mf’ and ‘pc’ countries dropped by about half.

After this introduction, it is now possible to explain the concept of Dutch Disease. There is a group of countries – both industrialized and developing – that exhibit a specific additional degree of de-industrialization. The Netherlands rightly gives its name to this phenomenon.

From this perspective, what happened in the Netherlands was a discovery of a natural resource (gas) leading manufacturing employment to switch from an ‘mf’ structure to a ‘pc’ one. When this occurs, as Figure 6A shows, the country experiencing this ‘disease’ moves along two different paths of de-industrialization. The first path consists of the three processes of de-industrialization discussed above (from ‘60-mf’ to ‘00-mf’). The second corresponds to a further component of de-industrialization resulting from the change in the reference group (from ‘00-mf’ to ‘00-pc’). In this context, the Dutch Disease should be regarded only as the additional level of de-industrialization associated with the latter movement. In the case of the Netherlands, then, it is the (five percentage points) difference between manufacturing employment falling by 10.9 percentage points between 1960 and 2000 (hypothetical non-Dutch Disease scenario), or by 15.9 percentage points (actual Dutch-Disease situation) – that is, manufacturing employment falling from 30.5 per cent of total employment in 1960, to 19.6 per cent in 2000 in the former scenario, or to 14.6 per cent in the latter one.

Figure 6

Dutch Disease is thus clearly not a phenomenon limited to the Netherlands or to the discovery of mineral resources; it has also occurred in other countries and for other reasons. One case is the United Kingdom, which had a boom in both oil and financial-services exports (see Figure 6B). As a result of this (and of Prime Minister Thatcher) the trade balance in manufacturing switched from a surplus of four per cent of GDP (late 1970s) to a deficit of four per cent (mid-2000s). Figure 6C shows that, by contrast, the share of manufacturing employment in other EU countries fell only according to the changes in the ‘mf’ scenario. In turn, Figure 6D shows that, although four other industrialized countries (major commodity exporters throughout the period) also found themselves in the ‘pc’ category in 2000, they did not suffer from the Dutch Disease simply because they were in the ‘pc’ category from the start. Although both the ‘EU-5’ and the ‘UCAN’ countries experienced a similar drop in the share of manufacturing employment (9.7 and 10.5 percentage points, respectively), neither switched from one reference group to another.

The phenomenon of the Dutch Disease also occurred in countries that developed flourishing service-exporting sectors, such as tourism (for example, Greece, Cyprus and Malta) and financial services (for example, Switzerland, Luxembourg and Hong Kong); see Palma (2005).

Finally, this ‘disease’ was also experienced after 1980s in some middle-income Latin American countries (and to some extent in South Africa) where state-led import-substituting industrialization (ISI) had achieved industrialization levels characteristic of the ‘mf’ group (despite the fact that these countries generated large trade surpluses in commodities). In these cases, radical change of the economic policy regime (from ISI to comprehensive trade and financial liberalization) resulted in the Dutch Disease; that is, the transformation of their employment structure from a policy-induced ‘mf’ to a more ‘Ricardian’ resource-rich ‘pc’.

Brazil and the three Southern Cone countries experienced the greatest de-industrialization following their economic reforms, while also being among the countries of the region that had previously industrialized the most and that had subsequently implemented the most drastic reforms (Figure 7).

Figure 7
Argentina, Brazil, Chile and Uruguay: catching the Dutch Disease, 1960–2000. Notes: Ar: Argentina; Br: Brazil; Cl: Chile; Ur: Uruguay; Ne: The Netherlands. The year 1990 has been omitted not to ‘congest’ the figure. South Africa’s share of manufacturing employment also fell from an ‘mf’ level in 1980 to close to a ‘pc’ one in 2000.
These four Latin American countries began this period – as did the Netherlands – with a level of manufacturing employment typical of countries aiming at a trade surplus in...
manufacturing (‘60-mf’), even though these resulted from different causes. The case of the Netherlands is due to its (pre-natural gas) poor resource endowment, whereas in the four Latin American countries their position was the result of a ‘structuralist’ industrialization agenda (see structuralism). And if both reached 2000 with levels of manufacturing employment typical of the ‘pc’ group, this was once again for different reasons: in the Netherlands, the discovery of a natural resource at a ‘mature’ stage of industrialization was decisive, whereas in Latin America the sharp reversal of the ISI policies was responsible. Note that in the latter the ‘extra’ degree of de-industrialization (‘mf’ to ‘pc’) took place over and above the already mentioned huge collapse of the ‘mf’ path for middle-income countries during the 1990s (Figure 3).

From this perspective, the key difference between developing Asia and ‘premature de-industrializers’ in Latin America in terms of the implementation of economic reforms is that in the latter these reforms seem to have obstructed their transition towards a more mature – that is, self-sustaining – form of industrialization. (For the concept of ‘self-sustaining industrialization’, see Kaldor, 1967.) Resource-poor and resource-rich developing Asia, instead, succeeded in combining these reforms with a dynamic ‘mf’ path (Figure 8).

Figure 8
Perhaps Latin America is in desperate need of a touch of the so-called East Asian Confucianism; that is, once a new development path has been chosen, a significant degree of pragmatism, self-confidence, a progressive capitalist elite and an avant-garde political leadership can be of great assistance in policymaking success.

In sum, the Dutch Disease should not be seen as simple ‘overshooting’ of de-industrialization, but as a specific type of ‘additional’ de-industrialization. In general, this has taken place for one of three different reasons: the discovery of natural resources (for example, the Netherlands); the development of export-service activities, mainly tourism and finance (for example, Greece in the former, and Hong Kong in the latter); and finally, changes in economic policy (for example, Brazil and South Africa).

All the above types of de-industrialization should also be distinguished from those of the late 1980s and 1990s in many sub-Saharan economies and countries of the former Soviet Union and eastern Europe, which experienced a process of de-industrialization associated with a fall in income per capita: a case of de-industrialization ‘in reverse’.

Finally, Finland, Sweden, Denmark, Malaysia, Vietnam and, to a lesser extent, other south-east Asian resource-rich countries (such as Thailand and Indonesia) prove both that economic policies do exist to avoid the Dutch Disease in commodities- and export-services-booming economies (see Pesaran, 1984; Palma, 2000), and that there is no such thing as an unavoidable ‘curse of natural resources’. Countries with high potential for developing commodities and export-services activities have sufficient degrees of policy freedom to follow ambitious and successful ‘industrialization agendas’ (not least of the commodities themselves, as in the Nordic case and Malaysia). Also, export rents could be used effectively in that direction. However, as the Latin American experience in particular shows, it seems that, as globalization progresses, fewer and fewer countries are willing to take advantage of such degrees of policy freedom. This is not only because forces in the new international institutional and financial order are rapidly working to reduce these degrees of policy freedom, but also because of domestic changes in economic ideologies and the structure of property rights.

However, whether a process of structural change that includes ‘premature’ de-industrialization can deliver rapid and sustainable economic growth is another matter altogether; so is the issue of whether the current ‘premature’ de-industrialization occurring in Latin America and South Africa contains important components of policy-induced ‘uncreative destruction’.

De-industrialization: does it matter?

Rapid de-industrialization has reopened an age-old debate in economic theory: is a unit of value added in manufacturing equal to one in commodities or services, especially in terms of its growth-enhancing properties?

Although a detailed discussion of this debate is beyond the scope of this article, from the perspective of de-industrialization we may classify growth theories into three groups (in doing this, of course, we have to acknowledge the necessary degree of simplification which every classification of intellectual tendencies entails). This requires a distinction between two concepts: ‘activity’ and ‘sector’. Examples of the former include R&D and education, and of the latter manufacturing. The first camp of growth theories includes those (mainly neoclassical models) that treat growth as both ‘sector-indifferent’ and ‘activity-indifferent’. Examples are Solow-Swan-type models (both traditional and ‘augmented’ ones), and the branch of ‘endogenous’ theories that associates growth with increasing returns which are activity-indifferent. Examples are early ‘AK’ models and more recent ones in which changes in the rate of growth are the result of the cumulative effect of market imperfections arising in the process of technical change. However, these imperfections, and the associated increasing returns, are somehow seen as stemming directly from within the production function (rather than being based on the use of R&D or the production of human capital).

The second camp still regards growth as ‘sector-indifferent’, but models it as ‘activity-specific’ (for example, Romer’s work and neo-Schumpeterian models). In these models, increasing returns, though generated by research-intensive activities, are explicitly not associated with manufacturing activities as such or with investment in manufacturing: nor do they allow for specific effects from manufacturing on R&D activities (except that investment in any sector could be ‘complementary’ to R&D through its effect on the profitability of research; see Aghion and Howitt, 1998). Therefore, in these models there is no room for Kaldorian-style effects concerning investment embedding or embodying technical change.

Finally, in the third camp are those (mainly Post Keynesian, Schumpeterian and structuralist theories) that argue that growth is both ‘sector-specific’ and ‘activity-specific’ (but the latter only in the sense that it is specific to the nature of the sector involved). For instance, the approaches to growth found in Hirschman, Kaldor, Kalecki, Prebisch, Furtado, Thirlwall and (arguably) Schumpeter follow this line of argument. What is common to these ‘sector-specific’ growth theories is that the pattern, the dynamic and the sustainability of growth are crucially dependent on the activities being developed. In particular, there are specific growth enhancing effects associated with manufacturing due to its capacity to set in motion processes of cumulative causation. This is because ‘learning by doing’, dynamic economies of scale, increasing returns, externalities and spillover effects are more prevalent
in manufacturing than elsewhere in the economy. Therefore, the crucial feature distinguishing this camp from the previous two is that issues such as technological change, synergies, balance-of-payments sustainability and the capacity of developing countries to ‘catch up’, are directly linked to the size, strength and depth of the manufacturing sector. Then, in terms of the possible growth consequences of de-industrialization, the first growth camp does not regard de-industrialization as a particularly relevant growth issue per se. Even when it becomes a major growth or employment issue, this is only due to market imperfections. For example, Sachs and Warner (1997) argue that if neoclassical competitive conditions prevail, a declining manufacturing sector implies no hindrance to growth or full employment. Furthermore, for these growth theories, even if the discovery of natural gas did produce some structural changes in output and employment in the Dutch economy, labelling these transformations a ‘disease’ would be a misleading dramatization. Also, from this perspective, if ‘premature’ de-industrialization in resource-rich countries consists of the transformation of employment structures from an artificially policy-induced ‘mf’ to a more Ricardian ‘pc’ path, that can hardly be bad for growth!

From the point of view of the second camp, de-industrialization in ‘mature’ economies may or may not have an impact on growth per se; this would all depend on the specific form that the de-industrialization takes. For instance, it could actually result in a stimulus for growth if the ‘upward’ de-industrialization in mature economies is associated with the reallocation of resources within manufacturing into more R&D-intensive products. However, in the case of ‘premature’ de-industrialization in middle-income countries it is more difficult to argue from this approach that such a phenomenon could be positive for long-term growth. Finally, except for normal (or ‘upward’) de-industrialization in properly mature economies, the third approach to economic growth understands de-industrialization and the Dutch Disease as unequivocally negative for growth and employment – especially if it involves ‘premature’ de-industrialization in developing countries. The same is true of the current narrowing-down of the policy space to fight them. For example, an interpretation from this perspective of the industrialized countries’ remarkable slowdown in productivity growth since the mid-1970s could be that this may well be the result of ‘wrong’ policies (such as monetarism) and ‘wrong’ structural change (such as ‘financialization’) excessively intensifying de-industrialization in the 1980s. (‘Financialization’ is the rise in size and dominance of the financial sector relative to the non-financial sector, as well as the diversification towards financial activities in non-financial corporations.) And one interpretation of the remarkably poor growth performance of most Latin American economies and South Africa since economic reform, especially Brazil, would be that this is the likely consequence of ‘premature’ de-industrialization – affecting not just the pace of their economic growth but its sustainability.

Demand price

J.K. Whitaker

Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Earlier economic literature doubtless contains casual usages of the phrase ‘demand price’, but its appropriation as a technical term appears to date from Alfred Marshall's *Principles of Economics* (Marshall, 1890: see Marshall, 1920, pp. 95–101). Marshall applied the term in the contexts of both individual and market demand. Starting with a commodity (tea) purchasable in integral units of a pound's weight, an individual's demand price for the \( x \)th pound is the price he is just willing to pay for it given that he has already acquired \( x - 1 \) pounds. The basic assumption is that this demand price is lower the larger is \( x \). A schedule of demand prices for all possible quantities (values of \( x \)) defines the consumer's demand schedule. Its graph is naturally drawn with quantity on the horizontal axis. In the case of a perfectly divisible commodity, the demand price of quantity \( x \) must be redefined as the price per unit which the consumer would be willing to pay for a tiny increment, given that he already possesses amount \( x \). The demand schedule then graphs as a continuous negatively sloped demand curve showing demand price in this sense as a function of \( x \).

If the individual is free to buy any quantity at a fixed price, his ‘marginal demand price’ is the demand price for that quantity ‘which lies at the margin or terminus or end of his purchases’ (Marshall, 1920, p. 95). For a perfectly divisible commodity, marginal demand price must equal market price. For a commodity purchasable in integral units only, market price may lie anywhere below marginal demand price, but not so low as to make the next unit marginal.

Marshall's discussion of consumer behaviour is based on two general assumptions, although these are informally relaxed at various points. The first is that the utility obtained from consuming a commodity depends only on the amount of that commodity. The second is that the marginal utility of ‘money’, or expenditure on all other goods, remains approximately constant with respect to variation in the expenditure on any particular commodity – the presumption being that the latter expenditure is only a small fraction of total expenditure. These assumptions have convenient consequences for the concept of demand price. If \( u(x) \) denotes the utility a consumer obtains from consuming quantity \( x \) of a given good in a specified period, while \( \lambda \) is the constant marginal utility of money to him, then demand price for quantity \( x \) is \( (du/dx)/\lambda \) in the case of divisible quantity and \( [u(x) - u(x - 1)]/\lambda \) in the case when only integral quantities are feasible. In either case, given the value of \( \lambda \), demand price depends on \( x \) alone.
and is proportional to marginal utility. The hypothesis of diminishing demand price is tantamount to that of diminishing marginal utility. A further advantage is that the demand price for quantity $x$ is independent of the pecuniary terms on which the earlier units were, or are to be, acquired, as these terms will not change the marginal utility of money.

Although demand price is, on the above assumptions, proportional to marginal utility it has the great advantage of being measured in operational money units. This permits a monetary measure of the net benefit or consumer surplus obtained from the option of buying the commodity in question on specified monetary terms, rather than having to divert the expenditure to other goods. The distinction between demand price and market price is an operational version of the classical distinction between value in use and value in exchange.

The concept of demand price features prominently in Marshall's analysis of the market for a single commodity sold at a fixed price which is uniform to all buyers. Demand price is now interpreted as the maximum uniform price at which any specified aggregate quantity of the commodity can be sold on the market during a given period. The negatively sloped market demand curve is simply a lateral addition of the individual demand curves and expresses the common demand price as a function of the aggregated quantity. Marshall recognized (1920, p. 457n) that it would be more natural when dealing with market demand to view quantity as a function of price, as Cournot (1838, pp. 44–55) had done, but chose the converse approach to maintain symmetry with his treatment of supply. Believing in the importance of scale economies in production, he deemed it generally impossible to treat quantity supplied per unit of time as a single-valued function of market price. Instead, adopting what he took to be the businessman's perspective, he introduced the concept of ‘supply price’; the minimum uniform price at which any given quantity will be supplied to the market.

Market equilibrium occurs at any quantity whose demand price and supply price are equal, so that the market demand curve intersects the market supply curve – the latter the graph of supply price as a function of aggregate quantity supplied, a lateral sum of individual supply curves. Equilibrium is locally stable if the demand curve cuts the supply curve from above at the equilibrium quantity. This result is justified by the argument that the rate of supply will increase if the current market price (always determined by demand price) exceeds supply price at the current quantity, so that additional production offers excess profit, decreasing in the opposite case (Marshall, 1920, pp. 345–7). The resulting dynamic process is usually referred to as the Marshallian adjustment process.

It is probably due to Marshall's influence that English-speaking economists still graph demand and supply curves with quantity on the horizontal axis even though adopting a more Walrasian perspective which treats quantities demanded and supplied as functions of market price.

Marshall's conception of the demand price of a lone commodity, segregated from other commodities by an assumed constancy of the marginal utility of money, does not feature prominently in modern theoretical work. Instead, a multi-commodity formulation of utility and demand is typically adopted. Consider a consumer maximizing the utility function $u(x_1, x_2, \ldots, x_n)$ subject to the budget constraint $\sum p_i x_i = M$. (Here the $x_i$ are quantities and the $p_i$ prices of the $n$ commodities and $M$ is a preset total expenditure level. The utility function, $u$, is assumed strictly increasing, strictly quasi-concave, and differentiable.) This maximization implies the consumer's direct demand functions $x_i = d_i(p_1/M, p_2/M, \ldots, p_n/M), i=1, 2, \ldots, n$, sometimes (but with dubious justification) referred to as Marshallian demand functions to distinguish them from Hicksian compensated or constant-utility demand functions. These
demand functions can usually be inverted to yield the indirect or inverse demand functions $p_i/M = g_i(x_1, x_2, \ldots, x_n)$, $i = 1, 2, \ldots, n$. However, these can be obtained more immediately from the budget constraint and the first-order conditions $\partial u / \partial x_i = \lambda p_i$, $i = 1, 2, \ldots, n$ (where $\lambda$ is the Lagrange multiplier associated with the budget constraint). We have, for $i = 1, 2, \ldots, n$,

$$\frac{p_i}{M} = \frac{\partial u / \partial x_i}{\lambda M} = \frac{\partial u / \partial x_i}{\sum \lambda p_j x_j} = \frac{\partial u / \partial x_i}{\sum x_j (\partial u / \partial x_j)} = g_i(x_1, x_2, \ldots, x_n)$$

(The $g_i$ are clearly unaffected by a monotone increasing transformation of $u$ and reduce to $\partial u / \partial x_i$ if $u$ is homogeneous of degree one.) The indirect demand functions (1) are the natural generalization of Marshall's demand-price concept at the individual level, defining an $n$-vector of normalized prices at which a given $n$-vector of commodities will be demanded. Indirect demand functions may be useful in the contexts of central planning or rationing, where they can indicate the prices planners should choose to clear markets given the quantities available, or the notional prices at which ration allotments would just be freely purchases (see Pearce, 1964, pp. 57–64). But unfortunately, although indirect demand functions are readily obtained for the individual, they are not as easily aggregated to the market level as are direct demand functions. The asymmetry arises from the fact that individuals face identical prices but do not make identical quantity choices. Thus, market-level indirect demand functions must generally be obtained by first aggregating the individual direct demand functions and then inverting the resulting market functions. The modern duality approach to consumer behaviour has revealed fundamental symmetries in the roles of prices and quantities. The alternatives of viewing quantity demanded as a function of price or demand price as a function of quantity can now be seen as only one of a variety of dual alternatives which considerably enrich theoretical and econometric analysis. (See Gorman, 1976, for a simple treatment.)

Demand theory describes and explains individual choice of consumption bundles. Traditional theory considers optimizing behaviour when the consumer's choice is restricted to consumption bundles that satisfy a budget constraint. The budget constraint is determined by price–income pairs. A demand correspondence assigns to each price–income pair a non-empty set of optimal consumption bundles. A demand function assigns to each price–income pair a unique optimal consumption bundle. Optimality of consumption bundles is based on a preference relation. The theory derives existence and properties of demand correspondences (demand functions) from assumptions on preference relations and, if applicable, their utility representations.

Article

The main purpose of demand theory is to describe and explain observed consumer choices of commodity bundles. Market parameters, typically prices and income, determine constraints on commodity bundles. Given a combination of market parameters, a commodity bundle or a non-empty set of commodity bundles, which satisfies the corresponding constraints, is called a demand vector or a demand set. The mapping which assigns to every admissible combination of market parameters a unique demand vector (or a non-empty demand set) is called a demand function (or a demand correspondence, respectively). Traditional demand theory considers the demand function (or correspondence) as the outcome of some optimizing behaviour of the consumer. Its primary goal is to determine how alternative assumptions on the constraints, objectives and behavioural rules of the consumer affect his observed demands for commodities. The traditional model of the consumer postulates preferences over alternative commodity bundles to describe the objectives of the consumer. Its behavioural rule consists in maximizing these preferences on the set of feasible commodity bundles which satisfy the budget constraint imposed by the market parameters. If there is a unique preference maximizer under each budget constraint, then preference maximization determines a demand function. If there is at least one preference maximizer under each budget constraint, then preference maximization determines a demand correspondence.

Once the traditional view is adopted, the occurrence of demand correspondences cannot be avoided. Compatibility of observed demand, which is always unique, with some demand correspondence poses a minor problem in general. However, the correspondence should be obtained through preference maximization. The last requirement leads to the main issues of modern demand theory: Which demand correspondences are compatible with preference maximization? Given any conditions necessary for demand correspondences to be compatible with preference maximization, are they sufficient? Which demand correspondences are compatible with a special class of preferences? What type of preferences yields a particular class of demand correspondences? When addressing these issues, modern demand theory attempts to link two concepts: preferences and demand.

Historically, the important concept was utility rather than preference. Before Fisher (1892) and Pareto (1896), utility was conceived as cardinal: that is, it was assumed to be a
measurable scale for the degree of satisfaction of the consumer. Fisher and Pareto were the first to observe that an arbitrary increasing transformation of the utility function has no effect on demand. Edgeworth (1881) had already written utility as a general function of quantities of all commodities and had employed indifference curves. It is now widely accepted in demand theory that only ordinal utility matters. That is, a utility function serves merely as a convenient device to represent a preference relation, and any increasing transformation of the utility function will serve this purpose as well.

Representability by utility functions imposes some restrictions on preferences. The problem of representability of a preference relation by a numerical function was solved by Debreu (1954; 1959; 1964) based on work by Eilenberg (1941), and by Rader (1963) and Bowen (1968). While still assuming cardinal utility, Walras (1874) developed the first ‘theory of demand’. His demand was a function of all prices and the endowment bundle, obtained through utility maximization. Slutsky (1915) finally assumed an ordinal utility function with enough restrictions to yield a maximum under any budget constraint and testable properties of the resulting demand functions. In particular, he obtained negativity of diagonal elements and symmetry of the ‘Slutsky matrix’.

Antonelli (1886) was the first to go the opposite way: construct indifference curves and a utility function from the so-called inverse demand function. Pareto (1906) took the same route. Katzner (1970) reports on recent results in this direction. The construction of preference relations from demand functions was achieved in two ways:

1. Samuelson (1947) and Houthakker (1950) introduced the concept of revealed preference into demand theory. Considerable progress in relating utility and demand in terms of revealed preference was achieved by Uzawa (1960), further refinements being due to Richter (1966).

2. Hurwicz and Uzawa (1971) contributed to the following so-called integrability problem: construct a twice continuously differentiable utility representation from a continuously differentiable demand function which satisfies certain integrability conditions (including symmetry and negative semi-definiteness of the Slutsky matrix).

Kihlstrom, Mas-Colell and Sonnenschein (1976) unified the two approaches by relating the axioms of revealed preference to properties of the Slutsky matrix.

Since there exists a sizable literature on demand theory, many of the concepts and results are well established and well-known. These have become so much part of standard knowledge in economic theory that they are included in any contemporary microeconomic textbook and other surveys. It would substantially reduce the space available for a presentation of the new results of recent decades if an extended introductory account of demand theory were to be included here as well.

Commodities and prices

Consumers purchase or sell commodities, which can be divided into goods and services. Each commodity is specified by its physical quality, its location, and the date of its availability. In the case of uncertainty, the state of nature in which the commodity is available may be added to the specification of a commodity. This leads to the notion of a contingent commodity (see Arrow, 1953; Debreu, 1959). We assume as in traditional theory that there exists a finite number l of such commodities. Quantities of each commodity are measured in real numbers. A commodity bundle is an l-dimensional vector x=(x₁,...,xₗ). The set of all l-dimensional vectors x=(x₁,...,xₗ) is the l-dimensional Euclidean space Rₗ which we interpret as the commodity space. |xₗ| indicates the quantity of commodity h=1,...,l. Commodities are assumed to be perfectly divisible, so that their quantity may be expressed as any (non-negative) real number. The standard sign convention for consumers assigns positive numbers for commodities made available to the consumer (inputs) and negative numbers for commodities made available by the consumer (outputs). Hence, a priori any commodity bundle x∈Rₗ is conceivable.

The price pₗ of a commodity h, h=1,...,l, is a real number which is the amount in units of account that has to be paid in exchange for one unit of the commodity. For the consumer, pₗ is given and has to be paid now for the delivery of commodity h under the circumstances (location, date, state) specified for commodity h. A price system or price vector is a vector p=(p₁,...,pₗ)∈Rₗ and contains the prices for all commodities. The value of a commodity bundle x given the price vector p is pₓ = ∑ₗ h=1 pₗ xₗ. This means that commodity bundles are priced linearly.

Consumption sets and budget sets

Typically, some commodity bundles cannot be consumed by a consumer for physical reasons. Those consumption bundles which can be consumed form the consumer’s consumption set. This is a non-empty subset X of the commodity space Rₗ. A consumer must choose a bundle x from his consumption set X in order to subsist. Traditionally, inputs in consumption are described by positive quantities and outputs by negative quantities. So in particular, the labour components of a consumption bundle x are all non-positive, unless labour is hired for a service. One usually assumes that the consumption set X is closed, convex, and bounded below. Vectors x∈X are sometimes called consumption plans.

Given the sign convention on inputs and outputs and a price vector p, the value px of a consumption plan x defines the net outlay of x, that is the value of all purchases (inputs) minus...
the value of all sales (outputs) for the bundle $x$. Trading the bundle $x$ in a market at prices $p$ implies payments and receipts for that bundle. Therefore, the value of the consumption plan should not exceed the initial wealth (or income) of the consumer which is a given real number $w$. If the consumer owns a vector of initial resources $\omega$ and the price vector $p$ is given, then $w$ may be determined by $w = p\omega$. The consumer may have other sources of wealth: savings and pensions, bequests, profit shares, taxes, or other liabilities. Given $p$ and $w$, the set of possible consumption bundles whose value does not exceed the initial wealth of the consumer is called the budget set and is defined formally by

$$\beta(p, w) = \{x \in X | px \leq w\}.$$

The ultimate decision of a consumer is to choose a consumption plan from his budget set. Those vectors in $\beta(p, w)$ which the consumer eventually chooses form his demand set $\phi(p, w)$.

Preferences and demand

The choice of the consumer depends on his tastes and desires. These are represented by his preference relation $\succeq$ which is a binary relation on $X$. For any two bundles $x, y \in X$, $x \succeq y$ means that $x$ is at least as good as $y$. If the consumer always chooses a most preferred bundle in his budget set, then his demand set is defined by

$$\phi(p, w) = \{x \in \beta(p, w) | x' \in \beta(p, w) \text{ implies } x \succeq x' \text{ or not } x' \succeq x\}.$$

Three basic axioms are usually imposed on the preference relation $\succeq$ which are taken as a definition of a rational consumer:

- **Axiom 1** (reflexivity). If $x \in X$, then $x \succeq x$, that is, any bundle is as good as itself.
- **Axiom 2** (transitivity). If $x, y, z \in X$ such that $x \succeq y$ and $y \succeq z$, then $x \succeq z$.
- **Axiom 3** (completeness). If $x, y \in X$, then $x \succeq y$ or $y \succeq x$.

A preference relation $\succeq$ which satisfies these three axioms is a complete preordering or weak order on $X$ and will be called a preference order. Already Axioms 2 and 3 define a preference order, since Axiom 3 implies Axiom 1. A preference relation $\succeq$ on $X$ induces two other relations on $X$, the relation of strict preference, $\succ$, and the relation of indifference, $\sim$.

**Definition:** Let $\succeq$ be a preference relation on the consumption set $X$. A bundle $x$ is said to be strictly preferred to a bundle $y$, that is $x \succ y$, if and only if $x \succeq y$ and not $y \succeq x$. A bundle $x$ is said to be indifferent to a bundle $y$, that is $x \sim y$, if and only if $x \succeq y$ and $y \succeq x$.

**Lemma:** Suppose $\succeq$ is reflexive and transitive. Then

1. (i) $\succ$ is irreflexive, that is, not $x \succ x$, and transitive;
2. (ii) $\sim$ is an equivalence relation on $X$, which means that $\sim$ is reflexive, transitive, and symmetric: that is, $x \sim y$ if and only if $y \sim x$.

For $Z \subseteq X$, $x \in Z$, $x$ is called maximal in $Z$, if for all $z \in Z$: not $z \succ x$, $x$ is called a best element of $Z$ or most preferred in $Z$, if for all $z \in Z$: $x \succeq z$. Best elements are maximal; maximal elements are not necessarily best elements. If $\succeq$ is complete, then best and maximal elements coincide. Obviously for any price vector $p$ and initial wealth $w$, the

$$\phi(p, w) = \{x \in \beta(p, w) | x \text{ is maximal in } \beta(p, w)\}.$$
Axioms 1–3 are not qsted in most of consumer theory. However, transitivity and completeness may be violated by observed behaviour. Recent developments in the theory of consumer demand indicate that some weaker axioms suffice to describe and derive consistent demand behaviour (see, for example, Sonnenschein, 1971; Katzner, 1971; Shafer, 1974; Kihlstrom, Mas-Colell and Sonnenschein, 1976; Kim and Richter, 1986). In an alternative approach, one could start from a strict preference relation as the primitive concept. This may sometimes be convenient. However, the weak relation $\succeq$ seems to be the more natural concept. If the consumer chooses $x$, although $y$ was a possible choice as well, then his choice can only be interpreted in the sense of $x \succeq y$, but not as $x > y$.

For the remainder of this section, let us fix a preference order $\succsim$ on $X$ and a non-empty subset $B$ of $\mathbb{R}_+^{m+1}$ such that for every $(p,w)\in B$, there is a unique $\succsim$-best element in $B$ $(p,w)$: that is, maximization of $\succsim$ defines a demand function $f: B \rightarrow X$ such that $f(p,w)=(f((p,w))$ for all $(p,w)\in B$.

Let $x, x' \in X, x \neq x'$. We call $x$ revealed preferred to $x'$ and write $xR^*x'$, if there is $(p,w)\in B$ such that $x=f((p,w))$ and $p x' \leq p x$. $xR^*x'$ implies that both $x$ and $x'$ belong to the budget set $B(p,w)$. Since $f$ is derived from $\succsim$-maximization, $xR^*x'$ implies $x \succ x'$. We call $x$ indirectly revealed preferred to $x'$ and write $x R^* x'$, if there exists a finite sequence $x_0 = x, x_1, \ldots, x_n = x'$ in $X$ such that $x_0 R x_1, \ldots, x_{n-1} R x'$. Obviously, $R^*$ is transitive. Since $\succ$ is transitive, $x R^* x'$ implies $x \succ x'$. Consequently, the following must hold (otherwise $x \succ x'$):

$$ (\text{SARP}) \quad x R^* x' \Rightarrow \neg (x' R^* x). $$

(\text{SARP}) implies

$$ (\text{SARP}) \quad x R x' \Rightarrow \neg (x' R x). $$

(\text{SARP}) is the strong axiom of revealed preference; (WARP) is the weak axiom. Hence $\succsim$-maximization implies the strong axiom and a fortiori the weak axiom. For the inverse implication, see Chipman et al. (1971, chs. 1, 2, 3 and 5). For $I \geq 3$, there exist demand functions which satisfy (WARP) but not (SARP), whereas for $I = 2$, (WARP) and (SARP) are equivalent; see Section 3J of Mas-Colell, Whinston and Green (1995) and Kihlstrom, Mas-Colell and Sonnenschein (1976, p. 977).

**Continuous preference orders and utility functions**

Axioms 1–3 have intuitive appeal. This is less so with the topological requirements of the following Axiom 4.

- **Axiom 4** (continuity). For every $x \in X$, the sets $\{ y \in X | y \succsim x \}$ and $\{ y \in X | x \succ y \}$ are closed relative to $X$.

If $\succsim$ is a preference order, then Axiom 4 is equivalent to: For every $x \in X$, the sets $\{ y \in X | y \succ x \}$ and $\{ y \in X | x \succ y \}$ are open in $X$.

Closedness of $\{ y \in X | y \succsim x \}$ requires that for any sequence $y^o_n, n \in \mathbb{N}$, in $X$ such that $y^o_n$ converges to $y \in X$ and $y^o_n \succsim x$ for all $n$, the limit $y$ also satisfies $y \succsim x$. Openness of $\{ y \in X | y \succ x \}$ means that if $y \succ x$, then $y' \succ x$ for any $y'$ close enough to $y$.

The sets $\{ y \in X | y \succsim x \}$ are called upper contour sets of the relation $\succsim$ and the sets $\{ y \in X | x \succ y \}$ are called lower contour sets of $\succsim$. For $x \in X$, the set $I(x) := \{ y \in X | y \succsim x \}$ is called the indifference class of $x$ with respect to $\succsim$ or the $\succsim$-indifference surface through $x$ or the $\succsim$-indifference curve through $x$. In the case $\succsim$ is reflexive and transitive, $I(x)$ is the equivalence class of $x$ with respect to the equivalence relation $\sim$.

There is a preference order $\succsim$ on $\mathbb{R}_+^I$, $i \geq 2$, which does not satisfy Axiom 4, namely the lexicographic order defined by $(x_1, \ldots, x_i) \succsim (y_1, \ldots, y_i)$ if and only if $x=y$ or there exists $k \in \{1, \ldots, I\}$ such that $x_k > y_k$ and $x_j = y_j$ for $j \neq k$. Few studies of the relationship between the order properties of Axioms 1–3 and the topological property of Axiom 4 have been made. We emphasize the following result.

**Theorem:** (Schmeidler, 1971). Let $\succsim$ denote a transitive binary relation on a connected topological space $X$. Assume that there exists at least one pair $\bar{x}, \bar{y} \in X$ such that $\bar{x} \succsim \bar{y}$. If for every $x \in X$, (i) $\{ y \in X | y \succsim x \}$ and $\{ y \in X | x \succ y \}$ are closed and (ii) $\{ y \in X | y \succ x \}$ and $\{ y \in X | x \succ y \}$ are open, then $\succsim$ is complete.

**Definition:** Let $X$ be a set and $\succsim$ be a preference relation on $X$. Then a function $u$ from $X$ into the real line $\mathbb{R}$ is a (utility) representation or a utility function for $\succsim$, if for all
Clearly, if \( u \) is a utility representation for \( \succsim \) and \( f: \mathbb{R} \to \mathbb{R} \) is an increasing transformation, then the composition \( f \circ u \) is also a representation of \( \succsim \). If \( u: X \to \mathbb{R} \) is any function, then \( \succsim \) is defined by \( x \succsim y \) if and only if \( u(x) \geq u(y) \) for \( x, y \in X \), is a preference order on \( X \) and \( u \) is a utility representation for \( \succsim \). Most utility functions used in consumer theory are continuous. If \( u \) is continuous and \( \succsim \) is represented by \( u \), then by necessity \( \succsim \) is a continuous preference order. In our case where \( X \subset \mathbb{R}^l \), the opposite implication also holds: If \( \succsim \) is a continuous preference order, then it has a continuous utility representation.

**Theorem:** (Debreu, Eilenberg, Rader). Let \( X \) be a topological space with a countable base of open sets (or a connected, separable topological space) and \( \succsim \) be a continuous preference order on \( X \). Then \( \succsim \) has a continuous utility representation.

In our context of Euclidean commodity spaces, explicit constructions of continuous utility representations for continuous and monotonic preference orders are available. See Arrow and Hahn (1971) for the ‘Euclidean distance approach’ and Neufeld (1972) for the ‘Lebesgue measure approach’. For topological spaces \( X \) with a countable base of open sets, it has further been shown by Rader (1963) and Bosi and Mehta (2002) that an upper semi-continuous preference order on \( X \) has an upper semi-continuous utility representation.

As an immediate consequence of the representation theorem for preference relations, one obtains one of the standard results on the non-emptiness of the demand set \( \phi(p, w) \), since any continuous function attains its maximum on a compact set (Weierstrass’s th), though a direct proof is also possible.

**Corollary:** Let \( X \subset \mathbb{R}^l \) be bounded below and closed, \( \succsim \) be a continuous preference order on \( X \). \( p \in \mathbb{R}^l_+ \) (that is, \( p \succsim 0 \)) and \( w \in \mathbb{R}^l \). Then \( \beta(p, w) \not= \emptyset \) implies \( \phi(p, w) \not= \emptyset \).

There has been a recent shift from proving existence to a more systematic study of the non-existence of utility representations. Needless to say that there are many preference orders on \( \mathbb{R}^l \) or on subsets thereof with continuous utility representations. There are also total orders \( \succsim \) (that is, preference orders \( \succsim \) with \( x \sim y \iff x = y \)) on \( \mathbb{R}^l \), \( l \geq 2 \), which admit utility representations, since there exist bijections \( u: \mathbb{R}^l \to \mathbb{R} \). However, for \( l \geq 2 \), there is no total order on \( \mathbb{R}^l_+ \) or on \([0,1]^l\) which has a continuous utility representation; see Candeal and Induráin (1993). Moreover, a preference order \( \succsim \) on \( X \), which is not continuous, need not have a utility representation. For instance, the lexicographic order on \( \mathbb{R}^l \), \( l \geq 2 \), a total order first discussed by Debreu (1954), does not have a utility representation, nor even a discontinuous one. Beardon et al. (2002) provide a classification of total orders which do not admit a utility representation. Estévez Toranzo and Hervés Beloso (1995) show that, if \( X \) is a non-separable metric space, then there exists a continuous preference order on \( X \) which cannot be represented by a utility function.

**Some properties of preferences and utility functions**

Some of the frequent assumptions on preference relations correspond almost by definition to analogous properties of utility functions, while other analogies need demonstration. We discuss the assumptions most commonly used.

**Monotonicity:** A preference order \( \succsim \) on \( X \subset \mathbb{R}^l \) is monotonic, if \( x, y \in X, x \succsim y, x \not= y \) implies \( x \succ y \).

This property means desirability of all commodities. If a monotonic preference order has a utility representation \( u \), then \( u \) is an increasing function (in all arguments). Inversely, if \( \succsim \) is represented by an increasing function, then \( \succsim \) is monotonic.

**Non-satiation:** Let \( \succsim \) be the preference relation of a consumer over consumption bundles in \( X \) and let \( x \in X \).

1. (i) \( x \) is a satiation point for \( \succsim \) if \( x \succsim y \) for all \( y \in X \) (that is, \( x \) is a best element in \( X \)).
2. (ii) The preference relation \( u \) is locally not satiated at \( x \), if for every neighbourhood \( U \) of \( x \) there exists \( z \in U \) such that \( z \succ x \).

Consider a utility representation \( u \) for \( \succsim \). Then \( x \in X \) is a satiation point if and only if \( u \) has a global maximum at \( x \). \( \succsim \) is locally not satiated at \( x \) if and only if \( u \) does not attain a local maximum at \( x \). Local non-satiation rules out that \( u \) is constant in a neighbourhood of \( x \). If \( \succsim \) is locally not satiated at all \( x \), then \( \succsim \) cannot have thick indifference classes or satiation points.

**Convexity:** A preference relation \( \succsim \) on \( X \subset \mathbb{R}^l \) is called

1. (i) convex, if the set \( \{ y \in X | y \succsim x \} \) is convex for all \( x \in X \).
2. (ii) strictly convex, if \( X \) is convex and \( \lambda x + (1 - \lambda) x' \succ x' \) for any two bundles \( x, x' \in X \) such that \( x \not= x' \) and for any \( \lambda \) such that \( 0 < \lambda < 1 \);
3. (iii) strongly convex, if \( X \) is convex and \( \lambda x + (1 - \lambda) x' \succ x'' \) for any three bundles \( x, x', x'' \in X \) such that \( x \not= x', x \succsim x'', x' \succsim x'' \) and for any \( \lambda \) such that \( 0 < \lambda < 1 \).

**Quasi-concavity:** A function \( u: X \to \mathbb{R} \) is called

1. (i) quasi-concave, if \( u(\lambda x + (1 - \lambda)y) \geq \min\{u(x), u(y)\} \) for all \( x, y \in X \) and any \( \lambda \in [0,1] \);
2. (ii) strictly quasi-concave, if \( u(\lambda x + (1 - \lambda)y) > \min\{u(x), u(y)\} \) for all \( x, y \in X \) with \( x \neq y \) and any \( \lambda \in (0,1) \).

Let \( u \) be a representation of the preference order \( \succeq \). Then \( u \) is (strictly) quasi-concave if and only if \( \succeq \) is (strictly) convex. Quasi-concavity is preserved under increasing transformations: that is, it is an ordinal property. In contrast, concavity is a cardinal property which can be lost under increasing transformations. With respect to the difficult problem to characterize those preference orders which have a concave representation, we refer to Kannai (1977). Clearly, if \( \succeq \) is locally not satiated at all \( x \), then \( \succeq \) does not have a satiation point. In general, the inverse implication is false. If, however, \( \succeq \) is strictly convex and does not have a satiation point, then \( \succeq \) is locally not satiated at all \( x \). Moreover, if \( \succeq \) is strictly convex, then it has at most one saturation point. An immediate implication is the following lemma.

**Lemma:** Let \( X \subseteq \mathbb{R}^j \) be bounded below, convex, and closed. Let \( \succeq \) be a strictly convex, continuous preference order on \( X \), \( p \in \mathbb{R}^k_+ \), and \( w \in \mathbb{R} \). Then \( \beta(p, w) \neq \emptyset \) implies that \( \phi(p, w) \) is a singleton.

**Separability** Separable utility functions were used in classical consumer theory long before associated properties of preferences had been defined. All early contributions to utility theory assumed without much discussion an additive form of the utility function over different commodities. It was not until Edgeworth (1881) that utility was written as a general function of a vector of commodities. The particular consequences of separability for demand theory were discussed well after the general non-separable case in demand theory had been treated and generally accepted. Among the many contributors are Sono (1945), Leontief (1947), Samuelson (1947), Houthakker (1960), Debreu (1960), Debreu (1960), and Koopmans (1972).

We follow Katzner (1970) in our presentation.

Let \( N = \{N_j\}_{j=1}^k \) be a partition of the set \( \{1, \ldots, l\} \) and assume that \( X = S_1 \times \cdots \times S_k \). Let \( J = \{1, \ldots, k\} \) and for any \( j \in J \), \( \nu \in X \), \( \nu = (\nu_1, \ldots, \nu_k) \in \prod_{i \in S_j} \mathbb{R} \).

For any \( j \), \( y \in \nu_\cdot \) a preference order \( \succeq \) on \( X \) induces a preference order \( \succeq \) on \( S_j \) which is defined by \( x_j \succeq y \) if \( x \succeq_j y \) for all \( x, y \in S_j \). In general, the induced ordering \( \succeq \) will depend on \( y \). The first notion of separability states that for any \( j \), the preference orders \( \succeq \) are independent of \( y \). The second notion of separability states that for any proper subset \( I \) of \( J \), the induced preference orders \( \succeq \) on \( \prod_{i \in I} \mathbb{R} \) are independent of \( \nu \).

**Definition:** Let \( \succeq \) be a preference order on \( X = \prod_{j \in S_j} \mathbb{R} \).

1. (i) \( \succeq \) is called weakly separable with respect to \( N \) if \( \succeq \) is \( \succeq \) for each \( j \in J \) and any \( \nu \).
2. (ii) \( \succeq \) is called strongly separable with respect to \( N \) if \( \succeq \) for each \( l \in \nu \), \( l \neq \emptyset \), \( l \neq j \) and any \( \nu \).

**Definition:** Let \( U: \prod_{j \in S_j} \mathbb{R} \to \mathbb{R} \) be called

1. (i) weakly separable with respect to \( N \), if there exist continuous functions \( V_j: S_j \to \mathbb{R}, j \in J \), and \( V: \mathbb{R}^k \to \mathbb{R} \) such that \( U(x) = V(\nu_1(x_1), \ldots, \nu_k(x_k)) \);
2. (ii) strongly separable with respect to \( N \), if there exist continuous functions \( V_j: S_j \to \mathbb{R}, j \in J \), and \( V: \mathbb{R}^k \to \mathbb{R} \) such that \( U(x) = V(\Sigma_{j \in V_j}(x_j)) \).

The two important equivalence results on separability are due to Debreu and Katzner. The version of Debreu's theorem given here is slightly weaker than his original result.

**Theorem:** (Katzner, 1970). Let \( \succeq \) be a continuous, monotonic preference order on \( X = \prod_{j \in S_j} \mathbb{R} \) with \( S_j = \mathbb{R}^N \) for all \( j \in J \). Then \( \succeq \) is weakly separable if and only if every continuous representation of \( \succeq \) is weakly separable.

**Theorem:** (Debreu, 1960). Let \( \succeq \) be a continuous, monotonic preference order on \( X = \prod_{j \in S_j} \mathbb{R} \) with \( S_j = \mathbb{R}^N \) for all \( j \in J \) = \{1, \ldots, k\} and \( k \succeq \). Then \( \succeq \) is strongly separable if and only if every continuous representation is strongly separable.

Under the assumptions of this theorem, if \( \succeq \) is strongly separable with representation \( U(x) = \nu(\Sigma_{j \in V_j}(x_j)) \), then \( V \) must be increasing or decreasing. Therefore,
is also a representation of \( 
abla \). This is the additive form of separable utility used by early economists who thought that each commodity had its own intrinsic utility representable by a scalar function \( u_h \). The overall utility was then simply obtained as the sum of these functions, \( u(x) = \sum_h u_h(x_h) \). Such a formulation is given by Jevons (1871) and Walras (1874) and implicitly contained in Gossen (1854).

In the case of uncertainty, with finitely many states of nature \( j \in J = \{1, \ldots, k\} \), respective probabilities \( \pi_j > 0 \) and consumption \( x_j \in S_j \) in state \( j \in J \), an additively separable utility representation \( u(x) = \sum_j \pi_j v_j(x_j) \) is tantamount to an expected utility representation \( u(x) = \sum_j \pi_j \mu_j(x_j) \) with \( u_j \equiv v_j \). Hence, an expected utility representation in the tradition of Savage (1954) implies separability with respect to states of nature. In contrast, the novel concept of Choquet expected utility à la Schmeidler (1986; 1989) typically violates separability with respect to states of nature.

For \( k = 2 \), weak and strong separability of preferences coincide. But there are separable preferences which do not admit a strongly separable utility representation, for instance \( X = \mathbb{R}_+^2 \).

**Continuous demand**

Given any price–wealth pair \( (p, w) \in \mathbb{R}^{j+1} \), the budget set of the consumer was defined as \( \beta(p, w) = \{x \in X | px \leq w\} \). Let \( S \subseteq \mathbb{R}^{j+1} \) denote the set of price–wealth pairs for which the budget set is non-empty. Then \( \beta \) describes a correspondence from \( S \) into \( X \); that is, \( \beta \) associates to any \( (p, w) \in S \) the non-empty subset \( \beta(p, w) \) of \( X \). There are two standard notions of continuity of correspondences, upper hemi-continuity and lower hemi-continuity (see Hildenbrand, 1974).

**Definition:** A compact-valued correspondence \( \Psi \) from \( S \) into an arbitrary subset \( T \) of \( \mathbb{R}^j \) is upper hemi-continuous (u.h.c.) at a point \( y \in S \) if, for all sequences \( (y^n, z^n) \in S \times T \) such that \( y^n \to y \) and \( z^n \in \Psi(y^n) \) for all \( n \), there exist \( z \in \Psi(y) \) and a subsequence \( z^{n_k} \) of \( z^n \) such that \( z^{n_k} \to z \).

**Definition:** A correspondence \( \Psi \) from \( S \) into an arbitrary subset \( T \) of \( \mathbb{R}^j \) is lower hemi-continuous (l.h.c.) at a point \( y \in S \) if, for any \( z \in \Psi(y) \) and any sequence \( y^n \in S \) with \( y^n \to y \) there exists a sequence \( z^n \) in \( T \) such that \( z^n \to z \) and \( z^n \in \Psi(y^n) \) for all \( n \).

**Definition:** A correspondence is continuous if it is both lower and upper hemi-continuous.

For single-valued correspondences, the notions of lower and upper hemi-continuity coincide with the usual notion of continuity for functions. For proofs of the following lemmas, see Debreu (1959) or Hildenbrand (1974).

**Lemma:** Let \( X \subseteq \mathbb{R}^j \) be a convex set. Then the budget correspondence \( \beta:S \to X \) has a closed graph and is lower hemi-continuous at every point \( (p, w) \in S \) for which \( w > \min \{px: x \in X\} \) holds.

Combining a previous corollary on the non-emptiness of the demand set and a fundamental theorem of Berge (1966) yields the next result.

**Lemma:** Let \( X \subseteq \mathbb{R}^j \) be a convex set. If the preference relation has a continuous utility representation, then the demand correspondence is defined (that is, non-empty valued), compact-valued, and upper hemi-continuous at each \( (p, w) \in S \) such that \( \beta(p, w) \) is compact and \( w > \min \{px: x \in X\} \).

It follows immediately from the definitions that \( \Phi(\lambda, p, \lambda w) = \Phi(p, w) \) for any \( \lambda > 0 \) and any price–wealth pair \( (p, w) \); that is, demand is homogeneous of degree zero in prices and wealth. For convex preference orders, the demand correspondence is convex-valued. For strictly convex preference orders, the demand correspondence is single-valued: that is, one obtains a demand function. The results of this section and of the section on continuous preference orders and utility functions are summarized in the following lemma, which uses the weakest assumptions of traditional demand theory to generate a continuous demand function.

**Lemma:** Let \( \Psi: \{ (p, w) \in \mathbb{R}^{j+1} | \beta(p, w) \text{ is compact and } w > \min \{px: x \in X\} \} \). If \( \gtrsim \) denotes a strictly convex and continuous preference order, then \( \Phi(p, w) \) defines a continuous demand function which satisfies: (i) homogeneity of degree zero in prices and wealth and (ii) the strong axiom of revealed preference.
Continuous demand without transitivity

Transitivity is often violated in empirical studies. This excludes utility maximization, but not necessarily preference maximization. However, as the next theorem indicates, existence and continuity of demand do not depend on transitivity as crucially as one may expect. The theorem follows from a result by Sonnenschein (1971).

Theorem: Let \( S^* = \{ (p, w) \in \mathbb{R}^l_+ \mid \phi(p, w) \neq \emptyset \} \). Suppose that \( X \) is compact and \( \succeq \) is complete and has a closed graph.

1. (i) If \( \{ x' \in X | x' \succ x \} \) is convex for all \( x \in X \), then \( \phi(p, w) \neq \emptyset \) whenever \( \beta(p, w) \neq \emptyset \) (that is, \( S^* = S \)).
2. (ii) If \( S^* = S \) and \( (p^0, w^0) \in S \) such that \( \beta \) is continuous at \( (p^0, w^0) \), then \( \phi \) is u.h.c. at \( (p^0, w^0) \).

The assumption that \( X \) is compact is not necessary. For case (i) it suffices that all budget sets \( \beta(p, w) \) under consideration be compact. For case (ii) it is sufficient that there exist a compact subset \( X^0 \) of \( X \) and a neighbourhood \( S^0 \) of \( (p^0, w^0) \) such that \( \phi(S^0) \subseteq X^0 \).

To complete this section we state a lemma on the properties of a demand function obtained under preference maximization without transitivity. This contrasts with the lemma at the end of the previous section. Intransitivity essentially implies that the strong axiom of revealed preference need not hold. The lemma follows from the theorem by Sonnenschein and the result by Shafer (1974).

Lemma: Let \( X = \mathbb{R}^i_+ \) and \( B = \mathbb{R}^{i+1}_+ \). Suppose continuity and strong convexity of \( \succeq \) (in addition to completeness). Then preference maximization yields a continuous demand function \( f: B \rightarrow X \) which satisfies (i) homogeneity of degree zero in prices and wealth and (ii) the weak axiom of revealed preference.

The converse statement of the lemma does not hold. For \( i = 2 \), \( X = \mathbb{R}^2_+ \) and \( B = \mathbb{R}^3_+ \), there is a \( C^1 \)-function \( f:B \rightarrow X \) which fulfills (i), (ii), and (iii) \( pf(p, w) = w \) for all \( (p, w) \in B \), but which cannot be obtained as the demand function for a continuous, complete and strictly convex preference relation (John, 1984; Kim and Richter, 1986). In addition, John (1995) has shown that continuity of \( f \), (ii) and (iii) imply (i).

Smooth preferences and differentiable utility functions

Owing to the representation theorem of Debreu, Eilenberg and Rader, continuity of a utility function and continuity of the represented preference order are identical under the perspective of demand theory. When continuous differentiability of demand is required, continuity of the preference relation will not suffice in general. The first rigorous attempt to study ‘differentiable preference orders’ goes back to Antonelli (1886). We follow the more direct approach of Debreu (1972) to characterize ‘smooth preference orders’. Smoothness of preferences is closely related to sufficient differentiability of utility representations and the solution of the integrability problem (see Debreu, 1972; also Debreu, 1976; Hurwicz, 1971; and the section below on integrability). For the purpose of this and subsequent sections, let \( P = \mathbb{R}^1_+ \) denote the (relative) interior of \( \mathbb{R}^1_+ \) and assume that \( X = P \). Let \( \succeq \) be a continuous and monotonic preference order on \( P \) which we may consider as a subset of \( P \times P \); that is, \( (x, y) \in \succeq \iff x \succeq y \) for \( (x, y) \in P \times P \). Also, the associated indifference relation \( \sim \) will be considered as a subset of \( P \times P \). To describe a smooth preference order, differentiability assumptions will be made on the (graph of the) indifference relation in \( P \times P \).

For \( k \geq 1 \), let \( C^k \) denote the class of functions which have continuous partial derivatives up to order \( k \), and consider two open sets \( X \) and \( Y \) in an Euclidean space \( \mathbb{R}^n \). A bijection \( h: X \rightarrow Y \) is a \( C^k \)-diffeomorphism if both \( h \) and \( h^{-1} \) are of class \( C^k \). A \( C^k \)- hypersurface, if for every \( z \in M \), there exist an open neighbourhood \( U \) of \( z \), an open subset \( V \) of \( \mathbb{R}^n \), a hyperplane \( H \subseteq \mathbb{R}^n \) and a \( C^k \)-diffeomorphism \( h: U \rightarrow V \) such that \( h(U \cap M) = V \cap H \). A \( C^k \)-hypersurface has locally the structure of a hyperplane up to a \( C^k \)-diffeomorphism.

Considering the indifference relation \( \sim \) as a subset of \( P \times P \), the set \( \bar{I} = \{ (x, y) \in P \times P | x \sim y \} \subseteq \mathbb{R}^2_+ \) constitutes the ‘indifference surface’ of the preference relation. Then \( \succeq \) is called a \( C^2 \)-preference order (or smooth preference order), if \( \bar{I} \) is a \( C^2 \)-hypersurface.

Theorem: (Debreu, 1972). Let \( \succeq \) be a continuous and monotonic preference order on \( P \) and \( \bar{I} \) be its indifference surface. Then \( \succeq \) is a \( C^2 \)-preference order if and only if it has a monotonic utility representation of class \( C^2 \) with no critical point.
Let $\succeq$ be a monotonic, strictly convex $C^2$-preference order on $P$ and $u: P \to \mathbb{R}$ be a $C^2$-utility representation of $\succeq$ with no critical point. Then $u$ is continuous, increasing in all arguments, and strictly quasi-concave. Moreover, all second-order partial derivatives $u_{ij}(x) = (\partial^2 u / \partial x_i \partial x_j)(x)$, $i, j = 1, \ldots, l$, $x \in P$, exist, all $u_{ij}$ are continuous functions of $x$ and $u_{ij} = u_{ji}$ for $i, j = 1, \ldots, l$. Let $D^2u = (u_{ij})$ denote the Hessian matrix of $u$. Then $D^2u$ is symmetric. The first-order derivatives $u_i(x) = (\partial u / \partial x_i)(x)$, $i = 1, \ldots, l$, are continuous functions of $x$. Assume that $u_i(x) > 0$ for $i = 1, \ldots, l$, $x \in P$ and define

$$Du(x) = \begin{bmatrix} u_1(x) \\ \vdots \\ u_l(x) \end{bmatrix}$$

as the gradient of $u$ at $x$. For any $m \times n$-matrix $M$, let $M'$ denote the transpose of $M$.

**Theorem:** If $u: P \to \mathbb{R}$ is a strictly quasi-concave utility function of class $C^2$, then $z' D^2 u(x) z \leq 0$ for all $x \in P$ and $z \in \{ z \in \mathbb{R}^l | 2Du(x) = 0 \}$.

(For a proof, see Barten and Böhm, 1982.)

It will be shown in the next section that the conclusion of this theorem does not guarantee the existence of a differentiable demand function. The following definition strengthens the property of strict quasi-concavity.

**Definition:** $u$ is called strongly quasi-concave if

$$z' D^2 u(x) z < 0 \text{ for all } x \in P, \ z \neq 0 \text{ and } z \in \{ z \in \mathbb{R}^l | 2Du(x) = 0 \}.$$

Consider the bordered Hessian matrix

$$H(x) = \begin{bmatrix} D^2 u(x) & Du(x) \\ [Du(x)]' & 0 \end{bmatrix}.$$

Then $u$ is strongly quasi-concave whenever $u$ is strictly quasi-concave and $H(x)$ is non-singular. (For a proof, see Barten and Böhm, 1982)

The properties of strict and strong quasi-concavity are invariant under increasing $C^2$-transformations. For other results and consequences of differentiable utility functions the reader may consult Barten and Böhm (1982) and the references listed there, or Debreu (1972), Mas-Colell (1974).

**Differentiable demand**

The earlier section on continuous demand without transitivity provides sufficient conditions on preferences for the existence of a continuous demand function which is homogeneous of degree zero in prices and wealth and satisfies the strong axiom of revealed preference. In this section, the implications of smooth preferences for differentiability of demand will be studied. Consider an assumption (D), consisting of the following three parts:

1. $u$ is strictly quasi-concave and $H(x)$ is non-singular.
2. The properties of strict and strong quasi-concavity are invariant under increasing $C^2$-transformations.
3. For other results and consequences of differentiable utility functions the reader may consult Barten and Böhm (1982) and the references listed there, or Debreu (1972), Mas-Colell (1974).
**D1** \( X = \mathbb{R}^n_+ \).

**D2** \( \preceq \) is a monotonic, strictly convex \( C^2 \)-preference order on \( X \) and the closure relative to \( \mathbb{R}^n_+ \times \mathbb{R}^n_+ \) of its indifference surface \( I \) is contained in \( P \times P \).

**D3** The price-wealth space is \( B = \mathbb{R}^{n+1}_+ \).

Given (D), there exists a demand function \( f : B \to X \) with \( p(f(p, w) = w \) for all \( (p, w) \in B \). Let \( \mu \) be an increasing strictly quasi-concave \( C^2 \)-utility representation for \( \preceq \). The following key result on the differentiability of demand was first given by Katzner (1968). For a detailed proof see Barten and Böhm (1982).

**Theorem:** Let \( (\bar{p}, \bar{w}) \in B \) and \( \bar{x} = f(\bar{p}, \bar{w}) \). Then the following assertions are equivalent:

1. (i) \( f \) is \( C^1 \) in a neighbourhood of \( (\bar{p}, \bar{w}) \).
2. (ii) \[
\begin{bmatrix}
D^2 u(\bar{x}) & \bar{p}'\\
\bar{p} & 0
\end{bmatrix}
\]
is non-singular.
3. (iii) \( H(\bar{x}) \) is non-singular.

Once the demand function \( f \) is continuously differentiable, it is straightforward to derive all of the well-known comparative statics properties, for the proof of which we refer again to Barten and Böhm (1982). Let \( f = (f^1, \ldots, f^l) \) be a demand function of class \( C^1 \) and define the respective partial derivatives

\[
\begin{align*}
\frac{\partial f}{\partial w} = \left( \frac{\partial f^1}{\partial w}, \ldots, \frac{\partial f^l}{\partial w} \right) \\
\frac{\partial f}{\partial p} = \left( \frac{\partial f^1}{\partial p}, \ldots, \frac{\partial f^l}{\partial p} \right) \\
\frac{\partial f}{\partial p} = \left( \frac{\partial f^i}{\partial w} f^i, \ldots, \frac{\partial f^i}{\partial w} f^i \right) \quad i, j = 1, \ldots, l.
\end{align*}
\]

From these we obtain the Jacobian matrix of \( f \) with respect to prices, \( J = (f^i_j) \), and the so-called Slutsky matrix \( S = (s^i_j) \).

**Theorem:**

1. (i) \( pf = 1, pf = -f \).
2. (ii) \( Sp' = 0 \).
3. (iii) \( S \) is symmetric.
4. (iv) \( ySy' < 0 \) if \( v \in \mathbb{R}^l, v \neq p \) for all \( \alpha \in \mathbb{R} \).
5. (v) \( \text{rank } S = l - 1 \).

Property (iv) implies that all diagonal elements of \( S \) are strictly negative: that is, \( s^i_j = f^i_j + f^i_w f^j_i < 0 \). If \( f^i_w > 0 \), commodity \( i \) is called a normal good which implies that \( f^i_j < 0 \); that is, demand is downward sloping in its own price. On the other hand, a negative income effect \( f^i_w < 0 \), that is, when commodity \( i \) is an inferior good, is a necessary, but not a sufficient condition for a positive own price effect \( f^i_j > 0 \), that is, for commodity \( i \) to be a Giffen good.
Duality approach to demand theory

With the notion of an expenditure function, an alternative approach to demand analysis is possible which was suggested by Samuelson (1947). For the further development and details, we refer to Diewert (1974; 1982).

As a matter of convenience and for ease of presentation, assumption (D) will be imposed on the preference relation $\succeq$. Let $u$ denote a strictly quasi-concave increasing $C^2$-utility representation for $\succeq$ and let $f: B \rightarrow X$ be the demand function derived from preference maximization. Let us further assume that $u(X) = \mathbb{R}$ (This requirement can always be fulfilled by means of an increasing transformation.) Define the indirect utility function $v: B \rightarrow \mathbb{R}$ associated with $u$ by $v(p,w) = u(f(p,w))$ for $(p,w) \in B$.

Given a price system $p \in \mathbb{R}^+_{++}$ and a utility level $c \in \mathbb{R}$, let $e(p,c) = \min \{ p \cdot x | x \in X, u(x) \geq c \}$. Since $u$ is strictly quasi-concave and increasing, there exists a unique minimizer $h(p,c)$ of this problem such that $e(p,c) = ph(p,c)$. $h: \mathbb{R}^+_{++} \times \mathbb{R} \rightarrow \mathbb{R}^+_{++}$ is called the Hicksian (income-compensated) demand function and $e: \mathbb{R}^+_{++} \times \mathbb{R} \rightarrow \mathbb{R}^+_{++}$ is called the expenditure function for $u$. Since assumption (D) holds, preference maximization and expenditure minimization imply the following properties and relationships:

1. (i) $c = v[p,e(p,c)]$ for all $(p,c)$.
2. (ii) $w = e[p,v(p,w)]$ for all $(p,w)$.
3. (iii) $v(p, \cdot)$ and $e(p, \cdot)$ are inverse functions for any $p$.
4. (iv) $h(p,c) = f[p, e(p,c)]$ for all $(p,c)$.
5. (v) $f(p,w) = h[p,v(p,w)]$ for all $(p,w)$.
6. (vi) $e$ is strictly increasing and continuous in $c$.
7. (vii) $e$ is non-decreasing, positive linear homogeneous, and concave in prices.
8. (viii) $v$ is strictly increasing in $w$, and continuous.
9. (ix) $v$ is non-increasing in prices and homogeneous of degree zero in income and prices.

Moreover, some interesting and important consequences of these properties can be obtained if the functions are sufficiently differentiable.

**Theorem:**

1. (i) $e$ is $C^k$ if and only if $v$ is $C^k$. ($k = 1, 2$).
2. (ii) If $e$ is $C^1$, then $\partial e / \partial p = h$.
3. (iii) If $f$ is $C^1$, then $v$ is $C^2$.
4. (iv) $f = - (\partial v / \partial p) / (\partial v / \partial w)$ (Roy’s identity).
5. (v) $h$ is $C^1$ and $e$ is $C^2$.
6. (vi) $\partial h / \partial p = S$ (Slutsky equation) with $\partial h / \partial p$ evaluated at $[p,v(p,w)]$ and $S$ evaluated at $(p,w)$.

**Integrability:**

A review of the previous discussions and analytical results involving the concepts of

- $\succeq$ preference
- $u$ utility
- $h$ income-compensated demand function
- $e$ expenditure function
- $v$ indirect utility
- $f$ (direct) demand function

makes apparent their relationships which can be characterized schematically by the following diagram:
where \( a \rightarrow b \) indicates that concept \( b \) can be derived from concept \( a \) under certain conditions. The integrability problem is to establish \( f \rightarrow u \): that is, to recover the utility function from...
Two recent developments

Advanced microeconomic theory assumes a distribution of consumer characteristics to determine mean demand of a consumption sector. In accordance with traditional demand theory, the primitive characteristics of a consumer are his preference relation $\succeq$ and his wealth $w$, and possibly his consumption set $X$. If we disregard the latter, the corresponding distribution of consumer characteristics is a preference–wealth distribution (see Hildenbrand, 1974). This approach lends itself to both positive and normative analysis. In contrast, Hildenbrand (1994) and others adopt a purely positive point of view and take pairs $(f, w)$ as the primitive concepts, where $f$ is a demand function not necessarily derived from preference maximization of ‘rational’ consumers.

Like traditional demand theory, most of theoretical and empirical economics has not distinguished between households and individual consumers. Chiappori (1988; 1992) and others have developed models of collective rationality of multi-person households where each member has his or her own preferences.

demand-pull inflation

George L. Perry

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The term ‘demand-pull inflation’ originated with the Keynesian macroeconomic model and was used to contrast price increases arising from excess demand with those arising from shocks to aggregate supply. Phillips curve models were initially amended by natural rate models and by models that appended rational expectations and flexible wages and prices to natural rate models. It is now recognized that the response of inflation and unemployment to shifts in aggregate demand itself depends on the inflation environment, and moderate inflation is the desired environment. Stabilization policy continues to distinguish between supply shocks affecting prices and the effects of aggregate demand.

Keywords

Article

The term ‘demand-pull’ inflation originated with the simple Keynesian model of the macroeconomy and was used as a contrast to price increases arising from shocks to aggregate supply. In the Keynesian model, there is a well-defined level of potential GDP corresponding to full employment levels of employment and unemployment. Nominal wages are downwardly rigid, so that below full employment aggregate supply increases with prices while aggregate demand decreases. The difference between potential and actual GDP is the output gap, and there is an asymmetry in the economy's response to shifts in demand when output gaps are positive and when they are not. With a positive gap – that is,
the operating region below full employment – an expansion of aggregate demand mainly raises employment and output and only moderately raises prices. But at full employment the aggregate supply curve is vertical, and an expansion of demand only pulls up wages and prices. Hence the term ‘demand-pull inflation’.

Macro models of fluctuations have evolved in important ways from this simple Keynesian case. The early empirical Phillips curves described an empirical relation between the level of unemployment and rates of change, rather than levels, of prices. Such relations were estimated from periods characterized by frequent cycles in activity. They did not control for expected or ongoing rates of inflation, so did not directly address the consequences of maintaining real aggregate demand at levels that raised prices. James Tobin (1972), among others, reasoned that the average wage and price increases associated with approaching full employment in the empirical Phillips curves came from the operation of a heterogeneous labour market in which demand constantly shifted among sectors. In his model, the short-run inflation that was observed in the typical cyclical episode reflected wage and price changes that reduced wasteful search unemployment, rather than a misguided attempt to sustain employment above the full employment level.

The first important departure came from theoretical models based on representative agents and firms that examined the consequences of permanently maintaining demand at levels that raised wages and prices in the short run. In the late 1960s Milton Friedman (1968) and Edmund Phelps (1969) independently formulated models of a natural rate of unemployment in which inflation fed back fully into wages and hence prices, so that an unemployment rate below the natural rate could be sustained only by ever-higher inflation rates. In effect, these accelerationist price models resurrected the vertical Keynesian supply curve at full employment for the long run, but allowed demand policies that raised the inflation rate in the short run to achieve lower levels of unemployment, but only temporarily. Since the higher employment associated with price increases could not be sustained, a corollary was that zero inflation was the appropriate target for policy. Tobin's model, with its heterogenous economy, denied that a natural rate identified by prices rising faster corresponded to full employment. However, the natural rate model became widely accepted as a theoretical construct, especially after the introduction of rational expectations models in which anticipation of faster or slower price increases would speed up the process of price acceleration or deceleration. Some theoretical models also assumed price and wage flexibility rather than stickiness. And some even rejected the idea that aggregate demand could leave the economy below full employment, modelling all cyclical variations in output and employment as shocks to aggregate supply. Modern neo-Keynesian models retain both the assumption of price and wage stickiness, which is supported by empirical research, and the implication that output can depart from its potential level. But they attach a more central role to expectations than do early Keynesian models.

All these models share the original idea of demand-pull inflation in that inflation arises when aggregate demand is excessive. They differ in their description of how the process works out over different time horizons and empirically in how the region of excess demand can be identified for informing forecasters and policymakers. Empirical implementation of rational expectations models continues to be elusive, and most empirical work has used adaptive expectations with accelerationist models to estimate the natural rate and the level of potential output. These estimates proved to be unreliable in the 1990s when economic expansion steadily reduced unemployment rates well below those predicted to cause accelerating inflation in those models. Some recent research has supported the idea that a modest rate of inflation, rather than complete price stability, is necessary to maintain the fullest utilization of resources.
This can be so for a variety of reasons. With downward wage rigidity, price stability will keep real wages above their efficient level in a noticeable fraction of firms. Moderate inflation will minimize this problem, permitting the economy to achieve optimal employment (Akerlof, Dickens and Perry, 1996). Furthermore, very low inflation rates will be ignored by many economic agents, leading firms to sustain output and employment at levels above those of a full expectational equilibrium (Akerlof, Dickens and Perry, 2000). And on the demand side, with very low or zero inflation, the zero floor on nominal interest rates may prevent monetary policy from getting real interest rates low enough to achieve full employment. The experience of Japan after its financial bubble burst is an example (Krugman, 1998).

Originally, the explicit modelling of demand-pull inflation was important because of the distinction it drew between price increases arising from excess demand and price increases originating in shifts up in the aggregate supply schedule, also referred to as cost-push. The sharp increases in wage costs that occurred in the heyday of union strength in industrialized economies are important historical examples of shifts in aggregate supply schedules. In the 1960s and 1970s, the experience with such cost-push shocks motivated the attempts to impose wage-price guideposts in the United States, and similar incomes policies in the United Kingdom and elsewhere. Such incomes policies were seen as a way to contain excessive wage and price increases that arose when the economy was operating below its full employment level.

Although there has been no recent interest in incomes policies, the distinction between price increases originating in excess aggregate demand and those originating from shifts in important supply schedules continues to be a feature of policy deliberations and of empirical work today. Core inflation rates, which omit the impact effect of energy and food prices on aggregate price indices, are routinely reported in monthly statistical releases, reflecting a distinction most analysts find useful. Core inflation rates are seen as more likely to feed back into wage increases, and are a better indicator of demand-pull effects on prices. And policymakers regularly make allowances for the effect of supply shocks in considering their stabilization response to changes in reported inflation rates.

History provides examples of significant inflation in which excess demand or major supply shocks or both were important. In the United States, during the Second World War and the Korean War maximizing output was the paramount goal of government even though it meant expanding demand well beyond the normal full-employment point. The potential inflation generated by operating in this excess-demand region was moderated, if not completely suppressed, by rationing and price controls. Demand-pull inflation was also a feature of the industrial economies in the late 1960s, when US military spending was greatly enlarged and labour and product markets became tight for an extended period throughout the industrial world. An abrupt explosion of wage increases at the end of the 1960s and in the early 1970s in most industrialized countries suggests that cost-push contributed importantly to the inflation of that period. The rise in food prices in 1973 and the oil supply shocks of 1973 and 1979 added further to the ongoing inflation of that decade and doubtless contributed to an increase in inflationary expectations and to the response of unions and firms to those expectations.

It was particularly striking that inflation was so little affected by the very deep recessions of the mid-1970s in the advanced economies. That episode convinced most economists of the shortcomings of the simple short-run Phillips curve model, which predicted that inflation would slow cyclically in the mid-1970s. But it was also not consistent with flexible price accelerationist models which predict that prices and wages will fall when the economy is operating below its natural rate. It did support the pessimistic verdict that a well-established inflation can persist long after the initiating shocks have disappeared and...
long after a reduction of demand has eliminated any excess demand from the economy. The stabilization challenge confronting policymakers in that period was seen not merely as avoiding excess aggregate demand, but also as choosing how much to accommodate inflation in order to maintain real growth and how much to give up in output and employment in order to suppress inflation. After the second OPEC oil price shock in 1979, Paul Volcker was appointed Chairman of the US Federal Reserve and, under his leadership, the Fed chose to strongly suppress demand until inflation receded sharply. The lower inflation that ensued is consistent with the predictions of some conventional cyclical models. The severity of the policy used, as reflected in the record high interest rates it produced and the very deep recession that policymakers tolerated, can also be interpreted as evidence that policymakers can shape expectations and that doing so affects how promptly the inflation rate changes.

In the United States, the period that began in the 1990s was a sharp contrast to the 1970s in that inflation had been moderate for many years. As noted above, by the end of the decade the unemployment rate had fallen well below existing empirical estimates from natural-rate models. Yet inflation remained very low, both before the modest recession of the early 2000s and in the several years after it, even after a new oil price shock. Most European economies experienced similarly low inflation in this period. However, several suffered from chronically high rates of unemployment. While considerable controversy surrounds the reasons for this persistence of unemployment, some analysts believe inadequate aggregate demand over an extended period is partly to blame. There are several implications for stabilization policies aimed at avoiding inflation from all this experience: While empirical estimates from the 1970s suggested inflation was prone to quicken through a wage-price spiral, the recent period suggests no such tendency so long as inflation rates are modest (Brainard and Perry, 2000). Furthermore, the economy's potential output and the attainable unemployment rate – the thresholds of the demand-pull region of resource utilization – cannot be adequately estimated using typical accelerationist models.

Finally, the contrasting experiences across the United States and European economies show that policies targeting inflation alone are not sufficient to assure full employment.

democratic paradoxes

Norman Schofield
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Formal models of voting have emphasized the mean voter theorem, namely, that all parties should rationally adopt identical positions at the electoral mean. The lack of evidence for this assertion is a paradox which this article attempts to resolve by considering an electoral model that includes ‘valence’ or non-policy judgements by voters of party leaders. In a polity such as Israel, based on proportional electoral rule, low-valence parties would adopt positions far from the centre, making coalition formation unstable. In Britain, by contrast, a party with a low-valence leader would be subject to the demands of non-centrist activists.

Condorcet, Marquis de; democratic paradoxes; Downs, A.; Hotelling, H.; local Nash equilibrium; Madison, J.; median voter theorem; mixed strategy Nash equilibrium; plurality electoral rule; political competition; proportional representation; pure strategy Nash equilibrium; valence; vote maximizing strategies; voting

Article

Models of elections tend to give two quite contradictory predictions about the result of political competition. In two-party competition, if the ‘policy space’ involves two or more independent issues, then ‘pure strategy Nash equilibria’ generally do not exist and instability or chaos may occur (see Plott, 1967; McKelvey, 1976; 1979; Schofield, 1978; 1983; 1985; McKelvey and Schofield, 1986; 1987; Saari, 1997; Austen-Smith and Banks, 1999). That is to say, whatever position is picked by one party, there always exists another policy point which will give the second party a majority over the other. Moreover, vote maximizing strategies could lead political candidates to wander all over the policy space. On the other hand, the earlier electoral models based on the work of Hotelling (1929) and Downs (1957) suggest that parties will converge to an electoral centre (at the electoral median) when the policy space has a single dimension. (An equilibrium can also be guaranteed as long as the decision rule requires a sufficiently large majority – Schofield, 1984; Strnad, 1985; Caplin and Nalebuff, 1988 – or when the electoral distribution has a certain concavity property – Caplin and Nalebuff, 1991.) Although a pure strategy Nash equilibrium generically fails to exist in competition between two agents under majority rule in high enough dimension, there will exist mixed strategy Nash equilibria (Kramer, 1978) whose support lies within a subset of the policy space known as the ‘uncovered set’ (see McKelvey, 1986; Banks, Duggan and Le Breton, 2002). These various and contrasting theoretical results can be seen as a paradox: will democracy tend to generate centrist compromises, or can it lead to chaos? This question is of fundamental importance in a world in which many countries are experimenting with democracy for the first time.

Partly as a result of these theoretical difficulties with the ‘deterministic’ electoral model, and also because of the need to develop empirical models of voter choice (Poole and Rosenthal, 1984), attention has focused on ‘stochastic’ vote models. A formal basis for such models is provided by the notion of ‘quantal response equilibria’ (McKelvey and Palfrey, 1995). In such models, the behaviour of each voter is modelled by a vector of choice probabilities (Lin, Enelow and Dorussen, 1999). A standard result in this class of models is that all parties converge to the electoral origin when the parties are motivated to maximize vote share or plurality (in the two-party case) (see McKelvey and Patty, 2006; Banks and Duggan, 2005). The predictions concerning convergence are at odds with empirical evidence that parties appear to diverge from the electoral centre (Merrill and Grofman, 1999; Adams, 2001; Schofield and Sened, 2006).
The paradox that actual political systems display neither chaos nor convergence is the subject of this article. The key idea is that the convergence result need not hold if there is an asymmetry in the electoral perception of the ‘quality’ of party leaders (Stokes, 1992). The average weight given to the perceived quality of the leader of the $j$th party is called the party’s ‘valence’. In empirical models this valence is independent of the party’s position, and adds to the statistical significance of the model. In general, valence reflects the overall degree to which the party is perceived to have shown itself able to govern effectively in the past, or is likely to be able to govern well in the future (Penn, 2003). The early empirical model of US presidential elections by Poole and Rosenthal (1984) included these valence terms. The authors noted that there was no evidence of candidate convergence.

Formal models of elections incorporating valence have been developed (Ansolabehere and Snyder, 2000; Groseclose, 2001; Aragones and Palfrey, 2002), but the theoretical results to date have been somewhat inconclusive. Extension to the multiparty case is of interest because of recent empirical models of voting in the Netherlands and Germany (Schofield et al., 1998; Quinn, Martin, and Whitford, 1999; Quinn, and Martin, 2002), Britain (Schofield, 2005a; 2005b), Israel (Schofield, Sened and Nixon, 1998; Schofield and Sened, 2002; 2005; 2006) and Italy (Giannetti and Sened, 2004). All these empirical models have suggested that divergence is generic. Most of these empirical models have been based on the ‘monomial logit’ assumption that the stochastic errors had a ‘Type I extreme value distribution’ (Dow and Endersby, 2004).

Schofield (2007) provides a ‘classification theorem’ for the formal vote model based on the same stochastic distribution assumption. The ‘policy space’ is assumed to be of dimension $w$, and there is an arbitrary number, $p$, of parties. The party leaders exhibit differing valence. A ‘convergence coefficient’ incorporating all the parameters of the model can be defined. Instead of using the notion of a Nash equilibrium, the result is given in terms of the existence of a ‘local Nash equilibrium’. It is shown that there are necessary and sufficient conditions for the existence of a ‘pure strategy vote maximizing local Nash equilibrium’ (LNE) at the mean of the voter distribution. When the necessary condition fails, then parties, in equilibrium, will adopt divergent positions. In general, parties whose leaders have the lowest valence will take up positions furthest from the electoral mean. Moreover, because a pure strategy Nash equilibrium (PNE) must be a local equilibrium, the failure of existence of the LNE at the electoral mean implies non-existence of such a centrist PNE. The failure of the necessary condition for convergence has a simple explanation: if the variance of the electoral distribution is sufficiently large in contrast to the expected vote share of the lowest-valence party at the electoral mean, then this party has an incentive to move away from the origin towards the electoral periphery. Other low-valence parties will follow suit, and the local equilibrium will result with parties distributed along a ‘principal electoral axis’.

An empirical study of voter behaviour for Israel for the election of 1996 (based on Schofield and Sened, 2005) is used to show that the necessary condition for party convergence failed for this election. The equilibrium positions obtained from the formal result, under vote maximization, are in general comparable with, but not identical to, the estimated positions. The two highest-valence parties (Labour and Likud) were symmetrically located on either side of the electoral origin, while the lowest-valence parties were located far from the origin. In such a polity, based on a proportional electoral system, it is generally necessary to form coalition governments. The existence of small, low-valence, radical parties on the electoral periphery may create serious difficulties in the formation of majority government. It is possibly for this reason that Ariel Sharon, formerly leader of Likud, and Shimon Peres, formerly leader of Labour, in 2005 formed Kadima, a new centrist party.

This article also presents results from analysis of the 1997 election in Britain (Schofield, 2005a; 2005b). In this case the empirical estimates of the parameters of the model, taken together with the formal analysis, suggest that convergence should have occurred. Instead the Conservative Party was estimated to be at a position far from the electoral centre. It is suggested that the discrepancy between the formal and the empirical models can be accommodated by considering the effect of activists on the optimal party position. Since concerned activists will raise funds for the party, but only if the party adopts a policy position that accords with activists’ concerns, there is a tension between activist demands and the electoral concerns of the party leadership. The model based on activist support estimates the marginal trade-off generated by opposed activist groups within a party. It is suggested that the low valence of recent Conservative leaders obliged them to seek support from activists supporting British sovereignty against the European Union, and thus to take up radical positions on the second, ‘European’ axis.

In contrast, the apparent move by the Labour Party towards the electoral centre between 1992 and 1997 was a consequence of the increase of the electoral valence of Tony Blair, the leader of the party, rather than a cause of this increase.

Recent work by Miller and Schofield (2003) using this model suggests that, in the United States, the movement of presidential candidates in a two-dimensional policy space generated by economic and social dimensions is the result of contending and opposed activist groups.

The underlying premise of the notion of the local Nash equilibrium, used in these models, is that party leaders will not consider ‘global’ changes in party policies, but will instead propose small changes in the party position in response to changes in beliefs about electoral response. These models regard elections as the aggregation of both electoral evaluation or ‘valence’ and electoral preferences. Valence can be regarded as that element of a voter’s choice which is determined by judgement rather than preference. This accords well with the arguments of James Madison in *Federalist 10* of 1787 (Rakove, 1999) and of Condorcet (1785) in his treatise on social choice theory. Schofield (2005c; 2006) provides a discussion of the relevance of these valence models for the constitutional basis of the US polity.

Empirical analysis for Israel

Figure 1 shows the estimated positions of the parties at the time of the 1996 Israeli election. Figure 1 also gives the estimated distribution of voter ideal points for the 1996 election,
based on a factor analysis of the survey responses derived from the survey of Arian and Shamir (1999). The two dimensions of policy deal with attitudes to the Palestine Liberation Organization (PLO) (the horizontal axis) and religion (the vertical). The party positions were obtained from analysis of party manifestos (Schofield, Sened and Nixon, 1998; Schofield and Sened 2005; 2006). With the use of information on the individual voter intentions, it is possible to construct a multinomial logit model (based on the Type I extreme value distribution).

Figure 1
Voter distribution and estimated party positions in the Knesset at the 1996 election
The model assumes that the voter utility vector has the form \( u_i(x, z) = (u_{i1}(x_i, z_1), \ldots, u_{ip}(x_i, z_p)) \), where

\[
\begin{align*}
  u_{ij}(x_i, z_j) &= u_{ij}^*(x_i, z_j) + \varepsilon_j \\
  \text{and } u_{ij}^*(x_i, z_j) &= \lambda_j - \beta \|x_i - z_j\|^2.
\end{align*}
\]

Here the position of voter \( i \) is \( x_i \) while the position of party \( j \) is \( z_j \). The term \( \|x_i - z_j\| \) is the distance between these two points. The valences of the \( p \) parties are given by the vector \( \lambda = (\lambda_p, \lambda_{p-1}, \ldots, \lambda_2, \lambda_1) \) and are ranked

\[
\lambda_p \geq \lambda_{p-1} \geq \ldots \geq \lambda_2 \geq \lambda_1.
\]

The error terms \( \{\varepsilon_j\} \) have the Type I extreme value distribution, \( \Psi \).

(The cumulative distribution, \( \Psi \), takes the closed form \( \Psi(\eta) = \exp[-\exp(-\eta)] \).)

The probability that a voter \( i \) chooses party \( j \) is

\[
\rho_{ij}(z) = \Pr\{u_{ij}(x_i, z_j) > u_{il}(x_i, z_l)\}, \text{ for all } l \neq j.
\]
Here Pr stands for the probability operator associated with $\Psi$. The expected vote share of agent $j$ is

$$V_j(z) = \frac{1}{n} \sum_{i \in N} \rho_i(z).$$

This model is denoted $M(\lambda, \beta, \Psi)$. A local pure strategy Nash equilibrium (LNE) is simply a vector $z = (z_1, \ldots, z_p)$ of party positions with the property that each $z_j$ locally maximizes $V_j(z)$, taking the other party positions $A$ necessary condition for $z^* = (0, \ldots, 0)$ to be pure strategy Nash equilibrium (PNE) is that it be a LNE and thus that all Hessians have eigenvalues at $z^*$ that are non-positive. This can be expressed as a single necessary condition on a ‘convergence coefficient’ defined terms of the Hessian of the vote share function of the party with the lowest valence (Schofield, 2006b). Since the lowest-valence party is the National Religious Party (NRP) (for the 1996 model for Israel), a necessary condition for the NRP vote share to be maximized at the origin is that both eigenvalues of this Hessian be non-positive. However, the calculation given below shows that that one of the eigenvalues was positive. It follows that the NRP position that maximizes its vote share is not at the origin. Thus the convergent position $(0, \ldots, 0)$ cannot be a Nash equilibrium to the vote maximizing game.

Indeed it is obvious that there is a principal component of the electoral distribution, and this axis is the eigenspace of the positive eigenvalue. It follows that low-valence parties should then position themselves on this eigenspace, as illustrated in the simulation given in Figure 2.

**Figure 2**
To present the calculation, we use the fact that the valence of the NRP was \(-4.52\). The spatial coefficient is \(\delta = 1.12\). Because the valences of the major parties are 4.15 and 3.14, the formal analysis implies that, when all parties are at the origin, the vote share, \(\rho_{NRP}\), can be computed to be

\[
\rho_{NRP} \approx \frac{1}{1 + e^{4.15 + 4.52} + e^{3.14 + 4.52}} \approx 0.
\]

Moreover, the Hessian of the NRP at the origin depends on the electoral variance and this is
The eigenvalues of the NRP Hessian at the origin are 2.28 and -0.40, giving a saddle point. Thus, the origin cannot be a Nash equilibrium. The ‘convergence coefficient’ can be calculated to be 3.88, larger than the necessary upper bound of 2.0. The major eigenvector for the NRP is (1.0,0.8), and along this axis the NRP vote share function increases as the party moves away from the origin. The minor, perpendicular axis is given by the vector (-1.25) and on this axis the NRP vote share decreases. Figure 2 gives one of the local equilibria, obtained by simulation of the model. The figure makes it clear that the vote maximizing positions lie on the principal axis through the origin and the point (1.0, 0.8). In all, five different LNE were located. However, in all the equilibria the two high-valence parties, Labour and Likud, were located at precisely the same positions, as shown in Figure 2. The only difference between the various equilibria was that the positions of the low-valence parties were perturbations of each other.

Figure 2 suggests that the simulation was compatible with the predictions of the formal model based on the extreme value distribution. All parties were able to increase vote shares by moving away from the origin, along the principal axis, as determined by the large, positive principal eigenvalue. In particular, the simulation confirms the logic of the above analysis. Low-valence parties, such as NRP and Shas, in order to maximize vote shares must move far from the electoral centre. Their optimal positions will lie in either the north-east quadrant or the south-west quadrant. The vote maximizing model, without any additional information, cannot determine which way the low-valence parties should move. As noted above, the simulations of the empirical models found multiple LNE essentially differing only in permutations of the low-valence party positions.

In contrast, since the valence difference between Labour and Likud was relatively low, their optimal positions would be relatively close to, but not identical to, the electoral mean. The simulation for the elections of 1988 and 1992 are also compatible with this theoretical inference. Figure 2 also suggests that every party, in local equilibrium, should adopt a position that maintains a minimum distance from every other party. The formal analysis, as well as the simulation exercise, suggests that this minimum distance depends on the valences of the neighbouring parties. Intuitively it is clear that, once the low-valence parties vacate the origin, then high-valence parties like Likud and Labour will position themselves almost symmetrically about the origin, and along the major axis.

Comparison between Figure 1, of the estimated party positions, and Figure 2, of simulated equilibrium positions, reveals a notable disparity particularly in the position of Shas. In 1996 Shas was pivotal between Labour and Likud, in the sense that, to form a winning coalition government, either of the two larger parties required the support of Shas. It is obvious that the location of Shas in Figure 1 suggests that it was able to bargain effectively over policy and, presumably, perquisites. Indeed, it is plausible that the leader of Shas was aware of this situation, and incorporated this awareness in the utility function of the party.

The only difference between the various equilibria was that the positions of the low-valence parties were perturbations of each other. The figure makes it clear that the vote maximizing positions lie on the principal axis through the origin and the point (1.0, 0.8). In all, five different LNE were located. However, in all the equilibria the two high-valence parties, Labour and Likud, were located at precisely the same positions, as shown in Figure 2. The only difference between the various equilibria was that the positions of the low-valence parties were perturbations of each other.

Figure 2 suggests that the simulation was compatible with the predictions of the formal model based on the extreme value distribution. All parties were able to increase vote shares by moving away from the origin, along the principal axis, as determined by the large, positive principal eigenvalue. In particular, the simulation confirms the logic of the above analysis. Low-valence parties, such as NRP and Shas, in order to maximize vote shares must move far from the electoral centre. Their optimal positions will lie in either the north-east quadrant or the south-west quadrant. The vote maximizing model, without any additional information, cannot determine which way the low-valence parties should move. As noted above, the simulations of the empirical models found multiple LNE essentially differing only in permutations of the low-valence party positions.

In contrast, since the valence difference between Labour and Likud was relatively low, their optimal positions would be relatively close to, but not identical to, the electoral mean. The simulation for the elections of 1988 and 1992 are also compatible with this theoretical inference. Figure 2 also suggests that every party, in local equilibrium, should adopt a position that maintains a minimum distance from every other party. The formal analysis, as well as the simulation exercise, suggests that this minimum distance depends on the valences of the neighbouring parties. Intuitively it is clear that, once the low-valence parties vacate the origin, then high-valence parties like Likud and Labour will position themselves almost symmetrically about the origin, and along the major axis.

Comparison between Figure 1, of the estimated party positions, and Figure 2, of simulated equilibrium positions, reveals a notable disparity particularly in the position of Shas. In 1996 Shas was pivotal between Labour and Likud, in the sense that, to form a winning coalition government, either of the two larger parties required the support of Shas. It is obvious that the location of Shas in Figure 1 suggests that it was able to bargain effectively over policy and, presumably, perquisites. Indeed, it is plausible that the leader of Shas was aware of this situation, and incorporated this awareness in the utility function of the party.

The close correspondence between the simulated LNE based on the empirical analysis and the estimated actual political consuggests that the true utility function for each party j has the form $U_j(z) = V_j(z) + \delta_j(z)$, where $\delta_j(z)$ may depend on the beliefs of party leaders about the post-election coalition possibilities, as well as the effect of activist support for the party.

This hypothesis leads to the further hypothesis that, for the set of feasible strategy profiles in the Israel polity, $\delta_j(z)$ is ‘small’ relative to $V_j(z)$. A formal model to this effect could indicate that the LNE for $\{U_j\}$ would be close to the LNE for $\{V_j\}$. Note, however, that this perturbation of the party utility function causes parties to leave the main electoral axis. It is possibly for this reason that coalition politics in Israel has been very complex.

The Likud Party, under Ariel Sharon, was constrained by the religious parties in its governing coalition. This apparently caused Sharon to leave Likud to set up a new centrist party, Kadima (‘Forward’) with Shimon Peres, previously leader of Labour. The reason for this reconfiguration was the victory on 10 November 2005 of Amir Peretz over Peres for leadership of the Labour Party, and Peretz’s move to the left along the principal electoral axis.

Consistent with the model presented here, Sharon’s intention was to position Kadima very near the electoral centre on both dimensions, to take advantage of his high valence among the electorate. Sharon’s subsequent hospitalization had an adverse effect on the valence of Kadima, under its new leader, Ehud Olmert. Even so, in the election of 28 March 2006 Kadima took 29 seats, against 19 seats for Labour, and only 12 for Likud. One surprise was a new centrist pensioners’ party with 7 seats. Because Kadima with Labour and the other parties of the left had 70 seats, Olmert was able to put together a majority coalition on 28 April, including the Orthodox party Shas. As Figure 1 illustrates, Shas is centrist on the security dimension, indicating that this was the key issue of the election.

**Empirical analysis for Britain**

This section analyses the general election in Britain in 1997 in order to suggest how activists for the parties may influence party positioning. The analysis shows that the valence model as presented above cannot always explain divergence of party positions. For example, Figure 3 shows the estimated positions of the party leaders, based on a survey of party MPs in 1997 (Schofield, 2005a; 2005b). In addition to the Conservative Party, Labour Party, and Liberal Democrats, responses were obtained from Ulster Unionists, Scottish
Nationalists and Plaid Cymru (Welsh Nationalists). The axis is economic, the second pro or anti the European Union. The electoral model was estimated for the election in 1997, using only the economic dimension.

Figure 3
Estimated party positions in the British Parliament for a two-dimensional model. Notes: Highest-density contours of the voter sample distribution at the 95%, 75%, 50% and 10% levels. CONS: Conservative Party; LAB: Labour Party; LIB: Liberal Democrats; PC: Plaid Cymru (Welsh Nationalists); SNP: Scottish National Party; UU: Ulster Unionist Party. Source: MP survey data and a National Election Survey.
For this election, we \( \lambda_{\text{lib}} = (1.24, 0.97, 0.0, 0.5) \) so the probability \( \rho_{\text{lib}} \) that a voter chooses the Liberal Democrats is

\[
\rho_{\text{lib}} = \frac{e^{0.0}}{e^{0.7} + e^{1.24} + e^{0.97}} = 0.14.
\]

The Hessian for this party at the origin is \( C_{\text{lib}} = -0.28 \), which is compatible with a Nash equilibrium at the origin. Extending the model to two dimensions gives a Hessian

\[
C_{\text{lib}} = (0.72) \begin{pmatrix} 1.0 & 0 \\ 0 & 1.5 \end{pmatrix} - I = \begin{pmatrix} -0.28 & 0 \\ 0 & 0.8 \end{pmatrix}.
\]

According to the formal model, all parties should have converged to the origin on the first axis. Because the eigenvalue for the Liberal Democrats is positive on the second axis, we have an explanation for its position away from the origin on the Europe axis. However, there is no explanation for the location of the Conservative Party so far from the origin on both axes. Schofield (2005a; 2005b) adapts the activist model of Aldrich (1983a; 1983b) wherein the falling exogeneous valence of the Conservative Party leader increases the marginal importance of two opposed activist groups in the party: one group ‘pro-capital’ and one group ‘anti-Europe’, as in Figure 4.

Left

Right

Political cleavage line

Indifference curve
The optimal Conservative position will be determined by balancing the electoral effects of these two groups. The optimal position for this party will be one which is ‘closer’ to the locus of points that generates the greatest activist support. This locus is where the joint marginal activist pull is zero. This locus of points can be called the ‘activist contract curve’ for the Conservative Party.

Note that in Figure 4 the indifference curves of representative activists for the parties are described by ellipses. This is meant to indicate that preferences of different activists on the two dimensions may accord different saliences to the policy axes. The ‘activist contract curve’ given in the figure, for Labour, say, is the locus of points satisfying the first order. This curve represents the balance of power between Labour supporters more interested in economic issues (centred at L in the figure and those more interested in Europe (centred at E). The optimal positions for the two parties will be at appropriate positions that satisfy the optimality condition.

According to this model, a party’s optimal position will tend to be nearer to the electoral origin when the valence of the party leader is higher. In contrast, a party whose leader has low valence will be more influenced by activist groups, and will tend to adopt a position further from the electoral centre and nearer to the position preferred by the dominant activist group. This model has been applied to the US polity by Miller and Schofield (2003) and Schofield, Miller and Martin (2003).

Proportional representation and plurality rule

Most of the early work in formal political theory focused on two-party competition, and generally concluded that there would be strong centripetal electoral forces causing parties to converge to the electoral centre. The extension of this theory to the multiparty context, common in European polities, has proved very difficult because of the necessity of dealing with coalition governments (Riker, 1962). However, the symmetry conditions developed by McKelvey and Schofield (1987) showed that a large, centrally located party could dominate policy if it occupied what is known as a ‘core position’. Thus, in situations where there is a stable policy core there would be certainty over the post-election policy outcome of coalition negotiation (Laver and Schofield, 1998). Absent a policy core, the post-election outcome will be a lottery across various possible coalitions, all of which are associated with differing policy outcomes and cabinet allocations. Modelling this post-election ‘committee game’ can be done with cooperative game theoretical concepts (Banks and Duggan, 2000).

Although the non-cooperative stochastic electoral model presented here can give insight into the relationship between electoral preferences and beliefs (regarding the valences of party leaders), it is still incomplete. The evidence suggests that party leaders pay attention not only to electoral responses but also to the post-election coalition consequences of their choices of policy positions. Nonetheless, the combination of the electoral model and post-election bargaining theory (Schofield and Sened, 2002) suggests the following.

In a polity based on a proportional electoral rule, the high-valence parties will be attracted towards the electoral centre. However, if there are two such competing parties of similar valence neither will locate quite at the centre. There may be many low-valence parties, whose equilibrium, vote maximizing positions will be far from the electoral centre. In order to construct winning coalitions, one or other of the high-valence parties must bargain with more ‘radical’ low-valence parties, and this could induce a degree of coalitional instability. However, it is possible that a charismatic leader, such as Sharon in Israel, can adopt a centrist position and dominate politics by controlling the policy core.

In a polity based on a plurality electoral rule, the disproportionality between votes and seats may increase the importance of activist groups. A party with a relatively low-valence leader will be forced to depend on activist support. Consequently, the party will be obliged to move to a more radical position so to attract activist support. This may provide a reason why Britain’s Labour Party appeared to acquiesce to the demands of its left-wing supporters during the leadership of Michael Foot in 1980–3 and of Neil Kinnock in 1983–92. This led to Labour defeats in the elections between 1983 and 1992. Tony Blair became Labour leader following the death of John Smith in 1994 and his high valence allowed him to overcome union opposition and to craft the centrist ‘New Labour’ policies that led to Labour victories in the elections of 1997, 2001 and 2005.

Concluding remarks

To sum up, these models suggest how the democrat paradox can be resolved: convergence to an electoral centre is not a generic phenomenon, but can occur when a party leader is generally regarded by the electorate to be of superior quality or valence. Chaos does not occur in these models, though a degree of coalitional instability is possible under proportional
electoral rule when there is no highly regarded political leader at the policy core.

**How to cite this article**

The demographic transition refers to the fall of fertility and mortality from initially high to subsequent low levels and accompanying changes in the population. It began around 1800 with declining mortality in Europe, and is expected to be complete worldwide by 2100. In that time the global population will have risen tenfold, the ratio of elders to children will have risen by a factor of ten, longevity will have tripled, and fertility fallen from six births per woman to two. Individual and population ageing will pose many challenges, from life-cycle planning to the rising costs of health care and retirement.

Article

The demographic transition is the process whereby fertility and mortality move from initially high levels to subsequent low levels, with accompanying changes in the size, growth rate and age distribution of the population.

Before the start of the demographic transition, life was short, fertility was high, growth was slow, and the population was young. Declining mortality starts the typical transition, followed after a considerable lag by fertility decline (France and the United States were important exceptions to this ordering). This pattern of change causes growth rates first to accelerate and then to slow again, as population moves towards low fertility, long life and an old age structure.

The transition began around 1800 with declining mortality in Europe. It has now spread to all parts of the world and is projected to be completed by 2100. This global demographic transition has brought momentous changes, reshaping the economic and demographic life cycles of individuals and restructuring populations. Global population size increased by a factor of 6.5 between 1800 and 2000, and by 2100 will have risen by a factor of ten. There will then be 50 times as many elderly but only five times as many children: the ratio of elders to children will have risen by a factor of ten. The length of life, which has already more than doubled, will have tripled, while births per woman will have dropped from six to two. In 1800, women spent about 70 per cent of their adult years bearing and rearing young children, but that fraction has decreased in many parts of the world to only about 14 per cent due to lower fertility and longer life (Lee, 2003). These changes are sketched in Table 1.

Before the demographic transition

According to Thomas Malthus (1798), slow population growth in the pre-industrial past was no accident. Faster population growth would depress wages, causing fertility to fall and mortality to rise due to famine, war or disease. Thus, population size was held in equilibrium with the slowly growing economy. The need to establish a separate household at marriage kept mean age at first marriage high, averaging around 25 years for women, and overall fertility low, at four to five births per woman. Mortality was moderately high, with life expectancy between 25 and 35 years. Outside of Europe and its offshoots, fertility and mortality were higher in the pre-transitional period. In India in the late 19th century, life expectancy was in the low twenties, while fertility was six or seven births per woman (Bhat, 1989). In Taiwan, the picture was similar around 1900. In the 1950s and 1960s, fertility in the less developed countries (LDCs, see UNPD, 2005, for definition) was typically six or higher.

Declining mortality

The demographic transition began first in north-west Europe, where mortality started its secular decline around 1800. In many low-income countries, the decline in mortality began in the early 20th century and then accelerated dramatically after the Second World War. The first stage of mortality decline is due to reductions in contagious and infectious diseases. Starting with the development of smallpox vaccine in the late 18th century, preventive medicine played a role in mortality decline in Europe. Public health measures were important from the late 19th century, and some quarantine measures may have been effective in earlier centuries. Improved personal hygiene also helped as the germ theory of disease became more widely known and accepted. Improving nutrition was also important in the early phases of mortality decline. Famine mortality was reduced by improvements in storage and transportation that permitted integration of regional and international food markets. Secular increases in incomes led to improved nutrition in childhood and throughout life. Better-nourished populations with stronger organ systems were better able to resist disease.

Today, the high-income countries have already largely achieved the potential mortality reductions through control of contagious disease and improved nutrition. For them, further reduction in mortality must continue to come from reductions in chronic and degenerative diseases, notably heart disease and cancer (Riley, 2001).

Most LDCs did not begin the mortality transition until the 20th century but then made rapid gains. Between 1950–4 and 2000–4, life expectancy in LDCs has increased from 41.1 years to 63.4, with average gains of 0.45 years of life per calendar year. Such rapid rates of increase in low-income countries will surely taper off as mortality levels approach those of the more developed countries (MDCs), whose gains have been less than half as rapid at 0.19 years per year. There are notable exceptions to this generally favourable picture. In sub-Saharan Africa, life expectancy has been declining since the early 1980s, largely due to HIV/AIDS. In the southern African region, life expectancy dropped from 62 to 48 between the early 1990s and the early 2000s. On average, eastern European (including the former USSR) life expectancy is lower now than it was in the late 1960s (UNPD, 2005).

How far and how fast will mortality fall and life expectancy rise in the 21st century? Methods that extrapolate historical trends in mortality by age suggest greater longevity gains than MDC government actuaries typically project, but past official projections have under-predicted subsequent gains, particularly at the older ages. Some experts argue that we are approaching biological limits and that these historical trends cannot be expected to continue; they foresee an upper limit of 85 years for life expectancy. Others, impressed by advances in genetic and stem cell research, foresee much more rapid gains for the future than occurred in the past.

Fertility transition

Most economic theories of fertility start with the idea that couples wish to have some number of surviving children rather than a number of births per se. On this assumption, once potential parents recognize an exogenous increase in child survival, fertility should decline. However, mortality and fertility interact in complicated ways. For example, increased survival raises the return on post-birth investments in children, while some of the improvement in child survival is itself a response to parental decisions to invest more in the health and welfare of a smaller number of children. Nonetheless, it is very likely that mortality decline has exerted an important independent influence on fertility decline. Economic change also influences fertility by altering the costs and benefits of childbearing and rearing, which are time-intensive. Technological progress and increasing physical and human capital make labour more productive, raising the value of time in all activities and making children increasingly costly relative to consumption goods. Since women have had
primary responsibility for childbearing and rearing, variations in the productivity of women have been particularly important. For example, physical capital may substitute for human strength, reducing or eliminating the productivity differential between male and female labour, and thus raising the opportunity cost of children. Rising incomes have shifted consumption demand towards non-agricultural goods and services, for which educated labour is a more important input. A rise in the rate of return to education then leads to increased investments in education. Overall, these patterns have several effects: children become more expensive, their economic contributions are diminished by school time, and educated parents have higher value of time, which raises the opportunity costs of childrearing. Furthermore, parents with higher incomes choose to devote more resources to each child, and, since this raises the cost of each child, it also leads to fewer children. Developing markets and governments replace many economic functions of the traditional family and household, to which children contributed, further weakening the value of children.

The importance of contraceptive technology for fertility decline in the past and future is hotly debated, with many economists viewing it as of relatively little importance (Pritchett, 1994). The European fertility transition, for example, was achieved using coitus interruptus, a widely known traditional method requiring no modern technology. Between 1890 and 1920, fertility within marriage began to decline in most European provinces, with a median decline of about 40 per cent from 1870 to 1930 (Coale and Watkins, 1986). The fertility transition in the MDCs largely occurred before the Second World War. After the war, many of these countries experienced baby booms and busts, followed by the ‘second fertility transition’ as fertility fell far below replacement level, marriage rates fell, and increasing proportions of births occurred outside marriage. Many LDCs began the fertility transition in the mid-1960s, and these later transitions have typically been more rapid than earlier ones, with fertility reaching replacement level (around 2.1 births per woman) within 20 to 30 years after onset. Fertility transitions in East Asia have been particularly early and rapid, while those in South Asia and Latin America have been slower (Bulatao and Casterline, 2001). The transition in sub-Saharan Africa started from a higher initial level of fertility and began later. By now, almost all countries have begun the fertility transition (UNPD, 2005; Bulatao and Casterline, 2001).

Currently, 66 countries with 44 per cent of the world's population have fertility at or below replacement level. Of these, 43 are MDCs, but 23 are LDCs. Average fertility in the MDCs is 1.56 births per woman, and in many it has fallen below 1.3. Many LDCs, particularly in East Asia, also have fertility far below replacement. It is not yet clear whether fertility will fall farther, rebound towards replacement, or stay at current levels.

Age at first marriage and first birth are generally moving to older ages throughout the industrial world and much of the developing world as well. This depresses the total fertility rate, which is a synthetic cohort measure, by 10–40 per cent below the underlying completed fertilities of generations. When the average age of childbearing stops rising, the total fertility rate should increase to this underlying level.

Population growth

A steady state population growth rate for a hypothetical zero migration population can be associated with each level of fertility and life expectancy, as depicted in Figure 1.

Figure 1
Life expectancy and total fertility rate with population growth isoquants: past and projected trajectories for more, less, and least developed countries. Source: Bhat (1989); UNPD (2005); see Lee (2003) for further details.
demographic transition

The New Palgrave Dictionary of Economics

Figure 1 plots growth rate contours or isoquants. These differ from actual growth rates due to net migration and the transitory influence of age distribution. In this figure, a demographic transition begins as a move to the right, representing a gain in life expectancy with little change in fertility and therefore movement to a higher population growth contour. Next, a diagonal downward movement to the right reflects a simultaneous decline in fertility and mortality, recrossing contours towards lower rates of growth and perhaps going negative, as do the MDCs. Historical data are extended using UNPD (2005) data and projections, by development status.

India, shown separately, had higher initial fertility and mortality than Europe, as did the least developed countries relative to the LDCs in 1950, which in turn had far higher mortality and fertility than the MDCs in that year. In all cases, the initial path is horizontally to the right, indicating that mortality decline preceded fertility decline, causing accelerating population growth approaching three per cent for the LDCs and least developed countries. Europe briefly attains 1.5 per cent steady state population growth, but then fertility plunges, a decline picked up after 1950 by the group of LDCs, ending with population decline at 1 per cent annually (the actual European population growth rate is slightly higher than this...
hypothesized steady state one due to age distribution and immigration. All three groups are projected by the UN to approach the zero-growth contour by 2050. Historical and projected population growth rates, as opposed to hypothetical steady state ones, can be seen over a longer time period in Figure 2. Growth rates in the MDCs rose about a half of one percent above those in the LDCs in the century before 1950. But after the Second World War, population growth surged in the LDCs, with the growth rate peaking at 2.5 percent in the mid-1960s, then dropping rapidly. The population share of the MDCs is projected to drop from its current 20 percent to only 13 percent in 2050. Long-term United Nations projections suggest that global population growth will be close to zero by about 2100. The projection for the MDC population is nearly flat, with population decrease in Europe and Japan offset by population increase in the United States and other areas.

Figure 2
Figure 3 plots the changes in age distribution that accompany a classic demographic transition, using historical data from India from 1896 to 2000 (stars) and United Nations projections through 2050 (hollow circles). These data are superimposed on a stylized transition that was simulated with the use of mathematical functions for the trajectories of fertility and life expectancy. Simulated fertility starts close to six births per woman and ends at 2.1. Life expectancy starts at 24 years and ends at 80. Mortality decline starts in 1900, 50 years before the fertility decline begins in 1950. The Indian fertility transition is slower than that of East Asia but similar to that of Latin America.

Figure 3
Changing age distribution over a classic demographic transition: actual and projected dependency ratios for India and simulations, 1900–2100. Source: Actual India data for the period 1891–1901 to 1941–51 are taken from Bhat (1989). Other actual and projected data are taken from UNPD (2003). Note: Lines indicate a simulated demographic transition superimposed over actual (*) and projected (o) dependency ratios for India.
demographic transition: The New Palgrave Dictionary of Economics

The distinctive changes in the age distribution can be seen in the ‘dependency ratios’, which take either the younger or the older population and divide it by the working-age population. The initial mortality decline, while fertility remains high, raises the proportion of surviving children in the population, as reflected in the increasing child dependency ratios. Counter-intuitively, mortality decline initially makes populations younger rather than older in a phase which here lasts 70 years. Families find themselves with increasing

Note: Lines indicate a simulated demographic transition superimposed over actual (*) and projected (o) dependency ratios for India.

The distinctive changes in the age distribution can be seen in the ‘dependency ratios’, which take either the younger or the older population and divide it by the working-age population. The initial mortality decline, while fertility remains high, raises the proportion of surviving children in the population, as reflected in the increasing child dependency ratios. Counter-intuitively, mortality decline initially makes populations younger rather than older in a phase which here lasts 70 years. Families find themselves with increasing
numbers of surviving children, and both families and governments may struggle to achieve human capital investment goals for the unexpectedly high number of children. Next, as fertility declines, child dependency ratios decline and soon fall below their pre-transition levels. The working age population grows faster than the population as a whole, so the total dependency ratio declines. This second phase may last 40 or 50 years. Some analysts have warned that the rapidly growing labour force in this phase might cause rising unemployment and falling capital–labour ratios, while others have stressed the advantages of this phase, calling these a demographic gift or bonus. Figure 3 shows that in India the bonus occurs between 1970 and 2015, when the total dependency rate is declining. The decline in dependents per worker would by itself raise per capita income by 22 per cent, other things equal, adding 0.5 per cent per year to per capita income growth over the 45-year span.

In a third phase, increasing longevity leads to a rapid increase in the elderly population while low fertility slows the growth of the working age population. The old-age dependency ratio rises rapidly, as does the total dependency ratio. In India, population ageing will occur between 2015 and 2060. If the elderly are supported by transfers, either from their adult children or a public-sector pension system supported by current tax revenues, then the higher total dependency ratio means a greater burden on the working-age population. However, to the extent that the elderly prepare for their retirement by saving and accumulating assets earlier in their lives and then dissave in retirement, population ageing may cause lower aggregate saving rates, as life-cycle savings models and some empirical analyses suggest. But even with lower savings rates the capital–labour ratio may rise, since the labour force is growing more slowly. The net effect would then be to stimulate growth in labour productivity due to capital deepening.

At the end of the full transitional process, the total dependency ratio is back near its level before the transition began, but now child dependency is low and old-age dependency is high. Presumably mortality will continue to decline in the 21st century, and the process of individual and population ageing will continue. No country in the world has yet completed this phase of population ageing, since even the industrial countries are projected to age rapidly over the next three or four decades. In this sense, no country has yet completed its demographic transition.

Population ageing is due both to low fertility and to long life. Low fertility raises the ratio of elderly to working-age people, with no corresponding improvement in health to facilitate a prolongation of working years. For this reason, it imposes important resource costs on the population, regardless of institutional arrangements for old-age support. Lower total expenditures on children and increased capital per worker will offset these costs. By contrast, population ageing due to declining mortality is generally associated with increasing health and vitality of the elderly. Such ageing may put pressure on pension programmes that have rigid retirement ages, but this problem is a curable institutional one, since the ratio of healthy, vigorous years over the life cycle to frail or disabled years has not changed, and individuals can adjust by keeping the fractions of their adult life spent working and retired constant, for example.

Some consequences of the demographic transition

The three centuries of demographic transition from 1800 to 2100 will reshape the world's population in a number of ways. Population will rise from 1 billion in 1800 to 9.5 billion in 2100. The average length of life will increase by a factor of two or three, fertility will have declined by two-thirds, and the median age of the population will double from the low twenties to the low forties. The population of Europe will decline by ten per cent between 2005 and 2050, and its share of world population will have declined by two-thirds since 1950. But many other changes will also have been set in train in family structure, health, institutions for saving and supporting retirement, and even in international flows of people and capital.

At the level of families, as the number of children born declines sharply, childbearing becomes concentrated into only a few years of a woman's life; combined with greater longevity, this means that many more adult years are available for other activities. Parents with fewer children are able to invest more in each child, reflecting the quality–quantity trade-off, which may also be one of the reasons parents reduced their fertility.

The processes which lead to longer life also alter the health status of the surviving population. For the United States, it appears that years of healthy life are growing roughly as fast as total life expectancy. In other industrial populations the story is more mixed. Trends in health, vitality and disability are of enormous importance for human welfare. The economic pressures on pension programmes caused by the increasing proportion of elderly are exacerbated in the MDCs by dramatic declines in the age at retirement, which for US men fell from 74 in 1910 to 63 in 2000. Population ageing will also generate intense financial pressures on publicly funded systems for health care and for long-term care.

At the international level, the flow of people and capital across borders may offset these demographic pressures. As population growth has slowed or even turned negative in the MDCs, it is not surprising that international migration from Third World countries has accelerated. Net international migration to the MDCs experienced a roughly linear increase from near-zero in the early 1950s to around 2.6 million per year in the 1990s. Of course, these net numbers for large population aggregates conceal a great deal of offsetting international gross migration flows within and between regions (UNPD, 2005). For example, prior to 1970 Europe was a net sending region, but from 1970 to 2000 it received 18 million net immigrants. During the 1990s, repatriation of African refugees reversed the net flows from the least developed countries. But overall, while MDCs may seek to alleviate their population ageing through immigration, United Nations simulations indicate that the effect will be only modest, since immigrants also grow old, and their fertility converges to levels in the receiving country.

Might international flows of capital cushion the financial effects of population ageing? Population ageing may cause declining aggregate saving rates, but, with slowing labour force growth, capital–labour ratios will probably rise and profit rates fall, particularly if there is a move towards funded pensions. Capital flows from the MDCs into the LDCs might help
keep the rate of return on investments from falling, but the possibilities are limited by the much smaller size of Third World economies. Dramatic population ageing is the inevitable final stage of the global demographic transition, and it will bring serious economic and political challenges. Meeting these challenges will require flexible institutional structures, adjustments in life-cycle planning, and a willingness to pay for rising costs of health care and retirement.

Abstract

This survey of demographic conditions in ancient Greek and Roman history discusses life expectancy and causes of death, reproduction and fertility control, marriage practices and household structure, population size and its change over time, and the relationship between demographic and economic development.

Keywords

ancient world; birth rates; death rates; demographics; family; Greece; life expectancy; marriage; population; Rome

Article

Ancient demography covers the population history of early civilizations from the third millennium BCE to the seventh century CE. Due to the uneven distribution of relevant evidence, scholars have focused primarily on Middle Eastern, Greek and Roman populations. This survey deals primarily with the demography of the Greco-Roman world. Demographic conditions in antiquity are generally only dimly perceptible, and attempts to reconstruct them inevitably entail considerable uncertainty and conjecture. Information is provided by tombstone inscriptions, census documents on papyri, skeletal remains and literary accounts. Ancient birth and death rates were extremely high by modern standards. Mean life expectancy at birth is commonly estimated to have been around 20 to 30 years. The distribution of ages recorded in census returns from Roman Egypt is consistent with model life tables that posit a mean life expectancy at birth of 22 to 25 years. This estimate receives additional support from a variety of other data samples including funerary inscriptions from Roman North Africa, a Roman schedule used to calculate annuities known as ‘Ulpian's Life Table’, and the age structure of a few cemetery populations. Roman emperors who died of natural causes had a similarly low life expectancy. This suggests that socio-economic standing had little effect on longevity. Mortality regimes were highly localized and determined primarily...
by the prevalence of particular infectious diseases. In parts of the Roman empire, seasonal variation in mortality can sometimes be reconstructed with the help of dates of death reported in tombstone inscriptions. These seasonality patterns also allow inferences about the underlying disease environments. According to these datasets, seasonal spikes in adult death rates were much stronger than in the more recent past, suggesting that even the most resilient age groups were susceptible to fatal infections. The main causes of death can be inferred from ancient medical texts and literary sources. Gastro-intestinal diseases, malaria and tuberculosis were particularly important. Both malaria and leprosy expanded during the Greco-Roman period. Smallpox epidemics occurred, possibly in Athens in 430 BCE and probably throughout the Roman empire in the 160/180s CE. Plague spread from 540 to 750 CE in a pandemic that foreshadowed the medieval Black Death.

High levels of mortality required correspondingly high birth rates. The average woman surviving to menopause had to give birth to five or six children to ensure reproduction at replacement level. Birth rates within marriage were higher still: it has been calculated that in Roman Egypt, a woman who had been continuously married between menarche and menopause would on average have given birth eight or nine times. According to census records from the same region, 95 per cent of freeborn children were born to married parents. These documents also allow us to reconstruct the maternal age distribution of childbirths, which implies what is known as a ‘natural fertility’ regime in which fecundity was a direct function of a woman’s age, peaking around age 20 and gradually declining over time. Signs of stopping behavior – that is, the cessation of reproduction in response to family size or composition – are absent from these data.

At the same time, early and near-universal marriage for women and high birth rates went hand in hand with fertility control within marriage. Census returns from Roman Egypt indicate mean birth intervals of three to four years. Birth-spacing may have been achieved by prolonged breastfeeding or by other means. Ancient medical texts discuss a variety of putative contraceptives and abortifacients. More drastic intervention in the form of child exposure and infanticide was often socially condoned, although the actual scale of these practices remains unknown. The extent to which parents discriminated against female offspring is particularly controversial. While Greek and Roman sources sometimes refer to femalecide, and evidence of male-biased sex ratios has been taken to reflect this custom, we are usually unable to determine whether ‘missing’ females had been killed or exposed after birth or were merely omitted from written records.

Among Greeks and Romans, (serial) monogamy was the norm. Polygamous unions were largely confined to ruling and elite families in Middle Eastern societies. At the same time, sexual access to slave women facilitated resource polygyny even in formally monogamous settings. In ancient Greek culture, women often appear to have been married off in their mid-teens while men took wives considerably later, around the age of 30. Funerary inscriptions from the western half of the Roman empire point to typical marriage ages of about 20 years for women and 30 years for men. Roman aristocrats generally married at younger ages. For Roman Egypt, the census records reflect mean marriage ages of 17 or 18 years for women and 25 years for men. They also show that whereas almost all women had married by their late 20s, it was only by age 50 that most men had married at least once. This pattern of moderately early female and late male marriage resembles the so-called ‘Mediterranean marriage pattern’ which prevailed in the more recent past, suggesting a measure of long-term continuity in that region. Divorce could be initiated by both husbands and wives, and commonly lacked strong stigma. Remarriage was much more common for men than for women, especially after age 30: according to the Roman Egyptian
census returns, two-thirds of men but only one-third of women were still married at the age of 50. In the pre-Christian period, celibacy was not normally considered desirable. Marriages were mostly virilocal or neolocal. Bridal dowries were common but are best attested for elite circles. Slaves could not legally marry but were able to enter informal unions, primarily (but not only) with other slaves. Consanguineous unions were more widespread in the eastern Mediterranean, and especially in the Middle East, than in western Europe. Thus, first-cousin marriage occurred mostly in the East, and occasional half-sibling unions are known from the Greek world. Scholars still debate whether references to married couples of full siblings found in Roman Egyptian census documents reveal genuinely incestuous unions or record the unions of cousins who had legally become siblings through adoption. However, instances of brother–sister and parent–child marriage are credibly attested for ancient Middle Eastern rulers, and more generally for members of the Zoroastrian community in Mesopotamia and Iran.

The Greek and Latin languages lack specific terms for what we would call the nuclear family. Notions of family and household were more inclusive: next to parents and their offspring, the Greek oikos and the Roman familia or domus routinely encompassed co-resident kin and slaves. At the same time, Roman funerary inscriptions tend to privilege commemorative ties within the nuclear family, showing it to have been the principal locus of familial sentiment and obligation, of inheritance, and probably also of residence. More complex households were common in the eastern Mediterranean and the Middle East. In Roman Egypt, for example, the majority of the rural population belonged to households comprised of extended or multiple families. High death rates offset high fertility, thereby limiting family size, which averaged 4.3 in the same region.

Owing to unpredictable mortality and the desire to preserve male lineages, adoption of relatives appears to have been common. Partible inheritance rather than primogeniture was the norm. Daughters either received dowries as a substitute for an inheritance or inherited alongside their brothers. The social effects of high death rates undermined the formally patriarchal character of ancient households. A significant share of Greeks and Romans must have lost their fathers as minors and were assigned guardians, while many widows were unable to remarry. For these reasons, family units in which women and children were under the control of fathers and husbands were less common and more fragile than modern observers have often imagined.

Population numbers are very poorly known and continue to generate controversy. Statistical documents survive only from parts of Egypt, and literary references to population size are commonly vitiated by rhetorical stylization, ignorance or indifference. Archaeological data help to fill this gap but pose their own problems of interpretation. What we do know is that the Mediterranean regions and its hinterlands underwent significant population growth in the Greco-Roman period. In the Aegean, the collapse of late Bronze Age civilization around 1200 BCE coincided with strong demographic contraction. Population recovered from the early first millennium BCE onward and peaked in the classical period, in the fifth and fourth centuries BCE, when Greece may have been more densely populated than at any other time prior to the 20th century.

During this growth phase, Greek settlers established hundreds of colonies in Sicily, South Italy and the Black Sea littoral. By the fourth century BCE, up to 1,000 Greek city-states were inhabited by 7 million people or more. Most of these communities were very small. The conquests of Alexander the Great in the late fourth century BCE triggered Greek emigration to Egypt, Syria, Mesopotamia, Iran and Central Asia. Large-scale state formation under his successors led to the creation of capital cities in excess of
100,000 residents, most notably Alexandria in Egypt. Meanwhile, populations expanded farther west in Italy, where this process drove the conflicts that eventually resulted in Roman regional hegemony, and more generally in western Europe and the Maghreb. A series of Roman census tallies from the last three centuries BCE offers insight into demographic change on the Italian peninsula. Even so, the total size of its population cannot be established with precision: depending on different interpretations of the extant census counts, by the beginning of the Common Era Italy may have been inhabited by no more than 6 million people (including slaves) or by two or even three times as many. These uncertainties interfere with modern assessments of Roman economic performance.

For a variety of reasons, an estimate between the extreme ends of spectrum seems appropriate: with a peak population of perhaps 10 or 12 million people, Roman Italy may well have matched the population densities of the high medieval and early modern periods. The population of the Roman empire as a whole is necessarily even more difficult to ascertain: while a total of 60 to 80 million seems realistic, a higher figure cannot entirely be ruled out. Maybe 10 to 20 per cent of these individuals lived in some 2,000 cities. The capital city of Rome appears to have grown to a million residents, an urban population unparalleled in Europe prior to London around 1800. Starting in the late second century CE, epidemics reduced population numbers, although settlement densities remained high into late antiquity. Massive population losses finally accompanied the disintegration of the western half of the Roman empire in the fifth century CE and the onset of recurrent plague pandemics in the 540s CE.

Despite its overall paucity and numerous shortcomings, demographic information from the Greco-Roman world is of considerable relevance to our understanding of ancient economic history. Centuries of continuous population growth, first in the eastern Mediterranean and later farther west, highlight the scale and persistence of an economic expansion which was driven by the spread of farming, technological innovation and gains from trade. Concurrent urbanization reinforces our impression of dynamic economic development. In the long run, however, ancient economies resembled other premodern economies in their inability to overcome Malthusian pressures through ongoing technological innovation. As population continued to expand, per capita economic growth eventually abated, first in Greece and later in the western Mediterranean. Judging by a variety of archaeological proxies of economic performance, by the time exogenous shocks in the form of plague and invasions began to affect the Roman empire in the second and third centuries CE the economy had already ceased to grow in real terms.

There is no indication that the Greco-Roman economic-demographic expansion significantly improved health or longevity: accretions to the stock of knowledge proved insufficient to mitigate the impact of the main causes of death, and potential gains from infrastructural provisions (such as aqueducts) may well have been offset by the demographic burden of urbanization and rising population densities which increased exposure to infection. In a number of skeletal samples, average body height was smaller in the Roman period than both immediately before and after, which likewise speaks against the notion of improvements in physiological well-being. Moreover, widespread skeletal evidence of deficiency diseases points to pervasive morbidity which would have curtailed productivity. High death rates discourage investment in education and impede human capital formation. Correspondingly high fertility depresses female labour participation and the status of women. In this environment, sustainable economic growth, let alone a fertility transition, was not feasible.

Article

Edward Denison was a major contributor to the development of the US national income accounts and one of the originators of growth accounting. He received a Ph.D. in economics from Brown University in 1941. Denison's early career (1941–56) was spent in the national income division of the US Commerce Department where he worked with Milton Gilbert, George Jaszi, and Charles Schwartz to develop the national accounts of the United States. The United States had published estimates of national income and its components in 1934; and Richard Stone and others developed both expenditure and income-side estimates of GNP for the United Kingdom that were published in 1941. The US expenditure-side estimates were first published in 1942. Denison participated in a 1944 tripartite meeting with Canada, the United Kingdom, and the United States that worked to establish consensus on a set of concepts and methods for the national accounts. That meeting and subsequent work provided much of the basis for the standardized system of national accounts (SNA) that was adopted and expanded by the United Nations and the OECD. The United States did not initially adopt the SNA; but by 2000 it was following the SNA in all of its important respects. Denison moved to the Committee on Economic Development (CED) in 1956 where his research focused on identifying the sources of economic growth. In expanding the framework of growth accounting, Denison sought to go beyond a simple partitioning of economic growth into the contributions of the factor inputs and a residual of total factor production. He incorporated changes in the quality of the inputs, such as job skills, economies of scale, and other contributors to the residual, such as research and development. His initial analysis was published by the CED in 1962 as *The Sources of Economic Growth in the United States and the Alternatives Before Us*. A distinctive feature of his approach was the extent to which he anchored it in the basic accounting framework of the national accounts rather than
the concepts of neoclassical production theory employed a few years later by Jorgenson and Griliches (1967). This aspect made it easy for other researchers to duplicate his methodology within their own countries.

Denison moved to the Brookings Institution in 1963 and extended his analysis to international comparisons with publication of Why Growth Rates Differ (1967). Two important later contributions were How Japan's Economy Grew So Fast (with W.K. Chung, 1976) and Accounting for Slower Economic Growth: The United States in the 1970s (1979). In Accounting for Slower Growth, he explored a wide range of popular explanations for the productivity slowdown, including higher energy prices, government regulation, and reduced R&D expenditures, and argued that their effects were too small to account for the magnitude and persistence of the slowdown. He received the Distinguished Fellow Award of the American Economic Association in 1981.

Denison's exchanges with Jorgenson and Griliches (1967; 1972a), while centred around differences in their approaches to measuring the contributions to growth, served to highlight an ongoing debate about the relative importance of capital accumulation and total factor productivity gains. Denison's approach, by minimizing several aspects of the measurement of capital's contribution, tended to support the conventional wisdom of the time that TFP accounted for a substantial portion of growth. Jorgenson and Griliches were attempting to argue that careful measurement of the factor inputs could drastically shrink the residual contribution of TFP. Denison won out on the issue of the relative importance of TFP by pointing to some problems with Jorgenson–Griliches adjustment for variations in capacity utilization; but the longer-term value of the debate was in showing that their approaches were quite similar. In subsequent years, the Jorgenson–Griliches approach, with its anchor in production theory, has dominated the conceptual discussion. However, many of the empirical studies continue to follow Denison's careful use of national income accounts data.

dependency

José Gabriel Palma
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The focus of all ‘dependency’ analyses is the development of peripheral capitalism (or lack of it). One approach, begun by Baran, Sweezy and Frank, attempted to construct a theory of the practical impossibility of capitalist development in the periphery. A second emerged from the Structuralist School, especially Furtado, Pinto and Sunkel, and tried to reformulate the classical ECLAC analysis from the perspective of the obstacles to ‘national’ development. A third, initiated by Cardoso and Faletto, concentrated on studying ‘concrete situations of dependency’ – how the specific dynamic of different peripheral societies emerges from the interaction between their internal and external structures.

Article

Dependency theories emerged in Latin America in the early 1960s as a challenge to traditional Marxist and structuralist thinking regarding whether capitalist development in the periphery was both still viable (given the transformations of the world economy after the Second World War), and still necessary (as an unavoidable transition step towards socialism). There can be little doubt that the Cuban Revolution was a turning point in Marxist analysis of capitalist development in the periphery. The events in Cuba gave rise to a new approach, of which most of the ‘dependency analyses’ form part. This argued that capitalism had totally lost its historical ‘progressive’ role in the periphery (if it ever had one); that is, it was both no longer capable of developing the productive forces of backward societies, and (thus) no longer able to bring them closer towards
socialism. Consequently, this approach also argued against the politics of the popular fronts in the periphery and in favour of an immediate transition towards socialism.

Following traditional Marxist analysis, the pre-dependency, pre-Cuban Revolution approach saw capitalism as still historically progressive in the periphery; however, it argued that its key historical task – the ‘bourgeois-democratic’ revolution – was being inhibited by a new alliance between imperialist forces and the traditional oligarchies. The bourgeois-democratic revolution was the revolt of the emerging capitalist forces of production against the old pre-capitalist order. This revolution would be based on an alliance between the rising bourgeoisie and other progressive forces of society; the principal battle line would be between the new capitalist elites and the traditional oligarchies – between industry and land, capitalism versus pre-capitalist forms of monopoly and privilege. Because it would be the result of the pressure of a rising class whose path was being blocked in political, economic and social terms, this revolution would bring to the periphery (as it had done in the centre) not only political emancipation but economic progress as well.

One of the main analytical challenges facing the pre-dependency Marxist analysis was to explain why the ‘bourgeois–democratic’ revolution in the periphery was not really happening as expected (a phenomenon that was seriously hindering the process of capitalist development there). Since Lenin, this analysis had identified imperialism as the unmistakable main obstacle facing this revolution. The traditional oligarchies could not be the reason for this as on their own, they were not expected to prove any match for the new emerging capitalist classes. Therefore, the principal target in this struggle was unmistakable: North American imperialism. The allied camp for this fight, by the same reasoning, was also clear: everyone, except those (pre-capitalist) internal groups allied with imperialism. Thus, the anti-imperialist struggle was at the same time a struggle for domestic capitalist development and industrialization. The state and the ‘national’ bourgeoisie appeared as the potential leading agents for the development of the new capitalist economy, which in turn was viewed as a necessary stage towards socialism.

The Cuban Revolution questioned the very essence of this approach, insisting that the domestic bourgeoisies in the periphery no longer existed as a progressive social force but had become ‘lumpen’, ‘rent seekers’, incapable of rational accumulation and rational political activity, dilapidated by their consumerism, and blind to their ‘real’ long-term interests. It is within this framework, and with the explicit motive of developing theoretically and documenting historically this new approach that dependency analysis appeared on the scene. At the same time, both inside and outside the Economic Commission for Latin America (ECLAC), two other major Dependency Schools began to develop (see structuralism).

The general focus of all ‘dependency’ analyses is the development of peripheral capitalism (or, rather, the lack of it). More specifically, these studies attempted to analyse the obstacles to capitalist development in the periphery from the point of view of the new interplay between ‘internal’ and ‘external’ structures that had emerged after the Second World War. However, this interplay was analysed in several different ways.

With the necessary degree of simplification that every classification of intellectual tendencies entails, I distinguish between three major approaches – not mutually exclusive from the point of view of intellectual history – in ‘dependency’ analysis. First is the approach begun by Paul Baran, Paul Sweezy and Andre Gunder Frank; its essential characteristic is that it attempted to construct a comprehensive theory of the practical impossibility of capitalist development in the periphery. In these theories the
‘dependent’ character of peripheral economies is the crux on which the whole analysis of underdevelopment turns; that is, dependency is seen as causally linked to permanent capitalist underdevelopment.

The second approach is associated with the ECLAC Structuralist School, especially Celso Furtado, Aníbal Pinto and Osvaldo Sunkel. These writers sought to reformulate the classical ECLAC analysis of Latin American development from the perspective of a critique of the obstacles to ‘national’ development. This attempt at reformulation was not just process of adding new elements (mainly political and social) that were lacking in the original Prebisch–ECLAC analysis (see Prebisch, Raúl), but a thoroughgoing attempt to proceed beyond that analysis, adopting an increasingly different perspective. Finally, the third approach, started by Fernando Henrique Cardoso and Enso Faletto, attempted to distance itself from the first by deliberately avoiding the formulation of a mechanico-formal theory of dependency and underdevelopment – specifically, by trying to avoid a mechanico-formal theory of the inevitability of underdevelopment in the capitalist periphery based on its dependent character. In turn, it concentrated on the study of what have been called ‘concrete situations of dependency’; that is to say, the precise forms in which the different economies and polities of the periphery have been articulated with those of the advanced nations at different times, and how their specific dynamics have thus been generated.

The first approach: dependency as a formal theory of the inevitability of capitalist underdevelopment: on cutting a knot that could not be unravelled

There is no doubt that the ‘father’ of this approach was Baran. His principal contribution (1957) took up the approach of the Sixth Congress of the COMINTERN regarding the supposedly irresolvable nature of the contradictions between the economic and political needs of imperialism and those of the processes of political transformation, economic development and industrialization of the periphery.

To defend its interests, international monopoly capital would not only form alliances with pre-capitalist domestic oligarchies intended to block progressive capitalist transformations in the periphery, but its activities would also have the effect of distorting the process of capitalist development in these countries. As a result, international monopoly capital would have easy access to peripheral resources and finance, and the traditional élites in the periphery would be able to maintain their monopoly on power and their traditional (mostly predatory and rent-seeking) modes of surplus extraction. Within this context the possibilities for any form of dynamic economic growth in dependent countries were extremely limited or non-existent; the surplus they were able to generate (mainly from primary commodity export activities) was largely appropriated by foreign capital, or otherwise squandered by traditional elites. Therefore, long-term economic stagnation and underdevelopment was inevitable. The only way out was political. At a very premature stage, capitalism had become a fetter on the development of the productive forces in the periphery and, consequently, its historical role had already come to an early end. Baran developed his ideas influenced both by the Frankfurt School's general pessimism regarding the nature of capitalist development (see Jay, 1996) and by Sweezy's (1946) proposition that the rise of monopolies imparts to capitalism a tendency towards stagnation and decay (see monopoly capitalism).

He also followed the main growth paradigm of his time, the Harrod–Domar model, which held that the size of the investable surplus was the crucial determinant of growth (together with the efficiency with which it was used: the incremental capital–output ratio).
Starting out with Baran's analysis, Frank (1967) attempted to prove the thesis that the only political and economic solution to capitalist underdevelopment was a radical transformation of an immediately socialist character. For our purposes we may identify three levels of analysis in Frank's model of the 'development of underdevelopment'. In the first (arguing against ‘dualistic’ analyses), he attempted to demonstrate that the periphery had been incorporated and fully integrated into the world capitalist economy since the very early stages of colonial rule. In the second, he tried to show that such incorporation into the world capitalist economy had transformed the countries in question immediately into capitalist economies. Finally, in the third level, Frank attempted to prove that the integration of these supposedly capitalist economies into the world capitalist system was achieved through an interminable metropolis–satellite chain, through which the surplus generated at each stage was successfully siphoned off towards the centre. Therefore, for Frank the choice was clear: continue to endlessly underdevelop within capitalism, or socialist revolution.

In my opinion, the real value of Frank's analysis is his critique of the supposedly dual structure of peripheral societies. Frank argues convincingly that the different sectors of the economies in question are and have been, since very early in their colonial history, well integrated to the world economy. Moreover, he has correctly emphasised that this integration has not automatically brought about capitalist economic development, such as ‘optimistic’ models (derived from Adam Smith) would have predicted, in which increased international trade and the division of labour would inevitably bring about economic growth and prosperity. Nevertheless, Frank's error lies in his attempt to explain this phenomenon by using the same economic deterministic framework of the model he purports to transcend. In fact, he merely turns it upside-down: integration into the world economy cannot possibly bring about capitalism development in the periphery because the development of the industrialised centre necessarily requires the underdevelopment of the periphery. Frank's error is characteristic of the whole tradition of which he is part, including Baran (1957), Sweezy (1946), Amin (1970) and Wallerstein (1974; 1980) among the better known. In their analysis, there is always a priority of external over internal structures; in order to do this, they have to separate almost metaphysically the two sides of the opposition (the internal and the external), losing in the process the notion of movement through the dynamic of the contradictions between these two structures. The analysis which emerges is one typified by ‘antecedent causation and inert consequences’.

It is not surprising that this type of analysis leads Frank to develop a circular concept of capitalism. Although it is evident that capitalism is a system where production for profits via exchange predominates, the opposite is not necessarily true: the existence of production for profits in the market is not necessarily an indication of capitalist relationship of production. For Frank, this is a sufficient condition for the existence of capitalist forms of surplus extraction (and for the periphery to have been ‘capitalist’ since the beginning of colonial rule).

Although Frank did not go very far in his analysis of the world capitalist system as a whole, of its origins and its development, Amin (1970) and Wallerstein (1974; 1980) tackled this tremendous challenge. The central concerns of Frank's theory of the ‘development of underdevelopment’ are also addressed by dos Santos (1970), Marini, Caputo, Pizarro, Hinkelammert, and continued later on by many non-Latin American social scientists. The most thoroughgoing critiques of these theories of underdevelopment have come from Brenner (1977), Cardoso (1972), Kay (1989), Laclau (1971), Lall (1975), Palma (1978), and Warren (1980).
I would argue that the theories of dependency examined here are mistaken not only because they do not ‘fit the facts’, but also – and equally important – because their mechanico-formal nature renders them both static and ahistorical. Their analytical focus has not been directed to the understanding of how new forms of capitalist development in the periphery have been marked by a series of specific economic, political, and social contradictions, instead only to assert the claim that capitalism had lost, or never had, a historically progressive role in the periphery.

Now, if the argument is that the progressiveness of capitalism has manifested itself in the periphery differently from in advanced capitalist countries, or in diverse ways in the different branches of the peripheral economies, or that it has generated inequality at regional levels and in the distribution of income, and has been accompanied by such phenomena as unemployment, and has benefited the elite almost exclusively, or again that it has taken on a cyclical nature, then this argument does no more than affirm that the development of capitalism in the periphery has been characterized by its contradictory and exploitative nature. The specificity of capitalist development in the Third World stems precisely from the particular ways in which these contradictions have been manifested, the different ways in which many of these countries have faced and temporarily overcome them, the ways in which this process has created further contradictions, and so on. It is through this process that the specific dynamic of capitalist development in different peripheral countries has been generated.

Reading their political analysis, one is left with the impression that the whole question of what course the revolution should take in the periphery revolves solely around the problem of whether or not capitalist development is viable. In other words, their conclusion seems to be that, if one accepts that capitalist development is feasible on its own terms, one is automatically bound to adopt the political strategy of waiting for and/or facilitating such development until its full productive powers have been exhausted, and only then to seek to move towards socialism. As it is precisely this option that these writers wish to reject, they have been obliged to make in their work a forced march back towards a pure ideological position to deny any possibility of capitalist development in the periphery.

The second approach: dependency as a reformulation of the ECLAC analysis of Latin American development

Towards the end of the 1960s the analysis of ECLAC regarding Latin American development suffered a gradual decline due to several key factors (see Furtado, Celso). The apparently gloomy panorama of capitalist development in Latin America in the 1960s led to substantial ideological changes in many influential ECLAC thinkers, and it strengthened the convictions of the Marxist ‘dependency’ writers reviewed earlier. The former were faced with the problem of trying to explain the apparent failure of their structuralist policies, particularly concerning import-substituting industrialization (see structuralism). The latter felt vindicated in their view of the unfeasibility of any form of ‘dependent capitalist development’.

Finally, by making a basically ethical distinction between ‘economic growth’ and ‘economic development’, most of the research done within the perspective of this second approach followed two separate lines, one concerned with the obstacles to economic growth (and in particular to manufacturing), the other with the apparently perverse character taken by capitalist development. The fragility of this formulation lies in its inability to distinguish between a socialist critique of capitalism and the analysis of the actual obstacles to capitalist development in the periphery.
The third approach: dependency as a methodology for the analysis of ‘concrete situations of development’

In my critique of the dependency studies reviewed so far, I have described the fundamental elements of what I understand to be the third of the three approaches within the dependency school. This approach is primarily associated with the work of Cardoso and Faletto, dating from the completion of their 1967 book.

Briefly, this third approach to the analysis of dependency can be summarized as follows.

1. In common with the two other approaches to ‘dependency’ discussed already, this third approach sees the Latin American economies as an integral part of the world capitalist system, in the context of increasing internationalization of the system as a whole. It also argues that the central dynamic of that system lies outside the peripheral economies and that, therefore, the options which are open to them are limited (but not determined) by the development of the system at the centre. In this way the ‘particular’ is in some way conditioned by the ‘general’. Therefore, a basic element for the analysis of these societies is given by the understanding of the general determinants of the world capitalist system, which is itself rapidly changing. However, the theory of imperialism, which was originally developed to provide an understanding of the dynamics of that system, has had enormous difficulty in keeping up with the significant and decisive changes in the capitalist system since the death of Lenin. During this period, capitalism underwent substantial changes, and the theory failed to keep up with them properly. One widely recognized characteristic of the third approach to dependency has been its effort to incorporate these transformations. For example, this approach was quick to grasp that the rise of the multinational corporations after the Second World War progressively transformed centre–periphery relationships, as well as relationships between the countries of the centre. As foreign capital became increasingly directed towards manufacturing industry in the periphery, the struggle for industrialization, which was previously seen as an anti-imperialist struggle, in some cases increasingly become the goal of foreign capital itself. Thus dependency and industrialization ceased to be necessarily contradictory processes, and a path of ‘dependent development’ for important parts of the periphery became possible.

2. The third approach has not only accepted but has also tried to enrich the analysis of how developing societies are structured through unequal and antagonistic patterns of social organization, showing the social asymmetries, the exploitative character of social organization and its relationship with the socio-economic base. This approach has also given considerable importance to the particular aspects of each economy like the effect of the diversity of natural resources, geographic location and so on, thus also extending the analysis of the ‘internal determinants’ of the development of peripheral economies.

3. However, while these improvements are important, the most significant feature of this approach is that it attempts to go beyond the analysis these internal and external elements, and insists that from the premises so far outlined one arrives at only a partial, abstract and indeterminate characterization of the historical process in the periphery, which can only be overcome by understanding how the ‘general’ and the ‘specific’ determinants interact in particular and concrete situations. It is only by understanding the specificity of ‘movement’ in the peripheral societies as a dialectical unity of both these internal and external factors that one can explain the particularity of social, political and economic processes in these societies.

Only in this way can one explain how, for example, the same process of mercantile expansion could simultaneously produce systems of slave labour, systems based on other forms of exploitation of
indigenous populations, and incipient forms of wage labour. What is important is not simply to show that mercantile expansion was the basis of the transformation of most of the periphery, and even less to deduce mechanically that that process made these countries immediately capitalist. Rather, this approach emphasizes the specificity of history and seeks to avoid vague, abstract concepts by demonstrating how, throughout the history of backward nations, different sectors of local classes allied or clashed with foreign interests, organized different forms of the state, sustained distinct ideologies or tried to implement various policies or defined alternative strategies to cope with a constantly changing imperialist challenge.

The study of the dynamic of dependent societies as a dialectical unity of internal and external factors implies that the conditioning effect of each on the development of these societies can be separated only by undertaking a static (and metaphysical) analysis. Equally, if the internal dynamic of the dependent society is a particular aspect of the general dynamic of the capitalist system, it does not imply that the latter produces concrete effects in the former, but only that it finds concrete expression in that internal dynamic.

The system of ‘external domination’ reappears as an internal phenomenon through the social practices of local groups and classes, who share the interests and values of external forces. Other internal groups and forces oppose this domination, and in the concrete development of these contradictions the specific dynamic of the society is generated. It is not a case of seeing one part of the world capitalist system as ‘developing’ and another as ‘underdeveloping’, or of seeing imperialism and dependency as two sides of the same coin, with the underdeveloped or dependent world reduced to a passive role determined by the other.

There are, of course, elements within the capitalist system that affect all developing economies, but it is precisely the diversity within this unity that characterizes historical processes. Thus the analytical focus should be oriented towards the elaboration of concepts capable of explaining how the general trends in capitalist expansion are transformed into specific relationships between individuals, classes and states, how these specific relations in turn react upon the general trends of the capitalist system, how internal and external processes of political domination reflect one another, both in their compatibilities and their contradictions, how the economies and polities of peripheral countries are articulated with those of the centre, and how their specific dynamics are thus generated.

However, as is obvious, this third approach to the analysis of peripheral capitalism is not unique to ‘dependency’ studies and as such, in time, has superseded them.

deposit insurance

Stephen G. Cecchetti
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The purpose of deposit insurance is to ensure financial stability, as well as protect the interests of small investors. But with government guarantees in hand, bankers take excessive risks, driving up the chances of failure. Evidence suggests that these schemes increase rather than decrease the probability of financial crises. There is a good chance that deposit insurance does more harm than good. This article surveys the rationale for and history of deposit insurance, and discusses its consequences and possible alternatives.

Keywords

Article

People living in countries where bank deposits are insured would never question the wisdom of an explicit insurance scheme. The idea that their savings are protected by a government-backed guarantee is something they simply take for granted. Only some crazy economist would ask whether deposit insurance makes sense. Well, does it? Surprisingly, the evidence is that it may not. Deposit insurance, which is supposed to stabilize the financial system, may do more harm than good.

This article examines the nature of deposit insurance by answering the following series of questions: (a) What do financial intermediaries do that warrants government intervention? (b) What is the history of deposit insurance? (c) Does deposit insurance do what it is designed to do? And (d), are there any alternatives?

Financial intermediaries, banks, and bank runs
The term ‘financial intermediaries’ encompasses a large set of institutions that include depository institutions as well as insurance companies, securities firms and pension funds. The first of these – what we all call ‘banks’ – are both the most commonly known to individuals and provide the broadest array of services. They pool savings, accepting resources from a large number of small savers in order to provide large loans to borrowers; provide access to the payments system, so that individuals can make and receive payments; provide liquidity, allowing depositors to transform their financial assets into money quickly and easily at low cost; and diversify risk, giving even the smallest saver a mechanism for diversification.

To appreciate the importance of financial intermediaries, consider what it would be like without them. If banks didn't exist, all finance would be direct, with borrowers obtaining funds straight from the lenders. Such a system would be costly and ultimately ineffective. It would be so difficult and expensive for borrowers and lenders to find each other, and then to come to agreement over the terms of a loan, that it is unlikely there would be any transactions at all. And without a financial system to transfer funds from savers to investors, there would be no economic development. The world would be a very different place. Because of the services they provide, banks face a risk that other financial institutions (and industrial firms) do not. They are vulnerable to runs. Here's why. Banks issue liquid liabilities in the form of short-term demand deposits, and hold illiquid long-term assets, structured as securities and loans. The bank promises all its depositors that, if they want the entire balance of their checking account, they just have to come and ask. If a bank has insufficient funds to meet requests for withdrawal on demand, it will fail. Banks not only guarantee their depositors immediate cash on demand; they promise to satisfy depositors’ withdrawal requests on a first-come, first-served basis – what is called a ‘sequential service constraint’. This commitment has important implications. Suppose depositors begin to lose confidence in a bank's ability to meet their withdrawal requests. True or not, reports that a bank has become insolvent can spread fear that it will run out of cash and close its doors. Mindful of the bank's first-come, first-served policy, panicked depositors rush to convert their account balances into cash before other customers arrive. Such a bank run can cause a bank to fail. Importantly, if people believe that a bank is in trouble, that belief alone can make it so.

While banking system panics and financial crises can result from false rumours, they can also come about for more concrete reasons. Widespread downturns in economic activity drive down the value of loans and securities, so bank capital (the difference between assets and liabilities) falls. If things get bad enough, banks become insolvent and fail. A big economic downturn can put the entire financial system at risk. Gorton (1988) reports that significant contractions are associated with all seven of the severe financial panics in the United States that occurred between 1871 and 1914.

In a market-based economy, the opportunity to succeed is also an opportunity to fail. It would be natural to dismiss bank failures as analogous to the closing of an unpopular restaurant. But, while individual banks should be, and are, allowed to fail, the fact that banks are dependent on one another (in a way that restaurants are not) means that when one bank fails it puts others at risk. Banks are linked both on their balance sheets and in their customers’ minds. In recent years in the United States, inter-bank loans make up roughly four per cent of bank assets – an amount that represents almost half of bank capital. If one bank fails, it could put the system at risk. Information asymmetries are the reason that a depositor run on a single bank can turn into a bank panic that threatens the entire financial system. Most of us are not in a position to assess the quality of a bank's balance sheet. So, when rumours spread that a certain bank is in trouble, depositors everywhere begin to worry about their...
own banks’ financial condition. Concern about even one bank can create a panic that causes profitable banks to fail, leading to a complete collapse of a country's banking system. Bank failure is contagious. All of this leads to the following conclusions. Not only are individual banks fragile and vulnerable to runs, but the entire banking system is prone to panics. Contagion creates an externality that provides the economic justification for government intervention in the system.

Deposit insurance and the government safety net

Government officials intervene in the financial system both to protect small investors and to ensure financial stability. They do it with two related tools: the lender of last resort, where a central bank that can issue liabilities without limit provides loans to banks that are illiquid but not insolvent; and deposit insurance.

History reveals that the presence of a lender of last resort significantly reduces, but does not eliminate, bank panics. The series of three bank panics in the United States during the Great Depression of the 1930s, described in Friedman and Schwartz (1963), is one example of a failure of this sort. The Federal Reserve System was in place and had the capacity to operate as a lender, but did not.

The first national deposit insurance scheme was enacted by the US Congress in 1935 as a direct response to the bank panics in the 1930s. White (1995) sets out the history, noting that the debate was contentious, and that the stated purpose of deposit insurance was to stabilize the banking system. As surprising at it may seem from a modern perspective, investor protection per se was not the point. When one thinks about deposit insurance, it is important to keep in mind that no private fund can be large enough to withstand a system-wide panic. Only the fiscal authority (possibly combined with the central bank) has the necessary resources.

For decades the US system was nearly unique. In 1974 only 12 countries had explicit national deposit insurance systems. Explicit deposit insurance is a phenomenon of the last quarter of the 20th century, when it became a part of the generally accepted best-practice advice international organizations gave to developing countries. Demirgüç-Kunt and Kane (2002) report that by 1999 the number of countries with deposit insurance had risen to 71 (with the insurable limits ranging up to more than eight times a country's per capita GDP). Prior to this, most systems were implicit, whereby depositors would exert their substantial political influence to force fiscal authorities to supply unlimited deposit guarantees in the event of a bank failure. This is all somewhat surprising, given the obvious political appeal of any system that has no immediate budgetary outlay associated with it. What politician wouldn't want to make an apparently costless promise to protect the bank deposits of his or her constituents?

Does deposit insurance work?

In their classic theoretical treatment of deposit insurance, Diamond and Dybvig (1983) show that, if self-fulfilling depositor runs result from information asymmetries, then government-supplied insurance can improve social welfare. But at what cost?

Insurance changes people's behaviour. Protected depositors have no incentive to monitor their bankers’ behaviour. Knowing this, a bank's managers take on more risk than they would otherwise, since they get the benefit of risky bets that pay off while the government assumes the costs of the ones that don't.
protecting depositors, then, the government creates moral hazard. This is not just a theory. In 1980, the deposit insurance limit in the United States was raised to $100,000, four times its earlier level. Over the following ten years, several thousand depository institutions (banks and savings and loans) failed. That was more than four times the number that failed in the first 46 years of explicit deposit insurance. While a vast majority of the institutions that failed in the 1980s were small, the cost of reimbursing depositors exceeded 3 percent of one year's GDP. The bill was ultimately paid by US taxpayers.

The problem of excessive risk taking did not stop with the resolution of the 1980s crisis. Today, the US banking system's assets are worth between 10 and 12 times their equity. In the 1920s, this same leverage ratio was closer to four. Industrial firms typically have leverage that is half that lower number. In other words, deposit insurance has driven up leverage in banking. And with the increase in leverage comes an equal increase in risk (as measured by the standard deviation of returns).

So, in an attempt to solve one problem, deposit insurance created another. And to combat bankers’ excessive risk taking, governments were forced to set up regulatory and supervisory structures. Among other things, there are now constraints on the assets banks can hold, rules governing the minimum levels of capital that banks must maintain, and requirements that banks make public information about their balance sheets. Supervisors have to enforce the detailed web of regulations.

Does this complex mechanism actually work to stabilize the financial system? The evidence is not encouraging. Demirgüç-Kunt and Kane (2002) summarize international research and conclude that explicit deposit insurance actually makes financial crises more likely. When countries have either implemented a new scheme or expanded an existing one, the probability of crises has increased.

To make matters worse, the creation of deposit insurance retards the evolution of non-bank financing mechanisms. Cecchetti and Krause (2005) find that countries with more extensive deposit insurance schemes tend to have both smaller financial markets and a fewer publicly traded firms per capita. To put it bluntly, deposit insurance is bad for financial development, and may be bad for real economic growth.

Are there alternatives?

So, if deposit insurance schemes do more harm than good, what should we do to stabilize the financial system? The natural response of an economist is to use the price system. Measure how risky a bank's balance sheet is, and set its deposit insurance premiums accordingly. Beginning in 1991, the US Federal Deposit Insurance Corporation did implement a risk-based premium structure. But this is extremely difficult to do well. Banks can always find ways to evade detailed rules, exploiting the system to reduce the prices they pay. In the end, this is not a solution.

There are three other options. We could implement changes that further restrict the assets held by banks, eliminating their asset transformation function. We could increase our reliance on the central bank's lender-of-last-resort function. Or it may be possible to design a scheme to ensure that large depositors will impose discipline on the risk taking of bank managers.

Proposals for narrow banking are in the first category. A narrow bank is an institution that holds only a very limited set of very low-risk, highly liquid assets, such as short-term government securities. Since insolvency is impossible for such an institution, liability holders would not have to worry about the quality of the narrow bank's assets, and there would be no fear of a run. Deposit insurance would be unnecessary.

Second, it may be possible to address the potential for systemic bank panics by improving the
effectiveness of the lender of last resort. In 1873, Walter Bagehot suggested that, in order to prevent the failure of solvent but illiquid financial institutions, the central bank should lend freely on good collateral at a penalty rate. By lending freely, he meant providing liquidity on demand to any bank that asked. Good collateral would ensure that the borrowing bank was in fact solvent, and a high interest rate would penalize the bank for failing to manage its assets sufficiently cautiously. While such a system could work to stem financial contagion, it has a critical flaw. For it to work, central bank officials who approve the loan applications must be able to distinguish an illiquid from an insolvent institution. But during times of crisis computing the market value of a bank’s asset is almost impossible, since there are no operating financial markets and no prices for financial instruments. Because a bank will go to the central bank for a direct loan only after having exhausted all opportunities to sell its assets and borrow from other banks without collateral, its illiquidity and its need to seek a loan from the government draw its solvency into question. Officials anxious to keep the crisis from deepening are likely to be generous in evaluating the bank’s assets, and to grant a loan even if they suspect the bank might be insolvent. And, knowing this, bank managers will tend to take too many risks.

Finally, we could require that banks issue subordinated debt. These are unsecured bonds, with the lender being paid only after all other bondholders are paid. Someone who buys a bank’s subordinated debt has a very strong incentive to monitor the risk-taking behaviour of the bank. The price of these publicly traded bonds then provides the market’s evaluation of the quality of the bank’s balance sheet and serves to discipline its management.

By eliminating the accountability of bank managers to their depositors, deposit insurance encourages risky behaviour. So, while financial stability is clearly in the public interest, deposit insurance may not be.

**How to cite this article**

Depreciation estimates the decline in the value of capital over time. It is highly important to capital accounting, since the rate of dividend is calculated as the ratio of the surplus to the current value of assets. The causes of the depreciation of equipment are twofold: its productivity may fall with age, and over time its expected remaining earning life is shorter. Depreciation is taken to be the difference between gross and net investment but total new employment is given by gross investment: the physical counterpart of replacement (of equipment or manpower) is needed give the full picture.

Article

Depreciation estimates the decline in the value of capital as a result of ageing, its maximum value being near its age of manufacture and its minimum value when it is dismantled and sold as scrap. It is of great importance to capital accounting, for the rate of dividend is calculated as the ratio of the surplus to the current value of assets. The reduction in value of equipment comes about from two causes – firstly that its productivity may fall with age; and secondly that, as time advances, the expected remaining earning life of the plant is shorter. Hence, the capitalized value of the present value of expected future stream of quasi-rents from an old piece of equipment is smaller for any given rate of interest than for a younger machine.

‘One-hoss shay’ assumption

The influence of declining productivity over time may be eliminated by assuming a ‘one-hoss shay’ type
of equipment, which keeps its efficiency constant over its service life and falls to pieces at the end. However, the product of a process is not only its current output but the stock of equipment which remains at the end of the production period – as stressed by von Neumann (1933) and by Sraffa (who in 1960 referred to Robert Torrens as having insisted in the years 1818 and 1821 on its being considered as a part of output).

On account of the shorter remaining service life of equipment at the end of a period (and the consequent smaller number of expected items of quasi-rent in its stream of earnings), there is lesser value of capital remaining at the end of a production period – a so-called ‘year’. This reduction in value of a stock output affects adversely the productivity in value terms (even with ‘one-hoss shay’ equipment) and it measures the depreciation. There is, therefore, an aggravated tendency of the value of capital embodied to fall as the plant is older.

**Shape of decline in valuation curve**

In a straight line approximation, depreciation is taken as constant in absolute amount per year. In a formula using the exponential concept depreciation is at a constant rate; hence, the fall in value is more when machines are younger and higher priced, than when they are older – as in radioactive decay, that is, it indicates a curve convex to the origin. But depreciation is at higher rates for older capital in service – not as would be given by an exponentially falling value of equipment at a constant rate with respect to time. When there is a rising rate of reduction of value, it makes the decline more than exponential as the machines are older, and yields a steeply falling value towards the end of the service life, that is, it yields a curve with respect to time which is concave to the origin. The straight line approximation of value of capital (with respect to its age) which is used in some calculations is thus wide of the mark; and even the exponentially falling value according to a constant rate of reduction does not make the value of old machines decline sufficiently markedly.

In a Sraffa or von Neumann valuation of capital (of different ages taken as different commodities) this decline is well brought out automatically, for differences between value of the commodity called ‘equipment $t$ years old’ and the one called ‘$t+1$ years old’, increases as $t$ becomes larger.

This aspect of the Sraffa system (1960) was not known to Joan Robinson or to Professor Richard Kahn and D.G. Champernowne in 1954 when the text of *Accumulation of Capital* (1956) was being finalized – especially its Mathematical Appendix (to a part of which the latter two had contributed as authors, their names appearing in the original printed text). It is all the more remarkable that it was discovered that, in the measurement of value of ageing equipment, one could strike upon another useful device – of balanced age composition of capital.

**Balanced age composition of capital**

In demographic studies as part of the subject of manpower, it is well known that, for a population of human beings growing at $g$ per cent, there are higher numbers of children of age $t$ in comparison to those a year older (of age $t+1$) by the factor $(1+g)$. The same principle can be applied to a population of plants, and we can derive a universe of plants ordered according to their ages in this particular manner. One can try to ascertain what the number of plants in a cohort of each age is and the value of capital embodied in
depreciation: The New Palgrave Dictionary of Economics

The value of plant at the centre of gravity of the age-composition pyramid may then be used as the standard unit of measurement of the value of a plant of any particular age. The result would be in agreement with the well-known, but rather mystifying, Kahn–Champernowne formula of the reciprocal value of a new plant in terms of value of the plant of average age. This reciprocal will be called a K–C unit in honour of those two authors who worked out the said formula.

Kahn–Champernowne units of measurement

In a generalized version of this concept, as the set of pieces of capital of constant physical productivity and of balanced age composition growing exponentially at a steady rate, keep the composition in terms of relative sizes of cohorts constant; hence the value of the average plant does not change. This is the justification of the K–C units.

In terms of a balanced age composition of equipment (with $T$ years expected service life since its manufacture), a piece of equipment $t$ ‘years’ old is replaced at the end of $t$ years by a piece which was $t - 1$ years old in the beginning of the year. Except for this replacement by equipment which is now of the same age as the piece it substitutes, there is no depreciation visible in the physical system or its statistical depiction.

Redundancy of gross and net concepts

It is to be remembered that Joan Robinson had correctly realized that depreciation was not a physical phenomenon but a notional or value one. The implication of depreciation not being a physical phenomenon in terms of effect upon the concepts of gross and net investment had to wait until the von Neumann model was integrated (in 1960) with the Robinsonian golden-age system. In traditional analysis the system is depicted as $z$ machines (newly produced and added) in a factory, and at the same time another $z$ machine rendered inoperative (by completion of their natural life). But the net investment is not an act of accretion–depreciation in physical terms; for the machines added through current investment are new ones and the depletion is of old machines – and it makes no sense if value measurement were not resorted to for calculating the excess of accretion over depreciation.

The balanced age composition is a device by which one can realize that in a von Neumann system as a growing economy $m$ machines of age $t$ years exist and $m(1 + g)$ of age $t - 1$ years are automatically substituted a year later by $m(1 + g)$ machines – also now of $t$ years age. The stock as well as each age cohort grows at rate $g$, and depreciation of value by ageing is exactly counterbalanced by that much capital of erstwhile younger age and erstwhile higher value (but now of the same age and the same value as the $m$ plants at the beginning of the year) replacing it. In addition one has $mg$ times more machine of age $t$. The total stock grows at a given rate of growth, and depreciation is also compensated for exactly, for $m(1 + g)$ is equal to $m$ for replacement, and $mg$ for accumulation for each age cohort.

In Sraffa–von Neumann analysis (as a simplified purposive model combining the two general constituents of those two models and integrating the resultant with the Robinsonian golden-age system), this fact was noticed in 1961, and it was discovered that in a state of steady growth and balanced age composition depreciation of a stock of inputs in terms of writing down of value of equipment (due to

Depreciation and maintenance

In manpower-employment terms, total new employment is given by gross investment and not by net investment, because the amount spent on activities of maintaining capital intact (repairing, renovating) also creates employment, and not only the building of new capital. Hence, in national income statistics, it is gross investment which creates manpower employment and not net investment by itself. The difference between gross and net is taken to be depreciation, but in manpower terms it does not so follow – for employment created for maintenance of a machine (like a sealed unit) might be very low, and yet the reduction of its value year by year very high due to ageing. When viewing manpower statistics, the activity of operatives of a particular type ought to be supplemented by statistics of valuation (Mathur, 1983). While figures in terms of counting heads are important for a physical count, greater economic significance would be acquired if the productivity of each type of human equipment were determined and its true value calculated in K–C units with respect to a balanced age composition and age structure (Mathur, 1964). But depreciation in value terms alone without the physical counterpart of replacement (of equipment or manpower) also tells us an incomplete story, and only valuation and quantification (in physical terms) together give the full picture.

at the end of Robinson (1956).

**How to cite this article**

The idea that the demand for intermediate goods is derived from the demand for the final goods they help produce is obvious and appealing. It was implied by Cournot (1838, pp. 99–116) and explicitly stated by Gossen (1854, pp. 31, 113) and Menger (1871, pp. 63–7). That the British classical school failed to make use of such a perspective – Mill's famous proposition that ‘demand for commodities is not demand for labour’ (1848, Book I, ch. 5) came close to denying it – was doubtless due to the strong emphasis placed on prior accumulation of capital as a prerequisite for production. But it was Alfred Marshall in his Principles of Economics (1890, pp. 381–93, 852–6) who introduced the term ‘derived demand’ and developed the concepts of the derived demand curve for an input and the elasticity of derived demand.

Marshall focused on a case in which a commodity is produced by the cooperation of several inputs, which are thus jointly demanded for the purpose, the demand for each being derived from the demand for the product. His formal analysis proceeded on the assumption that the inputs were all combined in fixed proportions (which might vary with the scale of output) although he suggested that the variable-proportions case would be similar.

A derived demand curve can be constructed for a selected input on the assumptions that production conditions, the demand curve for output, and the supply curves for all other inputs remain fixed, and that the competitive markets for output and all other inputs are always in equilibrium. The resulting derived demand curve can most easily be interpreted as the outcome of a hypothetical experiment. Make the selected input available, perfectly elastically, at an arbitrary price, $y$, per unit. Now ascertain, under the above conditions about the markets for output and other inputs, what quantity, $x$, of the selected input would be demanded. All other markets must be in equilibrium, and each seller or buyer must be optimally adjusted to the assumed terms of availability of the selected input. Repeating this experiment for different values of $y$ would generate the inverse of the relationship between $x$ and $y$, $y = f(x)$, whose
Graphical representation is Marshall's derived demand curve for the selected input. Bringing this demand curve into conjunction with the actual supply curve of the selected input will determine the actual equilibrium price and quantity for this input and thereby implicitly determine the actual equilibrium prices and quantities of output and all other inputs. But the point of obtaining the derived demand curve is not to permit such a two-stage determination of the actual equilibrium. It is rather to permit a simplified analysis of the effect of changes in the supply conditions of the selected input when supply conditions of other inputs, as well as technology and the demand conditions for output, remain unaltered.

Marshall invoked a simple example in which the final product, a knife, is obtained by joining costlessly a unit each of the two inputs, blades and handles. The derived demand curve for handles is then given by the rule that $y$, the derived demand price for $x$ handles, is the demand price for $x$ knives less the supply price for $x$ blades.

Marshall analysed the conditions producing a low elasticity of derived demand for an input, a condition which would encourage supply restriction. The first condition, the lack of a good substitute, is already implied by the fixity of production coefficients. The second is that the demand for the final output be inelastic. The third, aptly described by Henderson (1922, p. 59) as ‘the importance of being unimportant’, is that expenditure on the input in question be only a small fraction of total production cost. The final condition is that cooperating inputs be in inelastic supply. These last three conditions ensure that a large rise in the price of the input will not raise product price much, that a rise in the product price will not reduce sales much, and that a reduction in sales and production will lower the cost of cooperating inputs substantially.

The next major contribution was that of Hicks (1932, pp. 241–6) who formally relaxed the assumption of fixed production coefficients. He analysed the consequences of input substitutability for a two input case with constant returns to scale in production, making use of his newly invented concept of the elasticity of substitution. His principal finding was that, to get a low elasticity of derived demand, ‘It is “important to be unimportant” only when the consumer can substitute more easily than the entrepreneur’, that is, only when the elasticity of demand for the product exceeds the elasticity of input substitution (1932, p. 246). This finding, which is not easily explained intuitively, has been the subject of intermittent controversy, aptly summarized and resolved in Maurice (1975). The extension of Hicks’s analysis to the many-input case has been accomplished by Diewert (1971), using an elegant dual approach based on the cost function concept. However, modern theoretical work is more prone to work explicitly and symmetrically with complete systems of input demand equations for firm and industry.

More or less contemporaneously with Hicks, Joan Robinson (1933, chs. 23, 24) was studying the derived demand curve for an input in cases where the final product is sold by a monopolist, who might also acquire cooperating inputs monopsonistically. The question of when areas under a derived demand curve can be given a welfare interpretation, analogous to consumer surplus for a final demand curve, has been broached by Wisecarver (1974).

The concept of derived demand finds its main application in discussions of labour-market questions, and Marshall’s tools still play a significant part in the teaching and writing in that area.

French philosopher and economist, Tracy was born into a noble family of the ancien régime at Paris on 20 July 1754 and died in the same city on 10 March 1836. His life spanned the most tumultuous period of French history, from the twilight of the Old Regime to the dawn of capitalism, romanticism and socialism. One of the last philosophes, Tracy began as an 18th-century classical metaphysician, preoccupied with the sensationalist doctrine of Locke and Condillac, and ended up, in the words of Auguste Comte, as the philosopher ‘who had come closest to the positive state’. In the interim he knelt at the feet of Voltaire; served alongside Lafayette in the Royal Cavalry, and as deputy to the French Estates General and the Constituent Assembly; was imprisoned during the Reign of Terror; released after Thermidor (escaping the guillotine by a mere two days); subsequently helped to establish his country’s first successful national programme of public education; led the opposition to Napoleon from his seat in the French Senate; regained his title under the Bourbon Restoration; counted among his associates the likes of Mirabeau, Condorcet, Cabanis, DuPont de Nemours, Jefferson, Franklin, Lavoisier, Ricardo and Mill; and retained his early sympathies for liberty throughout. Long before it took on its pejorative sense at the hands of Marx, Tracy coined the term ‘ideology’ (by which he meant the science of ideas) to describe his philosophy, which embraced and intertwined psychological, moral, economic and social phenomena, but which gave primacy to economics because he thought that the purpose of society was to satisfy man's material needs and multiply his enjoyments. Tracy rejected the Physiocratic notion of value, substituting a labour theory that Ricardo subsequently endorsed in his Principles. Like Say, he denied Smith's distinction between productive and unproductive labour. But unlike Smith or Say, he reduced all wealth, including land, to labour. On numerous other topics (that is, wages, profits, rents, exchange, price variations, international trade) he was far less thorough and rigorous than either Smith or Say, but his exposition of the capitalization theory of taxation...
was superior to the rest. In the final analysis, his *Traité* was not properly a treatise on political economy so much as a part of a general study of the human will. Yet the resulting lack of depth did not impair his remarkable ability to allure great minds. Ricardo found him ‘a very agreeable old gentleman’, and Jefferson was influenced to the point of including ‘ideology’ among the ten projected departments in his plan for the University of Virginia.

Along with Say, Destutt de Tracy was one of the earliest members of the French liberal school. Patrician, philosopher and patriot, caught in the grips of major social and economic upheaval, he denounced the interests of his own class (the *rentiers*) and became the spokesman of a nascent capitalism in which he had neither role nor vested interest.

determinacy and indeterminacy of equilibria

Chris Shannon
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses work on the determinacy and indeterminacy of equilibria in models of competitive markets. Determinacy typically refers to situations in which equilibria are finite in number, and local comparative statics can be precisely described. The article describes basic results on generic determinacy for exchange economies and the general underlying principles, together with various applications and extensions including incomplete financial markets and markets with infinitely many commodities.

Keywords

Article

1 Introduction

The Arrow–Debreu model of competitive markets is one of the cornerstones of economics. Part of the explanatory power of this model stems from its flexibility in capturing price-taking behaviour in many different markets, and from the predictive power arising from the great generality under which equilibrium can be shown to exist. This predictive power is significantly enhanced when equilibria are determinate, meaning that equilibria are locally unique and local comparative statics can be precisely described. Instead, when equilibria are indeterminate, even arbitrarily precise local bounds on variables might not suffice to give a unique equilibrium prediction, the model might exhibit infinitely many equilibria, and each might be infinitely sensitive to arbitrarily small changes in parameters.

Simple exchange economies cast in an Edgeworth box with two agents and two goods illustrate the possibility of indeterminacy in equilibrium. One easy example arises when agents view the goods as perfect substitutes. In this case, every profile of initial endowments leads to a continuum of equilibria. Another example comes from the opposite extreme, in which each agent views the goods as perfect complements. Every profile of initial endowments dividing equal social endowments of the two goods leads to a continuum of equilibria. These examples may seem degenerate, since they involve individual demand behaviour either extremely responsive to prices, or extremely unresponsive to prices. Similar examples can be constructed using preferences that are less extreme, however, and that can be chosen to satisfy a number of regularity conditions including strict concavity, strict monotonicity, and smoothness. Problems from standard graduate texts illustrate this possibility. In fact, indeterminacy is unavoidable, at least for some endowment profiles, in almost any model that may exhibit multiple equilibria for some choices of endowments. The conditions leading to unique equilibria or unambiguous global comparative statics are well-known to be very restrictive, suggesting that equilibrium indeterminacy may be a widespread phenomenon.

In a deeper sense, however, these examples of indeterminacy remain knife-edge. Under fairly mild conditions on primitives, if an initial endowment profile leads to indeterminacy in equilibrium, arbitrarily small perturbations in endowment profiles must restore the determinacy of equilibrium. More powerfully, the set of endowment profiles for which equilibria are determinate is generic, that is, an open set of full Lebesgue measure. Explaining this remarkable result – originally postulated and established by Debreu (1970) – and its many
extensions and generalizations is the focus of this article. Section 2 lays out the basic question of determinacy of equilibrium in finite exchange economies, and sketches the results. Section 3 describes the general underlying principles, together with various applications and extensions. Section 4 concludes by examining recent work on determinacy in markets with infinitely many commodities.

2 Determinacy in finite exchange economies

Imagine a family of exchange economies, each with a fixed set of \( L \) commodities and a fixed set of \( m \) agents, with given preferences \( \{ x_i \}_{i=1}^{m} \), indexed by varying individual endowments \( (e_1, \ldots, e_m) \in \mathbb{R}^{mL}_{++} \). Denote the social endowment \( \tilde{e} = \sum_i e_i \) and a particular profile of individual endowments by \( e = (e_1, \ldots, e_m) \in \mathbb{R}^{mL}_{++} \). An economy \( E(e) \) then refers to the exchange economy with preferences \( \{ x_i \}_{i=1}^{m} \) and endowment profile \( e \). For simplicity, this article focuses on exchange economies. Mas-Colell (1985) is a comprehensive reference that includes discussion of extensions allowing for production.

The crucial departure in Debreu (1970) is to view each economy as a member of this parameterized family, and to ask whether perhaps almost no economies exhibit indeterminacy or pathological comparative statics when indexed this way. To formalize this, Debreu (1970) summaries an agent's choice behaviour by a \( C^1 \) demand function \( x_i : \mathbb{R}^L_{++} \times \mathbb{R}^{L-1}_{++} \rightarrow \mathbb{R}^L_{++} \) satisfying basic properties such as homogeneity of degree 0 in prices, Walras's Law, and boundary conditions as prices converge to zero. This leads to the familiar characterization of equilibria as zeros of excess demand:

\[
0 = z(p, e) := \sum_i x_i(p, e_i) - \tilde{e}.
\]

Two simplifying normalizations are then commonly adopted. Demand functions derived from optimal choices of price-taking agents are homogeneous of degree zero in prices, so normalize by setting \( P_1 = 1 \). Normalized prices thus can be taken to range over \( \mathbb{R}^{L-1}_{++} \). Next, Walras’s Law ensures that excess demand functions are not independent across markets, as \( p \cdot z(p, e) = 0 \) for each \( p \in \mathbb{R}^{L-1}_{++} \). This renders one market clearing equation redundant, and leads to the characterization of equilibria by normalized price vectors \( p \in \mathbb{R}^{L-1}_{++} \) such that

\[
z_{-L}(p, e) = 0
\]

where, adopting common conventions, the subscript \(-L\) refers to all goods except \( L \), so \( z_{-L}(p, e) = (z_1(p, e), \ldots, z_{L-1}(p, e)) \). Using these normalizations, the equilibrium correspondence can be defined by

\[
E(e) := \left\{ (x, p) \in \mathbb{R}^{mL}_{++} \times \mathbb{R}^{L-1}_{++} : z_{-L}(p, e) = 0, x_i = x_i(p, e) \text{ for } i = 1, \ldots, m \right\}.
\]

Fix a particular equilibrium price vector \( p^* \) in the economy \( E(e) \). One way to answer local comparative statics qts at this equilibrium is to apply the classical implicit function theorem. If \( D_p z_{-L}(p^*, e) \) is invertible, then the implicit function theorem provides several immediate predictions: the equilibrium price \( p^* \) is locally unique; locally, on neighbourhoods \( W \) of \( e \) and \( V \) of \( p^* \), the equilibrium price set is described by the graph of a \( C^1 \) function \( p : W \rightarrow \mathbb{R}^{L-1}_{++} \); and local comparative statics are given by the formula...
$Dp(e) = - \left| D_p z_L(p^*, e) \right|^{-1} D_z z_L(p^*, e)$.

If this analysis can be performed for each equilibrium, then there are only finitely many equilibria, because the equilibrium set is compact. Moreover, for each equilibrium $(x, p) \in E(e)$ there is a neighborhood $U$ of $(x, p)$ for which $E(\cdot \cap U$ has a unique, $C^1$ selection on a neighborhood $W$ of $e$, with the comparative statics derived from the preceding formula. Call such a correspondence \textit{locally } $C^1$ \textit{at } e. The following definition offers a convenient way to summarize these properties.

\textbf{Definition 1:} The economy $E(e)$ is \textit{regular} if it has finitely many equilibria, and $E$ is locally $C^1$ at $e$.

An alternative way to describe the problem uses the language of differential topology. For a $C^1$ function $f : \mathbb{R}^n \to \mathbb{R}^m$, $\forall \in \mathbb{R}^m$ is a \textit{regular value} of $f$ if $Df(x)$ has full rank for every $x \in f^{-1}(y)$. Notice that this is precisely the condition identified above, for the case of equilibrium prices, under which local uniqueness and local comparative statics could be derived from the implicit function theorem. Whenever 0 is a regular value of $z_L(\cdot, e)$, the corresponding economy $E(e)$ is regular. For a fixed function $f$, a given value $y$ may fail to be a regular value, but almost every other value is regular: this is the conclusion of Sard's theorem. Dually, the fixed value $y$ may fail to be a regular value for a particular function $f$, but is a regular value for almost every other function. When the set of functions is limited to those drawn from a particular parameterized family, the conclusion remains valid for almost all members of this family provided the parameterization is sufficiently rich. This idea of a rich parameterization can be expressed by requiring $y$ to be a regular value of the parameterized family, and this parametric version of Sard's theorem is typically called the transversality theorem. Figure 1 depicts this idea for smooth excess demand functions.

\textbf{Figure 1}

Generic determinacy for smooth excess demand
These observations suggest that, while extremely restrictive assumptions might be required to ensure that every economy is regular, generic regularity might follow simply from the differentiability of demand functions once the problem is framed this way. Straightforward calculations verify that 0 is a regular value of the excess demand function (viewed as a function of both prices and initial endowment parameters). From the transversality theorem we conclude that there is a subset $R^n \subseteq R^{m+n}$ of full Lebesgue measure such that for all $e \in R^n$, $E(e)$ is regular. With the use of additional properties of excess demand and equilibria, it is similarly straightforward to show that the set of regular economies is also open, giving a strong genericity result for regular economies.

This discussion follows Debreu's original development closely. This approach takes demand functions as primitives, and gives conditions on individual demand functions under which regularity is a generic feature of exchange economies. To take a step back and start with preferences as primitives, we seek conditions on preferences sufficient to guarantee that individual demand is suitably differentiable. Debreu (1972) addresses this point by introducing a class of ‘smooth preferences’, depicted in Figure 2.

Figure 2
Smooth preferences
Definition 2: The preference order \( \succ \) on \( \mathbb{R}^L_+ \) is ‘smooth’ if it is represented by a utility function \( U \) such that

- \( U : \mathbb{R}^L_+ \to \mathbb{R} \) is \( C^2 \) on \( \mathbb{R}^L_+ \).
- For each \( x \in \mathbb{R}^L_+ \), \( \{ y \in \mathbb{R}^L_+ : y \sim x \} \subset \mathbb{R}^L_+ \).
- For each \( x \in \mathbb{R}^L_+ \), \( DU(x) \succ 0 \).
- For each \( x \in \mathbb{R}^L_+ \), \( D^2 U(x) \) is negative definite on \( \ker DU(x) = \left\{ z \in \mathbb{R}^L_+ : DU(x) \cdot z = 0 \right\} \).

Fairly straightforward arguments, again using the implicit function theorem, establish that individual demand functions derived from smooth preferences are \( C^1 \). Putting all of these results together yields:

Theorem 1: Let \( \succ \) be a smooth preference order on \( \mathbb{R}^L_+ \) for each \( i = 1, \ldots, m \). There exists an open set \( \mathbb{R}^m \subset \mathbb{R}^{mL}_+ \) of full Lebesgue measure such that for all \( \theta \in \mathbb{R}^m_+ \), \( E(\theta) \) is regular.

3 Determinacy and indeterminacy: a new approach to many problems

Behind this result for equilibria in finite exchange economies is a broad, powerful, and simple principle that has found many important and ingenious applications in the 35 years since Debreu’s original 1970 paper. To cast the problem more generally, take a parameterized family of equations, captured by a function \( f : \mathbb{R}^m \times \mathbb{R}^k \to \mathbb{R}^n \). This describes a problem with \( m \) variables and \( k \) parameters simultaneously entering \( n \) different equations. Imagine that for each parameter value \( r \in \mathbb{R}^k \),

\[
E(r) = \{ x \in \mathbb{R}^m : f(x, r) = 0 \}
\]

gives the set of objects of interest. Moreover, imagine that the equations are sufficiently independent in determining the solutions, in the sense that 0 is a regular value of \( f \). Counting the number of equations and unknowns produces three distinct cases, corresponding in turn to three different sorts of applications.

In the canonical case exemplified by the simple exchange economy described above, the number of relevant endogenous variables, \( m \), is equal to the number of equations, \( n \). In this case, 0 being a regular value of \( f \) characterizes exactly the case in which the equations are sufficiently independent that the loose ‘counting equations and unknowns’ heuristic corresponds with the precise technical result of generic determinacy. One prominent illustration of this case is given by two-period incomplete markets models with real assets, that is, assets that pay off in bundles of commodities. In these models, there are as many distinct budget equations as there are states. If we let \( S \) denote the number of states, this means there are \( S+1 \) distinct Walras’s Law statements, leading to \( S+1 \) redundant market clearing equations. Because asset payoffs are in real terms, all budget constraints are homogeneous of degree 0 in state prices. This generates \( S+1 \) distinct normalizations of state prices, compensating exactly for the drop in independent market clearing equations determining equilibrium. Generic determinacy in this case is established by Geanakoplos and Polemarchakis (1987).

When \( m < n \), there are fewer equations than unknowns, and the regularity of the system of equations means that it is generically overdetermined. In this case, generically it is impossible to satisfy the equations simultaneously, that is, generically \( E(r) \) is empty. As a simple example of this argument, consider the prevalence of trade at equilibrium in an Edgeworth box economy. One market-clearing condition in one (normalized) price characterizes equilibria, and standard arguments show that this excess demand function has 0 as a regular value. In fact, varying the endowment of the first agent alone is enough. How often does equilibrium involve trade in some goods? With only two agents, trade occurs in equilibrium if and only if \( x_2 \neq \mathbb{E}_2 \), so the additional two equations \( x_2(p, \mathbb{E}) - \mathbb{E}_2 = 0 \) characterize endowment and price combinations for which there is no trade in equilibrium. A simple calculation shows that 0 is a regular value of \( f(p, \mathbb{E}) : \{ (z_2(p, \mathbb{E}), x_2(p, \mathbb{E}) - \mathbb{E}_2) \} \). Fixing the endowment profile \( \mathbb{E} \), however, this is a problem with three equations in a single variable, so there must be a set \( \mathbb{R}^m \subset \mathbb{R}^{mL}_+ \) of full Lebesgue measure such that for every \( \mathbb{E} \in \mathbb{R}^m_+ \), there are no solutions to the equation \( f(p, \mathbb{E}) = 0 \). For every endowment profile \( \mathbb{E} \in \mathbb{R}^m_+ \), every equilibrium then must involve trade, as every equilibrium price solves the first equation \( z_2(p, \mathbb{E}) = 0 \), so cannot also involve no trade, \( x_2(p, \mathbb{E}) \neq \mathbb{E}_2 \). Similar logic but more involved calculations show that equilibrium allocations are generically inefficient in incomplete markets models, and generically constrained inefficient in

Finally, when \( m > n \), generically indeterminacy arises, as generically the solution set \( E(r) \) is an \((m - n)\)-dimensional manifold. (A subset \( M \subset \mathbb{R}^m \) is a \( d \)-dimensional \( \mathcal{C}^\infty \) manifold if for each \( x \in M \) there exist open sets \( V \subset \mathbb{R}^m \) and \( W \subset \mathbb{R}^d \), where \( V \) is a neighbourhood of \( x \), and a \( \mathcal{C}^\infty \) diffeomorphism \( \varphi : V \to W \) such that \( \varphi(V \cap M) = W \).) In this case, generically there is a continuum of solutions, and the set of solutions is locally up to diffeomorphism, a set of dimension \( m - n \). An important example of this case is provided by two-period incomplete financial markets models with nominal assets. Here, asset payoffs are in nominal terms, in some specified unit of account. As in the case of real assets described above, there are \( S + 1 \) independent budget constraints when there are \( S \) possible states of nature, so there are \( S + 1 \) redundant market clearing equations. Because asset payoffs are nominal, however, budget constraints are not all homogeneous of degree zero, and price levels matter. With only two homogeneity conditions, one for period one prices and one relating all commodity and asset prices, this leaves \( S - 1 \) dimensions of indeterminacy in equilibria generically. The detailed result is established by Geanakoplos and Mas-Colell (1989).

These three cases, and the generic properties of solution sets that follow, are collected below.

**Theorem 2:** Let \( f : \mathbb{R}^m \times \mathbb{R}^k \to \mathbb{R}^n \) be a \( C^d \) function, where \( d > \max(m - n, 0) \), and suppose \( 0 \) is a regular value of \( f \).

1. (a) Suppose \( m = n \). There exists a set \( \mathbb{R}^r \subset \mathbb{R}^k \) of full Lebesgue measure such that, for every \( r \in \mathbb{R}^r \), \( E(r) \) contains only isolated points, \( E(r) \) is finite when compact, and \( E \) is locally \( C^1 \) at \( r \).

2. (b) Suppose \( m < n \). There exists a set \( \mathbb{R}^r \subset \mathbb{R}^k \) of full Lebesgue measure such that for every \( r \in \mathbb{R}^r \), \( E(r) \) is empty.

3. (c) Suppose \( m > n \). There exists a set \( \mathbb{R}^r \subset \mathbb{R}^k \) of full Lebesgue measure such that for every \( r \in \mathbb{R}^r \), \( E(r) \) is an \((m - n)\)-dimensional \( \mathcal{C}^\infty \) manifold.

The techniques pioneered by Debreu have found widespread applications, and have proven to be remarkably powerful. Nonetheless, the smoothness needed to study determinacy using the tools of differential topology does stem from assumptions that often carry real economic content. These assumptions restrict both the nature of admissible preferences and the nature of admissible constraints.

For example, to avoid problems arising when non-negativity constraints on consumption may become binding, these results rest on ‘boundary’ restrictions, both on endowments, because individual endowments are strictly positive, or on equilibrium consumption via boundary conditions on preferences that imply individual demands are strictly positive at all prices. Unless goods are aggregated extremely coarsely, neither pattern is supported by observations on consumer behaviour or characteristics. Relaxing the constraint on endowments turns out, perhaps surprisingly, to generate indeterminacy much more readily than relaxing the assumptions on positive consumptions, or incorporating other more general constraints on choices. Minehart (1997) shows by means of an example that for one natural case of restricted endowments, in which each agent is constrained to hold a single, individual-specific, good, an open subset of such parameters leads to indeterminacy in equilibrium. Highlighting the fact that the choice of parameterization can be important, Mas-Colell (1985) shows that this conclusion is not robust to perturbations in preferences; generic determinacy, in a topological sense, is restored by considering variations in preferences as well as constrained endowments. If the assumption that individual endowments of every good are positive is maintained, the restriction to positive individual demand for every good can be relaxed. For example, Mas-Colell (1985) provides generic determinacy results for exchange economies allowing for boundary consumptions; Figure 3 depicts such preferences.

Figure 3
Preferences allowing boundary consumption
Smooth preferences, as defined by Definition 2 above, obviously rule out preferences with non-differentiabilities in level sets, a restriction that also has important behavioural content.
Kinks have arisen as central manifestations of various behavioural phenomena, including loss aversion, ambiguity aversion, and reference dependence; examples include Kahneman and Tversky (1979), Tversky and Kahneman (1991), Koszegi and Rabin (2006), Sagi (2006), and Gilboa and Schmeidler (1989). Such kinks typically lead to excess demand functions that fail to be differentiable for some prices. Rader (1973), Pascoa and Werlang (1999), Shannon (1994), and Blume and Zame (1993) all develop methods to address such cases. With the exception of Blume and Zame (1993), these techniques can be roughly understood as expanding differential notions by adding to ‘regularity’ the condition that the function (for example, excess demand) is differentiable at every solution, and establishing that analogues of implicit function theorems, Sard’s theorem or the transversality theorem remain valid for sufficiently nice non-smooth functions, such as Lipschitz continuous functions; in particular, see Shannon (1994; 2006). Blume and Zame (1993) instead use results that exploit the structure of algebraic sets to establish generic determinacy for utilities that are, roughly, finitely piecewise analytic, and need not be strictly concave. Examples in which determinacy has been studied using techniques along these various lines include asset market models with restricted participation (for example, see Cass, Siconolfi, and Villanacci, 2001) and models of ambiguity aversion (for example, see Rigotti and Shannon, 2006). Figure 4.

Figure 4
Generic determinacy for non-smooth excess demand
4 Determinacy in infinite-dimensional economies

Many economic models require an infinite number of marketed commodities. Important examples include dynamic infinite horizon economies, continuous-time trading in financial markets, and markets with differentiated commodities. Such infinite-dimensional models present big obstacles to studying determinacy, starting with the fact that individual demand is not defined for most prices, precluding any straightforward parallel of Debreu’s arguments for finite economies. In addition, the positive cone in most infinite-dimensional spaces has empty interior in the relevant topologies, meaning individual consumption sets are ‘all boundaries’, and existence of equilibrium typically requires conditions, such as uniform properness or variants, that effectively bound marginal rates of substitution. Thus boundary conditions akin to those in Debreu’s smooth preferences are likely either to be impossible to satisfy or to contradict equilibrium existence in many important applications.

Provided there are finitely many agents and no market distortions, using the welfare theorems and Negishi’s argument provides an alternative characterization of equilibria, replacing excess demand with ‘excess savings’. Some version of this characterization of equilibria provides the framework for much of the existing equilibrium analysis in economies with infinitely many commodities, including the seminal work on existence of Mas-Colell (1986) and Aliprantis, Brown and Burkinshaw (1987), and the approach to determinacy for discrete-time infinite horizon models with time separability pioneered by Kehoe and Levine (1985). To explain this, let $X$ denote the commodity space. The efficient allocations are the solutions to a social planner’s problem of the following form: given $\lambda \in \Lambda = \{\lambda \in \mathbb{R}^m_+ : \sum_{i=1}^{m} \lambda_i = 1\}$, choose a feasible allocation $x(\lambda)$ to solve:

$$\max_{\lambda} \sum_{i=1}^{m} \lambda_i u_i(x) \text{ s.t. } \sum_{i=1}^{m} x_i \leq \bar{e}.$$ 

Under standard assumptions, the solution $x(\lambda)$ to this problem is well-defined and unique for each $\lambda \in \Lambda$, and a unique price $p(\lambda)$ supporting $x(\lambda)$ can be characterized. Equilibria then correspond to the solutions $\lambda$ to the budget equations

$$p(\lambda) \cdot (x_2(\lambda) - \bar{e}_2) = 0$$

$$p(\lambda) \cdot (x_m(\lambda) - \bar{e}_m) = 0$$

where Walras’s Law accounts for the missing equation. In parallel with excess demand, define the excess savings map $s: \Lambda \times X^m_+ \to \mathbb{R}^{m-1}$

$$s(\lambda, \bar{e}) := (p(\lambda) \cdot (x_2(\lambda) - \bar{e}_2), \ldots, p(\lambda) \cdot (x_m(\lambda) - \bar{e}_m)).$$
Through this construction, the question of determinacy for infinite-dimensional economies can be cast in close parallel to finite economies, with the only change that the set of parameters is now infinite-dimensional. This raises several technical issues, most importantly the choice between topological and measure-theoretic notions of genericity due to the impossibility of defining a suitable analogue of Lebesgue measure in infinite-dimensional spaces (see Hunt, Sauer and Yorke, 1992, and Anderson and Zame, 2001, for a discussion of these issues). This construction also makes imperative the need to link conditions on excess savings used to imply determinacy with conditions on preferences since, in contrast with excess demand, excess savings depends on artificial and unobservable constructs. Somewhat surprisingly, Shannon (1999) and Shannon and Zame (2002) show that generic determinacy follows from conditions on preferences that closely resemble Debreu's (1972) smooth preferences, after suitable renormalization. As in the finite case, these conditions can roughly be understood as strengthened notions of concavity, requiring that near feasible bundles utility differs from a linear approximation by an amount quadratic in the distance to the given bundle. These notions of concavity thus rule out preferences displaying local or global substitutes. Shannon and Zame (2002) provide a simple geometric argument showing that the excess spending mapping is Lipschitz continuous. Generic determinacy then follows by arguments similar to those sketched above for other problems with non-differentiabilities, making use of Shannon (2006) on comparative statics and a version of the transversality theorem for this setting. The direct, geometric nature of these arguments render them applicable in a wide range of examples, including models of continuous-time trading, trading in differentiated commodities, and trading over an infinite horizon.

Abstract

We review the literature on deterministic evolutionary dynamics in game theory. We describe the microfoundations of dynamic evolutionary models and offer some basic examples. We report on stability theory for evolutionary dynamics, and we discuss the senses in which evolutionary dynamics support and fail to support traditional game-theoretic solution concepts.

Article

1 Introduction

Deterministic evolutionary dynamics for games first appeared in the mathematical biology literature, where Taylor and Jonker (1978) introduced the replicator dynamic to provide an explicitly dynamic foundation for the static evolutionary stability concept of Maynard Smith and Price (1973). But one can find precursors to this approach in the beginnings of game theory: Brown and von Neumann (1950) introduced differential equations as a tool for computing equilibria of zero-sum games. In fact, the replicator dynamic appeared in the mathematical biology literature long before game theory itself: while Maynard Smith and Price (1973) and Taylor and Jonker (1978) studied game theoretic models of animal conflict, the replicator equation is equivalent to much older models from population ecology and population genetics. These connections are explained by Schuster and Sigmund (1983), who also coined the name ‘replicator dynamic’, borrowing the word ‘replicator’ from Dawkins (1982).

In economics, the initial phase of research on deterministic evolutionary dynamics in the late 1980s and early 1990s focused on populations of agents who are randomly matched to play normal form games, with evolution...
deterministic evolutionary dynamics: The New Palgrave Dictionary of Economics

Described by the replicator dynamic or other closely related dynamics. The motivation behind the dynamics continued to be essentially biological: individual agents are preprogrammed to play specific strategies, and the dynamics themselves are driven by differences in birth and death rates. Since that time the purview of the literature has broadened considerably, allowing more general sorts of large population interactions, and admitting dynamics derived from explicit models of active myopic decision making.

This article provides a brief overview of deterministic evolutionary dynamics in game theory. More detailed treatments of topics introduced here can be found in the recent survey article by Hofbauer and Sigmund (2003), and in books by Maynard Smith (1982), Hofbauer and Sigmund (1988; 1998), Weibull (1995), Vega-Redondo (1996), Samuelson (1997), Fudenberg and Levine (1998), Cressman (2003), and Sandholm (2007).

2 Population games

Population games provide a general model of strategic interactions among large numbers of anonymous agents. For simplicity, we focus on games played by a single population, in which agents are not differentiated by roles; allowing for multiple populations is mostly a matter of introducing more elaborate notation.

In a single-population game, each agent from a unit-mass population chooses a strategy from the finite set \( S = \{1, \ldots, n\} \), with typical elements \( i \) and \( j \). The distribution of strategy choices at a given moment in time is described by a population state \( x \in X = \{x \in \mathbb{R}_+^n : \sum_{i \in S} x_i = 1\} \). The payoff to strategy \( i \), denoted \( F_i : X \to \mathbb{R} \), is a continuous function of the population state; we use the notation \( F : X \to \mathbb{R}_+^n \) to refer to all strategies’ payoffs at once. By taking the set of strategies \( S \) as fixed, we can refer to \( F \) itself as a population game.

The simplest example of a population game is the most commonly studied one: random matching to play a symmetric normal form game \( A \in \mathbb{R}^{n \times n} \), where \( A_{ij} \) is the payoff obtained by an agent choosing strategy \( i \) when his opponent chooses strategy \( j \). When the population state is \( x \in X \), the expected payoff to strategy \( i \) is simply the weighted average of the elements of the \( i \)th row of the payoff matrix:

\[
F_i(x) = \sum_{j \in S} A_{ij} x_j = \langle A x \rangle_i
\]

Thus, the population game generated by random matching in \( A \) is the linear population game \( F(x) = A x \).

Many models of strategic interactions in large populations that arise in applications do not take this simple linear form. For example, in models of highway congestion, payoff functions are convex: increases in traffic when traffic levels are low have virtually no effect on delays, while increases in traffic when traffic levels are high increase delays substantially (see Beckmann, McGuire and Winsten, 1956; Sandholm, 2001). Happily, allowing nonlinear payoffs extends the range of possible applications of population games without making evolutionary dynamics especially more difficult to analyse, since the dynamics themselves are nonlinear even when the underlying payoffs are not.

3 Foundations of evolutionary dynamics

Formally, an evolutionary dynamic is a map that assigns to each population game \( F \) a differential equation \( \dot{x} = V F(x) \) on the state space \( X \). While one can define evolutionary dynamics directly, it is preferable to derive them from explicit models of myopic individual choice.

We can accomplish this by introducing the notion of a revision protocol \( \rho : \mathbb{R}_+^n \times X \to \mathbb{R}_+^{n \times n} \). Given a payoff vector \( F(x) \) and a population state \( x \), a revision protocol specifies for each pair of strategies \( i \) and \( j \) a non-negative number \( \rho_{ij}(F(x), x) \), representing the rate at which strategy \( i \) players who are considering switching strategies switch to strategy \( j \). Revision protocols that are most consistent with the evolutionary paradigm require agents to possess only limited information: for example, a revising agent might know only the current...
payoffs of his own strategy $i$ and his candidate strategy $j$.

A given revision protocol can admit a variety of interpretations. For one all-purpose interpretation, suppose each agent is equipped with an exponential alarm clock. When the clock belonging to an agent playing strategy $i$ rings, he selects a strategy $j \in S$ at random, and then switches to this strategy with probability proportional to $\rho_{ij}(F(x), x)$. While this interpretation is always available, others may be simpler in certain instances. For example, if the revision protocol is of the imitative form $\rho \hat{u} = x_j \times \hat{\rho} \hat{u}$, we can incorporate the $x_j$ term into our story by supposing that the revising agent selects his candidate strategy $j$ not by drawing a strategy at random, but by drawing an opponent at random and observing this opponent’s strategy.

A population game $F$ and a revision protocol $\rho$ together generate an ordinary differential equation $\dot{x} = V^F(x)$ on the state space $X$. This equation, which captures the population’s expected motion under $F$ and $\rho$, is known as the mean dynamic or mean field for $F$ and $\rho$:

$$\dot{x} = V^F_i(x) = \sum_{j \in S} x_j \rho_{ij}(F(x), x) - x_i \sum_{j \in S} \rho_{ij}(F(x), x).$$

(M)

The form of the mean dynamic is easy to explain. The first term describes the ‘inflow’ into strategy $i$ from other strategies; it is obtained by multiplying the mass of agents playing each strategy $j$ by the rate at which such agents switch to strategy $i$, and then summing over $j$. Similarly, the second term describes the ‘outflow’ from strategy $i$ to other strategies. The difference between these terms is the net rate of change in the use of strategy $i$. To obtain a formal link between the mean dynamic (M) and our model of individual choice, imagine that the population game $F$ is played not by a continuous mass of agents but rather by a large, finite population with $N$ members. Then the model described above defines a Markov process $\{X_t^N\}$ on a fine but discrete grid in the state space $X$. The foundations for deterministic evolutionary dynamics are provided by the following finite horizon deterministic approximation theorem: Fix a time horizon $T < \infty$. Then the behaviour of the stochastic process $\{X_t^N\}$ through time $T$ is approximated by a solution of the mean dynamic (M); the approximation is uniformly good with probability close to 1 once the population size $N$ is large enough. (For a formal statement of this result, see Benaïm and Weibull, 2003.)

In cases where one is interested in phenomena that occur over very long time horizons, it may be more appropriate to consider the infinite horizon behaviour of the stochastic process $\{X_t^N\}$. Over this infinite time horizon, the deterministic approximation fails, as a correct analysis must explicitly account for the stochastic nature of the evolutionary process. For more on the distinction between the two time scales, see Benaïm and Weibull (2003).

4 Examples and families of evolutionary dynamics

We now describe revision protocols that generate some of the most commonly studied evolutionary dynamics. In the table below, $\bar{F}(x) = \sum_{i \in S} x_i F_i(x)$ represents the population's average payoff at state $x$, and...
Deterministic evolutionary dynamics: The New Palgrave Dictionary of Economics

\[ b^F(x) = \arg \max_{y \in X} y' F(x) \] is the best response correspondence for the game \( F \).

A common critique of evolutionary analysis of games is that the choice of a specific revision protocol, and hence the evolutionary analysis that follows, is necessarily arbitrary. There is surely some truth to this criticism: to the extent that one's analysis is sensitive to the fine details of the choice of protocol, the conclusions of the analysis are cast into doubt. But much of the force of this critique is dispelled by this important observation: *evolutionary dynamics based on qualitatively similar revision protocols lead to qualitatively similar aggregate behaviour*. We call a collection of dynamics generated by similar revision protocols a ‘family’ of evolutionary dynamics. To take one example, many properties that hold for the replicator dynamic also hold for dynamics based on revision protocols of the form \( \rho_{ij} = x_j \rho_{ij} \) where \( \rho_{ij} \) satisfies

\[ \text{sgn} \left( (\hat{\rho}_{ki} - \hat{\rho}_{ik}) - (\hat{\rho}_{kj} - \hat{\rho}_{jk}) \right) = \text{sgn} (F_i - F_j) \text{ for all } k \in S. \]

(In words: if \( i \) earns a higher payoff than \( j \), then the net conditional switch rate from \( k \) to \( i \) is higher than that from \( k \) to \( j \) for all \( k \in S \).) For reasons described in Section 3, dynamics generated in this way are called ‘imitative dynamics’. (See Björnerstedt and Weibull, 1996, for a related formulation.) For another example, most properties of the pairwise difference dynamic remain true for dynamics based on protocols of the form \( \rho_{ij} = \phi (F_i - F_j) \), where \( \phi : \mathbb{R} \rightarrow \mathbb{R}^+ \) satisfies sign-preservation:

\[ \text{sgn}(\phi(d)) = \text{sgn}([d]_+) \]

Dynamics in this family are called ‘pairwise comparison dynamics’. For more on these and other families of dynamics, see Sandholm (2007, ch. 5).

5 Rest points and local stability

Having introduced families of evolutionary dynamics, we now turn to questions of prediction: if agents playing game \( F \) follow the revision protocol \( \rho \) (or, more broadly, a revision protocol from a given family), what predictions can we make about how they will play the game? To what extent do these predictions accord with those provided by traditional game theory?

A natural first question to ask concerns the relationship between the rest points of an evolutionary dynamic \( V^F \) and the Nash equilibria of the underlying game \( F \). In fact, one can prove for a very wide range of evolutionary dynamics that if a state \( x^* \in X \) is a Nash equilibrium (that is, if \( x \in B(x) \)), then \( x^* \) is a rest point as well.

One way to show that \( NE(F) \subseteq RP(V^F) \) is to first establish a *monotonicity* property for \( V^F \): that is, a property that relates strategies’ growth rates under \( V^F \) with their payoffs in the underlying game (see, for example, Nachbar, 1990; Friedman, 1991; and Weibull, 1995). The most general such property, first studied by Friedman (1991) and Swinkels (1993), we call ‘positive correlation’.
If \( x \notin RP(V^F) \), then \( F(x)'V^F(x) > 0 \).

(Property (PC))

Property (PC) is equivalent to requiring a positive correlation between strategies’ growth rates \( V^F_i(x) \) and payoffs \( F_i(x) \) (where the underlying probability measure is the uniform measure on the strategy set \( S \)). This property is satisfied by the first three dynamics in Table 1, and modifications of it hold for the remaining two as well. Moreover, it is not difficult to show that if \( V^F \) satisfies (PC), then all Nash equilibria of \( F \) are rest points of \( V^F \): that is, \( NE(F) \subseteq RP(V^F) \), as desired (see Sandholm, 2007, ch. 5).

</table>

In many cases, one can also prove that every rest point of \( V^F \) is a Nash equilibrium of \( F \), and hence that \( NE(F) = RP(V^F) \). In fact, versions of this statement are true for all of the dynamics introduced above, with the notable exception of the replicator dynamic and other imitative dynamics. The reason for this failure is easy to see: when revisions are based on imitation, unused strategies, even ones that are optimal, are never chosen. On the other hand, if we introduce a small number of agents playing an unused optimal strategy, then these agents will be imitated. Developing this logic, Bomze (1986) and Nachbar (1990) show that, under many imitative dynamics, every Lyapunov stable rest point is a Nash equilibrium.
As we noted at the onset, the original motivation for the replicator dynamic was to provide a foundation for Maynard Smith and Price's (1973) notion of an evolutionarily stable strategy (ESS). Hofbauer, Schuster and Sigmund (1979) and Zeeman (1980) show that an ESS is asymptotically stable under the replicator dynamic, but that an asymptotically state need not be an ESS.

More generally, when is a Nash equilibrium a dynamically stable rest point, and under which dynamics? Under differentiable dynamics, stability of isolated equilibria can often be determined by linearizing the dynamic around the equilibrium. In many cases, the question of the stability of the rest point $x^*$ reduces to a question of the negativity of certain eigenvalues of the Jacobian matrix $DF(x^*)$ of the payoff vector field. In non-differentiable cases, and in cases where the equilibria in question form a connected component, stability can sometimes be established by using another standard approach: the construction of suitable Lyapunov functions. For an overview of work in these directions, see Sandholm (2007, ch. 6).

In the context of random matching in normal form games, it is natural to ask whether an equilibrium that is stable under an evolutionary dynamic also satisfies the restrictions proposed in the equilibrium refinements literature. Swinkels (1993) and Demichelis and Ritzberger (2003) show that this is true in great generality under even the most demanding refinements: in particular, any component of rest points that is asymptotically stable under a dynamic that respects condition (PC) contains a strategically stable set in the sense of Kohlberg and Mertens (1986). While proving this result is difficult, the idea behind the result is simple. If a component is asymptotically stable under an evolutionary dynamic, then this dynamic stability ought not to be affected by slight perturbations of the payoffs of the game. A fortiori, the existence of the component ought not to be affected by the payoff perturbations either. But this preservation of existence is precisely what strategic stability demands.

This argument also shows that asymptotic stability under evolutionary dynamics is a qualitatively stronger requirement than strategic stability: while strategic stability requires equilibria not to vanish after payoff perturbations, it does not demand that they be attracting under a disequilibrium adjustment process. For example, while all Nash equilibria of simple coordination games are strategically stable, only the pure Nash equilibria are stable under evolutionary dynamics.

Demichelis and Ritzberger (2003) establish their results using tools from index theory. Given an evolutionary dynamic $V^F$ for a game $F$, one can assign each component of rest points an integer, called the index, that is determined by the behaviour of the dynamic in a neighbourhood of the rest point; for instance, regular, stable rest points are assigned an index of 1. The set of all indices for the dynamic $V^F$ is constrained by the Poincaré–Hopf theorem, which tells us that the sum of the indices of the equilibrium components of $V^F$ must equal 1. As a consequence of this deep topological result, one can sometimes determine the local stability of one component of rest points by evaluating the local stability of the others.

6 Global convergence: positive and negative results

To provide the most satisfying evolutionary justification for the prediction of Nash equilibrium play, it is not enough to link the rest points of a dynamic and the Nash equilibria of the underlying game, or to prove local stability results. Rather, one must establish convergence to Nash equilibrium from arbitrary initial conditions. One way to proceed is to focus on a class of games defined by some noteworthy payoff structure, and then to ask whether global convergence can be established for games in this class under certain families of evolutionary dynamics. As it turns out, general global convergence results can be proved for a number of classes of games. Among these classes are potential games, which include common interest games, congestion games, and games generated by externality pricing schemes; stable games, which include zero-sum games,
games with an interior ESS, and (perturbed) concave potential games; and supermodular games, which include models of Bertrand oligopoly, arms races, and macroeconomic search. A fundamental paper on global convergence of evolutionary dynamics is Hofbauer (2000); for a full treatment of these results, see Sandholm (2007).

Once we move beyond specific classes of games, global convergence to Nash equilibrium cannot be guaranteed; cycling and chaotic behaviour become possible. Indeed, Hofbauer and Swinkels (1996) and Hart and Mas-Colell (2003) construct examples of games in which all reasonable deterministic evolutionary dynamics fail to converge to Nash equilibrium from most initial conditions. These results tell us that general guarantees of convergence to Nash equilibrium are impossible to obtain.

In light of this fact, we might instead consider the extent to which solution concepts simpler than Nash equilibrium are supported by evolutionary dynamics. Cressman and Schlag (1998) and Cressman (2003) investigate whether imitative dynamics lead to subgame perfect equilibria in reduced normal forms of extensive form games – in particular, generic games of perfect information. In these games, interior solution trajectories do converge to Nash equilibrium components, and only subgame perfect components can be interior asymptotically stable. But even in very simple games interior asymptotically stable components need not exist, so the dynamic analysis may fail to select subgame perfect equilibria. For a full treatment of these issues, see Cressman (2003).

What about games with strictly dominated strategies? Early results on this question were positive: Akin (1980), Nachbar (1990), Samuelson and Zhang (1992), and Hofbauer and Weibull (1996) prove that dominated strategies are eliminated under certain classes of imitative dynamics. However, Berger and Hofbauer (2006) show that dominated strategies need not be eliminated under the BNN dynamic. Pushing this argument further, Hofbauer and Sandholm (2006) find that dominated strategies can survive under any continuous evolutionary dynamic that satisfies positive correlation and innovation; the latter condition requires that agents choose unused best responses with positive probability. Thus, whenever there is some probability that agents base their choices on direct evaluation of payoffs rather than imitation of successful opponents, evolutionary dynamics may violate even the mildest rationality criteria.

7 Conclusion

Because the literature on evolutionary dynamics came to prominence shortly after the literature on equilibrium refinements, it is tempting to view the former literature as a branch of the latter. But, while it is certainly true that evolutionary models have something to say about selection among multiple equilibria, viewing them simply as equilibrium selection devices can be misleading. As we have seen, evolutionary dynamics capture the behaviour of large numbers of myopic, imperfectly informed decision makers. Using evolutionary models to predict behaviour in interactions between, say, two well-informed players is daring at best.

The negative results described in Section 6 should be understood in this light. If we view evolutionary dynamics as an equilibrium selection device, the fact that they need not eliminate strictly dominated strategies might be viewed with disappointment. But, if we take the result at face value, it becomes far less surprising: if agents switch to strategies that perform reasonably well at the moment of choice, that a strategy is never optimal need not deter agents from choosing it.

A similar point can be made about failures of convergence to equilibrium. From a traditional point of view, persistence of disequilibrium behaviour might seem to undermine the very possibility of a satisfactory economic analysis. But the work described in this entry suggests that in large populations, this possibility is not only real but is also one that game theorists are well equipped to analyse.

Empirical economic analyses of deterrence attempt to test the central prediction of Becker's (1968) rational-actor model of criminal behaviour: that less crime occurs when the expected penalties are greater. When economists have broken the simultaneity of crime rates and crime-control policies, they have generally concluded that policing levels and the scale of incarceration reduce crime rates. Economists have made less progress in determining whether these reductions in crime are due to deterrence or incapacitation, but the research suggests that both effects are likely present. Evidence on the deterrent effect of capital punishment and particular victim precautions is far less convincing.

Article

Empirical economic analyses of deterrence seek to test the central prediction of the economic or rational-actor model of criminal behaviour that Becker (1968) pioneered. In the Beckerian model, a potential offender compares the expected costs and benefits of criminal activity, and when the expected utility of crime exceeds the expected utility loss of any punishment, the actor engages in the criminal activity. Economists have attempted to confirm or refute this model by relating geographic and temporal variation in punishment regimes, which proxy for the expected cost of offending, to aggregate crime rates, which measure the frequency of criminal activity. This approach poses two challenges. First, criminal justice policies are endogenous to crime rates, because jurisdictions often devote greater resources to crime control when the incidence of crime is higher. Second, even if the econometrician breaks the simultaneity of crime rates and crime-control policies, the estimates typically do not reveal
whether deterrence or incapacitation is the operative mechanism.

Estimates of the causal effect of policing levels on crime rates

The criminal justice policies that have most often received empirical evaluation are the scale of policing and imprisonment, which in the economic model of crime correspond to the probability of apprehension and the magnitude of the sanction, respectively. Early studies tried to infer the causal effect of police levels on crime rates by drawing cross-sectional comparisons across cities or states, but Fisher and Nagin (1978) showed that cross-sectional estimates suffer from simultaneity bias because jurisdictions with higher crime rates respond by employing more police. In the 1990s a second wave of literature emerged.

The new studies employed more sophisticated econometric strategies to break the simultaneity problem. For example, Marvell and Moody (1996) used Granger causality to identify the impact of policing levels on crime rates. A variable ‘Granger causes’ another when changes in the first variable generally precede changes in the second, and thus Granger causality refers to a temporal relationship between two variables rather than actual causation (Granger, 1969). Marvell and Moody (1996) applied this technique to more than 20 years of state and city data and found that police Granger-caused lower crime, or that increases in police were associated with future declines in crime.

Levitt (1997) employed a different econometric strategy: an instrumental variables or ‘natural experiment’ approach. He argued that mayoral and gubernatorial elections were valid instruments, because they correlate with police but do not correlate with crime, except through the other explanatory variables in the crime equation. He showed that sizable increases in the police forces in major cities were concentrated in election years, perhaps because greater police generate electoral benefits for politicians. His estimate, that a ten per cent increase in the police force produced at most a ten per cent reduction in crime rates, was comparable in magnitude to Marvell and Moody's (1996). McCrary (2002) argued that, when properly measured, electoral cycles induced insufficient variation in the size of police forces to measure the impact of crime. However, Levitt (2002) showed that an alternative instrumental variable, the number of firefighters, also produces negative and sizable estimates of the impact of police on crime. Recently, Evans and Owens (2005) demonstrated that the federal subsidies from the Clinton Crime Bill stimulated police hiring and produced similar reductions in crime rates.

Other authors used more finely disaggregated data to identify the effect of police on crime. In data with annual observations, any increase in crime and police occurring within a calendar year appears contemporaneous rather than sequential, and the short-term causal effect of police on crime is not observed. Corman and Mocan (2000) examined the short-term effect using nearly 30 years of monthly data from New York City and applying Granger causality techniques. They found that police hiring occurs approximately six months after a jump in crime and that the increase in police leads to reductions in crime as great as Levitt's (1997) largest estimate. Di Tella and Schargrodsky (2004) examined data decomposed to the level of city blocks. When the city of Buenos Aires reallocated police to temples and mosques in response to terrorist threats against them, Di Tella and Schargodsky observed that auto thefts immediately around those buildings declined abruptly but that the reduction in crime quickly decayed with distance.

Despite the use of different estimation procedures and different data-sets, the second wave of literature
on policing and crime produced quite similar estimates of the crime-reducing effect of police levels. The marginal reduction in crime associated with hiring an additional police officer in large urban environments roughly equals the marginal cost.

**Estimates of the causal effect of incarceration rates on crime rates**

Empirical analyses of the crime-reducing effect of prisons evolved in a similar manner to studies of policing. Early efforts failed to recognize or address the simultaneity problem and prematurely concluded that imprisonment has neither deterrent nor incapacitating effects (see Zimring and Hawkins, 1991). In the 1990s researchers again applied more sophisticated empirical strategies that attempted to break the simultaneity problem. Marvell and Moody (1994) applied Granger causality techniques to a repeated cross-section of states and found that a ten per cent increase in the prison population produced nearly a two per cent fall in crime rates. Levitt (1996) disentangled the simultaneity of crime and incarceration by using lawsuits challenging conditions in overcrowded prisons as instrumental variables. He showed that, when the suits produced court orders to reduce overcrowding, states typically complied by releasing prisoners who otherwise would have been incarcerated. His estimates implied that the reduction in crime from incarcerating an additional prisoner was two to three times larger than that predicted by Marvell and Moody (1994).

Although these studies indicate that imprisonment reduces crime, the relevance of their estimated parameters to social policy evaluation of present incarceration levels has already diminished. The prison population has grown so rapidly since the mid-1990s that its margin lies well outside the range in which the parameter estimates were generated. For most reasonable set of assumptions, the current scale of incarceration appears at or above the socially optimal level.

**Estimates distinguishing deterrence from incapacitation**

Although economists’ understanding of the causal relationships among policing, incarceration, and crime has improved, they have made less progress on the question of whether the declines in crime are due to deterrence or incapacitation. Determining the operative effect is crucial for evaluating the economic model of crime and for designing crime-control policy.

A few empirical economic studies attempted to assess the relative importance of deterrence and incapacitation by exploring responses to increased punishments. Kessler and Levitt (1999) studied the effect of a California referendum that provided sentence enhancements for certain serious crimes. The sentence enhancement imposed an additional incapacitating effect only upon completion of the standard prison term, and any decline in crime before that date was arguably attributable to deterrence. Kessler and Levitt found that the rate of crimes covered by the referendum fell relative to other states and that the rate of crimes not covered by the referendum did not change. After the expiration of the standard prison terms, the rate of the affected crimes continued to fall, and this further decline indicated that the full impact of the sentence enhancements included both deterrent and incapacitating effects. Another effort to distinguish deterrence from incapacitation proceeded from the observation that criminals do not specialize in particular types of offences, but instead are generalists who participate in potentially wide range of offences. Levitt (1998a) noted that, if deterrence is the operative mechanism, a
longer sentence for a particular type of crime implies that generalist criminals should substitute to other kinds of crime. If the primary effect is instead incapacitation, then a longer sentence for a particular crime should lower the rate of alternative offences. Using arrest rate data, Levitt (1998a) found mixed evidence for deterrence.

Levitt (1998b) evaluated the responsiveness of criminal activity to the transition from the juvenile to the adult criminal justice system as another means of distinguishing deterrence from incapacitation. In states where the criminal justice system is substantially more punitive than the juvenile system, deterrence predicts that juveniles should reduce their criminal activity immediately upon reaching the age of majority (before there is time for incapacitation to become a factor). States where the adult system was especially punitive relative to the juvenile system experience sharp declines in crime at the age of majority relative to states where the transition to the adult system is most lenient, consistent with deterrence.

Other empirical analyses of deterrence

Capital punishment seemingly offers a direct test of the deterrence hypothesis, because the alternative sentence for a death-eligible offender is typically life imprisonment, and any crime-reducing effect of capital punishment is therefore arguably attributable to deterrence. Ehrlich (1975; 1977a; 1977b) produced some of the earliest and most contested claims of capital punishment's deterrent effect. Cameron (1994) reviews the large literature on the death penalty, and criticisms of Ehrlich's conclusions focus on the sensitivity of the estimates to the time period, the states, and the control variables included in the analysis. Recently, a number of studies examined the relationship between the death penalty and crime rates using repeated cross-sections of states in the period since the Supreme Court's 1976 reinstatement of capital punishment. These studies use data disaggregated at the monthly (Mocan and Gittings, 2003) or county-level (Dezhbakhsh, Rubin and Shepherd, 2003) and study the impact on different kinds of homicide (Shepherd, 2004). All claim deterrent effects at least as large as Ehrlich's original estimates, despite their continuing sensitivity to minor specification changes. In contrast, Katz, Levitt and Shustorovich (2003) used state-level panel data covering the period 1950–90 and detected no effect of the death penalty on crime rates. Unlike the literature on policing and incarceration, the use of higher frequency data and additional control variables has broadened, rather than narrowed, the range of estimated impacts of the death penalty.

Although most empirical economic analyses of deterrence evaluate the role of public law enforcement, a few studies consider the responsiveness of crime to the precautions taken by potential victims. A victim's precaution may have a general deterrent effect only if the prospective offender cannot observe it before deciding to commit the crime. Otherwise, the observation of a precaution may induce the offender to substitute to a more vulnerable victim but have no effect on the total rate of offending (see Clotfelter, 1978; Shavell, 1991). Ayres and Levitt (1998) analysed a particular kind of anti-theft device for automobiles as an unobservable precaution. The device contained a radio transmitter that allows police with special equipment to track the vehicle, but its lack of outward indications made it unobservable to potential offenders. Ayres and Levitt found that, when the device became available in a city, vehicle thefts fell sharply and that it did not induce car thieves to substitute to other types of crimes or to other geographic areas.
Another purported unobservable precaution that received extensive empirical analysis is surreptitious gun possession. Lott and Mustard (1997) and Lott (1998) claimed that laws relaxing the requirements for concealed weapons permits had a general deterrent effect on crime rates, but numerous researchers challenged the Lott findings. Ayres and Donohue (1999) found that in more recent years the law correlated either positively or not at all with crime rates, and Duggan (2000) showed that crime rates in states that adopted concealed-weapons laws began to decline before the passage of the laws. Other researchers argued that additional tests of the hypothesis failed to confirm it. Ludwig (1998) found that that passage of these laws was associated with large declines in the victimization of juveniles, a group not permitted to carry concealed weapons under these laws. Kovandzic and Marvell (2003) reported no relationship between the number of concealed weapons permits issued and violent crime rates in a single state.

Abstract

In both its classical and modern versions the economic theory of crime is predicated on ‘the deterrence hypothesis’ – the assumption that potential and actual offenders respond to both positive and negative incentives, and that the volume of offences in the population is influenced by law enforcement and other means of crime prevention. This article traces the evolution of the modern approach to crime from the traditional focus on the interaction between offenders and law enforcers to the development of a more comprehensive ‘market model’ under both partial and general equilibrium settings. Theoretical extensions also emphasize alternative criteria for optimal law enforcement.

Article

The persistence of criminal activity throughout human history and the challenges it poses for determining optimal law-enforcement activity have already attracted the attention of utilitarian philosophers and early economists like Beccaria, Paley and Bentham. It was not until the late 1960s, however, especially following the seminal work by Becker (1968), that economists reconnected with the subject, using the modern tools of economic theory and econometrics.

In both its utilitarian and modern versions the economic approach to crime is predicated on what the new literature calls ‘the deterrence hypothesis’ – the assumption that potential and actual offenders respond to incentives, and that the volume of offences in the population is therefore influenced by law enforcement and other means of crime prevention. By its common connotation, deterrence generally refers to the threat of a criminal sanction, or any other form of punishment having some moderating
effect on the willingness to engage in criminal activity. To interpret this hypothesis so narrowly misses, however, the basic idea on which it is founded (Ehrlich, 1979). The hypothesis relates to the role of both negative incentives (such as the prospect of apprehension, conviction and punishment) and positive incentives (such as opportunities for gainful employment in legitimate relative to illegitimate occupations) as deterrents to actual or would-be offenders. It follows that not just conventional law enforcement matters in influencing the flow of offences but external market and household conditions as well, to the extent that these affect prospective gains and losses from illegitimate activity. For this approach to provide a useful approximation of the complicated reality of crime, it is not necessary that all those who commit specific crimes respond to incentives, nor is the degree of individual responsiveness prejudged; it is sufficient that a significant number of potential offenders so behave on the margin. By the same token, the theory does not preclude a priori any category of crime, or any class of incentives, as non-conforming. Indeed, economists have applied the deterrence hypothesis to a myriad of illegal activities, from tax evasion, drug abuse and fraud to skyjacking, robbery and murder.

The economic approach

In Becker's analysis the equilibrium volume of crime reflects the interaction between offenders and the law-enforcement authority, and the focus is on optimal probability, severity, and type of criminal sanction – the implicit ‘prices’ society imposes on criminal behaviour – in view of their impact on offenders and the relative social costs associated with their imposition. Subsequent theoretical work has focused on more complete formulations of specific components of the system and their micro foundations – primarily the supply of offences, the production of specific law-enforcement activities, and alternative criteria for achieving socially optimal law enforcement. A later evolution has aimed to expand the analytical setting within which crime is analysed to address the interaction between potential offenders (supply), consumers and potential victims (private actual or indirect ‘demand’), and deterrence and prevention by public authorities (government intervention). This ‘market model of crime’ (Ehrlich, 1981; 1996) has been further explored in recent years to include interactions between criminal activity and the general economy. For the specific articles on which the following discussion is based, see Ehrlich and Liu (2006, vols. 1 and 2).

Supply

The extent of participation in crime is generally modelled as an outcome of the allocation of time among competing legitimate and illegitimate activities by potential offenders. Since illegitimate activity carries the distinct risk of apprehension and punishment for illegitimate behaviour, individuals are assumed to act as expected-utility maximizers. This may generally lead many offenders to be multiple-job holders – being part-time offenders, or going in and out of criminal activity (see Ehrlich, 1973, and the empirical documentation in Reuter, MacCoun and Murphy, 1990). While the mix of pecuniary and non-pecuniary benefits varies across different crime categories, which attract persons of different earning opportunities or attitudes towards risk and moral values (‘preferences’), the basic opportunities affecting choice are identified in all cases as the perceived probabilities of apprehension, conviction and punishment, the marginal penalties imposed, and the expected net return on illegal over legal activity. Net returns from
crime rise with the level of community wealth, which enhances the potential loot from property crime, and fall with the probability of finding employment in the legitimate labour market and the prospective legitimate wages. Entry into criminal activity and the extent of involvement in crime are thus shown to be related inversely to deterrence variables and directly to the differential return it can provide over legitimate activity. Moreover, a one per cent increase in the probability of apprehension is shown to exert a larger deterrent effect than corresponding increases in the conditional probabilities of conviction and of any specific punishment if convicted (Ehrlich, 1975). Essentially due to conflicting income and substitution effects, however, sanction severity can have more ambiguous effects on active offenders: a strong preference for risk may weaken (Becker, 1968) or even reverse (Ehrlich, 1973) the deterrent effect of sanctions, and the results are even less conclusive if one assumes that the length of time spent in crime, not just the moral obstacle to entering it, generates disutility (Block and Heineke, 1975).

The results become less ambiguous at the aggregate level, however, as one allows for heterogeneity of potential offenders due to differences in legitimate employment opportunities or preferences for risk and crime: a more severe sanction can reduce the crime rate by deterring the entry of potential offenders even if it has little effect on actual ones (Ehrlich, 1973). In addition to heterogeneity across individuals in personal opportunities and preferences, the literature has also addressed the role of heterogeneity in individuals’ perceptions about probabilities of apprehension, as affected by learning from past experience (Sah, 1991). As a result, current crime rates may react, in part, to past deterrence measures. A different type of heterogeneity that can affect variability in crime rates across different crime categories and geographical units is identified by Glaeser, Sacerdote and Scheinkman (1996) and Glaeser and Sacerdote (1999) as stemming from the degree of social interaction: that is, the extent to which potential offenders are influenced by the behaviour of their neighbours.

**Private demand**

The incentives operating on offenders often originate from, and are partially controlled by, consumers and potential victims. Transactions in illicit drugs or stolen goods, for example, are patronized by consumers who generate a direct demand for the underlying offence. But even crimes that inflict pure harm on victims are affected by an indirect (negative) demand, which is derived from a positive demand for safety (Ehrlich, 1981). By their choice of optimal self-protection (lowering the risk of becoming a victim) or self-insurance (reducing the potential loss if victimized) through use of locks, guards, safes, and alarms, or selective avoidance of crime-prone areas (Bartel, 1975; Shavell, 1991; Cullen and Levitt, 1999), potential victims influence the marginal costs to offenders, and thus the implicit return on crime. And since optimal self-protection generally increases with the perceived risk of victimization (the crime rate), private protection and public enforcement will be interdependent. The interaction between the two and its impact on possible fluctuations in the equilibrium volume of offences is explored in Clotfelter (1977), and Phillipson and Posner (1996).

**Public intervention**

Since crime, by definition, causes a net social loss, and crime control measures are largely a public good,
collective action is needed to augment individual self-protection. Public intervention typically aims to ‘tax’ illegal returns through the threat of punishment, or to ‘regulate’ offenders via incapacitation and rehabilitation programmes. All control measures are costly. Therefore, the ‘optimum’ volume of offences as determined by the law-enforcement authority acting as a social planner cannot be nil, but must be set at a level where the marginal cost of each measure of enforcement or prevention equals its marginal benefit.

To assess the relevant net social loss, however, one must adopt a criterion for public choice. Becker (1968) and Stigler (1970) have chosen variants of aggregate income measures as the relevant social welfare function to be maximized, requiring the minimization of the sum of social damages from offences and the social cost of law-enforcement activities. This approach can lead to powerful propositions regarding the optimal magnitudes of probability and severity of punishments for different crimes and different offenders, or, alternatively, the optimal level and mix of expenditures on police, courts and corrections. The analysis reaffirms the classical utilitarian proposition that the optimal severity of punishment should ‘fit the crime’, and thus be assessed essentially by its deterrent value, as the marginal social cost is higher for offences causing greater marginal social damage. Moreover, it makes a strong case for the desirability of monetary fines as a deterring sanction, since fines involve pure transfer payments between offenders and the rest of society. Different criteria for public choice, however, yield different implications regarding the optimal mix of probability and severity of punishment, as is the case when the social welfare function is expanded to include concerns for the ‘distributional consequences’ of law enforcement on offenders and victims in addition to their aggregate income, in which case even fines can become socially costly. These considerations can be ascribed to aversion to risk (as in Polinsky and Shavell, 1979), or to aversion towards *ex post* inequality under the law as a result of the ‘lottery’ nature of law enforcement, by which only offenders caught and convicted for crime pay for the damage caused by all offenders, including the luckier ones who escape apprehension and conviction (as in Ehrlich, 1982). A positive analysis of enforcement must also address the behaviour of the separate agencies constituting the criminal justice system: police, courts, and prison authorities. For example, Landes’s analysis (1971) of the courts, which focuses on the interplay between prosecutors and defence teams, explains why settling cases out of court may be an efficient outcome of many court proceedings.

The optimal enforcement policy arising from the income-maximizing criterion can be questioned from yet another angle: a public-choice perspective. The optimization rule invoked in the aforementioned papers assumes that enforcement is carried out by a social planner. In practice, public law enforcement can facilitate the interests of rent-seeking enforcers who are amenable to malfeasance and bribes. Optimal social policy needs to control malfeasance by properly remunerating public enforcers (Becker and Stigler, 1974) or, where appropriate, setting milder penalties (Friedman, 1999).

**Market equilibrium**

In Ehrlich's (1981; 1996) ‘market model’, the equilibrium flow of offences results from the interaction between aggregate supply of offences, direct or derived demand for offences (through self-protection), and optimal public enforcement, which operates like a tax on criminal activity. The model derives the equilibrium volume of offences as well as the equilibrium net return, or premium, to offenders from...
illegitimate over legitimate activity as a result of the interaction between the relevant aggregate supply, ‘demand’, and government net taxation of crime in a competitive setting. One important application concerns a comparison of deterrence, incapacitation and rehabilitation as instruments of crime control. This is because the efficacy of deterring sanctions cannot be assessed merely by the elasticity of the aggregate supply of offences schedule, as it depends on the elasticity of the private demand schedule as well. Likewise, the efficacy of rehabilitation and incapacitation programmes cannot be inferred solely from knowledge of their impact on individual offenders (see Cook, 1975). It depends crucially on the elasticities of the market supply and demand schedules, as these determine the extent to which successfully rehabilitated offenders will be replaced by others responding to the prospect of higher net returns. This market setting has also been applied by Viscusi (1986), who links observed net returns on specific crimes to underlying parameters of the model, and in works by Schelling (1967), Buchanan (1973), and Garoupa (2000), who analyse various aspects of organized crime by viewing it in a monopolistic rather than a competitive setting.

Crime and the economy

The ‘market model’ has been developed largely in a static, partial-equilibrium setting in which the general economy affects the illegal sector of the economy, but not vice versa. More recently, the model has been extended to deal with the interaction between the two under static and dynamic conditions as well. For example, Ehrlich (1973) argues that income inequality, serving as a proxy for relative earning opportunities in illegal versus legal activities, induces time allocation in favour of illegal activity. A number of subsequent studies interpreted this relation to imply that the volume of offences can be lowered through subsidies to legitimate employment by workers with low legitimate earning capacity. Using a general-equilibrium setting, Imrohoroglu, Merlo and Rupert (2000) show, however, that, to the extent that subsidies must be paid for by raising taxes on legitimate production, such income distribution policies have an ambiguous effect on crime. The subsidy raises the opportunity cost of crime to apprehended offenders, but it also works as a disincentive to legitimate production because of an increased tax rate, which lowers the tax revenue available for crime detection. The choice between legitimate and illegitimate activity may have not just static effects on the economy's level of output but dynamic growth effects as well if it affects productive human capital formation, which serves as an engine of productivity growth. Bureaucratic corruption is a case in point. As Ehrlich and Lui (1999) argue, this is because, whenever government intervenes in private economic activity, bureaucrats have an opportunity to engage in rent seeking by collecting explicit or implicit bribes, which rise with their bureaucratic status. The return on corruption is thus higher the greater is one's investment in becoming a bureaucrat or attaining higher bureaucratic status, which competes with investment in productive human capital. The analysis explains why corruption is a barrier to growth especially in less developed countries, and why under benevolent autocratic regimes the rate of economic growth can be as high as under democratic regimes.

Investigating and implementing alternative versions of a comprehensive model of crime based on micro foundations remains an intriguing challenge for future research.

Abstract

This article surveys the current state of development economics, a subject that studies growth, inequality, poverty and institutions in the developing world. The article is organized around a view that emphasizes the role of history in creating development traps or slow progress. This ‘non-convergence’ viewpoint stands in contrast to a more traditional view, also discussed, based on the notion of economic convergence (across individuals, regions or countries). Some specific research areas in development economics receive closer scrutiny under this overall methodological umbrella, among them political economy, credit markets, legal issues, collective action and conflict.

Article

What we know as the ‘developing world’ is approximately the group of countries classified by the World Bank as having ‘low’ and ‘middle’ incomes. An exact description is unnecessary and not too revealing; suffice it to observe that these countries make up over five billion of the world's population, leaving out the approximately one billion who are part of the ‘high’ income ‘developed world’. Together, the low- and middle-income countries generate approximately six trillion (2001) dollars of national income, to be contrasted with the 25 trillion generated by high-income countries. An index of income that controls for purchasing power would place these latter numbers far closer together (approximately 20 trillion and 26 trillion, according to the World Development Report, World Bank, 2003), but the per capita disparities are large and obvious, and to those encountering them for the first
Development economics, a subject that studies the economics of the developing world, has made excellent use of economic theory, econometric methods, sociology, anthropology, political science, biology and demography, and has burgeoned into one of the liveliest areas of research in all the social sciences. My limited approach in this brief article is one of deliberate selection of a few conceptual points that I consider to be central to our thinking about the subject. The reader interested in a more comprehensive overview is advised to look elsewhere (for example, at Dasgupta, 1993; Hoff, Braverman and Stiglitz, 1993; Ray 1998; Bardhan and Udry, 1999; Mookherjee and Ray, 2001; Sen, 1999).

I begin with a traditional framework of development, one defined by conventional growth theory. This approach develops the hypothesis that given certain parameters, say savings or fertility rates, economies inevitably move towards a steady state. If these parameters are the same across economies, then in the long run all economies converge to one another. If in reality we see the utter lack of such convergence – which we do (see, for example, Quah, 1996; Pritchett, 1997) – then such an absence must be traced to a presumption that the parameters in question are not the same. To the extent that history plays any role at all in this view, it does so by affecting these parameters – savings, demographics, government interventionism, ‘corruption’ or ‘culture’.

This view is problematic for reasons that I attempt to clarify below. Indeed, the bulk of this article is organized around the opposite presumption: that two societies with the same fundamentals can evolve along very different lines – going forward – depending on past expectations, aspirations or actual history. To some extent, the distinction between evolution and parameter is a semantic one. By throwing enough state variables (‘parameters’) into the mix, one might argue that there is no difference at all between the two approaches. Formally, that would be correct, but then ‘parameters’ would have to be interpreted so broadly as to be of little explanatory value. Ahistorical convergence and historically conditioned divergence express two fundamentally different world views, and there is little that semantic jugglery can do to bring them together.

1 Development from the viewpoint of convergence

Why are some countries poor while others are rich? What explains the success stories of economic development, and how can we learn from the failures? How do we make sense of the enormous inequalities that we see, both within and across questions? These, among others, are the ‘big questions’ of economic development.

It is fair to say that the model of economic growth pioneered by Robert Solow (1956) has had a fundamental impact on ‘big-question’ development economics. An entire literature, including theory, calibration and empirical exercises, emanates from this starting point (see, for example, Lucas, 1990; Mankiw, Romer and Weil, 1992; Barro, 1991; Parente and Prescott, 2000; Banerjee and Duflo, 2005). Solow’s path-breaking work introduced the notion of convergence: countries with a low endowment of capital in relation to labour will have a high rate of return to capital (by the ‘law’ of diminishing returns). Consequently, a given addition to the capital stock will have a larger impact on per capita income. It follows that, if we suitably control for parameters such as savings rates and population growth rates, poorer countries will tend to grow faster and hence will catch up or converge to the levels of well-
being enjoyed by their richer counterparts. According to this view, development is largely a matter of getting some economic and demographic parameters right and then settling down to wait. It is true that savings and demography are not the only factors that qualify the argument. Anything that systematically affects the marginal addition to per capita income must be controlled for, including variables such as investment in ‘human capital’ or harder-to-quantify factors such as ‘political climate’ or ‘corruption’. A failure to observe convergence must be traced to one or another of these ‘parameters’. Convergence relies on diminishing returns to ‘capital’. If this is our assumed starting point, the share of capital in national income gives us rough estimates of the concavity of production in capital. The problem is that the resulting concavity understates observed variation in cross-country income by orders of magnitude. For instance, Parente and Prescott (2000) calibrate a basic Cobb–Douglas production function by using reasonable estimates of the share of capital income (0.25), but then huge variations in the savings rate do not change world income by much. For instance, doubling the savings rate leads to a change in steady-state income by a factor of 1.25, which is inadequate to explain an observed range of around 20:1 (in purchasing-power-parity incomes). Indeed, as Lucas (1990) observes, the discrepancy actually appears in a more primitive way, at the level of the production function. For the same simple production function to fit the data on per capita income differences, a poor country would have to have enormously higher rates of return to capital; say, 60 times higher if it is one-fifteenth as rich. This is implausible. And so begins the hunt for other factors that might explain the difference. What did we not control for, but should have?

This describes the methodological approach. The convergence benchmark must be pitted against the empirical evidence on world income distributions, savings rates, or rates of return to capital. The two will usually fail to agree. Then we look for the parametric differences that will bridge the model to the data.

‘Human capital’ is often used as a first port of call: might differences here account for observed cross-country variation? The easiest way to slip differences in human capital into the Solow equations is to renormalize labour. Usually, this exercise does not take us very far. Depending on whether we conduct the Lucas exercise or the Prescott–Parente variant, we would still be predicting that the rate of return to capital is far higher in India than in the United States, or that per capita income differences are only around half as much (or less) as they truly are. The rest must be attributed to that familiar black box – ‘technological differences’. That slot can be filled in a variety of ways: externalities arising from human capital, incomplete diffusion of technology, excessive government intervention, within-country misallocation of resources, and so on. All these – and more – are interesting candidates, but by now we have wandered far from the original convergence model; and if that model still continues to illuminate, it is by way of occasional return to the recalibration exercise, after choosing plausible specifications for each of these potential explanations.

This model serves as a quick and ready fix on the world, and it organizes a search for possible explanations. Taken with the appropriate quantity of salt, and viewed as a first pass, such an exercise can be immensely useful. Yet playing this game too seriously reveals a particular world view. It suggests a fundamental belief that the world economy is ultimately a great leveller, and that if the levelling is not taking place we must search for that explanation in parameters that are somehow structurally rooted in a society.

While the parameters identified in these calibration exercises go hand in hand with underdevelopment, so do bad nutrition, high mortality rates, or lack of access to sanitation, safe water and housing. Yet
there is no ultimate causal chain: many of these features go hand in hand with low income in self-reinforcing interplay. By the same token, corruption, culture, procreation and politics are all up for serious cross-examination: just because ‘cultural factors’ (for instance) seems more weighty an ‘explanation’, that does not permit us to assign them the status of a truly exogenous variable. In other words, the convergence predicted by technologically diminishing returns to inputs should not blind us to the possibility of non-convergent behaviour when all variables are treated as they should be – as variables that potentially make for underdevelopment, but also as variables that are profoundly affected by the development process.

2 Development from the viewpoint of non-convergence

This leads to a different way of asking the big questions, one that is not grounded in any presumption of convergence. The starting point is that two economies with the same fundamentals can move apart along very different paths. Some of the best-known economists writing on development in the first half of the 20th century were instinctively drawn to this view: Young (1928); Nurkse (1953); Leibenstein (1957); and Myrdal (1957) among them.

Historical legacies need not be limited to a nation's inheritance of capital stock or GDP from its ancestors. Factors as diverse as the distribution of economic or political power, legal structure, traditions, group reputations, colonial heritage and specific institutional settings may serve as initial conditions – with a long reach. Even the accumulated baggage of unfulfilled aspirations or depressed expectations may echo into the future. Factors that have received special attention in the literature include historical inequalities, the nature of colonial settlement, the character of early industry and agriculture, and early political institutions.

2.1 Expectations and development

Consider the role of expectations. Rosenstein-Rodan (1943) and Hirschman (1958) (and several others following them) argued that economic development could be thought of as a massive coordination failure, in which several investments do not occur simply because other complementary investments are similarly depressed in the same bootstrapped way. Thus one might conceive of two (or more) equilibria under the very same fundamental conditions, ‘ranked’ by different levels of investment. Such ‘ranked equilibria’ rely on the presence of a complementarity, a particular form of externality in which the taking of an action by an agent increases the marginal benefit to other agents from taking a similar action. In the argument above, sector-specific investments lie at the heart of the complementarity: more investment in one sector raises the return to investment in some related sector. Once complementarities – and their implications for equilibrium multiplicity – enter our way of thinking, they seem to pop up everywhere. Complementarities play a role in explaining how technological inefficiencies persist (David, 1985; Arthur, 1994), why financial depth is low (and growth volatile) in developing countries (Acemoglu and Zilibotti, 1997), how investments in physical and human capital may be depressed (Romer, 1986; Lucas, 1988), why corruption may be self-sustaining (Kingston, 2005; Emerson, 2006), the growth of cities (Henderson, 1988; Krugman, 1991), the suddenness of currency crises (Obstfeld, 1994), or the fertility transition (Munshi and Myaux, 2006);
could easily go on. Even the traditional Rosenstein-Rodan view of demand complementarities has been formally resurrected (Murphy, Shleifer and Vishny, 1989).

An important problem with theories of multiple equilibria is that they carry an unclear burden of history. Suppose, for instance, that an economy has been in a low-level investment trap for decades. Nothing in the theory prevents the very same economy from abruptly shooting into the high-level equilibrium today. There is a literature that studies how the past might weigh on the present when a multiple equilibria model is embedded in real time (see, for example, Adserà and Ray, 1998; Frankel and Pauzner, 2000). When we have a better knowledge of such models we will be able to make more sense of some classical issues, such as the debate on balanced versus unbalanced growth. Rosenstein-Rodan argued that a ‘big push’ – a large, balanced infusion of funds – is ideal for catapulting an economy away from a low-level equilibrium trap. Hirschman argued, in contrast, that certain ‘leading sectors’ should be given all the attention, the resulting imbalance in the economy provoking salubrious cycles of private investment in the complementary sectors. To my knowledge, we still lack good theories to examine such debates in a satisfactory way.

2.2 Aspirations, mindsets and development

The aspirations of a society are conditioned by its circumstances and history, but they also determine its future. There is scope, then, for a self-sustaining failure of aspirations and economic outcomes, just as there is for ever-progressive growth in them (Appadurai, 2004; Ray, 2006).

Typically, the aspirations of an individual are generated and conditioned by the experiences of others in her ‘cognitive neighbourhood’. There may be several reasons for this: the use of role models, the importance of relative income, the transmission of information, or peer-determined setting of internal standards and goals. Such conditioning will affect numerous important socio-economic outcomes: the rate of savings, the decision to migrate, fertility choices, technology adoption, adherence to norms, the choice of ethnic or religious identity, the work ethic, or the strength of mutual insurance motives.

As an illustration, consider the notion of an aspirations gap. In a relatively narrow economic context (though there is no need to restrict oneself to this) such a gap is simply the difference between the standard of living that is aspired to and the standard of living that one already has. The former is not exogenous; it will depend on the ambient standards of living among peers or near-peers, or perhaps other communities.

The aspirations gap may be filled, or neglected, by deliberate action. Investments in education, health, or income-generating activities are obvious examples. Does history, via the creation of aspirations gaps, harden existing inequalities and generate poverty traps? Or does the existence of a gap spur individuals on ever harder to narrow the distance? As I have argued in Ray (1998, Sections 3.3.2 and 7.2.4) and Ray (2006), the effect could go either way. A small gap may encourage investments, a large gap stifle it. This leads not only to history-dependence, but also a potential theory of the connections between income inequality and the rate of growth.

These remarks are related to Duflo's (2006) more general (but less structured) hypothesis that ‘being poor almost certainly affects the way people think and decide’. This ‘mindset effect’ can manifest itself in many ways (an aspirations gap being just one of them), and can lead to poverty traps. For instance, Duflo and Udry (2004) find that certain within-family insurance opportunities seem to be inexplicably
In broadly similar vein, Udry (1996) finds that men and women in the same household farm land in a way that is not Pareto-efficient (gains in efficiency are to be had by simply reallocating inputs to the women's plots). These observations suggest a theory of the poor household in which different sources of income are treated differently by members of the household, perhaps in the fear that this will affect threat points in some intra-household bargaining game. This in itself is perhaps not unusual, but the evidence suggests that poverty itself heightens the salience of such a framework.

2.3 Markets and history dependence

I now move on to other pathways for history dependence, beginning with the central role of inequality. According to this view, historic inequalities persist (or widen) because each individual entity – dynasty, region, country – is swept along in a self-perpetuating path of occupational choice, income, consumption and accumulation. The relatively poor may be limited in their ability to invest productively, both in themselves and in their children. Such investments might include both physical projects, such as starting a business, and ‘human projects’, such as nutrition, health and education. Or the poor may have ideas that they cannot profitably implement, because implementation requires start-up funds that they do not have. Yet, faced with a different level of initial inequality, or jolted by a one-time redistribution, the very same economy may perform very differently. The ability to make productive investments is now distributed more widely throughout the population, and a new outcome emerges with not just lower inequality, but higher aggregate income. These are different steady states, and they could well be driven by distant histories (see, for example, Dasgupta and Ray, 1986; Banerjee and Newman, 1993; Galor and Zeira, 1993; Ljungqvist 1993; Ray and Streufert, 1993; Piketty 1997; Matsuyama, 2000).

The intelligent layperson would be unimpressed by the originality of this argument. That the past systematically preys on the present is hardly rocket science. Yet theories based on convergence would rule out such obvious arguments. Under convergence, the very fact that the poor have limited capital in relation to labour allows them to grow faster and (ultimately) to catch up. Economists are so used to the convergence mechanism that they sometimes do not appreciate just how unintuitive it is.

That said, it is time now to cross-examine our intelligent layperson. For instance, if all individuals have access to a well-functioning capital market, they should be able to make an efficient economic choice with no heed to their starting position, and the shadows cast by past inequalities must disappear (or at least dramatically shrink). For past wealth to alter current investments, imperfections in capital or insurance markets must play a central role.

At the same time, such imperfections are not sufficient: the concavity of investment returns would still guarantee convergence. A first response is that ‘production functions’ are simply not concave. A variety of investment activities have substantial fixed costs: business start-ups, nutritional or health investments, educational choices, migration decisions, crop adoptions. Indeed, it is hard to see how the presence of such non-convexities could not be salient for the ultra poor. Coupled with missing capital markets, it is easy to see that steady state traps, in which poverty breeds poverty, are a natural outcome (see, for example, Majumdar and Mitra, 1982; Galor and Zeira, 1993). Surveys of the economic conditions of the poor (Fields, 1980; Banerjee and Duflo, 2007) are eminently consistent with this point of view.

A related source of non-convexity arises from limited liability. A highly indebted economic agent may have little incentive to invest. Similarly, poor agents may enter into contracts with explicit or implicit
lower bounds on liability. These bounds can create poverty traps (Mookherjee and Ray, 2002a).
Investment activities that go past these minimal thresholds are potentially open to ‘convexification’.
There are various stopping points for human capital acquisition, and a household can hold financial
assets which are, in the end, scaled-down claims on other businesses. According to this point of view,
dynasties that make it past the ultra-poor thresholds will exhibit ergodic behaviour (as in Loury, 1981;
Becker and Tomes, 1986) and so the prediction is roughly that of a two-class society: the ultra poor are
captured in a poverty trap and the remainder enjoy the benefits of convergence. History would matter in
determining the steady-state proportions of the ultra-poor.
But this sort of analysis ignores the endogenous non-convexities brought about by the price system. For
instance, even if there are many different education levels, the wage payoff to each such level will
generally be determined by the market. There is good reason to argue (see, for example, Ljungqvist,
1993; Freeman, 1996; Mookherjee and Ray, 2002b; 2003) that the price system will sort individuals into
different occupational choices, and that there will be persistent inequality across dynasties located at
each of these occupational slots. Thus an augmented theory of history dependence might predict a
particular proportion of the ultra-poor trapped by physical non-convexities (low nutrition, ill-health,
debt, lack of access to primary education), as well as a persistently unequal dispersion of dynasties
across different occupational choices, induced by the pecuniary externalities of relative prices.
Note that it is precisely the high-inequality, high-poverty steady states that are correlated with low
average incomes for society as a whole, and it is certainly possible to build a view of underdevelopment
from this basic premise. The argument can be bolstered by consideration of economy-wide externalities;
for instance, in physical and human capital (Romer, 1986; Lucas, 1988; Azariadis and Drazen, 1990).

2.4 History, aggregates and the interactive world

Theories such as these might yield a useful model for the interactive world economy. Take, for instance,
the notion of aspirations. Just as domestic aspirations drive the dynamics of accumulation within
countries, there is a role, too, for national aspirations that are driven by inter-country disparities in
consumption and wealth, with implications for the international distribution of income. Even the
simplest growth framework that exhibits the usual features of convexity in its technology and budget
constraints could give rise in the end to a bipolar world distribution. Countries in the middle of that
distribution would tend to accumulate faster, be more dynamic and take more risks as they see the
possibility of full catch-up within a generation or less. One might expect the greatest degree of ‘country
mobility’ in this range. In contrast, societies that are far away from the economic frontier may see
economic growth as too limited and too long-term an instrument, leading to a failure, as it were, of
‘international aspirations’. Groups within these societies may well resort to other methods of potential
economic gain, such as rent-seeking or conflict. (The aggregate impact of such activities would reinforce
the slide.)
Of course, an entirely mechanical transplantation of the aspirations model to an international context is
not a good idea. Countries are not individual units: a more complete theory must take into account the
aspirations of various groups in the different countries, and the domestic and international components
that drive such aspirations.
Next, consider the role of markets. Once again, tentatively view each country as a single economic agent
in the framework of Section 2.3. The non-convexities to be considered are at the level of the country as a whole – Young's increasing returns on a grand scale, or economy-wide externalities as in Lucas–Azariadis–Drazen. This reinterpretation is fairly standard, but, less obviously, the occupational choice story stands up to reinterpretation as well. To see this, note that the pattern of production and trade in the world economy will be driven by patterns of comparative advantage across countries. But in a dynamic framework, barring non-reproducible resources such as land or mineral endowments, every endowment is potentially accumulable, so that comparative advantage becomes endogenous. Thus we may view countries as settling into subsets of occupational slots (broadly conceived), producing an incomplete range of goods and services in relation to the world list, and engaging in trade.

For instance, suppose that country-level infrastructure can be tailored to either high-tech or low-tech production, but not both. If both high-tech and low-tech are important in world production and consumption, then one country has to focus on low-tech and another on high-tech. Initial history will constrain such choices, if for no other reason than the fact that existing infrastructure (and national wealth) determines the selection of future infrastructure. This is not to say that no country can break free of those shackles. For instance, as the whole world climbs up the income scale, natural non-homotheticities in demand will push commodity compositions increasingly in favour of high-quality goods. As this happens, more countries will be able to make the transition. But on the whole, if national infrastructure is more or less conducive to some (but not the full) range of goods, the non-convergence model that we discussed for the domestic economy must apply to the world economy as well.

This raises an obvious question: what is so specific about ‘national infrastructure’? Why is it not possible for the world to ultimately rearrange itself so that every country produces the same or similar mix of goods, thus guaranteeing convergence? Do current national advantages somehow manifest themselves in future advantages as well, thus ensuring that the world economy settles into a permanent state of global inequality? Might economic underdevelopment across countries, at least in this relative sense, always stay with us?

To properly address such questions we have to drop the tentative assumption that each country can be viewed as an individual unit. In a more general setting, there are individuals within countries, and then there is cross-country interaction. The former are subject to the forces of occupational structure (and possible fixed costs), as discussed in Section 2.3. The latter are subject to the specificities, if any, of ‘national infrastructure’, determining whether countries as a whole have to specialize (at least to some degree). The relative importance of within-country versus cross-country inequalities will rest, in large part, on considerations such as these.

I have not brought in international political economy so far (though see below); yet, as frameworks go, this is not a bad one to start thinking about the effects of globalization. It is certainly preferable to a view of the world as a set of disconnected, autarkic growth models.

### 2.5 Institutions and history

In many developing countries, the early institutions of colonial rule were directly set up for the purposes of surplus extraction. There would be variation, of course, depending on whether the areas were sparsely or densely populated to begin with, or whether there was widespread availability of mineral deposits. Resource deposits certainly favoured large-scale extractive industry (as in parts of South America), while soil and weather conditions might encourage plantation agriculture, often with the use of slave
labour (as in the Caribbean). On the other hand, a high pre-existing population density would favour extraction of a different hue: the setting up of institutional systems to acquire rents (the British colonial approach in large parts of India).

It has been argued, perhaps most eloquently by Sokoloff and Engerman (2000), that initial institutional modes of production and extraction in distant history had far-reaching effects on subsequent development. In their words, scholars ‘have begun to explore the possibility that initial conditions, or factor endowments broadly conceived, could have had profound and enduring impacts on long-run paths of institutional and economic development’ (2000, p. 220). The inequalities generated by such initial conditions may subsequently be inimical to development in a variety of ways (via the market-based pathways discussed earlier, for instance). In contrast, where initial settlements did not go hand in hand with systems of tribute, land grants, or large-scale extractive industries (as in several regions of North America), one might expect broad-based development to occur.

This is consistent with the market-based processes considered earlier. But a principal strand of the Sokoloff–Engerman argument, as also the lines of reasoning pursued in Robinson (1998), Acemoglu, Johnson and Robinson (2001; 2002) and Acemoglu (2006), emphasizes political economy. In the words of Sokoloff and Engerman,

[I]nitial conditions had lingering effects … because government policies and other institutions tended to reproduce them. Specifically, in those societies that began with extreme inequality, elites were better able to establish a legal framework that insured them disproportionate shares of political power, and to use that greater influence to establish rules, laws, and other government policies that advantaged members of the elite relative to nonmembers contributing to persistence over time of the high degree of inequality … In societies that began with greater equality or homogeneity among the population, however, efforts by elites to institutionalize an unequal distribution of political power were relatively unsuccessful … (Sokoloff and Engerman, 2000, p. 223–4)

The elite – erstwhile collectors of tribute, land-grant recipients, plantation owners and the like – may survive long after the initial institutions that spawned them are gone. Such survival may nevertheless be compatible with the maximization of aggregate surplus, provided that the elite are the most efficient of the economic citizenry in the generations to come. But there is absolutely no reason why this should be the case. A new generation of entrepreneurs, economic and political, may be waiting to take over in the wings. It is an open question as to what will happen next, but the elite may well engage in policy that has as its goal not economic efficiency but the crippling of political opposition. Some evidence of this reluctance to let go may be seen in literature that argues that more unequal societies redistribute less (see Perotti, 1994; 1996; the survey by Bénabou, 1996).

There are other routes. The elite may be unable to avoid an oppositional showdown. A theory of bad policy may then have to be replaced by a model of social unrest and conflict generated by initial inequality. While this mechanism is clearly different, the end result is the same. The channelling of resources to ongoing conflict will surely inhibit the accumulation of productive resources (Benhabib and Rustichini, 1996; González, 2007). There may also be effects running through legal systems (see, for example, La Porta et al., 1997; 1998) or the varying nature of different colonial systems (see, for
example, Bertocchi and Canova, 2002). There may be effects running through the insecurity of property rights or fear of elite expropriation (see, for example, Binswanger, Deininger and Feder, 1995). We do not yet have a systematic exploration of these mechanisms, nor an accounting of their relative importance. But there is some reduced-form evidence that historical institutions affect growth in the manner described by Sokoloff and Engerman. The problem in establishing an empirical assertion of this sort is fairly obvious: good institutions and good economic outcomes may simply be correlated via variables we fail to observe or measure, or any observed causality may simply run from outcomes to institutions. Acemoglu, Robinson and Johnson (2001) propose a novel instrument for (bad) institutions: the mortality rate among European settlers (bishops, sailors and soldiers to be exact). This is a clever idea that exploits the following theory: only areas that could be settled by the Europeans developed egalitarian, broad-based institutions. In the other areas, the same Europeans settled for slavery, dictatorship, highly unequal land grants and unbridled extraction instead. (The implied instrument is more convincing when the analysis is combined with controls for the general disease environment, which could have a direct effect on performance.)

The Acemoglu–Johnson–Robinson results, which show that early institutions have an effect on current performance, are provocative and interesting. It bears reiteration, though, that IV estimates are suggestive of an institutional impact on development, but one just cannot be sure of what the mechanism is. By relinquishing more immediate institutional effects on the grounds of, say, endogeneity, it becomes much harder to identify the structural pathways of influence. This appears to be an endemic problem with large, sweeping cross-country studies that attempt to detect an institutional effect. Good instruments are hard to find, and when they exist, their effect could be the echo of one or more of a diversity of underlying mechanisms.

Iyer (2005) and Banerjee and Iyer (2005) consider a somewhat different channel of influence. Both these papers study the differential impact of colonial rule within a single country, India. Iyer studies British annexations of parts of India, and the effect today on public goods provision across annexed and non-annexed parts. There is obvious endogeneity in the areas chosen for annexation (a similar observation applies, in passing, to countries ‘selected’ for colonization). Iyer instruments annexation by exploiting the so-called Doctrine of Lapse, under which the British annexed states in which a native ruler died without a biological heir. Banerjee and Iyer study the effect of variations in the land revenue systems set up by the British, starting from the latter half of the 18th century. In particular, they distinguish between landlord-based institutions, in which large landlords were used to syphon surplus to the British, and other areas based on rent payments, either directly from the cultivator or via village bodies. While these institutions of extraction no longer exist (India has no agricultural income tax), the authors argue that divided, unequal areas in the past cannot come together for collective action. Dispossessed groups are more worried about insecurity of tenure and fear of expropriation than about the absence of public goods, investment (public or private) or development expenditure.

2.6 Institutions and the interactive world

In Section 2.4, we applied market-based theories of occupational choice and persistent inequality to the interactive world economy, (tentatively) treating each country as an economic agent. Recall the main assumption for such an interpretation to be sensible: that countries must face infrastructural constraints
that limit full diversification. With these constraints in place, there will be persistent inequality in the world income distribution, with countries in ‘occupational niches’ that correspond to their infrastructural choices.

Bring to this story the role of institutional origins. Then a particular institutional history may be more suited to particular subsets of occupations, driving the country in question into a determinate slot in the world economy. From that point on, the persistent cross-country inequalities generated by the market-based theory will continue to link past institutions to subsequent growth. In short, initial institutional differences may be correlated with subsequent performance, but the magnitude of that under- or over-performance is not to be entirely traced to initial history. Distant history could simply have served as a marker for some countries to supply a particular range of occupations, goods and services. Today’s inequality may well be driven, not by that far-away history but simply by the world equilibrium path that follows on those initial conditions. If all goods are needed, there must be banana producers, sugar manufacturers, coffee growers, and high-tech enclaves, but there cannot be too little or too many of any of them.

The ‘inefficient political power’ argument used in Section 2.5 can also be transplanted to international interactions. It may well be that a large part of such interactions – protection of international property rights, restrictions on technology transfer, or barriers to trade – is used to deter the entry of developing countries onto a level playing field in which they can successfully compete with their compatriots in developed countries. It would certainly be naive to disregard this point of view altogether.

Looked at this way, our view of history fits in well with the entire debate on globalization. One might view one side of this debate as emphasizing the convergence attributes of globalization: outsourcing, the establishment of international production standards, technology transfer, political accountability and responsible macroeconomic policies may all be invoked as foot soldiers in the service of convergence. On the other side of the battle lines are equally formidable opponents. A skewed playing field can only keep tipping, so goes the argument. The protection of intellectual property is just a way of maintaining or widening existing gaps in knowledge. Technology transfers are inappropriate because the input mix is not right. Non-convexities and increasing returns are endemic.

My goal here is not to take sides on this debate (though like everyone, I do have an opinion) but to clarify it from a ‘non-convergence perspective’ that has so far received more attention within the closed economy. There is a strong parallel between globalization (and those contented or discontented with it, to borrow a phrase from Joseph Stiglitz, 2002) and the questions of convergence and divergence in closed economies.

3 Digging deeper: the microeconomics of development

There is no getting away from the big questions, even if they cannot be fully answered with the knowledge and tools we have to hand. The issues we have discussed (and our intuitive first-takes on them) determine our world view, the cognitive canvas on which we arrange our overall thoughts. But only the most hard-bitten macroeconomist would feel no trepidation about taking these models literally, and applying them without hesitation across countries, regions and cultures.

The microeconomics of development enables us to dig below the macro questions, unearthing insight and structure with far more confidence than we can hope to have at the world or cross-country level. From the viewpoint of economic theory, the assumptions made can be more carefully motivated and are
open to careful testing. From the viewpoint of empirical analysis, it is far easier to find instruments or natural experiments, or, for that matter, to conduct one's own experiments. There is the philosophical problem of scaling up the results, of using a well-controlled finding to predict outcomes elsewhere. In the end, the choice between the fuzzy, imprecise big picture and the small yet carefully delineated canvas is perhaps a matter of taste.

I need hardly add that my selectivity continues unabated: there is a whole host of issues, and I can but touch on a fraction of them. I focus deliberately on four important topics that are relevant to my overall theme of history dependence, and that have been the subject of much recent attention.

3.1 The credit market

As we have seen, a failure of the credit market to function is at the heart of market-based arguments for divergence. The fundamental reason for imperfect or missing credit markets is that individuals cannot be counted upon (for reasons of strategy or luck) to fully repay their loans. If borrowers do not have deep pockets, or if a well-defined system for enforcing repayment is missing, then it stands to reason that lenders would be reluctant to advance those loans in the first place. There is little point in asserting that a carefully chosen risk premium will deal with these risks: the premium itself affects the default probability. Therefore some borrowers will be shut out of the market, no matter what rate of interest they are willing to pay. Such a market will typically clear by rationing access to credit, and not by an adjustment of the rate of interest.

Three fundamental features characterize different theories of imperfect credit markets. There is classical adverse selection, in which borrower (or project) characteristics may systematically adjust with the terms of the loan contract on offer. Stiglitz and Weiss (1981) initiate this literature for credit markets, arguing that the higher the interest rate, the more likely it is that the borrower pool will be contaminated by riskier types. Then there is the moral hazard problem (see, for example, Aghion and Bolton, 1997), in which the borrower must expend effort ex post to increase the chances of project success. Moral hazard also ties into ‘debt overhang’, in which existing indebtedness makes it less credible that a borrower will put in sustained effort in the project. Finally, there is the enforcement problem (see, for example, Eaton and Gersovitz, 1981), in which a borrower may be tempted to engage in strategic default. Ghosh, Mookherjee and Ray (2001) survey some of the literature.

The poor are particularly affected, not because they are intrinsically less trustworthy, but because in the event of a project failure they will not have the deep pockets to pay up. The poor may well possess collateral – a small plot of land or their labour – but such collateral may be hard to adequately monetize: a formal sector bank may be unwilling to accept a small rural plot as collateral, much less bonded labour; but other lenders (a rural landlord, for instance) might. It is therefore not surprising to see interlinkages in credit transactions for the poor: a small farmer is likely to borrow from a trader who trades his crop, while a rural tenant is likely to borrow from his landlord. Even when the entire market looks competitive, these niches may create pockets of exploitative local monopoly (Ray and Sengupta, 1989; Floro and Yotopoulos, 1991; Floro and Ray, 1997; Mansuri, 1997; Genicot, 2002).

In short, the very fact of their limited wealth puts the relatively poor under additional constraints in the credit market. This is why imperfect capital markets serve as a starting point for many of the models that
study market-based history dependence.

The direct empirical evidence on the existence of credit constraints is surprisingly sparse, which is obviously not to say that they do not exist, but only to point out that this is an area for future research. Existing literature in a development context largely uses the existence of (presumably undesirable) consumption fluctuations in households to infer the lack of perfect financial markets (see Morduch, 1994; Townsend, 1995; Deaton, 1997). A direct test for credit constraints yields positive results for Indian firms (Banerjee and Duflo, 2004), though it is unclear how general this finding is (see, for example, Hurst and Lusardi, 2004). There is a sizeable literature dealing with the impact of credit constraints on outcomes such as health (Foster, 1995), education (Jacoby and Skoufias, 1997) or the acquisition of production inputs such as bullocks (Rosenzweig and Wolpin, 1993). Chiappori and Salanie (2000) and Karlan and Zinman (2006) are two examples of specific tests for different frictions, such as adverse selection and enforcement. Udry’s seminal (1994) paper on credit and insurance markets in northern Nigeria may be viewed as singling out enforcement as perhaps the most important binding constraint. The importance of enforcement constraints is, of course, not peculiar to credit or insurance; Fafchamps (2004) develops the point for a variety of markets in sub-Saharan Africa. For more on insurance, see Townsend (1993; 1995); Ligon (1998); Fafchamps (2003); and Fafchamps and Lund (2003). Coate and Ravallion (1993), Ligon, Thomas and Worrall (2002), Kocherlakota (1996) and Genicot and Ray (2003) develop some of the associated theory with limited enforcement. Finally, there is a literature on micro-credit, the lending of relatively small amounts to the very poor; Armendáriz and Morduch (2005) is a good starting point.

3.2 Collective action for public goods

There is a growing literature on the political economy of development. Unlike some mainstream approaches in political science and political economy, this literature appears to largely eschew voting models. In my view this is not a bad thing. Perhaps the most important criticism of voting models is that even in vigorous democracies, most policies are not subject to referenda among the citizenry at large. Certainly, there are periodic elections, and the sum total of enacted policies – and the package of future promises – are then up for voter scrutiny, but, nevertheless, there is a large and significant gap between voting and the enactment of a particular policy. Between that policy and the voter falls the shadow of collective action, lobbies, capture and influence, cynical trade-offs across special interests, and covert or open conflict. For countries with a non-democratic history, these considerations are expanded by orders of magnitude.

An important literature concerns the determinants of collective action for the provision of public goods, and how poverty or inequality affects the ability to engage in such action. The relationship here is complex. There are two potential reasons why inequality in a community may enhance collective action. First, the elite in a high-inequality community might largely internalize all the benefits from the resulting public good, and therefore pay for it (Olson, 1965). Good examples involve military alliances (Sandler and Forbes, 1980), technology adoption (Foster and Rosenzweig, 1995) or even ‘top-down interventions’ by local rulers or elites (Banerjee, Iyer and Somanathan, 2007). Second, the elite has a low opportunity cost of money, while the poor have a low opportunity cost of labour; in some situations,
the two resources can be usefully combined for collective action (an alliance for violent conflict, as in Esteban and Ray, 2007a, is a good example). But there are many situations in which inequality can dampen effective collective action: when all agents supply similar inputs – say effort – but their impact or cost of provision is nonlinear (Khwaja, 2004; Ray, Baland and Dagnielie, 2007), when there are unequally distributed private endowments (Baland and Platteau, 1998; Bardhan, Ghatak and Karaivanov, 2006), when different individuals in the same community want different things by virtue of their social differences or inequality (Alesina, Baqir and Easterly, 1999; Banerjee et al., 2001, Miguel and Gugerty, 2005; Alesina and La Ferrara, 2005), or when inequalities in wealth erode the informational basis of collective action (Esteban and Ray, 2006).

The importance of this area of research cannot be overemphasized. Several of the fundamental accompaniments of development require state intervention at a basic level: health, education, social safety nets and infrastructure. This is especially so in poor countries, where privatized health and education are often ruled out by the sheer force of economic necessity. Yet states often are set upon by numerous claims that compete for their attention. How are these claims resolved? The theory and practice of collective action demands more research.

Moreover, while it can be argued (as above) that inequality within a community might go either way in affecting that community's ability to obtain public goods, there is no escaping the fact that at the level of the entire society, high inequality serves to fracture and divide. Simply put, the very rich want state policy that is different from what the very poor desire, and rare is the society that has them in the same camp, and demanding the same things of their government. In the world of the median voter, one might simply resolve these issues by looking at the median voter's ideal policy, but even in this rarefied scenario there are complex issues that deserve our consideration. Political alliances can often redefine the median voter (Levy, 2004) and even without alliances it is unclear just who the median voter is (Bénabou, 2000). When we return to the 'real world' of collective action, these issues are magnified considerably. In that world, each citizen does not have an endowment of one vote. The real endowments are labour and money. How these commodities combine (or compete) is fundamental to our understanding of political economy and – via this channel – our views on persistent history-dependence.

### 3.3 Conflict

A more sinister expression of collective action is conflict. In the second half of the 20th century and well into the first decade of the 21st the loss of human life from conflicts in developing countries was immense; the costs are beyond measurement. Even the narrow economic costs of conflict can be extremely large (Hess, 2003).

That conflict contributes to economic regress is not surprising. But given our focus on history dependence, it is of equal interest to consider the causal chain running from underdevelopment to conflict. That chain has a natural and simple foundation: poverty reduces the opportunity cost of engaging in conflict. The grabbing of resources, often in an organized way, is often a far more lucrative alternative to the steady process of wealth accumulation. It is certainly a quicker alternative. (One might argue that there is less to gain as well, but this effect is attenuated in unequal societies.)

This unfortunate observation has substantial empirical support. For instance, Miguel, Satyanath and Sergenti (2004) use rainfall as an instrument for economic growth in 41 African countries and derive a
striking negative effect of growth on civil conflict: a negative growth shock of five percentage points raises the likelihood of civil conflict by 50 per cent; see also Dube and Vargas (2006) and Hidalgo et al. (2007), both of which also instrument for economic shocks to find significant effects on conflictual outcomes. Collier and Hoeffler (1998), Sambanis (2001), Fearon and Laitin (2003), and Do and Iyer (2006) all establish strong correlations between economic adversity and conflict, the last of these countries establishing this over regions in a single country (Nepal).

Yet conflict is demonstrably wasteful, and if warring parties could sit down at the negotiating table, why would societies engage in it? This is a classical question to which there are a number of possible answers. First, there may be a Prisoner's Dilemma-like quality to conflictual incidents, in the sense that one party can precipitate attacks while the other remains passive (Leventoglu and Slantchev, 2005).

Second, while conflict generates waste, there is no reason to believe that every group is thereby made worse off by it. It is entirely possible that a group prefers conflict to a peaceful outcome: the former involves a smaller pie, but the group may obtain a larger share of it (Esteban and Ray, 2001). Third, while one should be able to find a system of taxes and transfers that Pareto-dominate the conflict outcome, for various reasons – lack of commitment, a sparse informational base for the levying of taxes, dynamics with rapid power shifts – it may not be possible to implement that system (Fearon, 1995; Powell, 2004; 2006). Fourth, it is certainly possible that conflict is over indivisible resources such as political power or religious hegemony. It may then be absurd to imagine that side A compensates side B with suitable transfers in exchange for political power: the lack of credibility involved is only too apparent. Finally, conflict may be endemic because both parties to it have incomplete information regarding chances of success, though this view has come under increasing criticism from political scientists (see, for example, Fearon, 1995).

The next question of relevance concerns ethnic and social divisions. Might the presence of potentially divisive markers (caste, religion, geography, ethnicity in general) exacerbate conflictual situations? For instance, Esteban and Ray (2007a) argue that non-economic (‘ethnic’) markers may play a salient role in the outbreak of conflict even when society exhibits high economic inequality and may look prima facie more ripe for a class war.

A standard tool for measuring ethnic and social divisions is that of fractionalization, roughly defined as the probability that two individuals drawn at random will come from two distinct groups. While fractionalization seems to have a negative effect on economic outcomes such as per capita GDP (Alesina et al., 2003), growth (Easterly and Levine, 1997), or governance (Mauro, 1995), its effect on civil conflict appears to be insignificant (Collier and Hoeffler, 2004; Fearon and Laitin, 2003). Of course, as Horowitz (2000) and others have observed, it is the presence of large cleavages that is potentially conflictual, whereas fractionalization continues to increase with diversity. The solution is to drop fractionalization altogether. Montalvo and Reynal-Querol (2005) adapt Esteban and Ray's (1994) measure of polarization to show that measures of ethnic and religious polarization do indeed have a significant impact on conflict (see also Do and Iyer, 2006). Obviously, more research is called for on questions such as these. For instance, it is unclear how polarization should enter an empirical specification: Esteban and Ray (2007b) argue that highly polarized societies may actually avoid a showdown through deterrence, though conditional on the outbreak of conflict, polarization must vary positively with the intensity of conflict.
The continuing study of conflict in development demands our highest priority. Certainly, the social waste of conflict dominates the inefficiency of misallocated resources that so many mainstream economists prefer to emphasize. Indeed, it is entirely possible that the much-maligned (and much-studied) inefficiencies of incomplete information are also of a lower order of magnitude. But, most of all, it is the chain of cumulative causation that must ultimately drive our interest, from underdevelopment to conflict and back again to continuing underdevelopment. Conflict is one channel through which history matters.

3.4 Legal matters

Contract enforcement, property rights, and expropriation risks: these are a few instances of legal matters that are central to development. They bear closely on that much-used catchall phrase, ‘institutional effects on development’. For instance, Acemoglu, Robinson and Johnson (2001) as well as the recent survey by Pande and Udry (2007) clearly have the security of property rights high on the list when discussing ‘institutions’. La Porta et al. (1997; 1998; 2002) and Djankov et al. (2003) begin with the premise that common (English commercial) law and civil (French commercial) law afford different degrees of protection and support to investors, creditors and litigants, and argue that it has had dramatic effects on a variety of indicators across countries: corruption, stock-market participation, corporate valuation, government interventionism, judicial efficiency – and presumably, via these, to economic indicators.

It is little surprise that the security of property rights is generally conducive to investment, and that long-term investment is especially encouraged by such security (see, for example, Demsetz, 1967). Short-term efforts, in contrast, may well be enhanced by insecurity of tenure. Depending on the exact form that property rights assume, there may be further positive effects – for example, via access to credit – that arise from the ability to mortgage or sell property (Feder et al., 1988).

Empirical research into these matters is invariably assailed by questions of endogeneity and omitted variables. For instance, long-gestation investments may provoke – and permit – the establishment of property rights, and high-ability agents might use their ability to both invest and secure their rights. Nevertheless, the evidence on property rights is that by and large they are good for investment and production (Besley, 1995; Banerjee, Gertler and Ghatak, 2002; Do and Iyer, 2003; Goldstein and Udry, 2005), and even more obviously, property values where these are reasonably well-defined (Alston, Libecap and Schneider, 1996; Lanjouw and Levy, 2002). Instances in which property titling creates better access to credit are, intriguingly enough, somewhat harder to come by (Field and Torero, 2006, and Dower and Potamites, 2006, are two of the rarer examples that do document better access, but with some qualifications).

Indeed, economists have little trouble in finding numerous instances of changed (or changing) property rights regimes. This is because there is a plethora of situations in which the absence of well-defined rights is the rule rather than the exception. In rural societies the world over, land rights can be highly ambiguous, and land titles can be missing even when an unambiguous definition of property exists. If one adds to this the sizable proportion of land under tenancy, the effective security for cultivators becomes more tenuous still (and indeed this complicates matters, because their rights may be inversely related to those of the owner!). In non-rural settings, there are substantial uncertainties for those who
operate in the informal sector (such as the periodic ‘cleansing’ of informal retailers from city pavements). If the above studies are to be taken seriously, there are substantial production losses from such states of insecurity.

If imperfections of the law are so inimical to the fortunes of cultivators and producers (and especially for the small and the poor among them), why do we see such institutional ‘failures’ in equilibrium? The Coase–Posner view would presumably have none of this: in their view, legal systems would invariably develop to maximize social surplus. But of course, there could be several reasons for the persistence of ‘inefficient institutions’. When side payments are not feasible or credible, economic agents often prefer a larger share of a reduced pie to a smaller share of a more efficient pie. For instance, domestic businesses that can rely on a trusted network of kin or extended family might prefer an ambiguous legal system, which prevents entry. Or workers might prefer imperfect enforceability of a work norm, so that efficiency wages need to be paid. Borrowers might prefer that loan repayment cannot be fully enforced, so that incentives to repay must be built into the loan contract. And when tenancy is widespread in agriculture, the very design of overall property rights to maximize efficiency can be a highly complex problem.

The last three examples possess another feature that is worth some emphasis: ambiguous property rights often have equity effects that do not go the same way that efficiency-minded economists would like them to go (see Weitzman, 1974; Cohen and Weitzman, 1975; Baland and Platteau, 1996). The ambiguity of property rights can serve as insurance, buffer, or redistributive device. As examples, consider broad access to water resources or grazing land, or the efficiency-wage premia that may need to be paid to workers or borrowers.

Most importantly, the ambiguity of property rights slows down the emergence of an overt assetless class, and that has its own social value (it should not be forgotten that the flip side of unambiguous rights is exclusion). For example, Goldstein and Udry (2005) develop this point of view in the context of rural Ghana, arguing that the ambiguity in property rights prevented the outbreak of extreme poverty (and had an interesting efficiency effect in the bargain, as individuals were reluctant to leave the land fallow – an important investment – in the fear that this would signal a lack of need for land).

The political economy of rights is a messy business, but of central importance in development economics. Poverty in general enhances the social and political need for ambiguity, while to the extent that such ambiguity wears on efficiency, we have an extremely important instance of non-convergence. Sometimes such non-convergence assumes particularly dramatic form. In West Bengal (India) ‘Operation Barga’ provided widespread – and welcome – use rights to registered sharecroppers (see, for example, Banerjee, Gertler and Ghatak, 2001). Those very use rights now lie at the heart of recent difficulties in converting agricultural land in India for use in industry. In the world of the second best, few policies have unambiguously one-directional effects.

4 A concluding note: theory and empirics

While I have tried to provide a conceptual overview in this article, recent research in development economics has been almost entirely empirical. A veritable explosion in computing power, the expansion of institutional data-sets and their increased availability in electronic form, and the growing ease of collecting one's own data have bred a new generation of development economists. Their empirical sensibilities are of a high order; they are extremely sensitive to issues of endogeneity, omitted variables,
measurement error and biases induced by selection. They are constantly on the search for good instruments or natural experiments, and, when these are hard to find, they are adept at creating experiments of their own.

There is little doubt that we know little enough about the world we live in that it is often worth finding out the simple things, rather than continuing to engage in what some would term flights of theoretical fantasy. Are people really credit-rationed? Does rising income automatically make for better nutrition and health? If we had the option to throw in more textbooks, or reduce class size, or add more teachers, or install monitoring devices to track teacher attendance, which policy should we implement? Do women leaders behave differently from men in the policies that they adopt? Do households behave as one frictionless unit? Or, if one is the big-picture sort, have countries indeed converged over the last 200, or 500, years? Are richer countries more democratic? How many excess female deaths have occurred in China or India because of gender bias? Are poorer countries more ‘corrupt’? And so on. The list is practically endless.

The somewhat churlish theoretically minded economist might ask, why are well-trained statisticians unable to answer these questions? Why do we need economists, who are supposed, at the very least, to combine two observations to form a deduction? The answer, at one level, is very simple and not overly supportive of the churlish theorist’s complaint. While the questions are straightforward, the answers are often extremely difficult to tease out from the data, and one needs a well-trained economist, not a statistician, to understand the difficulty and eliminate it. Because of the aforementioned econometric issues, not a single one of the questions asked above admits a straightforward answer. Development economists spend a lot of time thinking of inventive ways to get around these problems, and it is no small feat of creativity, dedication and extremely hard work to pull off a convincing solution.

It is true that the very desire to obtain a clean, unarguable answer – with its attendant desire to have control over the empirical environment – sometimes narrows the scope of the enquiry. There is often great reluctance to rely on theoretical structure (for such reliance would contaminate the near-lexicographic desire for an unambiguous result). This means that the question to be asked is often akin to that for a simple production function (for example, ‘do students do better in exams if they are given more textbooks?’) or is focused on the direct effect of some policy intervention (‘does the provision of health check-ups improve health outcomes?’). So it is that a boring but well-identified empirical question will often be treated with a great deal more veneration (especially if a clever instrument or randomization device is involved) than a model that relies on intuitive but undocumented assumptions. That said, it is also a fact that we know very little about the answers to some of the most basic questions, such as the ones we have listed above. The great contribution of empirical development microeconomics is that we are building up this knowledge, piece by piece. Whether the search for that knowledge is informed by theory or not, there will be enough theorists to attempt to put these observations together. There will be enough empirical researchers to keep generating the hard knowledge. Development economics is alive and well.

Article

This notoriously elusive and multifaceted notion assumed importance in the history of political economy because Marx's 'critique of political economy', *Capital*, and particularly its first draft, the *Grundrisse* of 1857–8, was presented in a dialectical form. Part of the difficulty of encapsulating the dialectic within any concise definition derives from the fact that it may be conceived as a method of thought, a set of laws governing the world, the immanent movement of history or any combination of the three. The dialectic originated in ancient Greek philosophy. The original meaning of 'dialogos' was to reason by splitting in two. In one form of its development, dialectic was associated with reason. Starting with Zeno's paradoxes, dialectical forms of reasoning were found in most of the philosophies of the ancient world and continued into medieval forms of disputation. It was this form of reasoning that Kant attacked in his distinction between the logic of understanding which, applied to the data of sensation, yielded knowledge of the phenomenal world, and dialectic or the logic of reasoning, which proceeded independently of experience and purported to give knowledge of the transcendent order of things in themselves. In another form of dialectic, the focus was primarily upon process: either an ascending dialectic in which the existence of a higher reality is demonstrated, or a descending form in which this higher reality is shown to manifest itself in the phenomenal world. Such conceptions were particularly associated with Christian eschatology, neo-platonism and illuminism, and typically patterned themselves into conceptions of original unity, division or loss, and ultimate reunification.

For practical purposes, however, the form in which the dialectic was inherited and modified by Marx was that in which it had been elaborated by Hegel. 'Hegel's dialectics is the basic form of all dialectics, but only after it has been stripped of its mystified form, and it is precisely this which distinguishes my method' (Marx, letter to Kugelmann, 6 March 1868).
In Hegel, the dialectic is a self-generating and self-differentiating process of reason (reason being understood both to be the process of cognition and the process of the world). The Hegelian Absolute actualizes itself by alienating itself from itself and then by restoring its self-unity. This corresponds to the three basic divisions of the Hegelian system: the Logic, the Philosophy of Nature and the Philosophy of Mind. It is free because self-determined. Its freedom consists in recognizing that its alienation into its other (nature) is but a free expression of itself. The truth is the whole and it unfolds through a dialectical progression of categories, concepts and forms of consciousness from the most simple and empty to the most complex and concrete. Each category reveals itself to the observer to be incomplete, lacking and contradictory; it thus passes over into a more adequate category capable of resolving the one-sided and contradictory aspects of its predecessor, though throwing up new contradictions in its turn. Against Kant, this process of dialectical reason is not concerned with the transcendent, but is immanent in reality itself. Reflective understanding is not false, but partial. It abstracts from reality and decomposes objects into their elements. Analytic understanding represents a localized standpoint which sets up an unsurpassable barrier between subject and object and thus cannot grasp the systematic interconnection between things or the total process of which it is a part. The absolute subject contains both itself and its other (both being and thought) which is revealed to be identical with itself. Human history, human thought are vehicles through which the absolute achieves self-consciousness, but humanity as such is not the subject of the process. Thus the absolute spirit dwells in human activity without being reducible to it, just as the categories of the Logic precede their embodiment in nature and history.

The character of the Marxian dialectic is yet harder to pin down than that of Hegel. In some well-known lines in the Post-Face to the Second Edition of Capital in 1873, Marx stated,

I criticised the mystificatory side of the Hegelian dialectic nearly thirty years ago … [but] the mystification which the dialectic suffers in Hegel's hands by no means prevents him from being the first to present its general form of motion in a comprehensive and conscious manner. With him it is standing on its head. It must be inverted in order to discover the rational kernel within the mystical shell. (Marx, 1873, pp. 102–3)

This statement has satisfied practically no one. How can a dialectic be inverted? How can a rational kernel be extracted from a mystical shell? To critics from empiricist, positivist or structuralist traditions, anxious to free Marx from the clutches of Hegelianism, the dialectic is intrinsically unworkable and must either be dropped or stated in quite other terms (for example, Bernstein, 1899; Della Volpe, 1950; Althusser, 1965; Cohen, 1978; Elster, 1985). To a second group, the dialectical understanding of capitalism is only a particular instance of more general dialectical laws which govern reality as a whole, both natural and social (Engels, dialectical materialism). To a third group, the Hegelian roots of Marx's thought are not sufficiently emphasized in this statement; Marxism is only Hegelianism taken to its logical revolutionary conclusions in the discovery of the proletariat as the subject–object of history and the ‘totality’ as the distinguishing feature of its world-outlook (Lukács, 1923 and much of 20th-century Western Marxism). This Methodenstreit cannot be discussed here. All that can be attempted is to give some sense to Marx's statement and in particular to indicate how it informed his critique of political economy.

Marx specifically criticized ‘the mystificatory side of the Hegelian dialectic’ in his 1843 Critique of
*Hegel's Philosophy of Right* and in the concluding section of the *1844 Manuscripts* (both of which were only published in the 20th century). In these texts, Marx followed Feuerbach in considering Hegelian philosophy to be the conceptual equivalent of Christian theology; both were forms of alienation of man's species attributes; Christianity transposed human emotion into a religious Godhead, while Hegel projected human thinking into a fictive subject, the Absolute Idea, which in turn then supposedly generated the empirical world. Employing Feuerbach's ‘transformative method’ (the origin of the inversion metaphor), subject and predicate were reversed and hence the correct starting point of philosophy was the finite, man. Nature similarly was not the alienated expression of Absolute Spirit, it was irredicibly distinct. Thus there could be no speculative identity of being and thought. Man, however, as a natural being, could interact harmoniously with nature, his inorganic body. Once the absolute spirit had been dismantled and the identity of being and thought eliminated, it could be argued that the barrier against the harmonious interpenetration of man and nature and the free expression of human nature, was not ‘objectification’, the division between subject and object constitutive of the finite human condition, but rather the inhuman alienation of man's species life activity in property, religion and the state. True Communism, humanism, meant the re-appropriation of man's essential powers, the generic use of his conscious life activity. In contrast to the predominant Young Hegelian position, therefore, which counterposed Hegel's revolutionary ‘method’ (the dialectic) to his ‘conservative system’, Marx argued that there was no incompatibility between the two. For while Hegel's dialectic ostensibly negated the empirical world, it covertly depended upon it. Not only was the moment of contradiction a prelude to the higher moment of reconciliation and the restoration of identity, but the ideas themselves were tacitly drawn from untheorized experience. The effect of the dialectical chain which embodied the world was not to subvert the existing state of affairs, but to sanctify it.

In the crucial period that followed, that of the *German Ideology* and the *Poverty of Philosophy*, in which the basic architecture of the ‘materialist conception of history’ was elaborated, the attack upon speculative idealism was made more radical. The generic notion of ‘conscious life activity’, ‘praxis’, was replaced by the more specific notion of production. Hegel and the Idealist tradition were given credit for emphasizing the active transformative side of human history, but castigated for recognizing this activity only in the form of thought. Thought itself was now made a wholly derivative activity. The fundamental activity was labour and what developed in history were the productive powers men employed in their interaction with nature, ‘the productive forces’. Stages in the development of these productive forces were accompanied by successive ‘forms of human intercourse’, what became ‘the relations of production’. Finally, ‘man’ as a generic being was dispersed into the struggle between different classes of men, between those who produced and those who owned and controlled the means of production.

In this new theorization of history, explicit references to Hegel were few and the dialectic scarcely mentioned. But Hegel re-entered the story as soon as Marx attempted to write up a systematic theory of the capitalist mode of production in 1857–8. To see why, we must briefly survey his economic writings up to that date.

Marx's 1843 critique of Hegel had led him to the conclusion that civil society was the foundation of the state and that the anatomy of civil society was to be found in political economy. However, if his preoccupation with political economy dated from this point, it was not that of an economist. In the *1844 Manuscripts* what is to be found is a humanist critique of both political economy and civil society: not an alternative theory of the economy, but rather a juxtaposition between the ‘economic’ and the
‘human’, the former being judged in terms of the latter. No distinction is made between political economy and the economic reality it purports to address, the one is simply seen as the mirror of the other. The first attempt to define capitalism as an economic phenomenon occurred in the *Poverty of Philosophy* (1847). However, whatever the significance of that work in other respects, it did not outline any specifically Marxian portrayal of the capitalist economy. As in 1844 there was no internal critique of classical political economy. The main difference was that, whereas in 1844 Marx saw that economy through the eyes of Adam Smith, he now saw it through the eyes of Ricardo. In particular, he adopted what he took to be Ricardo's theory of value and belaboured Proudhon for positing as an ideal – the equivalence of value and price – what he considered to be the actual situation under capitalism. The only critique of Ricardo to be found there was a purely external historicist one: that Ricardo was the scientific expression of the epoch of capitalist triumph, but that that epoch had already passed away, that its gravediggers had already appeared and that its collapse was already at hand.

When Marx resumed his economic studies after the 1848 revolutions, Proudhonism was still the main object of attack. It occupied a major part of his unfinished economic manuscripts of 1850–1 and the attack on the Proudhonist banking schemes of Darimon took up the first part of the written-up notebooks of 1857–8, the *Grundrisse*. Proudhonism was the main object of attack because it could be taken for the predominant form of socialist or radical reasoning about the economy. Ricardo could again be utilized to attack such reasoning in order to argue that it represented a nostalgia for petty commodity production under conditions of equal exchange, a situation supposedly preceding modern capitalism rather than representing an emancipation from it. However, if the capitalist mode of production and its historical limits were to be grasped in theory, this would have to involve a critique of Ricardo himself. The form this critique took, involved problematizing Ricardo's theory of value (or rather Marx's reading of it:). Steedman (1979) has argued strongly that Marx misconstrued Ricardo's theory, though Ricardo's shifting of position between the three editions of the *Principles* and the fact that Marx only used the third edition makes his mistake an understandable one). On the one hand, it raised a question never posed by Ricardo: the source of profit in a system of equal exchange. On the other hand, it involved juxtaposing wealth in the form of productive forces, that is, as a collection of use values against the translation of all wealth into exchange values within capitalism. Ricardo, it was argued, possessed no criterion for distinguishing between the content – or the material elements – and the form of the economy, such as Marx possessed in the distinction between forces and relations of production. Ricardo never problematized the ‘value form’; he linked the object of measurement with the measurement itself. For this reason, Ricardo was considered to possess no conception of the historicity of capitalism. Once the material could be distinguished from the social, the content from the form, the capitalist mode of production could be conceived as a dynamic system whose principle of movement could be located in the contradictory relationship between matter and form.

It is here that Hegel came in. We know that during the writing of the *Grundrisse* at the beginning of 1858, Marx re-read Hegel, in particular the *Science of Logic*. He wrote to Engels, ‘I am getting some nice developments, e.g. I have overthrown the entire doctrine of profit as previously conceived. In the method of working, it was of great service to me that by mere accident I leafed through Hegel's *Logic* again’ (Marx to Engels, 16 January 1858).

What Marx found so useful in his reading of Hegel's *Logic* at this time is not really mysterious. It suggested a way of elaborating the contradictory elements that Marx had discerned in the value form into a theorization of the trajectory of the capitalist mode of production as a whole. The point is
emphasized by Marx in his Post-Face to *Capital*: the dialectic includes in its positive understanding of what exists a simultaneous recognition of its negation, its inevitable destruction; because it regards every historically developed form as being in a fluid state, in motion, and therefore grasps its transient aspect as well (1873, p. 103). The dialectic offered a means of grasping a structure in movement, a process – the subtitle of *Capital*, Volume 1, was ‘the process of capitalist production’. If capitalism could be represented as a process and not just a structure, then concomitantly its building blocks were not factors, but, as in Hegel, ‘moments’. As Marx put it in the *Grundrisse*:

> When we consider bourgeois society in the long view and as a whole, then the final result of the process of social production always appears as the society itself i.e. the human being itself in its social relations. Everything that has a fixed form, such as the product etc., appears as merely a moment, a vanishing moment in this movement. The conditions and objectifications of the process are themselves equally moments of it, and its only subjects are the individuals, but individuals in mutual relationships, which they equally reproduce and produce anew …. in which they renew themselves even as they renew the world of wealth they create. (Marx [1857–8], p. 712)

Marx’s attempt to utilize the *Logic* can be seen most clearly in the *Grundrisse*. There one can see the genesis of particular concepts which in *Capital* appear in more polished form. What is clear is that the *Logic* is used as a first means of setting terms in relation to each other. The text is littered with Hegelian expressions and turns of phrase; indeed, sometimes it appears as if lumps of Hegelian ratiocination have simply been transposed, undigested, to sketch the more intractable links in the chain. Here, for instance, is money striving to become capital: ‘… already for that reason, value which insists on itself as value preserves itself through increase; and it preserves itself precisely only by constantly driving beyond its quantitative barrier, which contradicts its character as form, its inner generality’ (p. 270). But at the same time we can see Marx remind himself to correct the ‘idealist manner of presentation, which makes it seem as if it were merely a matter of conceptual determination and of the dialectic of these concepts’ (p. 151).

But the interest of dialectical logic for Marx was not simply that it offered him a way of outlining a structure in movement; more fundamentally it enabled him to depict contradiction as the motor of this movement. This was why the dialectic was ‘in its very essence critical and revolutionary’ (Marx, 1873, p. 103), in that both in Hegel and in ancient Greek usage movement was contradiction. This appears closely in the dramatic relationship that Marx sets up between the circulation system and the production system in *Capital*. The system of exchange of the market is the public face of capitalism. It is ‘in fact a very Eden of the innate rights of Man’ (p. 280). Exchanges are equal. To look for the source of inequality in the exchange system, like the Proudhonists, is to look in the wrong place. Yet, if exchanges are equal, how does capital accumulation take place? Equal exchange implies the principle of identity, of non-contradiction. It is, in Hegel's sense, the sphere of ‘simple immediacy’, the world as it first appears to the senses. It cannot move or develop, because it apparently contains no contradictory relations. But this surface of things is not self-sufficient. It is ‘the phenomenon of a process taking place behind it’. As a surface it is not nothing, but rather a boundary or limit. Contradiction and therefore movement is located in production. Here there is non-identity, the extraction of surplus labour disguised by the surface value form and its tendency to limitless expansion.
Thus, there are two processes, on the one hand that of the surface, that of immediate identity lacking the motive power of its own regeneration; on the other hand, that beneath the surface, a process of contradiction. Thus in Hegelian terms, the whole could then be defined as ‘the identity of identity and non-identity’. In this whole, contradiction is the overriding moment, but the surface places increasingly formidable obstacles to its development, for instance, so-called ‘realization’ crises. Values can only be realized in an act of exchange and the medium of this exchange is money. But there is no guarantee that these exchanges must take place. The ‘anarchy’ of the market place is such that overproduction or disproportionality between sectors of production can only be seen after the event. Hence trade crises and slumps (see M. Nicolaus, Introduction to Marx [1857–8]).

This is only one example of how Marx employed dialectical principles in his attempt to conceptualize the process or movement of a contradictory whole. Another would be the six books Marx originally planned to write in 1857–8, the original blueprint of Capital. Their order would have been: Capital, Wage Labour, Landed Property, State, World Market, Crises. This plan is reminiscent of Hegel's Encyclopaedia. It describes a circle in a Hegelian sense. The point of departure is not capital per se, but commercial exchange as appearance, then proceeding through the contradictory world of production and eventually returning to commercial exchange again as the world market, but this time enriched by the whole of the preceding analysis.

There has been much controversy about the proximity or distance between the Hegelian and Marxian dialectics. Those who like Althusser (1965) argue for their radical dissimilarity, are on their strongest ground when arguing that in Marx the terms of the dialectic have been radically transformed. The contradiction between forces and relations of production cannot be reduced to the ultimate simplicity of that between Hegel's master and slave or of that between proletariat and bourgeoisie in the Hegelianized Marxist account of Lukacs. But it is far more difficult to establish as unambiguously the difference in the relationship between the terms in their respective dialectics. On the one hand, the relation between matter and form in Hegel is only one of apparent exteriority. Matter relates to form as other only because form is not yet posited within it. Once the terms are related, they are declared to be identical. Marx, on the other hand, insists upon the irreducible difference between matter and form, between the material and the social (even if he is not wholly successful in keeping them apart). Not only are matter and form different, but the one determines the other: value is determined in relation to the material production of use value; the opposite is not true. Relations of determination would seem to exclude identity, and this is confirmed by Marx's avoidance of the Hegelian notion of ‘sublation’ (Aufhebung), the higher moment of synthesis. The dialectical clash between forces and relations of production in the capitalist mode of production does not of itself produce a higher unity (socialism); rather what crises do, is to make manifest the otherwise hidden determination of value by use value, of form by matter. Against this, however, must be set one or two passages, including a famous peroration in Capital Volume 1, where Marx does conceive the end of capitalism as a return to a higher but differentiated unity and does employ the notion of the negation of the negation (Marx, 1873, p. 929), and, despite the best efforts of some modern commentators, it is difficult honestly to deny the strongly teleological imagination which underpins the whole enterprise of Capital.

Finally, in two important respects, Hegelian dialectic, however surreal, is less vulnerable than that of Marx. Firstly, Hegel's Science of Logic takes place outside spatio-temporal constraints. It is a purely logical progression of concepts, even if the principles on which one ontological category is derived from another ‘have resisted analysis to this day’ (Elster, 1985, p. 37). Marx's effort to avoid giving any
impression of the ‘self-determination’ of the concept, took the form of attempting to demonstrate that ‘the ideal is nothing but the material world reflected in the mind of man and translated into forms of thought’ (Marx, 1873, p. 102). In practical terms this implied that there was some systematic relationship between the logical sequence of concepts in the exposition of the argument and the chronological order of their appearance in historical time. But this turned out to impose insurmountable difficulties in terms of presentation (and it is significant that, having begun with the product in the Grundrisse, he began with the commodity in Capital). Thus Marx both stated his position and violated it, bequeathing insoluble ambiguities surrounding his interpretation of value, of the meaning of ‘reflection’ and of the relationship between history and logic which have plagued even his closest followers ever since. Secondly, when it came to applying his dialectic to history, Hegel was categorical in refusing to project his theory into the future. The philosopher could explain the rationality of what had happened; it was only then that it could be grasped in thought. Marx, despite all his strictures against the voluntarism of other Young Hegelians and some of his fellow revolutionaries, was unable by the very nature of his project, fully to abide by the Hegelian restriction. Thus, while Hegel's owl of Minerva flew at dusk, the Marxian owl, unfortunately, took flight at high noon.

Abstract

Carlos Díaz-Alejandro was the most prominent Latin American economist of his generation. In his short professional life he gave us powerful insights into Latin America's trade and development, and its economic and financial history. In true Kindlebergian tradition, he was particularly fascinated by the region's many financial crises. His contributions were characterized by a rare capacity to weave together history and theory, abstract economic theory and complex Latin American socio-political life. In this way, he avoided the sterility of pure formalistic theory that characterized so much of the economics of his own generation and the next.

O.; import substitution; import-substituting industrialization; inflation; International Monetary Fund; Kindleberger, C.; Prebisch, R.; redistribution of income

Article

Carlos Díaz-Alejandro was born in Havana and died in New York one day short of his 48th birthday. At 32, he became Yale's youngest ever full professor of economics. In 1983 he moved to Columbia, and at the time of his sudden death he had just accepted a chair at Harvard. During sabbatical leaves, he visited many Latin American and European universities. Among numerous other activities he was a (dissenting) member of the Kissinger Commission on Central America. He strongly criticized US support for the 'Contras' in Nicaragua (para-military groups associated with the Somoza dictatorship, opposed to the Sandinista government), and insisted that if the United States were serious about Central America it should tie economic assistance to human rights and allow Central
American exports free access into its own market. Needless to say, such quixotic attempts to influence US foreign policy were never among his greatest successes!

From a personal point of view I admired his sense of humour and wit, his approachability and ‘bridge-building’ capacity, his aversion to positions of administrative power, his independence of mind and his common sense.

His work gave us powerful insights into Latin America's trade and development, and its economic and financial history. He was particularly fascinated by the region's many financial crises. His contributions were characterized by a rare capacity to weave together history and theory, abstract economic theory and complex Latin American socio-political life.

In his doctoral dissertation at MIT, Díaz-Alejandro revisited the controversy between the ‘elasticity’ and ‘absorption’ approaches to the balance of payments in the context of Argentina's experience of devaluation, concluding that on balance it supported the first approach (1965a). He further argued that one of the main mechanisms through which devaluation influences both the balance of payments and economic growth is through its effects on income distribution. The apparent paradox that many devaluations improve the trade balance but negatively affect the overall growth of output could be explained by the complex redistributive effects of devaluation. In fact, the effectiveness of a devaluation may depend more on the nature of its distributational outcome than on its capacity to change relative prices. Therefore, the exchange rate could be seen as yet another sphere in the struggle between different groups over their shares in national income.

Another peculiar feature of semi-industrialized economies is that ‘[i]n the long run, the success or failure of a stabilisation effort will depend more on the capacity of governments to obtain a national consensus over the objectives and policy instruments than on the approval or help that they could receive from foreign investors or governments and international agencies’ (1985, p. 201).

Díaz-Alejandro also maintained a keen interest in Latin American economic history, writing first on Argentina (1970). Then, in an article on the 1930s crisis, he identified the causes of the dissimilar performances of Latin American economies in the fact that some countries pursued an ‘active’ approach to fighting recession, while others stuck to conventional ‘passive’ adjustment mechanisms (1982). The ‘active’ countries were mainly the large ones, but also included Chile and Uruguay. They performed much better by abandoning the gold standard and by adopting flexible monetary and fiscal policies, real devaluations, moratoria on their foreign debt, and spending massively on public works. This heterodox response of some countries was in part a reaction to the emergence after the 1929 crash of a protectionist, interventionist and nationalistic Centre.

Díaz-Alejandro's articles on trade and development also discussed the high import intensity of import substitution (1965b), and the transition from import-substituting industrialization to export-led growth (1974). Diaz-Alejandro was particularly sceptical about the idea that this transition would help achieve both faster and more equitable growth. He strongly supported export orientation, but did not believe that it could be achieved simply by ‘getting the prices right’; he also feared that it could contribute to ‘stop-go’ macroeconomics. Moreover, he thought that most of the advice given to Third World countries for their trade policies ‘… suggest evangelical fervour rather than scientific analysis’ (1980, p. 332). Díaz-Alejandro re-examined all these issues in his book on Colombia (1975).

He was also a critic of the intervention of the International Monetary Fund (IMF) in markets which were not within its competence:
It is the business of the IMF to insist on balance of payments targets ... It is not the business of the IMF to make loans conditional on ... food subsidies, utility rates, or controls over foreign corporations... It was a brilliant administrative stroke for the IMF staff to develop the ‘monetary approach to the balance of payments’ during the 1950s, allowing the translation of balance of payments targets into those involving domestic credit, but for many LDCs [less developed countries] the assumptions needed to validate such translation, such as a stable demand for money, have become less and less convincing. (1984, p. 169)

He also strongly criticized the IMF intervention in the debt crisis of the 1980s: ‘Since August 1982 the world has lived with ... a peculiar semi-cartelization shakily managed by central banks and the IMF [which] imposes on countries like Brazil the costs of monopoly (for example, larger spreads and fees) without some of its benefits (the ability to plan ahead)’ (1983, p. 32).

The economic reforms of the late 1970s and 1980s provided another major intellectual challenge. Not since the 1930s had Latin America witnessed such dramatic economic and political experiments. The new military regimes of the Southern Cone applied their Chicago-oriented policies with a degree of ferocity that rivalled their treatment of political dissent. As Velasco said, Díaz-Alejandro's wisdom was twice as useful because it was delivered in a timely fashion (1988, p. 5). His papers of the late 1970s contain the basic ideas which later became accepted wisdom regarding the policy mistakes of the pro-Chicago governments in Latin America and the irrational behaviour of borrowers and lenders in (highly liquid) national and international financial markets. He particularly questioned the feasibility of simultaneous current and capital account liberalization, the lack of capital controls on speculative inflows, and the use of exchange rate policy to fight inflation.

Among his many articles from this period, his ‘Southern Cone Stabilisation Plans’ (1981) stands out. Appearing just before the Mexican moratorium which triggered the debt crisis, his argument ran completely against the tide of dominant opinion. Finally, a detailed analysis of the dynamics of the 1982 crisis was the last – and probably best known – of Díaz-Alejandro's contributions (see Palma, 2003).

Díaz-Alejandro began his studies at MIT at the time when Fidel Castro landed clandestinely in Cuba in 1956, and graduated at the time of the Bay of Pigs invasion (an unsuccessful CIA-planned and funded invasion by Cuban exiles in south-west Cuba in 1961). He felt that the complexity of the situation was such that he opted for the Miltonian hope that ‘they also serve who only stand and wait’.

He had a fascination with Latin American economics. His approach was firmly grounded in the real world, and his work on economic history was rooted in the idea that all history is always the history of the present. As Gustav Ranis remarked, he always ‘respected history, used data carefully, and theory selectively’ (1989, p. xiv). Like his mentors Hirschman, Kindleberger, Lewis and Prebisch he basically belonged to the ‘markets are good servants but bad masters’ Keynesian school of economic thought, and always studied economic problems in their historical context, thus avoiding the sterility of pure formalistic theory that characterized so much of the economics of his own generation and the next.

CES production function; institutional rents; market socialism; neoclassical growth theory

Article

Dickinson went from the King’s School, Wimbledon, to Emmanuel College, Cambridge, where he took the Part II Tripos in both Economics and History. He carried out research at the London School of Economics under Cannan, then went to teaching posts at Leeds and Bristol, where he held the chair of economics from 1951 to 1964. Although his *Institutional Revenue* (1932) is of interest for generalizing the concept of institutional rents, he is deservedly known for a series of writings which attempted to reconcile choice and individual freedom with socialist planning, in the tradition of market socialism. Together with Taylor, Lange and Lerner he provided a rebuttal (based on actual markets) of von Mises’s view that rational allocation under socialism was impossible. He saw ‘the beautiful systems of economic equilibrium’ not as ‘descriptions of society as it is but prophetic visions of a socialist economy of the future’ (1933, p. 247). During the 1930s his writings were well known to intellectuals of the Left, including Cole, Dalton, Durbin and Laski. The best-known of his works is the *Economics of Socialism* (1939). His technical prowess was later exhibited in a *Review of Economic Studies* article of 1954–5 in which he formulated a constant elasticity of substitution production function (CES) for the first time and anticipated some of the neoclassical growth results of Solow and Swan. ‘Dick’, as he was universally known, was a much loved, unworldly, eccentric figure with a keen sense of fun and a most astute mind.

Dietzel, Heinrich (1857–1935)

H.C. Recktenwald

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Dietzel, H.; Eucken, W.; Freiburg School

Article

Born in Leipzig, Dietzel was appointed to a chair at the University of Dorpat in 1885 after studies in economics and law in Heidelberg, Göttingen and Berlin. In 1890 he accepted a chair in the philosophy faculty in Bonn. There he died in 1935.

Dietzel was a respected figure in circles of 19th-century German economists (such as Rau, von Thünen, von Hermann, von Mangoldt and Wagner) who were endeavouring to defend, pursue and modify classical methods and principles. He kept a sceptical distance from both the younger Historical School and the Austrian School, and was sharply opposed to popular Marxism. Nevertheless his excellent biography of Rodbertus and his writings on the early socialists are proof of his academic openness and liberal fairness. Enthusiastically though not successfully engaged in propagating free trade, Dietzel (in contrast to Manchester liberalism) was not dogmatic concerning the functions of the state in a concrete mixed economy.

His most important contribution to theory, the Theoretische Sozialökonomie (1895), unfortunately remained a torso. It is a pioneering analysis of the two main orders of an economy, namely, the individualistic system of competitive markets and the collective system of compulsion of the state. This concept of the two (centralized and decentralized) elementary forms replaced the unscientific notions of capitalism and socialism, with their ideological bias. It opened the way to the foundation of an order theory that his disciple in Bonn, Walter Eucken, and the Freiburg School further developed and later on applied in Germany.

Though Dietzel dealt with self-interest, methodological theory (1911) and value theory, he and his followers (as Smithians) did not attempt to unify Smith's three systems of ethics, economics and politics to an integrated order theory via reconstructing and developing his ‘obvious and simple system of natural liberty’. They also failed to produce an analysis of state and collective failures while they originally stressed the state's responsibility for ensuring sufficient market competition.
Nevertheless they made a number of contributions to the field and pointed to the right road to be taken in the future.

difference-in-difference estimators

Alberto Abadie
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses difference-in-differences (DID) estimators, which are commonly applied in evaluation research. In particular, the discussion focuses on (a) motivation, definition and interpretation of DID estimators, (b) conditions under which DID estimators are valid, (c) data requirements to compute DID estimators, (d) representative applications of DID estimators in the empirical economics literature, (e) extensions of DID estimators, and (f) a simple indirect test to assess the validity of these estimators.

Keywords

difference-in-differences estimators; evaluation studies; fixed effects; minimum wages

Article

Motivation and definition

Difference-in-differences (DID) estimators are often used in empirical research in economics to evaluate the effects of public interventions and other treatments of interest in the absence of purely experimental data. The usual goal of evaluation studies is to estimate the average effect of a treatment (for example, participation in a vocational training programme) on some outcome variable of interest (for example, earnings or employment). Often researchers concentrate on estimating the average effect of the treatment on the treated, that is, on those individuals exposed to the treatment or intervention (for example, the trainees). In the typical setting of an evaluation study, we observe an outcome variable, $Y_i$, for a sample of treated individuals and also for a sample of untreated individuals. The main challenge in evaluation research is to find an appropriate comparison group among the untreated individuals, in the sense that the distribution of the outcome variable for the untreated comparison group can be taken as an approximation to the counterfactual distribution that the outcome variable, $Y_i$, would have followed for the treated in the absence of the treatment. Sometimes the sample of untreated individuals may not provide an appropriate comparison group, and therefore differences in the distribution of the outcome variable between treated and untreated reflect not only the effect of the treatment but also intrinsic differences between the two groups. To address this problem, the DID estimator uses the assumption that in the absence of the treatment the average difference in the outcome variable, $Y_i$, between treated and untreated would have stayed roughly constant. Then, the average difference in the outcome variable between treated and untreated before the treatment can be used to approximate the part of the difference in average outcomes after the treatment that is created by intrinsic differences between the two groups and not by the effect of the treatment.

Let $\bar{Y}_t^T$ and $\bar{Y}_t^C$ be the average outcomes in period $t$ ($t = 1, 2$) in the treated and untreated samples, respectively. Period $t = 1$ takes place before the treatment and period $t = 2$ takes place after the treatment. The difference in average outcomes between treated and untreated after the treatment is $\bar{Y}_2^T - \bar{Y}_2^C$. The same difference for the pre-treatment period is $\bar{Y}_1^T - \bar{Y}_1^C$. Then, the DID estimator is defined as follows:
Figure 1 provides a graphical interpretation of the DID estimator. The solid lines represent the evolution in average outcomes for the treated and the untreated comparison group between the pre-treatment period \((t = 1)\) and the post-treatment period \((t = 2)\). The dashed line approximates the counterfactual evolution that the average outcome would have experienced for the treated in the absence of the treatment. This line is constructed under the DID assumption that, in the absence of the treatment, the difference in average outcomes between treated and untreated would have stayed roughly constant in the two periods. As reflected in Figure 1, an equivalent formulation of the DID assumption is that, in the absence of the treatment, average outcomes for treated and untreated would have followed a common trend. As a result, the untreated comparison group can be used to infer the counterfactual evolution of the average outcome for the treated in the absence of the treatment.

\[
\hat{\alpha} = \left( \bar{Y}_2^T - \bar{Y}_2^C \right) - \left( \bar{Y}_1^T - \bar{Y}_1^C \right)
\]

Figure 1
Difference in differences estimators have been applied to the study of a variety of issues in economics. Card and Krueger (1994) evaluate the employment effects of an increase in the minimum wage in New Jersey using a contiguous state (Pennsylvania), which did not increase the minimum wage, to approximate how employment would have evolved in New Jersey in the absence of the raise. Card (1990) applies DID estimators to evaluate the employment effects of the massive flow of Cuban immigrants to Miami during the 1980 Mariel boatlift. To estimate the effects of the boatlift, Card uses a group of four comparison cities to approximate how employment would have evolved in Miami in the absence of the 1980 immigration shock. Other applications of the DID estimator include studies of the effects of disability benefits on time out of work (Meyer, Viscusi and Durbin, 1995), the effect of anti-takeover laws on firms’ leverage (Garvey and Hanka, 1999), and the effect of tax subsidies for health insurance on health insurance purchases (Gruber and Poterba, 1994).

The DID estimator has a simple regression representation. Let $Y_{it}$ be the outcome of interest (for example, earnings) for individual $i$ at time $t$, with $i = 1, \ldots, N$ and $t = 1, 2$. Let $D_i$ be an indicator of membership to the treatment group, so $D_i = 1$ for the treated and $D_i = 0$ for the untreated. Finally, let $\Delta Y_i = Y_{i2} - Y_{i1}$ be the change in the outcome variable between the pre-treatment and the post-treatment period for individual $i$. The regression representation of the DID estimator is:

$$\Delta Y_i = \mu + \alpha D_i + u_i$$

where $u_i$ is a regression error, which is mean independent of $D_i$ (that is, $E(u_i|D_i = 1) = E(u_i|D_i = 0)$). It can be easily seen that the ordinary least squares estimator of $\alpha$ in eq. (2) is numerical identical to the DID estimator, $\hat{\alpha}$, in eq. (1). Regression standard errors along with the point estimate, $\hat{\alpha}$, can be used to construct confidence intervals for $\alpha$ and perform statistical hypothesis tests. As reflected in eq. (2) and emphasized in Blundell and MaCurdy (1999), the DID estimator is a particular case of fixed effects estimators for panel data, with only two time periods and a fraction of the sample exposed to the treatment in the second time period.

**Extensions**

In some instances, the common trend assumption adopted for DID is not plausible because treated and untreated differ in the distribution of some variables, $X_i$, that are thought to affect the trend of the outcome variable. In this situation, treated and untreated may exhibit different trends in the average of the outcome variable between $t = 1$ and $t = 2$, even if the treatment does not have any impact on the outcome of interest. The regression formulation of the DID estimator is useful to compute a conditional version of the DID estimator that corrects for the effect of $X_i$ on the trend of $Y_i$:

\[\Delta Y_i = \mu + \alpha D_i + u_i\]
\[ \Delta Y_i = \mu + \alpha D_i + X_i' \beta + u_i. \]

Abadie (2005) and Heckman, Ichimura and Todd (1997) develop semiparametric and nonparametric versions of the conditional DID estimator.

Panel data are not always necessary to apply the DID estimator. A simple inspection of eq. (1) indicates that \( \hat{\gamma} \) can be estimated from repeated cross sections, using a cross-section at time \( t = 2 \) to estimate \( \gamma_T^2 - \gamma_C^2 \) and a cross section at time \( t = 1 \) to estimate \( \gamma_T^1 - \gamma_C^1 \). A regression formulation of the DID estimator is also available for repeated cross sections (see, for example, Meyer, 1995; Abadie, 2005). When the DID estimator is constructed using repeated cross sections, it is important to check whether there exist compositional changes in the sample between the two periods. Compositional changes may constitute a threat to the assumption that the difference in the average outcome between treated and untreated would have stayed constant in the absence of the treatment.

In general, the DID assumption cannot be tested directly with data from \( t = 1 \) and \( t = 2 \) only. However, if the common trend assumption extends to more than one pretreatment period for which data are available, pre-existing differences in the trends of the outcome variable between treated and untreated can be detected by applying the DID estimator to pretreatment data. This is done by constructing \( \Delta Y_i \) as the difference in the outcome variable for individual \( i \) between two pretreatment periods. Then, a test of the hypothesis \( \alpha = 0 \) in eq. (2) is a test of the common trend assumption. In addition, the DID assumption can sometimes be rejected when the dependent variable has bounded support (for example, when \( Y_i \) is a binary variable). If the dependent variable has bounded support the DID assumption may imply that, in the absence of the treatment, the average outcome for the treated would have lain outside the support of the dependent variable (see Athey and Imbens, 2006).

A high rate of technological change is a major feature of modern agriculture. New technologies are introduced gradually; diffusion is the process through which technologies spread throughout the farm sector over time. While adoption is the decision by an individual producer to use a new technology at a given moment, diffusion is the aggregate measure of adoption decisions. Early studies of diffusion were conducted by sociologists. Rogers (1962) measured technology usage as a fraction of farmers that had adopted a certain technology at a given point in time. Other studies measured diffusion by the fraction of land employed with the new technology. Rogers noticed that diffusion rates of hybrid corn in the United States fit very well as an S-shaped function of time:

\[ S_t = \frac{K}{1 + \exp(-(a+bt))} , \]

where \( S_t \) is the level of diffusion at time \( t \), \( K \) is the diffusion level at the limit and \( K \leq 1 \), \( a \) is a measure of initial diffusion, and \( b \) is a measure of the speed of diffusion. Rogers modelled diffusion as a process of imitation. In the early and late stages of diffusion, the level of diffusion is low because either the potential population of adopters or the population of users of the new technology to be imitated is small. During the middle period the diffusion rate takes off as there is a sufficient number of potential adopters, as well as a large population of established users to imitate. Rogers (1962) emphasized the role of
distance from urban centres in explaining diffusion, finding that villages closer to urban centres had higher coefficients of diffusion. Griliches (1957) argued that diffusion is an economic phenomenon and showed, using the diffusion data for hybrid corn in Iowa, that the three parameters $K$, $a$, and $b$ are affected by profit. Other studies also found that the rate of diffusion tends to increase with farm size and the education of the farmer. However, as the review of Feder, Just and Zilberman (1985) suggests, the imitation model lacks a microeconomic foundation. An alternative model, the threshold model, suggests that the population of potential adopters is heterogeneous, and at every moment there is a critical variable that distinguishes between them. At every moment there is a threshold level of this variable that separates adopters from non-adopters.

Threshold models have three components: microeconomic behaviour, sources of heterogeneity, and a dynamic factor that drives the threshold level up or down. For example, adoption of mechanical innovation reflects the maximization of discounted net benefit. Farms vary in size, and at each moment there is a farm size threshold that distinguishes adopters from non-adopters. Over time, the cost of machinery may go down due to learning by doing, or the gain from adoption may go up because of learning by using, and that will reduce the adoption threshold. Empirical models, based on cross-sections of adopters, use discrete-choice estimation techniques to identify the key sources of heterogeneity. They found in many cases that size increases adoption of mechanical innovation, education explains adoption of more complex crops, and modern irrigation technologies that actually augment land quality are adopted earlier on lower-quality lands.

Much of the research has attempted to explain the diffusion of new ‘Green Revolution’ varieties in developing countries. In those cases, adoption was often partial (meaning farmers switched only a portion of their crops to the new technologies), and adoption rates were sometimes low, even given the significantly higher yields of Green-Revolution varieties. These facts emphasize the importance of risk considerations in explaining diffusion processes. Land allocation choices of risk-averse farmers were modelled as a portfolio, leading farmers to consider partial adoption of modern varieties because of their increased vulnerability to variable weather conditions. In addition to risk, wealth, human capital, and physical conditions, institutional forces have been identified as major determinants of diffusion rates. For example, renters are less likely to adopt new innovations than owners, especially when the rental contract is short. Lack of availability of credit is another deterrent to adoption. On the other hand, government policies, in the forms of output price subsidies and extension services that reduce the fixed costs of adoption, as well as technology and credit subsidies, can enhance the diffusion of modern agricultural technologies. For irrigation technologies, subsidies of water combined with restrictive trading regulations slow the diffusion of improved irrigation practices; water conservation can be enhanced by reducing constraints on water trading.

When demand for agricultural products is inelastic, the main beneficiary of the diffusion of more efficient technology is the consumer, while farmers are stuck on a ‘technology treadmill’. Early adopters also benefit from the introduction of the new technology, but followers, who make up the majority of the farm population, may adopt only to stay competitive, while sometimes the laggards may go out of business. When the demand for agricultural products is elastic, then the gain from adoption of modern technologies contributes to enhanced land values, but the individual farm operators may not gain significantly because of the technology treadmill effect.

The diffusion of technology has a major impact on per-capita income. Moreover, international convergence turns on whether technology diffusion is local or global. This article characterizes the creation of technological knowledge and discusses the primary determinants of diffusion. It is shown that even today technology diffusion is to an important degree local, allowing for many technological knowledge levels in the world to coexist. This article focuses on the data and empirical methods employed in the estimation of diffusion patterns.

Article

The technology of a firm or country determines the efficiency with which inputs are mapped into outputs. Technological change may result in the ability to produce entirely new products, or it may allow an existing product to be produced with fewer inputs. This process has long been viewed as central to economic growth. The question of whether or not there is convergence across firms and countries raises issues related not only to the process of technical change but also to the diffusion of technology. Beginning in the late 1950s, economists have formalized their thinking as to how such technological knowledge diffuses from one economic entity to another. The early efforts were primarily directed to understanding firms’ technology adoption decisions that often yield an S-shaped diffusion pattern over time. Since the 1990s, a vibrant literature has emerged in which the issues addressed are considerably broader, and where much more emphasis is placed on seeking high-quality empirical evidence.
A firm's technology and its productivity are closely related, and the two are identical if technology is identified with total factor productivity, an approach frequently adopted since the 1950s. The development of models of endogenous technical change in the early 1990s represented a step forward in that the R&D resources devoted to innovation were separated from the new technological knowledge itself. For example, consider the technology production function

\[ \dot{N} = \eta N^\lambda H_N, \quad (1) \]

where \( \eta \) and \( \lambda \) are parameters, \( \eta, \lambda > 0 \). The term \( H_N \) denotes the skilled-labour resources devoted the R&D, which according to eq. (1) lead to a flow of new technological knowledge of \( \dot{N} \). A higher level of R&D produces a higher level of technology, \( N \), and that in turn can be shown to result in higher productivity.

According to eq. (1), a higher stock of existing technological knowledge facilitates innovation. This stock of technological knowledge will rarely be entirely self-produced, so that (1) typically involves the diffusion of technology – diffusion between different persons, firms or countries. Technology is sometimes purchased or licensed in a market transaction, but, due to asymmetric information and other problems in the market for technology, non-market transactions in the form of technological externalities, called knowledge spillovers, are much more important. What are the nature and the size of these knowledge spillovers? Since technological knowledge is non-rival, such externalities can in principle benefit many economic agents.

A useful benchmark is the complete diffusion of technology, which describes the case where technological knowledge created anywhere in the world is available worldwide immediately. This could underlie the assumptions of common-to-all and free technological knowledge of neoclassical growth theory. Clearly, this is not true in reality, where the diffusion of technology is gradual and uneven.

Why? First of all, acquiring technology involves making complementary investments, and the equilibrium choice for such investments often implies that not all technology diffuses. For instance, in Keller's (1996) model, international trade enables domestic producers to raise productivity by importing specialized foreign intermediate goods. Since these goods embody foreign R&D investments, this means the diffusion of technology from one country to another. For this imported technological knowledge to trigger domestic innovation, however, additional investments are necessary. According to Keller (1996), these investments mean additional training of workers so that they have the skills to manufacture products according to new blueprints. In addition, domestic innovators may have to invest resources in reverse engineering the foreign intermediate goods in order to fully comprehend the underlying foreign technological knowledge.

Second, another major determinant of the firm's decision to acquire the existing technology and innovate is the degree of product market competition. For example, in early Schumpeterian endogenous growth models, a higher degree of product market competition leads to lower monopoly profits and thus to a lower rate of innovation. More recent work by Aghion et al. (2001), for example, shows that, if
technological laggards must first catch up with the leading-edge technology before battling for technological leadership in the future, the overall effect of more product market competition may be positive. The reason for this is that, even though more competition means lower monopoly profits, technological leaders now also have an incentive to innovate to avoid competition with technological laggards, and, if the latter effect is strong enough, product competition has a positive effect on technology diffusion and growth.

Third, there is no complete diffusion because it is simply not in the interest of the original creator of the technology, since his market for the technology would shrink if there were additional suppliers. In some cases, innovators obtain a patent that provides government-sanctioned protection of economic interests for a limited period of time in exchange for release of the technological information. Another strategy on the part of the original innovator is to use a varying amount of resources to keep the technological knowledge secret. At the same time, studies show that it often is no more than two years until new technology becomes publicly available.

Another, probably the most important, reason why knowledge spillovers are limited is that only the broad outlines of technology are codified – the remainder is the ‘tacit’ part of the knowledge. A person who is engaged in a problem-solving activity can often not fully define (and hence prescribe) what exactly he or she is doing. Along these lines, technology is only partially codified because it is impossible or at least very costly to fully codify it. For technology diffusion to occur completely, it may be necessary that the person who learns about the new technology can observe another person in the process of applying the technology. Even if this can be dispensed with, person-to-person contacts will generally be beneficial to the diffusion of technology.

Research has now turned to the essential task of assessing the importance of these processes empirically. As an intangible, technology is intrinsically difficult to measure, and economic data is hard to come by. This is even more the case for the non-market effects caused by technological knowledge. The main approach for quantifying technical change has been to study the relationship between R&D investments and productivity (Griliches, 1979). For example, Keller (2002a) estimates

$$ tT \prod_{i}^{p} = \beta s_{it} + X' \gamma + \varepsilon_{it}, \quad i = 1, \ldots, I, \quad \text{and} \quad t = 1, \ldots, T, \quad (2) $$

where $tT \prod_{i}^{p}$ is log total factor productivity in industry $i$ at time $t$, $s_{it}$ are industry $i$'s cumulative R&D investments (in logs) in period $t$, $X$ is a vector of other observed determinants of productivity, and the error $\varepsilon_{it}$ picks up unobserved effects. The parameter $\beta$, estimated in Keller (2002a) at $\beta = 0.15$, measures how R&D investments translate into higher productivity, thereby implicitly capturing the rate of technical change.

This approach is attractive since R&D spending is the main cause of technical change, and data on R&D expenditures is relatively easy to collect and compare across units (firms, industries and countries). A drawback is that measuring technical change this way requires an estimate of $\beta$. This can be complicated if productivity is badly measured, R&D is endogenous, or unobserved determinants on productivity are important, as in practice is often the case. Applications of instrumental-variable and
control-function approaches have shown much promise in addressing the major estimation concerns (see Gong and Keller, 2003). Patents are an alternative measure of technology, with the advantage that patent data is available for a broader set of countries and a longer time horizon than is data on R&D (Jaffe and Trajtenberg, 2002). While patent counts are an imperfect measure of technology because the distribution of patent values is extremely skewed, recent work using citations-weighted patent data has addressed this point since citations of a particular patent are a plausible indicator of its value. At the same time, patents cannot capture more than the codified part of technological knowledge, apart from the fact that across industries and firms the prevalence of patenting varies strongly for reasons that are difficult to fully ascertain.

Technology spillovers, as the major form of technology diffusion, are mainly analysed by extending eq. (2) above to estimate as well the effects of R&D investments conducted elsewhere. For example, in addition to the effects of own-industry R&D, Keller (2002a) estimates the effects of R&D in other domestic industries ($s_{it}^{d_o}$), as well as those of R&D in the same and other foreign industries ($s_{it}^{f}$ and $s_{it}^{f_o}$, respectively):}

$$t^f p_{it} = \beta_1 s_{it} + \beta_2 s_{it}^{d_o} + \beta_3 s_{it}^{f} + \beta_4 s_{it}^{f_o} + \tilde{\chi}' \gamma + \varepsilon_{it}. \quad (3)$$

In this framework, the estimates of $\beta_1$, $\beta_2$, $\beta_3$, and $\beta_4$ determine the relative strength of intra- and inter-industry, and of domestic and international technology diffusion. For his sample of eight large Organisation for Economic Co-operation and Development (OECD) countries, Keller (2002a) finds that intra-industry effects dominate inter-industry spillovers, and that about 25 per cent of the total effect is due to international technology diffusion.

Other interesting approaches have employed multi-country extensions of recent models of endogenous technical change that include international technology diffusion (Eaton and Kortum, 1999). Because here the economic environment is fully specified, it is straightforward to simulate a model and perform interesting policy experiments. At the same time, typically there is little data on technology diffusion employed in the econometric estimation of these models. Consequently, the model's structure has a great influence on the results, while the implications for the diffusion of technology are not clear.

One major finding has been that the diffusion of technology is geographically localized, both domestically and internationally. For example, Keller (2002b) studies international technology diffusion between the G-5 countries (the United States, Japan, Germany, France, and England) and nine smaller OECD countries by estimating

$$t^f p_{it} = \beta \left[ s_{it} + \sum_{j \in G5} \exp(-\delta Dist_{ij}) s_{jt} \right] + \tilde{\chi}' \gamma + \varepsilon_{it}, i = 1, \ldots, l, \text{ and } t = 1, \ldots, T.$$
Here, $Dist_{ij}$ is the geographic distance between country $i$ and G-5 country $j$. The parameter $\delta$ determines the extent of geographic localization: the higher is $\delta$, the stronger is the degree of the localization of technological knowledge, while if $\delta = 0$, international technology diffusion is complete in the sense that geography has no impact whatsoever. The geographic reach of technology spillovers is a critical determinant of the cross-country income distribution, since global spillovers favour income convergence while local spillovers lead to income divergence. Keller's (2002b) results for the years 1970 to 1995 strongly reject the null hypothesis of complete diffusion. Instead, he estimates that with every additional 1,200 kilometres there is a 50 per cent drop in technology diffusion. The results imply that the benefits of being located next to major technology producers are substantial, highlighting the danger for isolated areas of being left behind.

While distance still shapes technology diffusion in a major way, there is also evidence that between 1970 and 1995 geography's grip on technology diffusion has weakened. Keller (2002b) estimates that the size of the $\delta$ parameter in eq. (4) fell substantially from the late 1970s to the 1990s, consistent with the idea that innovations in information and communication technologies have led to a major improvement in technology diffusion.

Such improvements in countries’ abilities to draw on international innovations also imply that increasingly the ultimate sources of domestic productivity growth lie abroad. This is especially true for medium-sized and small countries, where the contribution of foreign technology to domestic productivity growth often exceeds 90 per cent. At the same time, because successful technology diffusion requires complementary investments in terms of adaptive R&D and/or human capital, domestic activities have a significant impact on the ease of technology diffusion.

Directly unproductive profit-seeking (DUP) activities are defined (Bhagwati, 1982a) as ways of making a profit (that is, income) by undertaking activities which are directly (that is, immediately, in their primary impact) unproductive, in the sense that they produce pecuniary returns but do not produce goods or services that enter a conventional utility function or inputs into such goods and services.

Typical examples of such DUP (pronounced appropriately as ‘dupe’) activities are (i) tariff-seeking lobbying which is aimed at earning pecuniary income by changing the tariff and therefore factor incomes; (ii) revenue-seeking lobbying which seeks to divert government revenues towards oneself as recipient; (iii) monopoly seeking lobbying whose objective is to create an artificial monopoly that generates rents; and (iv) tariff-evasion or smuggling which de facto reduces or eliminates the tariff (or quota) and generates returns by exploiting thereby the price differential between the tariff-inclusive legal and the tariff-free illegal imports.

While these are evidently profitable activities, their output is zero. Hence, they are wasteful in their primary impact, recalling Pareto's distinction between production and predation: they use real resources to produce profits but no output.

DUP activities of one kind or another have been analysed by several economic theorists, among them (i) the public-choice school's leading practitioners, their major work having been brought together in Buchanan, Tullock and Tollison (1980), (ii) Lindbeck (1976) who has worked on 'endogenous politicians', and (iii) the Chicago 'regulation' school, led by Stigler, Peltzman, Posner and also Becker (1983).
However, a central theoretical breakthrough has come from the work of trade theorists who have systematically incorporated the analysis of DUP activities in the main corpus of general equilibrium theory.

The early papers that defined this general-equilibrium-theoretic approach, and which were set in the context of the theory of trade and welfare, were: Bhagwati and Hansen (1973) which analysed the question of illegal trade (that is, tariff-evasion), Krueger (1974) which analysed the question of rent-seeking for rents associated with import quotas specifically and quotas more generally, and (iii) Bhagwati and Srinivasan (1980) who analysed the phenomenon of revenue-seeking, the ‘price’ counterpart of Krueger’s rent-seeking, where a tariff resulted in revenues which were then sought by lobbies.

The synthesis and generalization of these and other apparently unrelated contributions, showing that they all related to diversion of resources to zero-output activities, was provided in Bhagwati (1982a) where they were called DUP activities. The following significant aspects of the theoretical analysis of DUP activities are noteworthy.

First, they are generally related to policy interventions (but they need not be: plunder, for instance, predates the organization of governments). In so far as policy interventions induce DUP activities, they are analytically divided into two appropriate categories (Bhagwati and Srinivasan, 1982):

**Category I: Policy-triggered DUP activities.** One class consists of *lobbying* activities. Examples include: rent-seeking analysis of the cost of protection via import licences (Krueger, 1974); revenue-seeking analysis of the cost of tariffs (Bhagwati and Srinivasan, 1980), of shadow prices in cost–benefit analysis (Foster, 1981), of price versus quantity interventions (Bhagwati and Srinivasan, 1982), of non-economic objectives (Anam, 1982), of rank-ordering of alternative distorting policies such as tariffs, production and consumption taxes (Bhagwati, Brecher and Srinivasan, 1984), of the optimal tariff (Dinopoulos, 1984), of the transfer problem (Bhagwati, Brecher and Hatta, 1985), and of voluntary export restrictions relative to import tariffs (Brecher and Bhagwati, 1987).

**Category II: Policy-influencing DUP activities.** The other generic class of DUP activities is not triggered by policies in place but is rather aimed at influencing the formulation of the policy itself. The most prominent DUP-theoretic contributions in this area relate to the analysis of tariff-seeking. Although Brock and Magee (1978; 1980) pioneered here, the general equilibrium analyses of endogeneous tariffs began with Findlay and Wellisz (1982) and Feenstra and Bhagwati (1982), the two sets of authors modelling the government and the lobbying activities in contrasting ways. Notable among the later contributions are Mayer (1984), who extends the analysis formally to include factor income-distribution and therewith voting behaviour, and Wellisz and Wilson (1984). Magee (1984) has an excellent review of many of these contributions. The implication of endogenizing the tariff for conventional measurement of the cost of protection has been analysed in Bhagwati (1980) and Tullock (1981).

The *choice* between alternative policy instruments when modelling the response of lobbies and governments to import competition has also been extensively analysed. The issue was raised by
Bhagwati (1982b) and analysed further by Dinopoulos (1983) and Sapir (1983) in terms of how different agents (for example, ‘capitalists’ and ‘labour’) would profit from different policy responses such as increased immigration of cheap labour and tariffs when import competition intensified. It has subsequently been explored more fully by Rodrik (1986), who compares tariffs with production subsidies.

Second, Bhagwati (1982a) has noted, generalizing a result in Bhagwati and Srinivasan (1980), that DUP activities, while defined to be those that waste resources in their direct impact, cannot be taken as ultimately wasteful, that is, immiserizing, since they may be triggered by a suboptimal policy intervention. For, in that event, throwing away or wasting resources may be beneficial. The shadow price of a productive factor in such ‘highly distorted’ economies may be negative. This is the obverse of the possibility of immiserizing growth (Bhagwati, 1980). Thus, Buchanan (1980), who has addressed the issue of DUP activities and defined them as activities that (ultimately) cause waste, has been corrected in Bhagwati (1983): the definition of DUP activities cannot properly exclude the possibility that DUP activities are ultimately beneficial rather than wasteful. This central distinction between the direct and the ultimate welfare impacts of DUP activities is now universally accepted. DUP activities are therefore defined now, as in Bhagwati (1982b) and subsequent contributions, as wasteful only in the direct sense.

Third, Bhagwati, Brecher and Srinivasan (1984) have raised yet another fundamental issue concerning DUP activities. Thus, where DUP activities belong to Category II distinguished above, full endogeneity of policy can follow. If so, the conventional rank-ordering of policies is no longer possible. We have the determinacy paradox: policy is chosen in the solution to the full ‘political-economy’, DUP-theoretic solution and cannot be varied at will. These authors have therefore suggested that, where full endogeneity obtains, the appropriate way to theorize about policy is to take variations around the observed DUP-theoretic equilibrium. Thus, traditional economic parameters such as factor supply could be varied; similarly now the DUP-activity parameters such as, say, the cost of lobbying could be varied. The impact on actual welfare resulting from such variations can then be a proper focus of analysis, implying a wholly different way of looking at policy questions from that which economists have employed to date.

Finally, DUP activities are related to Krueger's (1974) important category of rent-seeking activities. The latter are a subset of the former, in so far as they relate to lobbying for quota-determined scarcity rents and are therefore part of DUP activities of Category II distinguished above (Bhagwati, 1983).

directly unproductive profit-seeking (DUP) activities: The New Palgrave Dictionary of Economics

**How to citethisarticle**

Aaron Director's enduring contribution to economics came via his role in the development of the Chicago law and economics tradition. Director was born in Charterisk (in present-day Ukraine) in 1901 and emigrated to the United States with his family in 1913. He received his undergraduate degree from Yale University and his graduate training at the University of Chicago. Although he came to Chicago in 1927 to work with Paul Douglas on labour economics, it was Frank Knight and Jacob Viner who, via their price theory courses, had the greatest influence on him. Director remained at Chicago as a graduate student and part-time instructor until 1934. The 1930s were a heady period at Chicago, where the student body included George Stigler, Paul Samuelson (who credits Director's teaching with stimulating his interest in economics), and Milton Friedman – each of whom helped to reshape economic thinking in the middle third of the 20th century – as well as Rose Director (Aaron's sister and, eventually, Rose Friedman). Aaron Director was very much part of this milieu. He left the University of Chicago for the US Treasury Department in 1934 and, save for an aborted attempt to complete a dissertation on the history of the Bank of England, remained in Washington, DC, until 1946, when he returned to the University of Chicago to take up a position in the Law School, where he remained until his retirement in 1966.

Director's appointment in the Law School was a result of the efforts of Henry Simons, the first economist on the law faculty at Chicago, and Friedrich Hayek, whose Road to Serfdom was published in the United States largely because of Director's intervention with the University of Chicago Press. The plan, as laid out by Simons, was for Director to head up the ‘Free Market Study’, a Volker Fund-financed project, housed in the Law School and dedicated to undertaking ‘a study of a suitable legal and institutional framework of an effective competitive system’ (Coase, 1998, p. 246). However, Simons committed suicide in the summer of 1946, and Director was asked to take on Simons's basic Law School
price theory course, ‘Economic Analysis of Public Policy’. This provided Director with an initial forum for bringing the perspective he had learned from Knight and Viner into the Law School's teaching programme.

The transition from having an economist on the Law School faculty to the establishment of a law and economics tradition at Chicago began not long after this, when Edward Levi invited Director to collaborate in the teaching of the antitrust course. Levi would teach a traditional antitrust course for four days each week; Director would then come in on the fifth day and, using the tools of price theory, show that the traditional legal approach could not stand up to the rigours of economic analysis. The basic pattern was very simple: Director would ask whether the practice in question was, in general, consistent with monopolistic profit maximization. The answer was often negative, which meant that there had to be some sort of legitimate rationale for the supposedly anti-competitive practice in question. What Director's price theory showed was that the 'simple and obvious' answers were often wrong-headedly simplistic. This process had a profound impact on students and colleagues alike. Director's antitrust students – a group that included Robert H. Bork, Ward Bowman, Kenneth Dam, Edmund Kitch, Wesley J. Liebeler, John S. McGee, Henry Manne, and Bernard H. Siegan – have often spoken of the 'conversion' they experienced in this class, and even Levi himself became a partial convert (see Kitch, 1983; Director and Levi, 1951). What was perhaps Director's most significant contribution on the missionary front came after his retirement, when he and Richard Posner spent time together at Stanford in 1968 – Posner's first year on the Stanford Law School faculty. It was Director who taught Posner to think like a Chicago economist, introduced him to Stigler and Ronald Coase, and in this and other ways was instrumental in Posner's move to the Chicago Law School after only one year on the Stanford faculty. The rest, as they say, is history.

Although Director's published output was slight, his influence extended well beyond the classroom. His insights made their way into the antitrust literature – and, eventually, antitrust policy – through the writings of students and colleagues, as Sam Peltzman (2005) has detailed. Director's primary legacies are in the analysis of predatory pricing (via McGee, 1958), resale price maintenance (via Telser, 1960), and tie-in sales (see Director and Levi, 1951; Bowman, 1957; Burnstein, 1960), but his influence was also prominent in Stigler's view of oligopoly and antitrust policy, Posner's (1969) perspective on oligopoly and cartels, and Robert Bork's influential articles on antitrust (for example, Bork and Bowman, 1965; Bork, 1967). These contributions coalesced in a distinctive Chicago approach to antitrust analysis, an approach that Herbert Hovenkamp (1986, p. 1020) says ‘has done more for antitrust policy than any other coherent economic theory since the New Deal’, and whose influence is inescapable.

Director's impact at the Law School went far beyond antitrust: He was also the prime mover in the early professionalization of law and economics. Director formally established the nation's first law and economics programme, which maintained visiting fellowships for law and economics scholars, and, in 1958, founded the Journal of Law and Economics. Within a few decades, Director's efforts at Chicago had been replicated in a set of thriving and well-funded law and economics programmes at major law schools around the country. One would be hard pressed to name an individual in our discipline who has had as much influence as Director without a much more extensive bibliography.

Dispute Resolution

Amy Farmer and Paul Pecorino
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The high cost of disputes creates an incentive for parties to disputes to settle. In civil litigation and arbitration, settlement failure may arise from asymmetric information or optimism. Devices to induce settlement include voluntary disclosure and mandatory discovery. The effects of these are considered, as are the English rule (whereby the loser at trial pays the reasonable legal costs of the winner), the use of contingency fees, and the operation of conventional arbitration and final offer arbitration. Researchers continue to propose new arbitration mechanisms in the hope of improving the dispute resolution process.

Keywords

asymmetric information; bargaining; signalling; screening; arbitration; final offer arbitration; contingency fees; English rule; fee-shifting; optimism; self-serving bias

Article

Disputes may arise in a variety of settings, including labour negotiations, civil disputes and family conflict. If individuals fail to reach an agreement, there exist a variety of mechanisms for resolving the dispute. These include civil litigation, arbitration and, in labour relations, the strike. Resolving disputes in these ways is costly, thereby creating a contract zone within which both parties strictly prefer to settle. Given the high cost of disputes, considerable research has been devoted to understanding why settlement sometimes fails to occur and how different mechanisms affect the dispute rate. Here we focus on dispute resolution in the context of civil litigation and arbitration.

Why settlement fails

The dominant rational choice explanation for settlement failure is asymmetric information. An alternative explanation, not consistent with the assumption of full rationality, is optimism. If agents have
symmetric information and beliefs about the expected outcome of a dispute, theory suggests a settlement will occur. However, if one party has private information about the expected outcome of the dispute, settlement failure can occur. Similarly, if one or both parties to the dispute are subject to optimism, a contract zone may fail to exist.

There are two basic models in the asymmetric information literature, which make different assumptions about the structure of information. When the uninformed party makes the offer, we have a screening model which was developed by Bebchuk (1984). When the informed party makes the offer we have a signalling model developed by Reinganum and Wilde (1986). Both models’ predictions are consistent with the existence of costly disputes in equilibrium.

To explore the intuition behind these models, consider a civil dispute in which the failure of negotiations would result in a trial. Suppose a plaintiff known to be harmed has private information concerning the damages she has incurred and that this information would be revealed at trial. Further, suppose the plaintiff is one of two types: a weak type with a low expected payoff at trial or a strong type with a high expected payoff. A risk-neutral plaintiff will accept a settlement offer if and only if it equals or exceeds her expected net payoff from trial. The defendant knows the probability that he is facing a weak or strong plaintiff but not the plaintiff’s exact type. In a screening model, the uninformed defendant makes an offer to the plaintiff. He will choose between a low (screening) offer that only weak plaintiffs would accept and a high (pooling) offer that both types would accept. If he makes the low offer, then a strong plaintiff would proceed to trial. The screening offer is more likely to be optimal for the defendant when there is a high prevalence of weak plaintiffs, when court costs are low, and when the difference in expected trial awards for the two plaintiff types is large.

If the informed plaintiff is allowed to make the offer, this is called the signalling game. While these games generally have multiple equilibria, the D1 refinement (Cho and Kreps, 1987) has been employed to focus on a separating equilibrium in which the weak plaintiff submits a low demand to the defendant, while the strong plaintiff submits a high demand. Under D1, it is assumed that an out of equilibrium offer is made by the plaintiff willing to make that offer for the largest set of acceptance probabilities. In equilibrium, the high demand must be rejected with a sufficiently high probability so as to discourage the weak plaintiff from also making this demand. These rejections lead to a positive probability of trial with the strong plaintiff.

While we used a two-type model to motivate the discussion, the Bebchuk and Reinganum and Wilde models employ a continuum of types whose distribution is known by the uninformed party. These models have been extended in numerous ways by allowing for two-sided information asymmetries (Schweizer, 1989; Daughety and Reinganum, 1994) and multiple offers (Spier, 1992) among other extensions. While the effects of policy variables (such as cost shifting at trial) are often sensitive to the modelling details, the prediction that asymmetric information can result in costly disputes is quite robust. Excellent surveys of the literature are provided by Spier (1998) and Daughety (1999).

The optimism or self-serving bias explanation for settlement failure relies on bargainers who have potentially inaccurate beliefs about the expected outcome at trial. For example, the plaintiff's belief about the probability she will prevail at trial may exceed the defendant's belief about this same probability. If these differences in beliefs are not based on differences in information, then we are in the
realm of the optimism model. Versions of this model have been employed by Landes (1971), Posner (1973), Shavell (1982), and Priest and Klein (1984). Optimism violates rationality, but Bar-Gill (2002) finds that cautious optimism can allow the optimistic party to obtain a larger portion of the joint surplus from settlement. As a result, cautious optimism can persist in an evolutionary setting. Babcock and Loewenstein (1997) survey an experimental literature documenting the existence of a self-serving bias which leads players in the role of a plaintiff to expect a greater payoff at trial than the defendant, even though both are exposed to the same set of facts. When players are exposed to the facts of the case before being assigned their role as plaintiff or defendant, the self-serving bias tends to disappear. Waldfogel (1998) and Farmer, Pecorino and Stango (2004) find empirical evidence that is consistent with the optimism model. Note that the optimism and asymmetric information explanations are not mutually exclusive. It is possible that each factor is responsible for some proportion of observed disputes.

**Mandatory discovery and voluntary disclosure**

If asymmetric information causes disputes, it is logical to ask whether voluntary disclosures and mandatory discovery can eliminate these asymmetries. In a screening model where credible disclosure is costless, Shavell (1989) shows that plaintiffs with strong cases will reveal enough information to ensure that all cases settle. Plaintiffs who do not reveal their information (those with weak cases) receive a pooling offer that all accept. However, the work of Sobel (1989) shows that this result is not robust to the introduction of positive costs of disclosure. He also shows that a costless (to the plaintiff) discovery procedure will lead to greater settlement. Farmer and Pecorino (2005) consider costly discovery and disclosure in both the signalling and the screening games. Costly disclosures may be made in the signalling game but not the screening game, while costly discovery may be invoked in the screening game but not the signalling game. If the cost of these procedures is not too high, the combination of the two will lead to a great deal of information transmission and a large reduction in the dispute rate.

Why then do disputes persist? Perhaps, as Shavell (1989) suggests, private information has strategic value if withheld until trial. Hay (1995) develops a model in which an initial informational asymmetry on the merits of the case is resolved by mandatory discovery, but by the time this occurs a new asymmetry – namely, the extent of attorney preparation – has emerged. This second asymmetry leads to trials in the equilibrium of the model. Hay notes that the extent of attorney preparation is not subject to discovery. This is also true of preferences. Farmer and Pecorino (1994) show that asymmetric information on risk preferences can lead to trial, and that this information is neither subject to discovery nor easy to credibly transmit. As a result, this type of asymmetry may tend to persist in the face of mandatory discovery and opportunities for voluntary disclosure.

**Other institutional features**

There is a voluminous literature which examines how a variety of institutional features affect settlement in civil litigation. What follows is a much abbreviated discussion of a large and complex literature. One difficulty in addressing this question is that even a single institution is likely to have multiple effects on the litigation process. Thus, a single institution may have conflicting effects on the dispute rate and may
also have important influences on other aspects of the litigation process. A classic example of this difficulty is reflected in the analysis of the English rule under which the loser at trial pays the reasonable legal costs of the winner. If the probability of a finding for the plaintiff at trial is private information, then fee shifting at trial reduces settlement rates by, in effect, spreading out the distribution of player types (Bebchuk, 1984). If players are optimistic in their assessments of the probability that the plaintiff will prevail, then fee shifting will aggravate this optimism and reduce the probability that a contract zone will exist (Shavell, 1982).

This prediction – that fee shifting will increase the probability of trial – is made with expenditure at trial held constant. It is well established that the fee shifting at trial will increase expenditure (Braeutigam, Owen, and Panzar, 1984). If the expenditure effect is strong enough, it can result in fewer (but more costly) disputes (Hause, 1989). The English rule also affects the mix of cases which are filed. It discourages cases where there are large stakes but a low probability of success, and encourages low stakes cases with a high probability of success (Shavell, 1982).

Many of the theoretical predictions on fee shifting at trial appear to be borne out in the data (see Hughes and Snyder, 1998).

Under a contingency fee, the plaintiff's lawyer receives a percentage of the judgment at trial if the plaintiff wins the case and nothing if she loses. The effects of contingency fees on the litigation process are very complex and wide ranging (see Rubinfeld and Scotchmer, 1998, for a survey). However, one effect of contingency fees on settlement is clear: if the attorney controls the settlement decision, he will have an excessive incentive to settle the case relative to the interests of his client. The reason is that the attorney bears most of the costs of a trial but is paid only a fraction of the award. On the other hand, if the client controls the case, she may have an excessive incentive to reject a settlement offer and bring the case to trial. (This is particularly true if the contingency percentage is not lower for cases which settle early.)

When a single defendant faces multiple plaintiffs in sequence, some interesting issues regarding settlement arise. Spier (2003a; 2003b) and Daughety and Reinganum (2004) have analysed the use of most favoured nation (MFN) clauses in the context of repeat litigation. Suppose a plaintiff settles early under MFN. If another plaintiff later settles for more, the early settlement is adjusted upward. An MFN clause can be a mechanism whereby the defendant commits to not raising his offer to plaintiffs who settle later in the process. While there is some ambiguity of the effects of MFN on settlement rates and the overall dispute costs (see especially Spier, 2003a), the general thrust of these papers suggests that MFN clauses are efficiency enhancing in the sense that they will reduce the expected dispute costs associated with litigation.

Arbitration

Under conventional arbitration (CA), the arbitrator is free to impose her preferred settlement on the bargaining parties. Under final offer arbitration (FOA), each party to the dispute submits an offer to the arbitrator who must pick one of the submitted offers. While there is some evidence that submitted offers affect the outcome in CA (Farber and Bazerman, 1986), for the purpose of the following discussion we assume that they do not. From a modelling standpoint, this makes CA look exactly like a simple version
of civil litigation. Under FOA, the submitted offers clearly affect the outcome, a feature which has important implications for dispute resolution.

Consider the two-type version of the screening model where the plaintiff can have a strong or a weak case. In CA, the defendant will either make an offer that only a weak plaintiff will accept or a pooling offer that both types will accept. If all negotiation takes place prior to the submission of offers to the arbitrator, then under FOA it is possible that the defendant will make an offer that neither type will accept, resulting in a 100 per cent dispute rate (Farmer and Pecorino, 2003). This can occur because the sequentially rational offer submitted to the arbitrator influences the acceptable settlement prior to arbitration. The lack of early settlement allows the defendant to commit to an offer which is optimal against the entire distribution of plaintiff types. Farmer and Pecorino (2003) also show (in contrast to CA) that costless voluntary disclosure never takes place when FOA is the dispute resolution mechanism. The reason is that information has strategic value in this game. Both of the impediments to settlement discussed above disappear if bargaining is permitted after offers are submitted to the arbitrator but prior to the arbitration hearing.

While not totally conclusive on this point, the results of Farmer and Pecorino (1998) also suggest that allowing for bargaining after offers are submitted to the arbitrator can increase settlement for reasons different from those discussed above. Because a submitted offer affects the outcome of arbitration, it will tend to reflect private information. This may in turn promote settlement. Taken together, the results on FOA suggest that the effects of this institution on settlement are sensitive to whether or not bargaining occurs in the face of offers submitted to the arbitrator. In major league baseball, a prominent use of FOA, a good deal of bargaining and settlement occurs after offers have been submitted to the arbitrator.

FOA was proposed by Stephens (1966) and has since become an important alternative to CA. Researchers continue to propose new arbitration mechanisms in the hope of improving the dispute resolution process. Combined arbitration (Brams and Merrill, 1986) is a mixture of FOA and CA. Other proposed mechanisms include tri-offer arbitration (Ashenfelter et al., 1992) and amended final offer arbitration (Zeng, 2003).

distributed lags

Philip Hans Franses
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews various aspects of distributed lag models. Specific attention is paid to the interpretation of model parameters.

Keywords

Almon lags; ARMA models; cointegration; distributed lags; error correction models; Koyck transformation; maximum likelihood; multicollinearity; nonlinear least squares; ordinary least squares; vector autoregressions

Article

Distributed lag models correlate a single dependent variable with its own lags and with current and lagged values of one or more explanatory variables. Examples concern the current and dynamic correlations between output and investment and between sales and advertising. Distributed lag models typically assume that the explanatory variable is exogenous. (In case of doubt, one usually resorts to vector autoregressive models where two or more variables can be endogenous; see Sims, 1980.)

This article highlights a few aspects of distributed lag models. The two main aspects are representation and interpretation. Useful extended surveys appear in Dhrymes (1971), Griliches (1967) and Hendry, Pagan and Sargan (1984).

Representation

Consider a dependent variable \( y_t \) and, for ease of notation, a single explanatory variable \( x_t \). Indicator \( t \) runs from 1 to \( n \) and it can concern seconds, hours, days or even years. A general (autoregressive) distributed lag model is given by

\[
y_t = \mu + \alpha_1 y_{t-1} + \ldots + \alpha_p y_{t-p} + \beta_0 x_t + \beta_1 x_{t-1} + \ldots + \beta_m x_{t-m} + \varepsilon_t
\]

(1)
where \( p \) and \( m \) can take any positive integer value, and where it is usually assumed that \( \varepsilon_t \) is an uncorrelated variable with mean zero and variance \( \sigma^2 \). (Part of the literature assumes the label distributed lags model for the case where \( p = 0 \) and \( m = \infty \). Below we will see that such a model is often approximated by a model as in (1).)

As the model contains the lagged dependent variables, it is called an autoregressive distributed lag model with orders \( p \) and \( m \), in short ADL(\( p, m \)). The model allows for delayed effects of \( x_t \), as \( \beta_0 \) can be 0, and it also allows for time gaps in these effects when some \( \beta \) parameters are zero and others are not.

### Reducing the number of parameters

Basically, given fixed and finite values of \( p \) and \( m \), the parameters in (1) can be consistently estimated with ordinary least squares (OLS). (Typically one uses information criteria as those of Akaike or Schwarz to choose the relevant values of \( p \) and \( m \) in practice.) In practice, \( p \) and \( m \) can be large, and in theory even as large as \( \infty \). This can be inconvenient, for two reasons. First, the variables \( y_t \) and \( x_t \) each can be strongly autocorrelated, and then the regression in (1) suffers from multicollinearity. Second, with many parameters in a model there might be many values to evaluate and interpret.

To reduce the number of parameters and to facilitate interpretation, one can impose restrictions. Early suggestions are the Almon and Shiller lag structures, where the parameters are made functions of \( i, i = 0, 1, 2, \ldots, m \) (see Almon, 1965, and Shiller, 1973), and the so-called Koyck transformation (see Koyck, 1954).

### Almon and Shiller transformations

Consider the version of (1) with \( p = 0 \) and \( m = m \) and set \( \mu \) at 0 for convenience, that is, consider

\[
y_t = \beta_0 x_t + \beta_1 x_{t-1} + \cdots + \beta_m x_{t-m} + \varepsilon_t.
\]

(2)

Almon (1965) proposes to reduce the number of parameters by assuming the approximation

\[
\beta_i = \alpha_0 + \alpha_1 i + \alpha_2 i^2 + \cdots + \alpha_q i^q,
\]

(3)

with \( q > m \). This makes the sequence of \( \beta_i \) parameters a polynomial and hence a smooth function without possibly implausible spikes.

Working out the Almon lags, one can derive that the structure implies that
\[ \beta_{i+1} - 2\beta_i + \beta_{i-1} = Y_i \] (4)

where \( Y_i \) is a function of \( \alpha_i \) values. Shiller (1973) considers this as too restrictive and he proposes to assume that

\[ \beta_{i+1} - 2\beta_i + \beta_{i-1} \sim N(0, \zeta^2), \] (5)

for \( i = 1, 2, ..., m - 1 \).

**Koyck transformation**

The Koyck model can be interpreted as a model which includes adaptive expectations. Suppose that

\[ y_t = \alpha + \beta x_t^* + \varepsilon_t, \] (6)

where \( x_t^* \) denotes the expected value of \( x_t \), an expectation formed at \( t - 1 \). When the adaptive expectations schedule is assumed, like

\[ x_t^* = \lambda x_{t-1}^* + (1 - \lambda) x_t, \] (7)

with again \( |\lambda| < 1 \), then substituting (7) into (6) gives

\[ y_t = \alpha (1 - \lambda) + \lambda y_{t-1} + \beta (1 - \lambda) x_t + \varepsilon_t - \lambda \varepsilon_{t-1}. \] (8)

The short-run effect of \( x_t \) on \( y_t \) is \( \beta (1 - \lambda) \), while the long-run effect is \( \frac{\beta (1 - \lambda)}{1 - \lambda} = \beta \), as could be expected given
Consider the case were $m = \infty$, and where all $\alpha$ parameters are set to zero. When it is further assumed that $\beta_j = \beta_0 \lambda^j - 1$, with $|\lambda| < 1$ for $j = 1, 2, \ldots$, then (1) becomes

$$
\gamma_t = \mu + \beta_0 x_t + \beta_0 \lambda x_{t-1} + \beta_0 \lambda^2 x_{t-2} + \ldots + \varepsilon_t.
$$

(9)

Subtracting $\lambda \gamma_{t-1}$ from this expression gives

$$
\gamma_t = (1 - \lambda)\mu + \lambda \gamma_{t-1} + \beta_0 x_t + \varepsilon_t - \lambda \varepsilon_{t-1},
$$

(10)

which is again (8). This Koyck transformation leads to a rather simple model with a moving average (MA) error term. The appropriate estimation method is maximum likelihood, as it is described in, for example, Hamilton (1994, p. 132) for general ARMA models. Note that the parameter $\lambda$ appears in the autoregressive part and in the MA part.

### Restructuring the model

An alternative way to reduce the number of parameters, also in order to facilitate interpretation, is to restructure the model. To overcome multicollinearity, one can rewrite model (1) in the so-called error correction format. This format combines levels and differences of levels, which is convenient as these are usually much less correlated than the levels themselves, and hence multicollinearity will be much less of a problem. An additional feature of the error correction format is that it provides an immediate look at key parameters such as the total effect, the current effect, and the speed at which the total effect is accomplished.

With $\Delta_j$ denoted as the $j$-th order differencing filter, that is, $\Delta \gamma_t = \gamma_t - \gamma_{t-j}$, an error correction representation for (1) reads as

$$
\Delta_1 \gamma_t = \mu + \left( \sum_{j=1}^p \alpha_j - 1 \right) \left[ \gamma_{t-1} - \frac{\sum_{i=0}^m \beta_i}{1 - \sum_{j=1}^p \alpha_j} x_{t-1} \right] + \beta_0 \Delta_1 x_t - \sum_{i=2}^m \beta_i \Delta_{i-1} x_{t-1} - \sum_{j=2}^p \alpha_j \Delta_{j-1} \gamma_{t-1} + \varepsilon_t,
$$

(11)

where lagged levels are suitably combined into differenced variables such that at each lag a higher-order differenced variable appears. This representation even further reduces chances of having multicollinearity. Note
that the model can also be written in terms of lagged levels and first differences only, that is as

\[
\Delta_1 Y_t = \mu + \left( \sum_{j=1}^{p} \alpha_j - 1 \right) \left[ Y_{t-1} - \frac{\sum_{i=0}^{m} \beta_i}{1 - \sum_{j=1}^{p} \alpha_j} x_{t-1} \right] + \beta_0 \Delta_1 x_t + \sum_{i=1}^{m} \gamma_i \Delta_1 x_{t-i} + \sum_{j=1}^{p} \theta_j \Delta_1 Y_{t-j} + \epsilon_t
\]  

(12)

With the use of (11), all but two parameters (that is, \( \alpha_1 \) and \( \beta_1 \)) can be directly estimated by using OLS, while \( \hat{\alpha}_1 \) and \( \hat{\beta}_1 \) straightforwardly follow from applying OLS to (1). Note that model (11) can also be written such that the levels (now at \( t-1 \)) enter at \( t-2 \) or, say, \( t-\rho \).

Interpretation

We now turn to the interpretation of distributed lag models.

Long-run and short-run effects

The error correction model in (11) provides immediate estimates of current and dynamic effects. (Fok et al., 2006, show that when the series \( y_t \) and \( x_t \) have a unit root and are cointegrated, as defined by Engle and Granger, 1987, one should speak of the long-run effect, while when the series are stationary there is a total or cumulative effect. For the latter, see also Hendry, Pagan and Sargan, 1984.) The current effect is \( \beta_0 \) and the long-run or total effect is

\[
\frac{\sum_{i=0}^{m} \beta_i}{1 - \sum_{j=1}^{p} \alpha_j}.
\]

(13)

Note that the long-run effect can be larger or smaller than the short-run effect, depending on the values of the parameters. The parameters in the error correction model, when written as

\[
\Delta_1 Y_t = \mu + \rho \left[ Y_{t-1} - \gamma x_{t-1} \right] + \beta_0 \Delta_1 x_t - \sum_{i=2}^{m} \beta_i \Delta_i x_{t-1} - \sum_{j=2}^{p} \alpha_j \Delta_j Y_{t-j-1} + \epsilon_t
\]

(14)

can be estimated using non-linear least squares. This method provides direct estimates of the long-run effect \( \gamma \).
and its associated standard error.

**Duration interval**

As well as the long-run and short-run effects, one may also be interested in the speed with which the effect of $x_t$ decays over time. To be able to compute this so-called duration interval, one needs explicit expressions for $\frac{\partial y_{t+k}}{\partial x_t}$ for all values of $k$ running from 1 to, potentially, $\infty$. Given the expression in (1), these expressions are easily derived as

\[
\frac{\partial y_t}{\partial x_t} = \beta_0 \\
\frac{\partial y_{t+1}}{\partial x_t} = \beta_1 + \alpha_1 \frac{\partial y_t}{\partial x_t} \\
\frac{\partial y_{t+2}}{\partial x_t} = \beta_2 + \alpha_1 \frac{\partial y_{t+1}}{\partial x_t} + \alpha_2 \frac{\partial y_t}{\partial x_t} \\
\vdots \\
\frac{\partial y_{t+k}}{\partial x_t} = \beta_k + \sum_{j=1}^{k} \alpha_j \frac{\partial y_{t+(k-j)}}{\partial x_t}
\]

where it should be noted that $\alpha_k = 0$ for $k > p$, and that $\beta_k = 0$ for $k > m$. Hence, the final form of a distributed lag model (see Harvey, 1990), is

\[
y_t = \sum_{i=0}^{\infty} \delta_i x_{t-i} + \text{error},
\]

where

\[
\delta_i = \frac{\partial y_{t+i}}{\partial x_t}.
\]

With these $\delta_i$, one can derive all kinds of summary effects (like mean and median, or half lives of shocks) of $x_t$.
on $y_t$. When $\delta_i$ decays monotonically, it is useful to define the decay factor by

$$p_k = \frac{\partial y_t}{\partial x_t} - \frac{\partial y_{t+k}}{\partial x_t}.$$  

(17)

This can be computed only for discrete values of $k$ as there are only discrete time intervals. This decay factor is a function of the model parameters. Through interpolation, one can decide on the time $k$ it takes for the decay factor to be equal to some value of $p$, which typically is equal to 0.95 or 0.90. This estimated time $k$ is then called the $p$ per cent duration interval. This measure is frequently used in advertising research (see Clarke, 1976; Leeflang et al., 2000; Franses and Vroomen, 2006).

Final issues

Distributed lag models continue to be a standard empirical approach. When the models are applied, there are at least two further issues that one needs to address, that is, next to selecting $p$ and $m$ and a useful transformation. The first concerns the statistical analysis of the model. For example, if $y_t$ and $x_t$ are not stationary, one needs to rely on cointegration techniques that involve non-standard asymptotic theory. The theory that is most relevant here is formulated in Boswijk (1995). Also, in the case of the Koyck model, one faces the so-called Davies (1987) problem. Under the null hypothesis that $\beta_0 = 0$, the model collapses to $y_t = \varepsilon_t$, and hence $\lambda$ is not identified then.

The second issue concerns aggregation over time. It may be that $y_t$ and $x_t$ are not available at the same sampling frequency. For example, television commercials last for 30 seconds and recur each hour, say, while sales data are available only at the weekly level. Tellis and Franses (2006) have a few recent results, but more work is needed.

distributive politics and targeted public spending

Brian G. Knight
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article analyses common pool problems associated with the provision of local public goods by central legislatures. In response to incentives associated with common pool problems, legislators act to maximize spending for their home jurisdiction but to restrain spending elsewhere due to the associated tax costs. The resolution of this conflict between jurisdictions depends in the United States upon the distribution of political power across Congressional delegations. Incumbents are rewarded for delivering federal spending to their jurisdiction through increased voter support.

Keywords

common pool problems; distributive politics; earmarked projects; lobbying; local public goods; proposal power; targeted public spending

Article

While conventional models of political economy, such as the median voter model, focus on the provision of national public goods, most federal spending programmes, such as the US interstate highway system, are more aptly characterized as local in nature. While in the United States the benefits of federal spending are concentrated in specific geographic units, such as states, counties, and Congressional districts, the associated tax costs are, by contrast, geographically dispersed. This common pool feature of federal spending – concentrated spending but dispersed financing – leads to a geographic tug-of-war in which jurisdictions attempt to increase own-jurisdiction spending but to reduce spending elsewhere due to the associated tax costs. This conflict between jurisdictions is reflected most intensely in the budget process within the US Congress, whose members are locally elected and thus naturally respond to these common pool incentives.

In this article, I first summarize evidence suggesting that Congressional representatives are responsive to the common pool incentives associated with concentrated spending but dispersed costs. Having established the empirical saliency of this common pool problem in Congress, I then summarize the
literature examining how this conflict is resolved. In particular, I analyse the effects of Congressional delegation characteristics, such as size, ideology, seniority, and committee assignments, on the geographic allocation of federal funds. Finally, I review evidence on the effects of the geographic distribution of federal funds on electoral outcomes.

As described in Knight (2006), common pool problems underpin several theoretical models of the legislative process, such as the universalism model of Weingast, Shepsle, and Johnsen (1981) and the legislative bargaining model of Baron and Ferejohn (1989). Whether or not Congressional delegations respond to these incentives in practice, however, is primarily an empirical question. It may be the case, for example, that political parties, or related Congressional organizations, serve as collective mechanisms through which legislators internalize the tax costs in other jurisdictions associated with own-jurisdiction spending. One of the first papers to directly measure the responsiveness of representatives to common pool problems is by DelRossi and Inman (1999), who examine the geographic distribution of water projects authorized by the Water Resources Development Act of 1986. In particular, the authors compare the size of project requests before and after changes in local matching requirements, which significantly increased the fraction of project costs financed by local governments. As hypothesized, districts experiencing larger increases in matching rates requested significantly less funding for water projects. In a similar vein, Knight (2004b) examines Congressional voting in 1998 over whether to finance a set of transportation projects, which were earmarked for specific Congressional districts and were funded primarily via federal gasoline taxes. As predicted, support for funding was concentrated in those districts receiving more in funding and also in those districts with lower gasoline tax burdens.

How is this geographic battle between jurisdictions resolved? Which states and Congressional districts win and why? Regarding the mere size of delegations, an important feature of the US Congress is its bicameral structure in which each state has an equal number of delegates in the Senate but in which seats are apportioned between states according to population in the House of Representatives. This equality of delegation sizes in the US Senate provides small states with power disproportionate to their population; Senators from California, the largest state, currently have over 60 times as many constituents as do senators from Wyoming, the smallest state. In attempting to measure the magnitude of this small-state bias, Atlas et al. (1995) and Lee (1998) find that small states receive significantly more per capita in aggregate federal spending than do large states. While this finding is certainly provocative, it is difficult to distinguish between the role of Senate representation and other factors, such as population density, that make small states inherently different from larger states. In attempting to address this issue of unobserved differences between small and large states, Knight (2004a) demonstrates that small states receive considerably more per-capita funding in projects earmarked in Senate bills; in House bills, by contrast, small and large states receive similar project spending on a per-capita basis. Knight (2004b) also identifies two theoretical channels underlying this small-state bias in the US Senate. Relative to their population, small states are disproportionately represented on key committees (the proposal power channel) but are also cheaper coalition partners (the vote cost channel) given that they pay a smaller share of federal taxes. Interestingly, both channels are shown to be empirically important and, taken together, explain over 90 per cent of the measured small-state bias. In a related study of the size of delegations, Falk (2006) studies discontinuities in the apportionment of seats in the US House arising from both timing (re-apportionment occurs once every ten years) and rounding issues (delegation sizes must be integers). Using this variation in delegation sizes, he finds that increases in seats per capita lead
to statistically significant increases in federal spending per capita. Delegations of similar sizes, however, may differ significantly in their composition. Key differences between delegations in the degree of political power include majority party affiliation, seniority, and representation on key committees. Regarding majority party affiliation, Levitt and Snyder (1995) find that the Democratic Party used its majority control of Congress to channel federal funds into Congressional districts with a high percentage of Democratic voters during the period 1984–90. However, they find no evidence that, conditional on the percentage of Democratic voters, districts represented by Democrats received higher federal spending. Levitt and Poterba (1999) report that states with very senior Democratic representatives experienced more rapid economic growth than did other states. However, they find no relationship between the partisan affiliation of delegations and the geography of federal spending, a key hypothesized channel of the measured differences in economic growth. Regarding the role of Congressional committees, Knight (2005) finds that Congressional districts represented on key committees received substantially more funding in projects earmarked in transportation bills authorized in 1991 and 1998. He interprets this result as evidence of the importance of proposal power associated with the committee's ability to set the legislative agenda. De Figueiredo and Silverman (2002) examine interactions between committee representation and lobbying in an empirical examination of earmarked projects for universities. In particular, they find a strong correlation between lobbying outlays by universities and the receipt of federal funding; this link between lobbying and spending, however, is found to be much stronger for those universities located in districts that are represented on key appropriations committees.

We have focused throughout this survey on the determinants of the geographic distribution of federal funds. Politicians, however, have an incentive to put forth the effort to secure project funding only if they perceive that the associated political gains are sufficiently high. While clearly important, measurement of the effects of federal spending on incumbent vote shares is plagued with endogeneity problems. For example, incumbents facing the strongest opposition have the strongest incentives to put forth effort in securing funds. Thus, there may be a downward bias in ordinary least squares (OLS) estimates of the effect of federal spending on incumbent vote shares. As an instrument for district-specific federal spending, Levitt and Snyder (1997) use federal spending outside of the district but within the state. The idea is that other actors, such as Senators or governors, also play a role in the geographic distribution of federal funds. Using this exogenous variation in federal spending, they conclude that an additional $100 per capita in spending translates into an additional two percentage points in incumbent vote shares.

We conclude that common pool problems associated with concentrated project benefits but dispersed costs are reflected not only in the behaviour of Congressional delegations but also in the resulting distribution of federal funds. Who wins and who loses in this geographic battle is determined in part by state size and the political power of delegations. Consistent with these results, evidence suggests that incumbent re-election prospects are significantly enhanced by increases in federal spending.

Abstract

Dividends represent the primary means by which invested capital is returned to common stockholders. In this article we summarize the development of academic thinking on dividend policy, focusing on three primary perspectives: (a) the effect of dividend policy on common stock value and firm performance, (b) the determinants of dividend policy, and (c) macroeconomic trends in the propensity of firms to pay dividends.

Keywords

agency costs; asymmetric information; capital gains; capital gains taxation; dividend change; dividend policy; dividend taxation; dividends; manager–shareholder conflict; Modigliani–Miller theorem; regular vs special dividends; stock repurchases; stockholders

Article

There are two major ways in which a firm can distribute cash to its common stockholders. The firm can either declare a cash dividend which it pays to all its common stockholders or it can repurchase shares. Stock repurchases may take the form of registered tender offers, open market purchases, or negotiated repurchases from a large shareholder. In a share repurchase, shareholders may choose not to participate. In contrast, dividends are direct cash payments to shareholders and are distributed on a pro rata basis to all shareholders.

Most firms pay cash dividends on a quarterly basis. The dividend is declared by the firm's board of directors on a date known as the ‘announcement date’. The board's announcement states that a cash payment will be made to stockholders who are registered owners on a given ‘record date.’ The dividend checks are mailed to stockholders on the ‘payment date,’ which is usually about two weeks after the record date. Stock exchange rules generally dictate that the stock is bought or sold with the dividend until the ‘ex-dividend date’, which is a few business days before the record date. After the ex-dividend
Dividend policy: The New Palgrave Dictionary of Economics

date, the stock is bought and sold without the dividend.
Dividends may be either labelled or unlabelled. Most dividends are not given labels by management. Unlabelled dividends are commonly referred to as ‘regular dividends’. When managers label a dividend, the most common label is ‘extra’.

A historical perspective

Prior to 1961, academic treatments of dividends were primarily descriptive, as, for example, in Dewing (1953). To the extent that economists considered corporate dividend policy, the commonly held view was that investors preferred high dividend payouts to low payouts (see, for example, Graham and Dodd, 1951). The only question was how much value was attached to dividends relative to capital gains in valuing a security (Gordon, 1959). This view was concisely summarized with the saying that a dividend in the hand is worth two (or some multiple) of those in the bush. The only question was: what is the multiple?

In 1961, scientific inquiry into the motives and consequences of corporate dividend policy shifted dramatically with the publication of a classic paper by Miller and Modigliani. Perhaps the most significant contribution of the Miller and Modigliani paper was to spell out in careful detail the assumptions under which their analysis was to be conducted. The most important of these include the assumptions that the firm's investment policy is fixed and known by investors, that there are no taxes on dividends or capital gains, that individuals can costlessly buy and sell securities, that all investors have the same information, and that investors have the same information as the managers of the firm. With this set of assumptions, Miller and Modigliani demonstrate that a firm's stockholders are indifferent among the set of feasible dividend policies. That is, the value of the firm is independent of the dividend policy adopted by management.

Because investment policy is fixed in the Miller–Modigliani set-up, all feasible dividend policies involve the distribution of the full present value of the firm's free cash flow (that is, cash flow in excess of that required for investment) and are, therefore, equally valuable. If internally generated funds exceed required investment, the excess must be paid out as a dividend so as to hold investment constant. If internally generated funds are insufficient to fund the fixed level of investment, new shares must be sold. It is also possible for managers to finance a higher dividend with the sale of new shares.

The key insight from the Miller–Modigliani analysis is that investors will be indifferent among the feasible dividend choices because they can costlessly create their own dividend stream by buying and selling shares. If investors demand higher dividends than the amount paid by the firm, they can sell shares and consume the proceeds, leaving themselves in the same position as if the firm had paid a dividend. Alternatively, if shareholders prefer to reinvest rather than to consume, they can choose to purchase new shares with any dividends paid. In this instance, shareholders would be in the same position that they would have been had no dividends been paid. Thus, regardless of corporate dividend policy, investors can costlessly create their own dividend position. For this reason, stockholders are indifferent to corporate dividend policy, and, as a consequence, the value of the firm is independent of its dividend policy.

After a brief flurry of debate, the Miller–Modigliani irrelevance proposition was essentially universally accepted as correct under their set of assumptions. There nevertheless remained an underlying notion
that dividend policy must ‘matter’ given that managers and security analysts spend time worrying about it. If so, and if the Miller–Modigliani proposition is accepted, it must be due to violation of one or more of the Miller–Modigliani assumptions in the real world. Since the early 1960s, the dividend debate has been lively and interesting. Economists have analysed theoretically whether the relaxation of the various Miller–Modigliani assumptions alters their irrelevance proposition. In addition, economists have analysed the data from several perspectives. First, they have undertaken an array of analyses to determine the effect, if any, of dividend policy on stock value and firm performance. Second, they have sought to identify the characteristics associated with dividend payments (or the lack thereof) by individual firms. Third, they have attempted to characterize macroeconomic trends in the level and propensity of firms to pay dividends, and in the form of the payout. Our discussion of these issues focuses primarily (though not exclusively) on studies of US firms since these are the studies most accessible to us.

Relaxing the Miller–Modigliani assumptions

Taxes

Perhaps the obvious starting point for an investigation into the effect of relaxing the Miller–Modigliani assumptions is to introduce taxes. In the United States, dividend payments by a corporation do not affect that firm's taxes. However, at least historically, dividends have been taxed at a higher rate than capital gains at the personal level. Thus, superficially, the US tax code appears to favour a low dividend payout policy, with payouts occurring primarily through share repurchases.

Under the assumption that dividends and capital gains are taxed differentially, Brennan (1970) derives a model of stock valuation in which stocks with high payouts have higher required before-tax returns than stocks with low payouts. As a counterpoint to this proposition, Miller and Scholes (1978) argue that under the US tax code there exist sufficient loopholes so that investors can shelter dividend income from taxation, thereby driving the effective tax rate on dividends to zero. Early studies of the association between stock returns and dividend yield (for example, Black and Scholes, 1974; Litzenberger and Ramaswamy, 1979; Miller and Scholes, 1982) yielded mixed results using different definitions of dividend yield. Subsequent studies indicated that the correlation between dividend yield and stock returns (if any) appeared to be due to omitted risk factors that were correlated with dividend yield. For example, Chen, Grundy and Stambaugh (1990) report that dividend yield and risk measures are cross-sectionally correlated. Similarly, Fama and French (1993) show that, when a three-factor model for expected returns is used, there is no significant relation between dividend yields and stock returns. Other studies have analysed the potential effects of the differential taxation of dividends and capital gains by studying the behaviour of stock prices and trading volume around ex-dividend days. The logic of these studies is that, in order for investors to be indifferent between selling a stock just before it goes ex dividend and just after, stocks should be priced so that the marginal tax liability would be the same for each strategy. Thus, if dividends are taxed more heavily than are capital gains, stock prices should fall by less than the size of the dividend on the ex-dividend day. Evidence consistent with a tax effect in stock price behaviour around ex-dividend days is provided in Elton and Gruber (1970), Eades, Hess and Kim (1984), Green and Rydqvist (1999), Bell and Jenkinson (2002), and Elton, Gruber and Blake
dividend policy: The New Palgrave Dictionary of Economics (2005). In addition, evidence of tax-motivated trading around ex-dividend days is provided in Lakonishok and Vermaelen (1986), Michaely and Vila (1995) and Green and Rydqvist (1999). Collectively, the evidence in these studies indicates that the differential taxation of dividends and capital gains affects both ex-dividend day stock returns and trading activity. This conclusion has been reinforced in studies that examine changes in tax laws (for example, Poterba and Summers, 1984; Barclay, 1987; Michaely, 1991). Nonetheless, the fact that individual investors in high tax brackets receive large amounts of taxable dividends each year (Allen and Michaely, 2003) casts doubt on taxes being a first-order determinant of dividend policy.

Agency costs

A second real-world violation of the Miller–Modigliani assumptions is the existence of agency costs associated with stock ownership. In particular, managers of firms maximize their own utility, which is not necessarily the same as maximizing the market value of common stock. The costs associated with this potential conflict of interest include expenditures for structuring monitoring and bonding contracts between shareholders and managers, and residual losses due to imperfectly constructed contracts (Jensen and Meckling, 1976).

Several authors have argued that dividends may be important in helping to resolve manager–shareholder conflicts. If dividend payments reduce agency costs, firms may pay dividends even if these payments are taxed disadvantageously. Easterbrook (1984) and Rozeff (1982) argue that establishing a policy of paying dividends enables managers to be evaluated periodically by the capital market. By paying dividends, managers are required to tap the capital market more frequently to obtain funds for investment projects. Periodic review by the market is one way in which agency costs are reduced, which in turn raises the value of the firm. Similarly, Jensen (1986) argues that establishing a policy of paying dividends reduces agency problems of overinvestment by reducing the amount of discretionary cash controlled by managers.

An implication of the agency models is that dividends will be more valuable in mature firms with substantial cash flow and poor investment opportunities. Early tests of this implication focused on the stock price reaction to dividend change announcements and produced mixed results. Lang and Litzenberger (1989) find that firms with less valuable growth opportunities exhibit a larger stock price reaction to dividend increase announcements than firms with more valuable growth opportunities. Although this finding is consistent with the agency cost hypothesis, Denis, Denis and Sarin (1994) find that when they control for other factors, particularly the change in dividend yield, they find no difference in the stock price reaction to dividend changes between firms with good growth opportunities and those with poor growth opportunities. Moreover, they find no evidence that increases in dividends reduce corporate investment.

More recent tests of the agency models have focused on the cross-sectional determinants of dividend policy. Fama and French (2001) find that the propensity to pay dividends is positively related to firm size and profitability, and negatively related to the value of future growth opportunities. DeAngelo, DeAngelo and Stulz (2006) find that the propensity to pay dividends is strongly associated with the proportion of the firm's equity that comes from retained earnings. These findings support the primary
prediction of the agency models that dividends are more valuable for mature firms with high cash flow and poor growth opportunities.

La Porta et al. (2000) and Faccio and Lang (2002) provide further support for the agency models of dividend policy by analysing international evidence. La Porta et al. hypothesize that agency conflicts will differ across countries because of differences in the extent of investor protection. In a sample of 33 different countries, they find that dividend payments are higher in countries with better investor protection. This indicates that when investors are better able to monitor managers, they are able to force higher dividend payouts. Faccio and Lang (2002) show that in western Europe and in Asia dividend payments are higher when controlling shareholders have a higher ratio of voting rights to cash flow rights – that is, those situations in which minority shareholders are otherwise at greatest risk of expropriation by the controlling shareholder.

Asymmetric information

Contrary to the Miller–Modigliani assumption that investors have the same information as managers, a large number of studies assume that managers possess more information about the prospects of the firm than individuals outside the firm, and that dividend changes convey this information to outsiders. This idea was suggested by Miller and Modigliani and has roots in Lintner's (1956) classic study on dividend policy. Lintner interviewed a sample of corporate managers. One of the primary findings of the interviews is that a high proportion of managers attempt to maintain a stable regular dividend. In Lintner's words, managers demonstrate a ‘reluctance (common to all companies) to reduce regular rates once established and a consequent conservatism in raising regular rates’ (1956, p. 84).

If managers change regular dividends only when the earnings potential of the firm has changed, changes in regular dividends are likely to provide some information to the market about the firm's prospects. More formal models in which dividends convey information to outsiders include Bhattacharya (1979; 1980), John and Williams (1985), and Miller and Rock (1985). The common assumption in these models is that managers have information not available to outside investors. Typically, the information has to do with the current or future earnings of the firm.

Empirical evidence on the information content of dividends has taken three forms. First, a large set of studies has analysed whether dividend changes are associated with abnormal stock returns of the same sign. Second, studies have analysed whether dividend changes are associated with subsequent earnings changes. Third, studies have analysed the association between dividend changes and changes in investor expectations regarding future earnings.

Studies have consistently documented that stock returns around the announcement of a dividend change are positively correlated with the change in the dividend (Aharony and Swary, 1980; Asquith and Mullins, 1983; Brickley, 1983; Healy and Palepu, 1988; Grullon, Michaely and Swaminathan, 2002; Michaely, Thaler and Womack, 1995; Pettit, 1972). These studies are robust over time and are robust to controls for contemporaneous earnings announcements. Moreover, in general, the studies indicate that the market reacts more strongly to a dividend decrease than to a dividend increase.

The findings described above indicate that dividend announcements provide information to the market. Subsequent studies have investigated whether this information is correlated with current or future earnings. On this issue, the evidence is more mixed. In a study of dividend initiations and omissions,
Healy and Palepu (1988) find that the initiation of dividends follows a period of abnormal earnings growth and that earnings continue to grow in subsequent years. For omissions, however, earnings decline in the year of omission, then rebound in the following years. Using a comprehensive sample of dividend changes, Benartzi, Michaely and Thaler (1997) find no evidence that dividend changes are associated with subsequent earnings changes of the same sign. Miller's interpretation of the evidence (1987) is that dividends appear to be better described as lagging earnings than as leading earnings.

One difficulty in testing whether dividend changes ‘signal’ unexpected future earnings is that it is difficult to identify what level of earnings would be expected by the market if the dividend change did not take place. To address this issue, Ofer and Siegel (1987) study how analysts alter their estimates of current year earnings when firms announce dividend changes. They find that analysts revise their earnings estimates in the direction of the dividend change and that the size of the earnings revision is positively associated with the stock price reaction to the dividend change. Similarly, Fama and French (1998) report a positive association between dividends and firm value after controlling for past, current and future earnings, as well as investment and debt. They conclude that dividends contain information about value that is not contained in earnings, investment and debt.

The accumulated empirical evidence thus indicates that dividend announcements provide information to the market. Whether they convey information about future earnings is less clear. Moreover, other findings indicate that information signalling is unlikely to be a first-order determinant of dividend policy. For example, as noted earlier, dividends are paid primarily by larger, more mature firms with higher cash flow and poorer growth opportunities. These types of firm would seem to be least in need of signalling their true value to the market.

Firm value and the form of the payout

As with increases in regular cash dividends, specially labelled cash dividends and share repurchases have been shown to be accompanied by permanent increases in stock prices (Brickley, 1983; Dann, 1981; Vermaelen, 1981). However, there is little agreement on the factors that lead managers to choose one method over another.

Given the Miller–Modigliani assumptions, the choice of the payout mechanism, like the choice of dividend policy itself, does not affect the value of the firm. Therefore, if the form of the payout is to matter, it must be due to violation of one or more of the Miller–Modigliani assumptions. To develop a theory to explain the choice of payout mechanism, it must be that there are differential costs or benefits associated with the alternative payout methods. Furthermore, the relative benefits or costs must be especially significant because, in general, dividends have been tax-disadvantaged (at the personal level) relative to share repurchases.

Economists have explored several possible explanations as to why a particular form of payout is chosen, including adverse selection effects (Barclay and Smith, 1988; Miller and McConnell, 1995), the impact on equity ownership structure (Stulz, 1988; Denis, 1990), the signalling power of alternative payout mechanisms (Ofer and Thakor, 1987; Jagannathan, Stephens and Weisbach, 2000), and the impact of executive stock options (Fenn and Liang, 2001). The evidence indicates that share repurchases are more likely when recent earnings increases are temporary, when earnings are riskier, when firms make heavy...
use of stock options in executive compensation contracts and when firms seek to protect themselves from a hostile takeover.

As regards the choice between regular cash dividends and specially labelled cash dividends, reasonable explanations have been relatively scarce. Brickley (1983) does provide evidence that specially labelled dividends convey a less positive message about firm value than do increases in regular cash dividends. Nonetheless, it is unclear why this is so. Moreover, there has been little examination of the choice between special dividends and share repurchases.

What managers say

Lintner's (1956) classic empirical study began with a survey of corporate executives. The results of that survey and the accompanying evidence laid the foundation for much of the empirical and theoretical work that has followed over the succeeding half century. Brav et al. (2005) have conducted a new and more extensive survey of chief financial officers (CFOs) regarding their views of corporate payout policy. Their survey yields further insights into what managers think about dividend policy, and complements the existing empirical evidence.

Brav et al. report that CFOs view dividends as inflexible in that, once a dividend level has been established, any dividend cut is likely to have a significantly adverse impact on the company's stock price. Thus, consistent with Lintner's (1956) original observation, managers tend to be conservative when adjusting dividends upward in order to avoid having to cut the dividend at a later date. Rather than establishing a target payout ratio, managers set a per share payment that is downwardly inflexible. According to the survey, managers do not explicitly view dividends as a mechanism for signalling information that would distinguish their companies from competitors, and they consider tax effects only as an afterthought. These observations accord with the conclusions drawn from empirical studies in that both imply that taxes and signalling are not first-order determinants of dividend policy.

In contrast to dividends, repurchases are viewed by managers as a parallel but more flexible way to distribute cash to shareholders in that they can be initiated and discontinued as funds are available. This observation is consistent with the empirical evidence cited earlier that repurchases tend to be associated with temporary increases in earnings, while dividends are associated with earnings changes that are more permanent. Whether the modern survey of Brav et al. leads to the volume of additional empirical work that followed Lintner's study remains to be seen.

Summary and recent trends

Since the mid-1960s, rigorous consideration has added considerably to progress in what is known about dividend policy. We know that firms pay out to stockholders substantial amounts of cash annually in the form of regular cash dividends, share repurchases and specially labelled dividends. We also know that stock prices increase permanently when regular dividends are increased, when special dividends are declared, and when shares are repurchased, and that stock prices decline when regular dividends are reduced. While these findings imply that dividend changes reflect information available to managers that is not otherwise available to outside investors, it is still not clear what information is being conveyed through the dividend payment. Moreover, although we now know a considerable amount about the
empirical determinants of the size of payout and the form of payout, there is little agreement as to whether the level of cash payout affects the value of the firm or and whether the choice of the payout method matters.

We conclude by outlining several recent trends that pose additional challenges to our understanding of dividend policy. First, Fama and French (2001) document that the propensity to pay dividends has declined substantially since the late-1970s. Second, despite this decline in the propensity to pay dividends, aggregate dividends have not declined (DeAngelo, DeAngelo and Skinner, 2004). Rather, dividends and earnings have become increasingly concentrated among larger firms. Third, specially labelled dividends have nearly disappeared (DeAngelo, DeAngelo and Skinner, 2000). Fourth, share repurchases have increased substantially so that aggregate payouts through share repurchases now exceed those through regular dividends (Grullon and Michaely, 2002). These trends are difficult to explain given our current understanding of dividend policy. Undoubtedly, therefore, economists will continue to devote substantial effort to understanding the puzzles of dividend policy.

Divisia index

Charles R. Hulten
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Divisia index, it its modern application, is a continuous-time index related to an underlying economic structure via a potential function. Under certain conditions, the index can retrieve important characteristics of the underlying structure using prices and quantities alone, without full knowledge about the structure itself. The Divisia index is widely used in theoretical discussions of productivity analysis, and has important applications elsewhere. In practice, it is approximated by discrete-time superlative indexes, like the Tornqvist, or by chain indexes. Older applications of the Divisia stressed its discrete-time axiomatic properties.

Keywords

aggregation; chain indexes; continuous-time indexes; discrete-time indexes; Divisia index; Divisia, F.; duality; path dependence; production functions; productivity (measurement problems); Solow, R.; Törnqvist index

Article

The Divisia index is a continuous-time index number formula due to François Divisia (1925–6) that has been widely used in theoretical discussions of data aggregation and the measurement of technical change. It is defined with respect to the time paths of a set of prices \([P_1(t), \ldots, P_N(t)]\) and commodities \([X_1(t), \ldots, X_N(t)]\). Total expenditure on this group of commodities is given by:

\[
Y(t) = P_1(t)X_1(t) + \ldots + P_N(t)X_N(t).
\]
With dots over variables indicating derivatives with respect to time, total differentiation of (1) yields:

\[
\frac{\dot{Y}(t)}{Y(t)} = \sum_{i=1}^{N} \frac{P_i(t)X_i(t)}{Y(t)} \frac{\dot{P}_i(t)}{P_i(t)} + \sum_{i=1}^{N} \frac{P_i(t)X_i(t)}{Y(t)} \frac{\dot{X}_i(t)}{X_i(t)}.
\]

(2)

The growth rates of the Divisia price and quantity indexes are the respective weighted averages of the growth rates of the individual \(P_i(t)\) and \(X_i(t)\), where the weights are the components’ shares in total expenditure. The levels of these indexes are obtained by line integration over the trajectory followed by the individual prices and quantities over the time interval \([0, T]\). For the quantity index, the line integral has the following form:

\[
I_q(0, T) = \exp \left\{ \int \left[ \sum_{i=1}^{N} \frac{P_i(t)X_i(t)}{\sum P_j(t)X_j(t)} \frac{\dot{X}_i(t)}{X_i(t)} \right] \right\} = \exp \left\{ \int \varphi(X) dX \right\},
\]

(3)

where \(\varphi\) is a vector-valued function whose arguments are \(P_i(t)/Y(t)\), prices are assumed to be a function of the \(X_i\), and \(\Gamma\) is the curve described by \(X_i\). A similar expression characterizes the Divisia price index (for a more extensive discussion of Divisia line integrals, see Richter, 1966; Hulten, 1973; Samuelson and Swamy, 1974).

The value of the index defined by (3) depends on the solution of the line integral. This can be obtained by identifying a ‘potential function’ \(\Phi\) whose partial derivatives are the vector-valued function \(\varphi\), that is, \(\varphi = \nabla \Phi\). Writing \(\Phi = \log F\) function, the value of the index can be shown to equal \(F[X(T)] / F[X(0)]\), implying that the index is unique only up to a scalar multiple.

In economic terms, the solution to (3) is associated with some underlying economic relationship among the variables being indexed. Assume, for example, there is a constant returns to scale production function \(F(X)\) and \(F_i = \lambda P_i\) (\(F_i\) denotes the partial derivative of \(F\) with respect to \(X_i\) and \(\lambda\) is a factor of proportionality). Then the function \(\log F\) can serve as the requisite potential function for (3), and in this particular case, the Divisia index of inputs can be interpreted as the ratio of output at time \(T\) to output at time zero.

If the form of the potential function is known a priori, the value of the index could be computed directly from the function \(F\). However, the rationale for the Divisia index is that it provides a way of obtaining the ratio \(F[X(T)] / F[X(0)]\) by using data on prices and quantities alone, without direct knowledge of \(F\). Intuitively, this is possible because, under sufficiently restrictive assumptions, information about the
slope of the function $F$ (as estimated by relative prices) over the path followed by the inputs is sufficient to characterize $F$ up to a scalar multiple.

When the objective is to form an index of a subset of inputs – aggregate labour input, for example – the required potential function is a ‘piece’ of a production function. Specifically, if one wants to form a Divisia index of the first $M$ inputs, the production function needs to be weakly separable into a function of these inputs, that is, $F \{G[X_1(t), \ldots, X_M(t)], X_{M+1}(t), \ldots, X_N(t)\}$. The function $\log G$ serves as the potential function for the line integration (see also Balk, 2005).

These considerations apply to Divisia price indexes as well. The relevant potential function is now the factor price frontier $\Psi[P_1(t), \ldots, P_N(t)]$. A basic result of duality theory shows that the partial derivatives of $\Psi$ are proportional to the corresponding $X_i(t)$.

The discussion suggests that the existence of the Divisia index is closely linked to the conditions for consistent aggregation. Furthermore, the required existence of a potential function implies that aggregation cannot proceed with just any set of prices or quantities. There must be an a priori reason for supposing that the variables to be indexed are theoretically related. This is an important characteristic of the Divisia index, one which it shares with the broader class of economic index numbers (in contrast to the non-structural axiomatic approach associated with Irving Fisher, 1921; see also Balk, 2005). The potential function theorem establishes the conditions under which the Divisia index is an ‘exact’ index number (to use the terminology of Diewert, 1976) for some underlying economic structure.

Divisia indexes have the desirable property that they are invariant when the path of integration lies entirely in the same level set of the potential function. That is, if one input is substituted for another along a given isoquant, the value of the index will not change. However, there is no guarantee of invariance when the path of integration lies across several level sets. This reflects the mathematical property that line integrals are, in general, path dependent.

Path dependence means that the index (3) will generally have a different value for a path $\beta(t) \in \Gamma_1$ than path $\alpha(t) \in \Gamma$, even though the beginning and end points of $\Gamma_1$ and $\Gamma$ are identical. This can lead to the following situation: the economy moves along $\Gamma_1$ from $X$ from $X'$ (which is on a different isoquant); the economy then returns along $\Gamma$ to the original point $X$; because of path dependence, the vector of quantities represented by the vector $X$ will have a different Divisia index value after the trip around the composite path, and subsequent circuits will produce still different values. The value of the Divisia index at any point $X$ is thus arbitrary under path dependence. The uniqueness of the Divisia index thus involves path independence.

The condition for path independence is the existence of a homothetic potential function, $\log F$, such that $\varphi = \nabla \log F$, where $\varphi$ is defined in (3). Given the existence of the potential function, the value of (3) is $F(X(T))/F(X(0))$, implying path independence since (3) depends only on the end points of the path, $X(0)$ and $X(T\star)$. Conversely, if (3) is path independent, there exists a potential function $\log F$ such that $\nabla \log F = \varphi$. In some applications in productivity analysis, the homotheticity condition must be strengthened to linear homogeneity, but this can be weakened depending on data availability (Hulten, 2001, pp. 11–12).

We note, finally, that the Divisia index is defined using time as a continuous variable. Data on prices and quantities typically refer to discrete points in time, and the indexes constructed from them must therefore have a discrete-time form. The continuous-time Divisia index is nevertheless useful, both for informing
the structure of these discrete-time indexes (for example, for the determining which variables are conceptually related), and for interpreting the results. The Divisia framework is also appropriate for the theoretical analysis of many economic problems, such as the use of Divisia indexes by Solow (1957) in growth accounting.

One approach to linking discrete and continuous index numbers is to approximate the continuous variables of (2) with their discrete time counterparts. Under the Törnqvist (1936) approach, the growth rates of prices and quantities are approximated by logarithmic differences, and the continuous weights by two period arithmetic averages. The Törnqvist approximation to the growth rate of the Divisia quantity index can then be written:

\[
\sum_{i=1}^{T} \frac{1}{2} \left[ \frac{P_{i,t} X_{i,t}}{Y_i} + \frac{P_{i,t-1} X_{i,t-1}}{Y_{t-1}} \right] \left( \log X_{i,t} - \log X_{i,t-1} \right)
\]

A similar approximation applies to the growth rate of the Divisia index of prices.

While the Törnqvist index may be regarded as approximate, Diewert (1976) has shown that it is exact when the underlying potential function has the (continuous) translog form. This result is very important in its own right, but can also be regarded as an important conceptual link between the discrete and continuous-time families of index numbers, given the exact properties of the Divisia index in continuous time.

The continuous Divisia index can also be approximated by using chain indexing procedures (the Divisia index is sometimes regarded as a chain whose links are defined over infinitesimal time periods). Other numerical approximation techniques can also be employed.

Article

Divisia was born in Tizi-Ouzou, Algeria. He received baccalaureate degrees in mathematics and philosophy at Algiers. After two years in the Ecole Polytechnique he worked for the government as a civil engineer (Ponts et Chaussées). His graduate engineering work at the Ecole Nationale des Ponts et Chaussées was completed in 1919 after the interruption of the First World War. After nearly ten years as a government engineer he joined the ministry of national education to continue research and teaching economics. He became a professor of applied economics at the Ecole Nationale des Ponts et Chaussées (1932–50), the Conservatoire National des Arts et Métiers (1929–59), and the Ecole Polytechnic (1929–59). He was a founding member of the Econometric Society and its president in 1935. Subsequently he was also president of the Paris Statistics Society (1939) and of the International Econometric Society. He was a Fellow of the American Statistical Association and of the American Association for the Advancement of Science.

His major contributions to economics can be found centred in several books on economics and applied statistics. The Divisia Index, a variable-weight price index, was developed in *L'indice monétaire et la théorie de la monnaie* (1926). His *Economique rationnelle* (1928) was widely acclaimed in mathematical economics and was awarded prizes by the Academy of Sciences and by the Academy of Moral Sciences and Politics. Using a microeconomic perspective he cautioned against uncritical acceptance of macroeconomic research in *Traitement économétrique de la monnaie, l'intérêt, l'emploi* (1962).

Division of labour has been a very important topic for economic writings from the earliest times, and was treated in great detail by major economists, including especially Adam Smith and Alfred Marshall. This article surveys the development of ‘division of labour’ from its beginnings in the writings of Greek philosophers through the centuries and up to the 21st century. It therefore also reflects on its offshoots: international division of labour, sexual division of labour and its contemporary revival as an essential adjunct to the theory of economic growth, labour productivity, inter-firm cooperation, and its modern limits in coordination and communication costs.

W.; technical change; Torrens, R.; Tucker, J.; Turgot, A. R. J.; Ure, A.; Verdoorn's Law; women's work; Xenophon; Young, A. A.
Division of labour, or specialization, may be defined as the division of a process or employment into parts, each of which is carried out by a separate person, or any system of production in which tasks are separated to enable specialization to occur. This includes the separation of employments and professions within society at large or social division of labour as well as the division of labour which takes place within the walls of a factory building or within the limits of a single industry, the manufacturing division of labour. Division of labour as a form of specialization can also be practiced by small firms which all contribute to the production of parts (inputs) for the manufacturing of a complex output, as in the case of aircraft production or sophisticated electronic equipment. This form of business organization requires excellent coordination and communication between its various parts to ensure continuous supply of the necessary parts for the manufacturer of the final output. It is a geographical form of division of labour, developed from the notion of clustering related firms in a particular area or industrial district (for a survey, see Dosi, 1988).

Division of labour and its consequences for productivity were analysed as early as the time of the Greek philosophers, including Plato, Aristotle and Xenophon. Early analysis of the manufacturing division of labour had to await industrial developments of the 17th and 18th centuries and underwent further qualitative change in the 19th, 20th and 21st centuries. Hence manufacturing and more detailed division of labour should not be seen as a simple continuum of the social division of labour. By the end of the Middle Ages, social division of labour was extensively practiced; manufacturing division of labour, generally speaking, came with the Industrial Revolution. Under modern capitalism, social division of labour remains largely a market influenced phenomenon but manufacturing division of labour is enforced by those who plan and control the manufacturing process. Furthermore, the one divides society: the other human activity within the workshop, or within an industry: labour generally enhances ‘the individual and the species, [a manufacturing division] of labour, when carried on without regard to human capabilities and needs, is a crime against the person and against humanity’ (Braverman, 1974, p. 73). Division of labour was first practiced within the household, a sexual division of labour between women’s activities in or near the house, and those of men further afield. When applied to local specialization of industries both nationally and internationally, it has produced a variety of conceptions of the territorial or international (global) division of labour.

Adam Smith (1776) placed the division of labour at the forefront of his discussion of economic growth and progress. Neither in its social nor in its manufacturing forms did the idea originate with him. It retained a varying, but often very prominent, place in 19th-century writings (particularly those of Senior, Babbage, John Stuart Mill, Marx and Marshall). ‘About 1890, Schmoller, Semmel, Bücher, Durkheim and Maunier all wrote on religious and sociological aspects of specialization’ (Salz, 1934, p. 284). For much of the 20th century, division of labour and specialization virtually disappeared as a major topic from economic texts. Reasons for this varied. Some economists believed such discussions were more appropriate to technical handbooks of production engineering and factory management. Other writers wished to confine analysis of its effects to sociological studies assessing the general impact of division of labour on society. The return of economic growth as an important part of the economist’s research programme from the 1950s onwards, and earlier the work of Young (1928), brought renewed interest in the division of labour in its wake, as did growing dissatisfaction with the narrow view confining economics to studying ‘the disposal of scarce commodities’ (Robbins, 1932, p. 38). Global organization of manufacturing made possible by improvements in transport and communication implies modern
adaptations of the division of labour which economists cannot ignore. An example is the formation of industrialized districts, first observed and analysed by Alfred Marshall (1890), to be rediscovered and adapted to the post-Second World War Italian situation by Becattini (for example, 1990; 2001) and his colleagues (for a survey, see Goodman and Pamford, 1989). The various dimensions of division of labour raised in these introductory paragraphs suggest that a broad-based treatment of the subject is warranted by featuring highlights within its continuous development.

The Greeks

Many of the major Greek philosophers discussed aspects of the division of labour in their writings. In Book 2 of the Republic, Plato stated the necessity for a division of labour or specialization in occupations for social well-being and the adequate satisfaction of primary wants linking the phenomenon with exchange, the requirements of ‘a market, and a currency as a medium of exchange’ (Plato, 380 bc, pp. 102–6). Aristotle, though very conscious of the social need for a division of labour, did not depart much from Plato's earlier discussion (see Bonar, 1893, p. 34). More importantly, Xenophon linked division of labour and specialization to great cities, because they provided a substantial demand for individual products while the subdivision of work raised the skill of individual workers. Extracts from the work of these Greek pioneers on the division of labour have been often reprinted (see, for example, Sun, 2005, chs 2–4). Knowledge of these Greek texts among Arabian Islamic scholars during the middle ages enabled them to produce sophisticated treatments of the division of labour. Examples are the writings of Islamic theologian, al-Ghazali (1058–1111) and, more importantly, the writings of fourteenth century Islamic philosopher and historian, Ibn Khaldun, whose Muqaddima contains a detailed account of the division of labour (Sun, 2005, pp. 7–8, ch. 5).

Subsequent pre-Smithian developments

Towards the end of the seventeenth century, English economic literature rediscovered the concept of the division of labour and began to analyse the more modern manufacturing forms, linking them to productivity growth, cost reduction, increased international competitiveness and associating its scope with the more extensive markets made possible through urbanization. For example, Petty's Political Arithmetick written in 1671 compared the benefits of division of labour in textile production with specialization in ship building:

> For as Cloth must be cheaper made, when one Cards, another Spins, another Weaves, another Draws, another Presses and Packs; than when all the Operations above-mentioned, were clumsily performed by the same hand; so those who command the Trade of Shipping [need] to build...a particular sort of Vessels for each particular Trade. (Petty, 1671, pp. 260–1)

Ten years later, in Another Essay on Political Arithmetick Concerning the Growth of the City of London (1683, p. 473), Petty showed that a major gain from a vast city like London came from the improvement
and growth of manufactures it encouraged:

For in so vast a City Manufacturers will beget one another, and each Manufacture will be divided into as many parts as possible, whereby the Work of each Artisan will be simple and easy; As for example in the making of a Watch, if one Man shall make the Wheels, another the Spring, another shall Engrave the Dial-plate, and another shall make the Cases, then the Watch will be better and cheaper, than if the whole Work be put upon any one man.

In continuing this argument Petty also suggested that specialization benefits could be achieved from concentrating certain manufactures on a particular location, partly because of the savings in transport and communication costs such concentration entailed (Petty, 1683, pp. 471–2). The anonymous author of Considerations on the East India Trade (1701, pp. 590–2) illustrated productivity gains from the division of labour by examples drawn from cloth making, watch making and shipbuilding. He clearly indicated that sufficient demand and regular trade were a precondition for such improvements, which lowered manufacturing labour costs without the need to lower wages. During the 18th century, examples of authors aware of the benefits and preconditions for a division of labour become more common. Practical writers like Patrick Lindsay (1733), Richard Campbell (1747) and Joseph Harris (1757) tended to concentrate on manufacturing division of labour using examples from linen and pin production as well as from the familiar watch making. Those writing from the position of moral or political philosophy, like Mandeville (1729), Hutcheson (1755), Ferguson (1767) and Josiah Tucker (1755; 1774) concentrated more on aspects of the social division of labour.

Discussion of the division of labour was of course not confined to English economic literature. A treatise on wealth published in the 1720s by Ernst Ludwig Carl discussed the benefits of the division of labour, applying them also to demonstrate the gains from free trade through an international division of labour based on different climates, resource availability and locational advantages (cited in Hutchison 1988, pp. 161–2). Among the Physiocrats, Quesnay dealt briefly with the social aspects of the division of labour in his article ‘Natural Right’ (1765, p. 51). Turgot developed the subject more thoroughly, making it the starting point of his Reflections, subsequently associating it with the introduction of money, the extension of commerce and the accumulation of capital (1766, pp. 44–6, 64, 70). Earlier, Turgot (1751, pp. 242–3) had linked the spread of social division of labour to inequality, arguing that this particular consequence of inequality improved living standards for even the humblest members of society and made possible cultivation of the arts and sciences. Among the general principles with which Beccaria (1771, pp. 387–8) commenced the argument of his Elementi, the division of labour and its benefits in terms of increased skills and dexterity are clearly set out. Finally, it may be noted that the Encyclopédie of Diderot and d’Alembert in its article ‘Art’ discussed the essentials of the manufacturing division of labour, listing its consequences as improvements in skill, better quality products, saving of time and of materials, and ‘of making the time or the labour go further, whether by the invention of a new machine or the discovery of a more suitable method’. In its article on pins (‘Epingle’) their manufacture is described as being generally subdivided into eighteen separate operations and thereby a prime example of the manufacturing division of labour (see Cannan, 1929, pp. 94–5).
Adam Smith's treatment of the division of labour

Adam Smith's discussion of the division of labour deserves separate treatment not because of its 'originality' or 'completeness of exposition' (Cannan, 1929, p. 96) but because 'nobody either before or after [him], ever thought of putting such a burden upon division of labour. With A. Smith, it is practically the only factor in economic progress' (Schumpeter, 1954, p. 187). The first three chapters of the *Wealth of Nations* were devoted to its analysis because it provided one of the two causes explaining increases in per capita output by which Smith defined the wealth of the nation. Although therefore only one of two causes, the other being 'the proportion between the number of those who are employed in useful labour, and that of those who are not so employed' (Smith, 1776, p. 10), it is the dominant one. Smith seems to have believed that scope for substantial increases in the proportion of the labour force to productive activities was limited. Using the equation, \[ g = (k \cdot p / w) - 1 \], developed by Hicks (1965, p. 38) to summarize the Smithian growth progress, if a change in \( k \), the proportion of productive labour in the labour force, is more or less ruled out, a substantial growth rate \( g \), given the real wage \( w \), depends exclusively on rising productivity \( p \) through extensions of the division of labour. Smith's emphasis on the division of labour as a factor in growth via its enormous influence on productivity makes his treatment of the subject so novel. Surprisingly, this aspect of his contribution was taken up by few 19th-century writers and had to be largely rediscovered in the work of Young (1928) and Kaldor (1972) who reiterated dynamic aspects of the phenomenon Smith was analysing.

Even though it was the most frequently revised part of his economics (see Meek and Skinner, 1973), Smith's basic account of the division of labour contains a number of weaknesses. First, Smith failed to develop aspects of the manufacturing division of labour with which he ought to have been familiar. Marglin (1974) points out that Smith ignored organizational features from a division of labour taking place within the one building of relevance to some well-established industries like textiles and the manufacture of metal implements. These organizational features which Smith omitted were associated with growing labour discipline problems, wasting time and materials, inherent in the putting-out system, then the dominant form of manufacturing organization. In fact it can be suggested that if this aspect of the division of labour is more fully taken into account, its important role in explaining economic growth so much emphasized by Smith is more easily integrated as a major factor explaining the industrial revolution (see Groenewegen, 1977). Marglin (1974) also questioned the force of 'the three different circumstances' by which Smith (1776, p. 17) explained the productivity gains from the division of labour: increased dexterity, saving of time, and invention of machinery. Although increased dexterity is clearly a product of a division of labour in a manufacturing process, its scope there is rather limited when compared to that of the continual practice of surgeons, concert pianists and opera singers, to give some examples. Time saved in eliminating time lost in passing from job to job is trivial and not the 'very considerable' benefit Smith (1776, pp. 18–19) had suggested. Savings in materials and time through transforming a putting-out to a factory system, an organizational feature of the division of labour Smith had ignored, was more important, particularly through eliminating losses from pilfering. Rae (1834, pp. 164–5) saw savings in the use of tools as far more significant than time saved, and for him (pp. 352–7) this provided the basic reason for extending the division of labour. Other 19th century writers, particularly Babbage (1832), expanded further on this aspect of the matter. Smith's association of
division of labour with inventions (1776, pp. 19–22) covered both ‘on the job improvements’ and scientific inventions by specialists originating from within a more sophisticated division of professions. It ignores, as Hegel (1821, p. 129) was one of the first to point out (cf. Stewart, 1858–75, vol. 8, pp. 318–19), that as division of labour makes ‘work more and more mechanical,…man is able to step aside and install machines in his place’. This feature of the process was subsequently noted by Babbage (1832, pp. 173–4), Ure (1835, p. 21) and developed by Marx (1867). In short, the three circumstances Smith saw as explaining the productivity consequences from the division of labour derive their basic validity from reasons different to those Smith advanced. Further, Smith's remarks (1776, pp. 16–17) on the smaller benefits from applying the division of labour to agriculture than to manufacturing can be contrasted with his quite different and controversial analysis of the primacy of agricultural investment in terms of its employment of productive labour. Agriculture's more substantial contribution to gross revenue as Smith (1776, Book II, ch. 5) subsequently argued, was used by him to define the ‘natural’ course of economic development (Book II, ch. 1) and recommended as superior practice for newly settled regions like the American colonies. Perelman (1984, p. 185) explained this seeming contradiction in Smith by suggesting Smith was the ‘first theorist of neo-imperialism’ because his strategy of development forces developing regions to specialize in raw material production whose terms of trade with manufactures are invariably poor. More likely, Smith's views on the productivity of agriculture relative to manufacturing are posed in terms of different yardsticks: agricultural activity by the very nature of its processes is less amenable to division of labour, even though its ability to employ productive labour is greater than produced by equal investments in manufacture and trade. However, growing mechanization of agriculture, especially in the 20th century, together with the greater scope for exporting agricultural surplus with modern transport, encouraged specialization in agriculture and very large scale farming (Salz, 1934, p. 283).

A final controversial issue from Smith's treatment of the division of labour concerns its social consequences, an argument he placed in the context of public education. The ‘few simple operations’ which under a division of labour most ordinary labouring people are asked to perform, renders them ‘as stupid and ignorant as it is possible for a human creature to become’ and increased ‘dexterity at his own particular trade’ is purchased with a reduction in ‘intellectual, social and martial virtues…unless government take some pains to prevent it’ through providing general education (Smith, 1776, pp. 781–5). Smith was not alone in presenting this disadvantage in an extensive division of labour: similar views were put by Ferguson (1767, p. 280) and Kames (1774). Ferguson described ‘ignorance as the mother of industry’ and argued that prosperous manufactures arise ‘where the mind is least consulted, and where the workshop may…be considered as an engine, the parts of which are men.’ At the turn of the century, and after, German philosophers (for example, Schiller, 1793, Hegel, 1821 and the young Marx, 1844) developed this into a humanist critique of industrial society, suggesting like Smith that these detrimental consequences were removable by education, especially aesthetic education. Such sentiments were resurrected in mid-19th century England by Carlyle (1843) and Ruskin (1851–3, pp. 197–8). For others, Smith's remarks were an aberration, ‘as unfounded [a statement] as can well be imagined’ (McCulloch, 1850, p. 350) or even a contradiction with the division of labour's ability to inspire inventive faculties in labourers (West, 1964). Despite its deficiencies, Smith's account of the division of labour proved particularly hardy and was
division of labour: The New Palgrave Dictionary of Economics

invariably praised in most general terms by major textbook writers of the 19th century and after, though few followed the emphasis Smith gave it as the key factor explaining growth. Cannan (1929, p. 97) ascribed this success to ‘the popularity of its form’. It can also be attributed to the striking productivity increase inherent in the pin example (cf. Mill, 1821, p. 215) and the unambiguous connection Smith drew between increased division of labour, extending the market and human proclivities ‘to truck and barter’ (McCulloch, 1825, pp. 54–5). The account of the division of labour is undoubtedly one of Smith's best remembered performances in economics.

19th-century developments

With the growth of the factory system and more extensive use of increasingly sophisticated machinery, the manufacturing form of division of labour was considerably expanded. Consequently, some economic writers focused on a number of new aspects of the phenomenon, linking the division of labour with developments in the machine tool industry, large scale production and its advantages, and hence, on a more theoretical level, with increasing returns to scale and explicit recognition of a different pattern of productivity growth in manufacturing from that in agriculture.

Charles Babbage was in many respects the pioneer in presenting the division of labour as ‘the most important principle on which the economy of a manufacture depends’ (1832, p. 169). He therefore carefully revised the advantages of a division of labour as first expounded by Adam Smith. In this discussion, time (and cost) savings were also related to time saved in learning a skill and reduced waste of materials during the learning process (pp. 170–1), as well as economy in tool using (p. 172), while the association between division of labour, dexterity and the introduction of new machines was developed more precisely and rigorously. More significantly, Babbage pointed to a hitherto ignored additional advantage of the division of labour he had derived from observation. This had earlier been discussed by Gioja (1815–17) whose interesting contribution on this subject was analysed by Scazzieri (1981, ch. 3).

*By dividing the work to be executed into different processes of skill or of force,…the master manufacturer…can purchase exactly that precise quantity of both which is necessary for each process; whereas, if the whole work were executed by one workman, that person must possess sufficient skill to perform the most difficult, and sufficient strength to execute the most laborious, of the operations into which the art is divided.*

(Babbage, 1832, pp. 175–6; emphasis in original)

This economy of skill, Babbage demonstrated from a pin example, not only reinforced the cost advantages traditionally associated with division of labour, but was also a major cause of establishing large factories: ‘When the number of processes into which it is most advantageous to divide it, and the number of individuals to be employed in it, are ascertained then all factories which do not employ a direct multiple of this number, will produce the article at a greater cost’ (Babbage, 1832, p. 213).

Detailed division of labour, Babbage also argued, as in its manufacturing form, can also be applied to mental labour (p. 191). An illustration of its application to mining highlights these control and information gathering features, two aspects of the division of labour to which Babbage paid particular attention. His analysis of the division of labour is even more important because the process as he
described it is made interdependent with machine production, increased factory size, lower costs and prices from such concentration of industry and hence induces growth in demand and an extended market (see Corsi, 1984).

Ure's (1835) contribution must also be noted. It likewise linked development of the factory system to division of labour, summarizing ‘the principle of the factory system...as substituting mechanical science for hand skills, and the partition of a process into its essential constituents’ (1835, p. 20). Ure commented on two other consequences of the division of labour in modern factories: deskilling of the workforce when workers become ‘mere overlookers of machines’ and the development of mechanical engineering since the ‘machine factory displayed the division of labour in manifold gradations’ and facilitated the substitution of skilled hands by ‘the planning, the key-groove cutting, and the drilling machines’ (pp. 20–1).

Accounts of the division of labour by economists of the middle of the century were generally less innovative than those of Babbage and Ure, though they did occasionally provide some new points of departure. Senior (1836, pp. 74–5, 77), after classifying division of labour as one major advantage from the use of capital, concentrated on listing its benefits additional to those given by Smith. Illustrating from the post office, he argued that the fact that ‘the same exertions which are necessary to produce a single given result are often sufficient to produce many hundreds or many thousands similar results’ was one aspect of the division of labour omitted by Smith. The development of retailing as a separate profession was likewise something Smith had failed to consider adequately. More importantly, for a number of reasons, but particularly the division of labour, Senior suggested ‘additional Labour when employed in Manufactures is MORE, when employed in Agriculture is LESS efficient in proportion’, linking manufacturing activity implicitly to increasing returns to scale (1836, pp. 81–2). Mill (1848) treated division of labour as an important aspect of cooperation, arguing that irrespective of its well known productivity advantages, without this complex cooperation in the modern division of labour ‘few things would be produced at all’ (Mill, 1848, p. 118) In discussing the productivity advantages, Mill cited the modification and additional advantages provided by Babbage (1832) and Rae (1834), adding little to their discussion. However, in Chapter 9 dealing with large scale and small scale production, he highlighted the point, so ‘ably illustrated by Mr Babbage...[that] the larger the enterprise, the farther the division of labour may be carried...as one of the principal causes of large manufactories’ (Mill, 1848, p. 131), thereby bringing the argument firmly into the corpus of economics. Mill's account was largely followed by Fawcett (1863) and in most of its essentials by Nicholson (1893).

Marx's account (1867, chs. 13–15) combines much of this discussion, endowing it in the process with sharper analytical insights derived from his study of both the technical literature and his appreciation of the significance of the qualitative changes underlying the evolution of the division of labour. To Marx is owed the important distinction between manufacturing and social division of labour, as well as the precise assessment of the organizational features of its application to modern manufacture, derived from his careful study of Babbage, Ure and many other sources. No wonder that Nicholson (1893, p. 105) described Marx's treatment as ‘both learned and exhaustive and...well worth reading’. More recently, Rosenberg (1976) expressed regret that Marx's close study of ‘both the history of technology, and its newly emerging forms’ has had so few imitators among contemporary economists.

Marshall is another economist from the second half of the 19th century who fully appreciated the importance of the division of labour and revealed it in its more modern forms. In 1879, the Economics of
The division of labour, immediately after its Chapter 7 on organization of industry. It distinguished the opportunity to apply a division of labour as inherent in the nature of the work, as dependent on direction and control by an entrepreneur as earlier indicated by Bagehot, and as applied to firms: ‘If there are any producers, large and small, all engaged in the same process, Subsidiary Industries will grow up to meet their special wants.’ These include special machine tool makers for the industry, improved transport to enhance communication between related firms, as well as auxiliary enterprises in banking and credit provision (Marshall and Marshall 1879, p. 52). Localization of industry also fosters ‘education of skills and taste’ and ‘diffusion of linked knowledge’, and encourages large firms. Hence division of labour is closely related to economies of scale, where size has enabled specialization to grow more and more. Marshall also devoted no less than three chapters to division of labour in his Principles (1890, Book IV, chs 9–11), not only covering points traditionally dealt with under this heading, but often introducing subtle modifications. For example, Marshall (1890, p. 263) discounted detrimental social consequences from monotonous work by pointing to the mental stimulus from the ‘social surroundings of the factory’ and the view that factory work was not inconsistent with ‘considerable intelligence and mental resources’. Likewise, he extended Babbage’s principle of ‘economy of skill’ to economy of machinery and materials (1890, p. 265), used it as a major explanatory factor for the localization of specialized industry (p. 271) and made it the chief advantage of large scale production in his famous discussion of economies of scale (p. 278). Later, Marshall applied these aspects of his work to his detailed study of industry and trade to explain such things as America’s leadership in standardized production (seen by Marshall, 1919, p. 149, as an ‘unprecedented’ application of Babbage’s ‘great principle of economical production’), the successful specialization of plant during the First World War, and new issues concerning the growth of the firm. It is therefore paradoxical that Marshall’s work in other respects induced the demise of the division of labour in theoretical literature. This arose from the incompatibility of increasing returns to scale with stable demand and supply equilibrium (Marshall, 1890, Appendix H). Apart from this, modern equilibrium analysis found it difficult to come to grips with the dynamic features of the division of labour process, and it is presumably at least partly for this reason that division of labour was dropped as an important subject from the economic textbooks (see Kaldor, 1972).

However, the locational aspects of the division of labour were further addressed by Becattini (for example, 1990; 2001) in his development of the notion of industrial districts as a concentration of related firms. Marshall had discovered this aspect of industrial organization through the factory tours in the British midlands and Scotland he engaged in from the late 1860s, on which he first reported in 1879. When division of labour for technical reasons could not take place within the same building, small firms spring up specializing in part of the manufacturing process, thereby generating a division of labour among firms concentrated in a particular geographical area (for a survey, see Goodman and Pamford, 1988).

International division of labour

Torrens (1808) appears to have been the first economist to distinguish the territorial division of labour from the mechanical division, suggesting that the former is inspired by ‘different soils and climates [being] adapted to the growth of different production’ thereby inducing regional specialization in those
products which best suit ‘the varieties of their soil’ and climate. Taking advantage of territorial division of labour through regional and international trade enhances productivity and increases the wealth of nations as much as a manufacturing division of labour. Senior (1836, p. 76) also drew attention to this aspect of the division of labour, attributing its discovery to Torrens. Marshall (1890, pp. 267–77) covered territorial division of labour under localization of industry while Taussig (1911, pp. 41–7) called it ‘the geographical division of labour’ with gains arising from ‘the adaptation of different regions to specific articles’ for climatic and resource endowment reasons as well as from the general increase in proficiency which all specialization brings. During the 1970s a new dimension of the international division of labour was analysed, concentrating on its direct foreign investment aspects. Its novel features were a tendency to ‘undermine the traditional bisection of the world into a few industrialized countries on the one hand, and a great majority of developing countries integrated into the world economy solely as raw material producers on the other, and [secondly, to compel] the increasing subdivision of manufacturing processes into a number of partial operations at different industrial sites throughout the world’ to take advantage of favourable labour market circumstances, relatively cheap transport opportunities, tax breaks and other government inducements for foreign investors (Fröbel, Heinrichs and Kreye, 1980, p. 45). This multinational dimension to application of the division of labour is a direct descendent from the concept as understood by Smith, Babbage, Ure and Marx. The characteristics of the contemporary global division of labour have been well captured by Hobsbawm (2000, pp. 65–6):

Thus, while the global division of labour was once confined to the exchange of products between particular regions, today it is possible to produce across the frontiers of states and continents. This is what the process is founded on. The abolition of trade barriers and liberalization of markets is, in my opinion, a secondary phenomenon. This is the real difference between the global economy before 1914 and today. Before the Great War, there was pan global movement of capital, goods and labor. But the emancipation of manufacturing and occasionally agricultural products from the territory in which they were produced was not yet possible. When people talked about Italian, British and American industry, they meant not only industries owned by citizens of these countries, but also something that took place almost entirely in Italy, Britain, or America, and was then traded with other countries. This is no longer the case. How can you say that a Ford is an American car, given that it is made of Japanese and European components, as well as parts manufactured in Detroit?

Sexual division of labour

The first explicit reference to a sexual division of labour in economic literature I could find is Hodgskin (1829, pp. 111–12). He argued that

There is no state of society, probably, in which division of labour between the sexes does not take place. It is and must be practiced the instant a family exists. Among even the most barbarous tribes, war is the exclusive business of the males; they are in general the
principal hunters and fishers…the woman labours in and about the hut…In modern as well as in ancient times,…we find the men as the rule taking the out-door work to themselves, leaving the women most of the domestic occupations….The aptitude of the sexes for different employments, is only an example of the more general principle, that every human being…is better adapted than another to some particular occupation.

Marx and Engels (1845–6, pp. 42–3) ascribed beginnings of the division of labour ‘originally [to] nothing but the division of labour in the sexual act’ and only later to that ‘spontaneously’ or ‘naturally’ derived from predisposition, needs, accidents, and so on. Engels (1884, esp. p. 311) elaborated further on the matter presenting the sexual division of labour in the family as a barrier to the ‘emancipation of women’. Such an emancipation, he argued, was ‘possibly only as a result of modern large-scale industry [which] actually called for the participation of women in production and moreover, strives to convert private domestic work also into a public industry’. Both aspects of the sexual division of labour to which Engels referred in the context of women’s emancipation have been taken up in more recent research. The role of domestic labour has been analysed by contemporary writers (see, for example, Himmelweit and Mohun, 1977; Gershuny, 1983) while attention has also been drawn to the shift in the provision of services from domestic production to production for the market (laundromats, take-away-food) as a result of the gradual break-down of the traditional sexual division of labour within the family (Gouverneur, 1978). Sexual division of labour issues have also been applied in segmented labour market analysis, thereby enriching this particular aspect of labour economics.

Becker (1985) has analysed the sexual division of labour in the context of human capital investment and allocating the work load of parties within the household. Thus both the allocation of effort within a household, and the advantages of investing in specific human capital are designed to enhance the social division of labour and its benefits without necessarily diminishing the exploitative aspects of such arrangements (Becker 1985, p. S41). Social factors are, however, equally important. Increasing returns by itself cannot explain the traditional division of labour within the household; a division of labour itself subject to change. The increased contribution to housework by men during the 1970s is one observed aspect of this social change (Becker 1985, p. S56). Furthermore, as Posner (1992, pp. 54, 129) has noted in particular, women were not fully brought into the work place on a large scale until the two world wars, and this only became a dominant pattern in employment from the 1950s onwards. Cigno (1991) discusses many of these issues as part of his economics of the family.

Decline and rehabilitation of division of labour in the 20th and 21st centuries

The association between division of labour and increasing returns, the consequent possibility of falling supply and cost curves, created problems for equilibrium analysis already noticed as a factor explaining decline in emphasis on the division of labour and induced its virtual elimination from much of the theoretical literature. Attempts to remove division of labour from economics were also based on other grounds. Robbins (1932, pp. 32–8) argued that study of the ‘technical arts of production’ belonged to engineering and not to economics or, in the case of ‘motion study’, to industrial psychology even if this meant removal of traditional topics like division of labour from economics. Robbins's approach followed
Sidgwick’s (1883, pp. 104–7) treatment, removing all technical aspects from the topic, leaving only what he called the pure economics side. Others suggested it was better to leave discussion of division of labour to sociologists because Durkheim, and before him Comte and Herbert Spencer, had absorbed it within this emerging discipline. However, some economists in the 20th century objected to removal of the division of labour from economics. In particular, this would reduce understanding of the dynamics of economic progress.

Allyn Young (1928) was one of these economists. He made Adam Smith’s theorem that the division of labour is limited by the extent of the market the central theme of his address to section F of the British Association, arguing this was ‘one of the most illuminating and fruitful generalizations which can be found in the whole literature of economics’ (Young, 1928, p. 529). Rather than covering all aspects of the division of labour, Young concentrated on two interdependent matters: ‘growth of indirect and roundabout methods of production and the division of labour [or increased specialization] among industries’ (Young, 1928, p. 529) but the former, as Kaldor (1975, pp. 355–6) pointed out, was not to be confounded with the Austrian capital theoretic notion. From this he deduced division of labour as a cumulative, self-reinforcing process, because every re-organization of production, sometimes described as a new invention, involves fresh application of scientific progress to industry,

alters the conditions of industrial activity and initiates responses elsewhere in the industrial structure which in turn have further unsettling effects….The apparatus of supply and demand in their relation to prices does not seem to be particularly helpful for the purpose of an inquiry into these broader aspects of increasing returns. (Young, 1928, p. 533)

However, apart from this damaging conclusion for competitive price theory, the ‘possibility of economic progress’ could not really be grasped by ignoring these factors of greater specialization, better combinations of advantages of location, and a consequent increased number of specialized producers between basic raw materials and final producers (Young, 1928, pp. 538–40).

Kaldor was a major economist who took up Young's challenge in both its critical (Kaldor, 1972; 1975) and more constructive aspects (Kaldor, 1966; 1967). The major thrust of Kaldor's positive argument proclaimed that faster growth is derived from faster growth in the manufacturing sector, partly from the cumulative features linking the growth of manufacturing to growth of labour productivity via static and dynamic economies of scale, or the notion of increasing returns as developed by Young from the division of labour. This strong and powerful interaction of productivity growth and manufacturing growth is also posited in Verdoorn's Law (1949) but its association with aspects of the division of labour is what is relevant here. Faster manufacturing growth draws labour from other sectors of the economy, inducing faster productivity growth, but as the scope of transferring such labour from lower productivity sectors like agriculture dries up, the growth process slows down (see Thirlwall, 1983). A key feature of the process, as Rowthorn (1975, p. 899, n. 1) noticed in one his skirmishes with Kaldor on the subject, is that it is an interdependent, cumulative historical process where ‘higher productivity means more exports which means greater industrial output which via its effects on investment, innovation and scale of production reacts back on productivity growth’. The importance of such a process was given detailed
empirical examination in a discussion of the Taiwan machine tools industry in the 1970s as an application of the division of labour, envisaged as increases in output increasing productivity, with ‘technological change, broadly defined, sandwiched in between’ (Amsden, 1985, p. 271). Writers in the new growth economics, who emphasized the impact of increasing returns from specialization on growth performance (Romer, 1987) drew in part for their inspiration on the literature of the division of labour, in Romer's case as represented by Marshall (1890) and possibly Young (1928).

Research from the 1990s has particularly stressed the importance of communication and co-ordination costs of the division of labour. Becker and Murphy (1992) portray these costs as setting limits on the division of labour more important than that exerted by the extent of the market so heavily emphasized by Adam Smith. Subsequent, Camacho (1996) has studied this aspect in more detail, drawing a clear and direct relationship between increases in the division of labour and rises in both communication and co-ordination costs, as an essential extension to the modern theory of the firm and the market. Perlin (1993) has treated inter-firm cooperation and its benefits from a similar angle, assessing the benefits for production from such cooperation as an economy of conventions and inter-firm agreements. This analysis thereby treats division of labour once again as part of the organizational theory of the firm or a production unit in which much emphasis is placed on the potential trade-offs between the economies reaped from specialization and the transaction costs it generates (Yang and Ng 1993). In this way, division of labour has also become an important part of the foundations for a new classical micro-economic analytic framework.

Conclusion

Viewed dynamically within the context of economic growth, as Smith (1776) and others had intended the division of labour to be contemplated, it continues to be a powerful tool for understanding the process of growth and development. On this ground alone it can therefore not be jettisoned from economics as unwanted baggage, as Robbins (1932) mistakenly suggested. When its importance for understanding aspects of the labour process, the labour market, the theory of production and the theory of the firm contemplated at the plant and the industry level are included, this argument is even stronger. As mentioned in the previous paragraph, on these grounds division of labour is making a definite comeback as part of the theory of a new classical micro-economics. Last, but not least, the importance of the division of labour for economics is underlined by the fact that some of the major economic minds from both past and present have invariably included it as an important part of their economic analysis.

Maurice Dobb was undoubtedly one of the outstanding political economists of this century. He was a Marxist, and was one of the most creative contributors to Marxian economics. As Ronald Meek put it, in his obituary of Dobb for the British Academy, ‘over a period of fifty years [Dobb] established and maintained his position as one of the most eminent Marxist economists in the world’. Dobb's *Political Economy and Capitalism* (1937) and *Studies in the Development of Capitalism* (1946) are his two most outstanding contributions to Marxian economics. The former is primarily concerned with economic theory (including such subjects as value theory, economic crises, imperialism, socialist economies), and the latter with economic history (particularly the emergence of capitalism from feudalism). These two fields – economic theory and economic history – were intimately connected in Dobb's approach to economics. He also wrote an influential book on Soviet economic development. This was first published under the title *Russian Economic Development since the Revolution* (1928), and later in a revised edition as *Soviet Economic Development since 1917* (1948).

Maurice Dobb was born on 24 July 1900 in London. His father Walter Herbert Dobb had a draper's retail business and his mother Elsie Annie Moir came from a Scottish merchant's family. He was educated at Charterhouse, and then at Pembroke College, Cambridge, where he studied economics. This was followed by two postgraduate years at the London School of Economics, where he did his Ph.D. on ‘The Entrepreneur’. The thesis formed the basis of his book *Capitalist Enterprise and Social Progress* (1925). Dobb returned to Cambridge at the end of 1924 on being appointed as a lecturer in economics. He taught in Cambridge until his retirement in 1967. He was a Fellow of Trinity College, and was elected to a University Readership in 1959. He received honorary degrees from the Charles University of Prague, the University of Budapest, and Leicester University, and was elected a Fellow of the British Academy.
After retirement he and his wife, Barbara, stayed on in the neighbouring village of Fulbourn. He died on 17 August 1976.

Dobb was a theorist of great originality and reach. He was also, throughout his life, deeply concerned with economic policy and planning. His foundational critique of ‘market socialism’ as developed by Oscar Lange and Abba Lerner, appeared in the *Economic Journal* of 1933, later reproduced along with a number of related contributions in his *On Economic Theory and Socialism* (1955). His relatively elementary book *Wages* (1928) presented not merely a simple introduction to labour economics, but also an alternative outlook on these questions, including their policy implications, leading to interesting disputations with John Hicks, among others. In later years Dobb was much concerned with planning for economic development. In three lectures delivered at the Delhi School of Economics, later published as *Some Aspects of Economic Development* (1951), Dobb discussed some of the central issues of development planning for an economy with unemployed or underutilized labour, and his ideas were more extensively developed in his later book, *An Essay on Economic Growth and Planning* (1960).

Maurice Dobb also published a number of papers on more traditional fields in economic theory, including welfare economics, and some of these papers were collected together in his *Welfare Economics and the Economics of Socialism* (1969). In his *Theories of Value and Distribution since Adam Smith: Ideology and Economic Theory* (1973), he responded inter alia to the new developments in Cambridge political economy, including the influential ‘Prelude to a Critique of Economic Theory’ by Piero Sraffa (1960). Maurice Dobb's association with Piero Sraffa extended over a long period, both as a colleague at Trinity College, and also as a collaborator in editing *Works and Correspondence of David Ricardo*, published in 11 volumes between 1951 and 1973 (on the latter, see Pollitt, 1990).

In addition to academic writings, Maurice Dobb also did a good deal of popular writing, both for workers’ education and for general public discussion. He wrote a number of pamphlets, including *The Development of Modern Capitalism* (1922), *Money and Prices* (1924), *An Outline of European History* (1926), *Modern Capitalism* (1927), *On Marxism Today* (1932), *Planning and Capitalism* (1937), *Soviet Planning and Labour in Peace and War* (1942), *Marx as an Economist: An Essay* (1943), *Capitalism Yesterday and Today* (1958), and *Economic Growth and Underdeveloped Countries* (1963), and many others. Dobb was a superb communicator, and the nature of his own research was much influenced by policy debates and public discussions. Dobb the economist was not only close to Dobb the historian, but also in constant company of Dobb the member of the public. It would be difficult to find another economist who could match Dobb in his extraordinary combination of genuinely ‘high-brow’ theory, on the one hand, and popular writing on the other. The author of *Political Economy and Capitalism* (from the appearance of which – as Ronald Meek (1978) rightly notes – ‘that future historians of economic thought will probably date the emergence of Marxist economics as a really serious economic discipline’: was also spending a good deal of effort writing pamphlets and material for labour education, and doing straightforward journalism. It is not possible to appreciate fully Maurice Dobb's contributions to economics without taking note of his views of the role of economics in public discussions and debates. Another interesting issue in understanding Dobb's approach to economics concerns his adherence to the labour theory of value. The labour theory has been under attack not only from neoclassical economists, but also from such anti-neoclassical political economists as Joan Robinson and, indirectly, even Piero Sraffa. In his last major work, *Theories of Value and Distribution since Adam Smith* (1973), Maurice Dobb speaks much in support of the relevance of Sraffa's (1960) major contribution, which eschews the use of labour values (on this see Steedman, 1977), but without abandoning his insistence on the
importance of the labour theory of value. It is easy to think that there is some inconsistency here, and it is tempting to trace the origin of this alleged inconsistency to Dobb's earlier writings, which made Abram Bergson remark that ‘in Dobb's analysis the labour theory is not so much an analytic tool as excess baggage’ (Bergson, 1949, p. 445).

The key to understanding Dobb's attitude to the labour theory of value is to recognize that he did not see it just as an intermediate product in explaining relative prices and distributions. He took ‘the labour-principle’ as ‘making an important qualitative statement about the nature of the economic problem’ (Dobb, 1937, p. 21). He rejected seeing the labour theory of value as simply a ‘first approximation’ containing ‘nothing essential that cannot be expressed equally well and easily in other terms’ (Dobb, 1973, pp. 148–9). The description of the production process in terms of labour involvement has an interest that extends far beyond the role of the labour value magnitudes in providing a ‘first approximation’ for relative prices. As Dobb (1973, pp. 148–9) put it,

there is something in the first approximation that is lacking in later approximations or cannot be expressed so easily in those terms (e.g., the first approximation may be a device for emphasising and throwing into relief something of greater generality and less particularity).

Any description of reality involves some selection of facts to emphasize certain features and to underplay others, and the labour theory of value was seen by Dobb as emphasizing the role of those who are involved in ‘personal participation in the process of production per se’ in contrast with those who do not have such personal involvement.

As such ‘exploitation’ is neither something ‘metaphysical’ nor simply an ethical judgement (still less ‘just a noise’) as has sometimes been depicted: it is a factual description of a socio-economic relationship, as much as is Marc Bloch's apt characterisation of Feudalism as a system where feudal Lords ‘lived on the labour of other men’. (Dobb, 1973, p. 145)

The possibility of calculating prices without going through value magnitudes, and the greater efficiency of doing that (on this see Steedman, 1977), does not affect this descriptive relevance of the labour theory of value in any way. Maurice Dobb also outlined the relationship of this primarily descriptive interpretation of labour theory of value with evaluative questions, for example, assessing the ‘right of ownership’ (see especially Dobb, 1937). The importance for Dobb of descriptive relevance is brought out also by his complex attitude to the utility theory of value. While he rejected the view that the utility picture is the best way of seeing relative values (‘by taking as its foundation a fact of individual consciousness’), he lamented the descriptive impoverishment that is brought about by replacing the subjective utility theory by the ‘revealed preference’ approach.

If all that is postulated is simply that men choose, without anything being stated even as to how they choose or what governs their choice, it would seem impossible for economics to
provide us with any more than a sort of algebra of human choice. (Dobb, 1937, p. 171)

Indeed, as early as 1929, a long time before the ‘revealed preference theory’ was formally inaugurated by Paul Samuelson, Dobb (1929, p. 32) had warned:

Actually the whole tendency of modern theory is to abandon such psychological conceptions: to make utility and disutility coincident with observed offers in the market; to abandon a ‘theory of value’ in pursuit of a ‘theory of price’. But this is to surrender, not to solve the problem.

Maurice Dobb's open-minded attitude to non-Marxian traditions in economics added strength and reach to his own Marxist theorizing. He could combine Marxist reasoning and methodology with other traditions, and he was eager to be able to communicate with economists belonging to other schools. Dobb's honesty and lack of dogmatism were important for the development of the Marxist economic tradition in the English-speaking world, because he occupied a unique position in Marxist thinking in Britain. As Eric Hobsbawm (1967, p. 1) has noted,

for several generations (as these are measured in the brief lives of students) he was not just the only Marxist economist in a British university of whom most people had heard, but virtually the only don known as a communist to the wider world.

The Marxist economic tradition was well served by Maurice Dobb's willingness to engage in spirited but courteous debates with economists of other schools. Dobb achieved this without compromising the integrity of his position. The distinctly Marxist quality of his economic writings was as important as his willingness to listen and dispassionately analyse the claims of other schools of thought with which he engaged in systematic disputation. The gentleness of Dobb's style of disputation arose from strength rather than from weakness.

Dobb's willingness to appreciate positive elements in other economic traditions while retaining the distinctive qualities of his own approach is brought out very clearly also in his truly far-reaching critique of the theory of socialist pricing as presented by Lange, Lerner, Dickinson and others in the 1930s. Dobb noted the efficiency advantages of a price mechanism, especially in a static context. He was, however, one of the first economists to analyse clearly the conflict between the demands of efficiency expressed in the equilibrium conditions of the Langer–Lerner price mechanism (and also of course in a perfectly competitive market equilibrium), and the demands that would be imposed by the requirements of equality, given the initial conditions. In his paper called ‘Economic Theory and the Problems of a Socialist Economy’ published in 1933, Maurice Dobb argued thus:

If carpenters are scarcer or more costly to train than scavengers, the market will place a higher value upon their services, and carpenters will derive a higher income and have greater ‘voting power’ as consumers. On the side of supply the extra ‘costliness’ of carpenters will receive expression, but only at the expense of giving carpenters a differential ‘pull’ as consumers, and hence vitiating the index of demand. On the other
hand, if carpenters and scavengers are to be given equal weight as consumers by assuring them equal incomes, then the extra costliness of carpenters will find no expression in costs of production. Here is the central dilemma. Precisely because consumers are also producers, both costs and needs are precluded from receiving simultaneous expression in the same system of market valuations. Precisely to the extent that market valuations are rendered adequate in one direction they lose significance in the other. (1933, p. 37)

The fact that given an initial distribution of resources the demands of efficiency and those of equity may – and typically will – conflict is, of course, one of the major issues in the theory of resource allocation, with implications for market socialism as well as for competitive markets in a private ownership economy. As a matter of fact, Marx had *inter alia* noted this conflict in his *Critique of Gotha Programme*, but in the discussion centring around Langer–Lerner systems, this deep conflict had attracted relatively little attention, except in the arguments presented by Maurice Dobb. The fact that even a socialist economy has to cope with inequalities of initial resource distribution (arising from, among other things, differences in inherited talents and acquired skills) makes it a relevant question for a socialist economy as well as for competitive market economies, and Dobb's was one of the first clear analyses of this central question of resource allocation. The second respect in which Maurice Dobb found the literature on market socialism inadequate concerns allocation over time. In discussing the achievements and failures of the market mechanism, Maurice Dobb argued that the planning of investment decisions

may contribute much more to human welfare than could the most perfect micro-economic adjustment, of which the market (if it worked like the textbooks, at least, and there were no income-inequalities) is admittedly more fitted in most cases to take care. (Dobb, 1960, p. 76)

In his book *An Essay in Economic Growth and Planning* (1960), Dobb provided a major investigation of the basis of planned investment decisions, covering overall investment rates, sectoral divisions, choice of techniques, and pricing policies related to allocation (including that over time). This contribution of Dobb relates closely to his analysis of the problems of economic development. In his earlier book *Some Aspects of Economic Development* (1951), Dobb had already presented a pioneering analysis of the problem of economic development in a surplus-labour economy, with shortage of capital and of many skills. While, on the one hand, he anticipated W.A. Lewis's (1954) more well-known investigation of economic growth with ‘unlimited supplies of labour’, he also went on to demonstrate the far-reaching implications of the over-all savings rates being socially sub-optimal and inadequate. Briefly, he showed that this requires not only policies directly aimed at raising the rates of saving and investment, but it also has implications for the choice of techniques, sectoral balances, and price fixation.

In such a brief note, it is not possible to do justice to the enormous range of Maurice Dobb's contributions to economic theory, applied economics and economic history. Different authors influenced by Maurice Dobb have emphasized different aspects of his many-sided works (see, for example, Feinstein, 1967, and the *Cambridge Journal of Economics*’ Maurice Dobb Memorial Issue (1978)). He
has also had influence even outside professional economics, particularly in history, especially through his analysis of the development of capitalism.

Dobb argued that the decline of feudalism was caused primarily by ‘the inefficiency of Feudalism as a system of production, coupled with the growing needs of the ruling class for revenue’ (1946, p. 42). This view of feudal decline, with its emphasis on internal pressures, became the subject of a lively debate in the early 1950s. An alternative position, forcefully presented by Paul Sweezy in particular, emphasized some external developments, especially the growth of trade, operating through the relations between the feudal countryside and the towns that developed on its periphery. No matter what view is taken as to ‘who won’ the debates on the transition from feudalism to capitalism, Dobb's creative role in opening up a central question in economic history as well as a major issue in Marxist political economy can scarcely be disputed. Indeed, Studies in the Development of Capitalism (1946) has been a prime mover in the emergence of the powerful Marxian tradition of economic history in the English-speaking world, which has produced scholars of the eminence of Christopher Hill, Rodney Hilton, Eric Hobsbawm, Edward Thompson and others.

It is worth emphasizing that aside from the explicit contributions made by Maurice Dobb to economic history, he also did use a historical approach to economic analysis in general. Maurice Dobb's deep involvement in descriptive richness (as exemplified by his analysis of ‘the requirements of a theory of value’), his insistence on not neglecting the long-run features of resource allocation (influencing his work on planning as well as development), his concern with observed phenomena in slumps and depressions in examining theories of ‘crises’, and so on, all relate to the historian's perspective. Dobb's works in the apparently divergent areas of economic theory, applied economics and economic history are, in fact, quite closely related to each other.

Maurice Dobb was not only a major bridge-builder between Marxist and non-Marxist economic traditions (aside from pioneering the development of Marxist economics in Britain and to some extent in the entire English-speaking world): he also built many bridges between the different pursuits of economic theorists, applied economists and economic historians. Dobb's political economy involved the rejection of the narrowly economic as well as the narrowly doctrinaire. He was a great economist in the best of the broad tradition of classical political economy.

Dollarization

Roberto Chang
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article focuses on dollarization, a situation in which a foreign currency (often the US dollar) replaces a country's currency in performing one or more of the basic functions of money. The distinction between official dollarization and endogenous dollarization is discussed, as are the concepts of currency substitution and liability dollarization. Implications for monetary and exchange rate policy are emphasized.

Keywords
aggregate demand; capital asset pricing model; currency substitution; dollarization; euro; financial dollarization; inflation; lender of last resort; liability dollarization; monetary policy; net worth effects; portfolio balance; search theory; seigniorage; stabilization; transaction costs

Article

Dollarization is a situation in which a foreign currency (often the US dollar) replaces a country's currency in performing one or more of the basic functions of money. Thus in Ortiz (1983) the term ‘dollarization’ refers to the widespread usage of US dollars for transaction purposes in Mexico. More recently, Ize and Levy-Yeyati (2003) use ‘financial dollarization’ for episodes in which domestic financial contracts are denominated in dollars or another foreign currency. In some countries, dollarization has been the outcome of official government policy. Examples include Ecuador in 2000 and El Salvador in 2001, where the domestic currency was retired from circulation and the US dollar became the official currency. An immediate implication of such ‘official dollarization’ is that domestic prices of tradable goods are tied to world prices, so domestic inflation is closely related to US inflation. Hence official dollarization has been advocated for countries suffering from chronic, high, and volatile inflation.

On the other side of the ledger, official dollarization implies the surrender of independent monetary
policy, leaving only fiscal policy available as a stabilization tool. In addition, the domestic government
gives up seigniorage, or the revenue from money creation, which accrues to the US Federal Reserve.
While both effects are widely regarded as costly for the domestic economy, their welfare implications
depend on details about the policymaking process and, in particular, on whether the monetary authorities
can credibly commit to implement optimal policy (see Chang and Velasco, 2002, for a discussion).
Finally, official dollarization implies that the domestic central bank is no longer available as a lender of
last resort, which may be conducive to financial fragility and crises. Calvo (2005) argues, however, that
last resort lending can be provided by alternative arrangements.
Impetus for official dollarization as a policy alternative was greatest at the turn of the millennium, as
emerging economies had to cope with a sequence of financial and exchange rate crises while several
European countries were abandoning their national currencies in favour of the newly created euro.
Support for official dollarization appears to have subsided since, however.
More frequently, dollarization has emerged as a spontaneous response of domestic agents to inflation.
The special case in which such a process has resulted in the dollar becoming a widespread medium of
exchange is known as ‘currency substitution’. Currency substitution has been the subject of a large
literature, much of it focused on the determinants of the relative demand for domestic vis-à-vis foreign
currencies and on implications for monetary management. Early research followed Girton and Roper
(1981) in postulating ad hoc aggregate demand functions for domestic and foreign currency, in the
portfolio balance tradition. Somewhat later, Calvo (1985) derived similar demand functions from an
optimizing model in which domestic and foreign currencies entered the representative household's utility
function. Those approaches emphasized the possibility that increasing substitutability between the
domestic and the foreign currencies would lead to monetary and exchange rate instability. However,
they did not identify the basic determinants of substitutability, which was buried in the specification of
the postulated demand function for foreign currency or the properties of the representative agent's utility
function. Hence the early studies were of little use in understanding how to cure the ills associated with
dollarization, and, in particular, they failed to trace the consequences of common policies designed to
deal directly with currency substitution, such as outright prohibitions on the holdings of foreign currency.
Subsequent studies have attempted to address these shortcomings by modelling more explicitly the
fundamental frictions underlying currency substitution. Thus Guidotti and Rodriguez (1992) developed a
cash-in-advance model of currency substitution on the assumption that using foreign currency entailed
fixed transaction costs, while Chang (1994) studied the implications of a similar assumption in an
overlapping generations setting. These models still left unexplained where the assumed transaction costs
were coming from. Therefore, recent work on this area models currency substitution entirely from first
principles, in the search theoretic tradition (see, for instance, Craig and Waller, 2004).
Another focus of recent literature has been the increased use of the dollar as the currency of
denomination of the debts of domestic residents in emerging economies, a problem that Calvo (2005)
terms ‘liability dollarization’. A substantial degree of liability dollarization places an economy in a
vulnerable situation, since presumably many of the agents with dollar debts have assets denominated in
domestic currency. Such a currency mismatch situation means that a depreciation of the domestic
currency reduces the net worth of domestic agents. If, in turn, aggregate demand depends on net worth
(as would be the case in the presence of financial imperfections), a currency depreciation may lead to a
reduction in income and employment. In other words, liability dollarization may render depreciations
contractionary, not expansionary as assumed by conventional analysis (Aghion, Bachetta and Banerjee, 2001; Cespedes, Chang and Velasco, 2004). The combination of liability dollarization and net worth effects has been blamed for the severity of the income and output contractions in recent emerging markets crises.

At this point, no consensus exists as to the causes of liability and financial dollarization, although research on this question is rather active. Ize and Levy-Yeyati (2003), in particular, have examined the choice of currency denomination of assets and liabilities from a capital asset pricing model (CAPM) perspective, while Jeanne (2005) models liability dollarization as the private sector response to the lack of credibility in monetary policy. Finally, several studies estimate how measures of financial dollarization depend empirically on other characteristics of an economy. For example, Arteta (2005) has found that the dollarization of bank deposits is empirically more frequent in countries with a higher degree of exchange rate flexibility.

Domar, Evsey David (1914–1997)

E. Cary Brown

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Domar, E. D.; economic growth; Harrod–Domar growth model; portfolio theory; proportional income tax; slavery; technical change

Article

Domar (Domashevitsky) was born in 1914 in Lodz, Russia (now Poland), spent most of his early life in Harbin, Manchuria, and moved permanently to the United States in 1936. His undergraduate degree in economics (1939) was from the University of California (Los Angeles); his graduate work was at the Universities of Michigan (MA, Mathematical Statistics) and Harvard (Ph.D., 1947), where he studied with Alvin Hansen, the leading American Keynesian and most important single intellectual influence on Domar. Domar is best known for his leadership role, along with Roy Harrod, in the initiation of modern growth theory.

His first position was with the research staff of the Board of Governors of the Federal Reserve System, where he worked on fiscal problems from 1943 to 1946. His subsequent academic career took him briefly to the Carnegie Institute of Technology, the Cowles Foundation and the University of Chicago, the Johns Hopkins University in 1948 for ten years, and the Massachusetts Institute of Technology in 1958, from which he retired in 1984. An avid traveller, he held more than a dozen visiting professorships in universities at home and abroad.

While the claim to the earliest statement of the famous Harrod–Domar growth model was clearly Harrod's (1939), Domar arrived independently at a structurally similar model but from a different point of view (1946; 1947). By incorporating into static Keynesian analysis the capacity changes associated with investment, he found that steady-state capacity growth required investment to grow at a rate equal to the savings rate multiplied by the capital–output ratio. From this simple beginning, growth theory took off to become a major focus, one might almost say obsession, of the profession in the 1950s and 1960s. Domar also made important contributions to some of its conceptual and measurement problems, such as the proper treatment of depreciation (1953) and the measurement of technological change (1961), and he coined the term ‘residual’ for the fraction of expanding output unexplained by the
contribution of factors of production.

In fiscal theory, his early investigation, with Richard Musgrave (1944a), of the effect of a proportional income tax, with and without loss offsets, on portfolio choice was very similar in style and approach to portfolio theory of a decade later. Given individual preferences, the portfolio decision was modelled as a choice between alternative portfolios weighing their expected net returns against their risks (expected losses). The unconventional conclusion was reached that, given risk aversion, the imposition of a proportional income tax with symmetrical treatment of gains and losses would induce individuals to adjust their portfolios towards riskier assets. The reminder that expected risks and yields are both reduced by an income tax was an important correction to a simplistic focus on yields alone.

As an applied theorist, Domar had the knack of getting important results with simple theory. At a time when deficit finance was harshly criticized for increasing the debt burden and tax rate, Domar showed (1944b) that in a growing economy even continuous deficit finance resulted in only limited debt–income ratios and tax rates. Second, he made a fertile historical hypothesis (1970) – that the economic basis for the introduction of serfdom (or slavery) was a low land-to-labour cost. Third, he ingeniously modified the administrative rules that guided the behaviour of collective farms (1966) or that determined the compensation of socialist managers (1974) to induce them towards more efficient price–output decisions. Domar's work was informed by a rare combination of historical, empirical and theoretical breadth. His profound scholarship, in several languages, periods, and areas, often resurrected important findings of earlier writers previously overlooked.

Historian of American economic thought, Dorfman was born in Russia in 1904 and educated at Reed College and at Columbia University, where he earned a Ph.D. degree in 1935 and taught from 1931 until his retirement 40 years later. Dorfman was a student of Clarence Ayres at Reed, and of Wesley C. Mitchell and John Maurice Clark at Columbia. Mitchell in turn had been a student of Thorstein Veblen. These four economists, all with institutional leanings, stand out among the formative influences that affected Dorfman's early career. He made Veblen the subject of his doctoral dissertation, which was published under the title *Thorstein Veblen and His America* in 1934. This was at the time the only book-length appraisal of a modern economist that gave close attention not only to the subject's writings but also to biographical detail, the contemporary climate of opinion, and the general social and cultural setting of the work.

This type of holistic approach is characteristic also of Dorfman's monumental *The Economic Mind in American Civilization*, a five-volume work that he published from 1946 to 1959. It is dedicated ‘To the pioneering spirit of Thorstein Veblen and the first-born of his intellectual heirs, Wesley C. Mitchell’. The work is a detailed history of American economic thought from colonial times to 1933, the first of its kind and not likely to be replaced for many years. It is based on extensive research and in many instances provides the first comprehensive account of a writer's life and work. Dorfman sees a break of emphasis in the history of American economic thought at the time of the Civil War: it was commerce before, and industry later. He notes with respect the achievements of the past, and is a critical but tactful chronicler of past foibles. He was a pioneer in exploring not only the printed page but also archival material made up of ‘papers’, ‘letters’, and similarly elusive sources of information, the first writer to do so on a large and systematic scale in the history of economic thought.

Dornbusch, Rudiger (1942–2002)

Kenneth Rogoff

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Rudiger Dornbusch was one of the leading researchers in international macroeconomics in the late 20th century. He introduced the influential concept of exchange rate ‘overshooting’ to explain the excessive volatility of exchange rates after the break-up of the Bretton Woods system of fixed exchange rates in the early 1970s. Along with Stanley Fischer and Paul Samuelson, he revived the Ricardian theory of international trade whereby trade was driven by differences in technology; their simple tractable framework became similarly influential in the study of international trade.

comparative advantage; Dornbusch, R.; exchange rate dynamics; exchange rates (floating vs. fixed); Fischer, S.; Heckscher-Ohlin framework; new open economy macroeconomics; non-traded goods; overshooting; Ricardian trade theory; Samuelson, P.; sticky prices; value at risk (VAR)

Article

Rudiger Dornbusch was born in Germany on 8 June 1942. He received his Licence es Sciences Politiques from the University of Geneva in 1966, and his Ph.D. in Economics from the University of Chicago in 1971. He was an assistant professor at the Department of Economics at the University of Rochester from 1972 to 1974, an associate professor at the Graduate School of Business at Chicago University from 1974 to 1975, and a member of the MIT Department of Economics from 1975 to 1978. He became a Professor of Economics at MIT in 1978. From 1984 until his death from cancer on 25 July 2002, he was Ford International Professor of Economics at MIT.

Dornbusch was, by any measure, one of the giants of late 20th century international macroeconomics. His celebrated *Journal of Political Economy* paper ‘Expectations and exchange rate dynamics’ (1976), which introduced the concept of exchange rate ‘overshooting’, became the workhorse of international macroeconomics over the ensuing two decades. His *American Economic Review* paper (with Stanley...
Fischer and Paul Samuelson) ‘Comparative advantage, trade and payments in a Ricardian model with a continuum of goods’ (1977) introduced a simple tractable framework that became similarly influential in the study of international trade. This entry begins by reviewing Dornbusch's two most important scientific contributions, and goes on to give a brief sketch of his broader influence on the profession through students (he served as an advisor on over 125 doctoral dissertations), through his leading intermediate textbook *Macroeconomics* (written with Stanley Fischer), and through his role as an important voice in the public policy debate.

**Exchange rate overshooting**

Dornbusch's overshooting model of exchange rates (1976) captured the imagination of policymakers and academics alike during the early years of floating exchange rates. The model attracted enormous attention because, after the break-up of the Bretton Woods system of fixed exchange rates in the early 1970s, exchange rates seemed far too volatile relative to the underlying fundamentals. Although subsequent empirical work has undermined the model's original bold claim to explain floating exchange rates (see Meese and Rogoff, 1983), the model is still viewed as relevant, especially during episodes of major shifts in monetary policy. In fact, an informal survey conducted by Alan Deardorff of eight top economics departments found that, as late as 1990, Dornbusch's overshooting model was the only paper taught in every one of their graduate international finance courses. The idea of overshooting is so simple and elegant that the small-country version can be illustrated with just a couple of equations (the analysis here draws on Rogoff, 2002). The assumption of 'uncovered interest parity' relates the home nominal interest rate to the exogenous foreign nominal interest rate and the expected rate of depreciation of the exchange rate:

\[
i_t = i_t^* + E(e_{t+1} - e_t)
\]

where \(i_t\) is the level home nominal interest rate and \(e_t\) is the logarithm of the exchange rate (the home currency price of foreign currency), so that \(E(e_{t+1}-e_t)\) is the expected rate of change in the exchange rate. The second key relationship is a money demand equation that relates the real balances to the nominal interest rate.

\[
m_t - p_t = \lambda i_t + \eta y_t
\]

where \(y\) denotes the log of output, \(m\) is the nominal money supply and \(p\) is the price level.
interest rates lower the demand for real balances, and an increase in output raises it. Dornbusch posed the question of what would happen if there were a one-time permanent increase in the money supply, \( m \). If prices were fully flexible, it would be possible to maintain equilibrium in the above two equations by having prices and exchange rates all rise permanently in proportion to the increase in the money supply. In this case, money would be neutral and have no real effects.

In reality, however, while asset markets (including the exchange rate) adjust very quickly, goods markets adjust more slowly partly due to temporary price rigidities. Therefore, in this set-up money is neutral only in the long run (in which the price level rises proportionately to the money supply). But with goods markets clearing only slowly, what is the impact of a money shock on exchange rates and interest rates? Assume that output, \( y \), is also fixed. If domestic prices are constant, then a rise in the money supply implies a rise in real balances, \( m - p \). But this means that the home nominal interest rate \( i \) must fall, so there is a corresponding rise in the demand for real balances. Then, however, the uncovered interest parity equation (eq. (1) above) implies that \( e_t \) must fall, or depreciate, relative to expectations of \( e_{t+1} \). That is, after any initial movement of the exchange rate in response to an unexpected shock, the currency must subsequently be expected to appreciate. But recall that in the long run, even with sticky prices, money is still neutral, so the exchange rate has to depreciate by the same amount as the rise in the domestic price level, thus producing no real effect.

How is all this possible? The answer, Dornbusch deduced, is that the initial money shock must cause the exchange rate to depreciate by more in the short run than it does in the long run. It ‘overshoots’. Therefore, Dornbusch's model offered a highly plausible explanation of why exchange rates seem to be so volatile relative to fundamentals. At one level of abstraction, of course, ‘overshooting’ is an application of Paul Samuelson's ‘Le Chatelier's principle’ theorem: when prices in some markets are inflexible in the short run, prices in others may overreact in the short run. But Dornbusch's model did much more than innovatively contrast the fast adjustment of asset markets with the slow adjustment of goods markets (an insight that any realistic short-run dynamic macroeconomic model should take into account). It offered a concrete and coherent analysis of an extremely important practical phenomenon. Over the decades since Dornbusch’s article appeared, the term ‘overshooting’ has become deeply woven into the popular economic lexicon.

Modern research has advanced considerably beyond the overshooting model, of course, and the Mundell-Fleming-Dornbusch model has largely been supplanted by ‘new open economy macroeconomics’ (see Obstfeld and Rogoff, 1996). And the notion of looking at money shocks via a money demand equation has increasingly been supplanted by frameworks which view the overnight interest rate as the key instrument of monetary policy. Nevertheless, these newer frameworks typically include sticky prices – perhaps the most fundamental, and controversial, element of Dornbusch's model – and hence can all replicate a similar phenomenon to ‘overshooting.’

Although Dornbusch's overshooting paper was his best-known work, with over 900 citations in refereed journals, he published numerous other very well-known articles, including his 1973 *American Economic Review* paper that was among the first to incorporate non-traded goods in a monetary model (see also his elegant 1974 contribution to the collection edited by Robert Aliber), his 1983 *Journal of Political Economy* paper that illustrated how changes in the real interest rate could affect exchange rates and current accounts, and his 1987 *American Economic Review* paper that demonstrated a link between market structure and the adjustment of relative prices to exchange rate movements. Without doubt, however, his other extremely influential paper was not in international finance but in trade.
Ricardian model of trade

Dornbusch's 1977 *American Economic Review* paper with MIT colleagues Stanley Fischer and Paul Samuelson almost single-handedly revived the analysis of Ricardian trade; a ‘Ricardian’ model of trade is one with only one factor of production (usually taken to be labour). Trade is driven by differences in technology. The Ricardian model is contrasted with the Hecksher–Ohlin framework, where countries have identical technologies but different relative endowments of the factors of production (labour and capital, in the simplest canonical case). Prior to Dornbusch–Fischer–Samuelson (DFS), the Ricardian approach had been dormant for years, having been largely supplanted by the Hecksher–Ohlin framework. The Ricardian model had lost out not so much because of poor empirical results but because it had come be viewed as intractable for all but illustrative purposes. By introducing a continuum of goods (rather than a discrete number), DFS were able to analyse elegantly a broad range of comparative static questions that had previously seemed unapproachable. DFS showed, for example, how to mobilize the combination of comparative advantage and trade costs to endogenize the dividing line between ‘traded’ and ‘non-traded’ goods, and how to analyse the classic ‘transfer’ problem where one country owes debt to another. Although at first only a trickle of papers followed DFS, the power of their continuum specification has led to a recent explosion of related research. DFS have become the starting point for a number of applied papers (see, for example, Copeland and Taylor, 1994). In addition, DFS form the basis for a broad range of empirical papers (see, for example, Eaton and Kortum, 2002; Kehoe and Ruhl, 2002; Kraay and Ventura, 2002; Kei-Mu Yi, 2003; Ghironi and Melitz, 2005; see also Feenstra and Hanson, 1996). As the empirical work following DFS deepens, it is fair to say that trade economists have increasing faith in the fundamental underpinnings of the model.

Broader contributions

Aside from his path-breaking research, Dornbusch made important contributions to economics in a number of other dimensions. His intermediate undergraduate textbook with Stanley Fischer, *Macroeconomics*, written in the mid-1970s, became a worldwide best-seller. The book was really the first to integrate modern supply-side economics into the standard demand-driven framework of the day. As such, students were able to gain a far deeper understanding of problems such as the effects of oil price shocks.

Dornbusch was enormously influential as a graduate teacher at MIT. At his regular early-morning international economics ‘breakfasts’, Dornbusch would dissect recent models and serve up provocative questions in a fast-paced freewheeling style; many students remember these unique seminars as their most influential experiences as Ph.D. students. Dornbusch served as thesis advisor to scores of economists (as noted earlier, more than 125 in all), including Jeffrey Frankel, Paul Krugman, Maurice Obstfeld and Kenneth Rogoff. His dynamic, Socratic lecturing style also attracted students from outside MIT to his advanced graduate classes, including the likes of Jeffrey Sachs and Lawrence Summers. Many Dornbusch students went on to become finance ministers and heads of central banks throughout the world.

Through clear and incisive policy analysis embodied in editorials, speeches, and private meetings,
Dornbusch exercised an enormous influence on global macroeconomic policy. He was a frequent guest of leading government officials throughout the world, who greatly valued and respected his advice. Arguably, no other recent economist has had so great an impact on the global macroeconomic policy debate, especially in emerging markets such as Brazil, Korea and Mexico, but also in more advanced countries such as Italy and Germany. Notably, in his later writing he succeeded in drawing ever more concrete insights from contemporary academic research, displaying a magnificent ability to translate complex theoretical models into ideas of immediate practical relevance. For example, his 1994 Brookings paper (with Alejandro Werner) argued that Mexico's pegged exchange rate had become overvalued to an extent that was unsustainable. Dornbusch's comments on markets prior to the currency collapse at the end of 1994 were highly influential. He also advanced a number of innovative ideas for dealing with international debt problems. His policy analysis was notable in that he managed to adopt strong views while continuing to be perceived as an independent and objective thinker. Over the last ten years of his life, Dornbusch became especially well-known for his monthly ‘Economic Perspectives’ newsletter, which covered with panache a broad range of topical global economic problems. One innovative idea, first developed in the newsletter and then formally published in his ‘Primer on Emerging Market Crises’ (2002) was to apply ‘value at risk’ analysis to the balance sheet of a country. In his primer, he wrote:

…the right answer to crisis avoidance is controlling risk. The appropriate conceptual framework is value at risk (VAR) – a model-driven estimate of the maximum risk for a particular balance sheet situation over a specified horizon. There are surely genuine issues with the specifics of VAR surrounding modelling as has been widely discussed with respect to bank risk models used for meeting BIS requirements. But just as surely there is no issue whatsoever in recognizing that this general approach is the right one. If authorities everywhere enforced a culture of risk-oriented evaluation of balance sheets, extreme situations such as those of Asia in 1997 would disappear or, at the least, become a rare species. (2002, pp. 743–54)

In this short space it has not been possible to do full justice to the range and breadth of Dornbusch's contributions. But I hope the reader has gained some perspective on why he will have a lasting influence.

double-entry bookkeeping

Basil S. Yamey
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Double-entry bookkeeping is a system for arranging and organizing accounting information. It requires that each transaction (or other change) recorded in the accounting system must be recorded twice, and for the same money amount, once in debit form and once in credit form. Because it is concerned with the organization of information rather than with the scope and detail of that information, the system of double-entry bookkeeping is highly adaptable. It neither generates nor requires any particular set of valuation rules or profit concepts, and it is compatible with different treatments for changes in the value of money.

Keywords

accounting; assets and liabilities; balance-sheet equation; double-entry bookkeeping; national accounting; Pacioli, L.; Sombart, W.; Spengler, O.; transaction analysis; van Gezel, W.

Article

Firms of all kinds need, in different degrees, to maintain records of their transactions with other firms and persons, of the debts they owe or are owed, and of their assets. The records they keep for this purpose constitute their accounting records. Traditionally they have consisted of account-books of various kinds, but they can take the form also of magnetic tapes and so on. If the records are kept on a systematic basis, one can speak of an accounting system. From the accounting records one can prepare a variety of accounting statements in which the detailed accounting information is rearranged, regrouped and presented in summary form. The balance sheet and the profit-and-loss (or income) account or statement are important examples of such accounting statements.

Double-entry bookkeeping is a system or method for the arrangement and classification of accounting information. It developed in Italy, possibly in the second half of the 13th century. A description of the system was first published in Venice in 1494 as one part of a famous compendium of mathematical and commercial information: Luca Pacioli's *Summa de Arithmetica Geometria Proportioni et
Proportionalità. Knowledge of the double-entry system spread gradually from Italy to the rest of Europe by way of commercial contacts, schools and published treatises. It is not possible to establish how widely the system was used by merchants and others, say, in the 18th century. But by the late 19th century it had become the standard system for accounting records. Today it is used by virtually all corporate enterprises and many other firms as well as non-profit-making organizations in the West and also elsewhere. It has also proved suitable to serve as a useful scaffolding for the construction of the national income and related accounts for countries or regions.

Double-entry bookkeeping is no more than a system for arranging and organizing accounting information. It does not itself define the scope and detail of that information. Thus, for example, the double-entry system does not require that all transactions with third parties should be recorded, although it is the convention now to record all of them. What is more important, it does not prescribe which occurrences or changes that do not involve external transactions should be recorded in the accounts. Thus it does not prescribe whether changes in the value of the firm's assets should be recorded, how they should be determined, or how they should be recorded. Double entry neither generates nor requires any particular set of valuation rules or profit concepts. Different valuation bases or conventions, and different treatments for changes in the value of money, are all compatible with the use of the double-entry system. The system itself is highly adaptable, since it is concerned with arrangement and organization rather than with scope and content. Its adaptability has made it possible for it to serve as the basis for arranging the records needed by the relatively small-scale merchants in the early modern period of economic expansion as well as for those of the largest corporate enterprises operating today. But this does not mean that asset values were recorded and profits calculated in the same way by 17th-century merchants as they are by today's corporate enterprises. In fact, 17th-century merchants used several alternative bases for recording changes in asset values. And some of these would not be used by companies today.

Moreover, although all the companies within the same jurisdiction are subject to the same laws and the same institutional constraints (for example, those imposed by the stock-market authorities and those reflecting professional accounting standards), there is still scope for considerable variation in the determination and statement of accounting profits and asset values. However, because of developments in legislation and in the other constraining forces operating on corporate enterprises, it is no longer the case that a company chairman in the United Kingdom would be able to say (as Arthur Chamberlain, chairman of Tube Investments said in 1935) that he ‘would almost undertake to draw up two balance-sheets for the same company, both coming within an auditor's statutory certificate, in which practically the only recognizable items would be the name and the capital authorised and issued’.

Double entry requires that each transaction (or other event) recorded in the accounting system must be recorded twice, and for the same money amount, once in debit form and once in credit form. In double entry, as Pacioli expressed it, ‘all the entries placed in the ledger must be double, that is if you make a creditor (entry) you must make a debtor (entry)’. The debit and credit entries are made in the ledger, on the basis of the information entered in preliminary records. The ledger, which may for convenience be subdivided into a series of specialized ledgers, consists of a number of ledger accounts, pertaining, for example, to particular debtors or creditors, particular assets or particular categories of expenditure. It is the convention that the debit entry is made on the left-hand (debit) side of the appropriate ledger account, and the corresponding off-setting credit entry on the right-hand (credit) side of the other appropriate ledger account.
The duality of entries for each transaction (or other recorded event) ties together the ledger accounts into an interlocking system of recorded information. Moreover, as each transaction gives rise to two equal but opposite entries, the system of accounts (if properly kept) is always in balance or equilibrium. The total of debit entries must be equal to the total of credit entries. Similarly, the total of the balances on all ledger accounts that have debit balances must be equal to the total of the balances on all the remaining ledger accounts that have credit balances. (If debit balances are taken as positive amounts and credit balances as negative amounts, the algebraic sum of the balances on all ledger accounts is zero.) The equality of debits and credits is the basis for the trial balance. This is a list of the balances on all open (that is, unbalanced) accounts in the ledger, distinguishing between debit and credit balances. If the trial balance does not balance, there is some error in the ledger. Postlethwayt in his Dictionary (1751) wrote of the ‘agreeable satisfaction’ of getting a trial balance to balance, and said that the trial balance will ‘shew you that this [double entry], of all methods, is the most excellent’. The fact that a trial balance does not balance is proof that the ledger does contain some error. The converse is, of course, not correct.

Roger North, son of the prominent Turkey merchant Sir Dudley North, wrote in 1714 as follows: ‘The making true Drs. (debtors) and Crs. (creditors) is the greatest Difficulty of Accompting, and perpetually exerciseth the Judgment; being an Act of the Mind, intent upon the Nature and Truth of Things.’ Writers of instructional books on bookkeeping and accounts through the centuries have devised various lists, rules or approaches to help the accountant decide which debit and credit entries he should make for the various categories of transaction.

An early rule, widely used, was as follows (taken from a verse, ‘Rules to be Observed’, in a book of 1553 by James Peele):

To make the thinges Received, or the receiver,
Debter to the thinges delivered, or to the deliverer.

This rule is obviously readily applicable to many categories of transaction. If cash is received from a debtor, debit the cash account; and credit the debtor's account. If office furniture is bought on credit, debit the furniture account; and credit the supplier's account. If the owner withdraws cash from the business, debit the capital (that is, owner's) account; and credit the cash account. But it is evidently a straining of the language to say, when an amount is written off the book value of, say, a ship, in order to reflect diminution of value due to wear and tear, that the profit-and-loss account, which is to be debited, ‘receives’ something that has been ‘delivered’ to it by the ship account. Teachers and textbook writers not surprisingly looked for a rule that is robust enough to cover comfortably all transactions and events to be recorded, and to indicate unambiguously in each case where the debit and where the credit are to be placed.

The most common rule or approach adopted today in transaction analysis in the double-entry system derives from the so-called balance-sheet equation. The earliest formulation of this approach can be traced to the work of a Dutchman, Willem van Gezel, published in 1681.

The basic balance-sheet equation is:

Owner's Equity
(or the firm's net worth)=Assets – Liabilities=Net Assets; or Owner's Equity
+Liabilities=Assets.
The ledger contains accounts for the various assets and liabilities; and there are accounts in it for the capital contributed or withdrawn by the owner(s) and for any increases (decreases) in ‘net worth’ resulting from the activities of the firm. In the double-entry system, increases in assets are indicated by debits to an asset account – the extent to which assets are subdivided into separate ledger accounts is for each firm to decide. Conversely, decreases in assets are recorded as credits to asset accounts. The total of a firm’s assets is represented by the total of claims on those assets; namely, its liabilities (that is, its debts to third parties) and its owner’s equity. The total of these claims must be a credit amount that equals the debit amount representing the assets. An increase (decrease) in a claim is therefore represented by a credit (debit) in a liability account or an equity account. (Again, the extent to which claims are subdivided into various ledger accounts is a matter for each firm to decide. As regards the equity element, it is common for a ledger to contain separate accounts for each major category of business expenditure and income, a trading account, perhaps subdivided by type of activity, for showing the gross profit, and a profit-and-loss account to bring together the results from all the subordinate ledger accounts.)

Transaction analysis follows readily. The payment of salaries reduces the asset ‘cash’ and reduces the owner's equity, since the payment, taken by itself, represents a loss to the firm: hence, debit the salaries (eventually, profit-and-loss) account; and credit the cash account. The depreciation of an asset likewise reduces an asset and reduces the equity: debit the depreciation account (eventually profit-and-loss) account; and credit the ship account.

As has already been emphasized, the double-entry system does not itself dictate whether or in what circumstances increases or decreases in assets are to be recognized in the accounts. Neither does the system dictate the basis on which, or the circumstances in which, assets are to be revalued in the accounts. Decisions of these kinds are accounting decisions; and whenever such decisions are taken, the double-entry system of recording will accommodate them in accordance with its own logical structure. It follows from this that, although the value of the owner’s equity in the ledger will always be equal to the value of the firm’s net assets (that is, assets minus liabilities to those outside the firm) as stated in the accounts, those two values depend on the bases on which the values of assets are stated in the accounts. Subject to this crucial qualification, it follows from the equilibrium feature of the double-entry system that the change (increase or decrease) in the value of the net assets of a firm over a period will be reflected as entries in the various ledger accounts that represent the owner’s equity. Those entries in the various equity accounts that relate to the firm's operations, when they are brought together in the profit-and-loss account, yield a balance that is equal to the change in the value of the net assets over the period. It is the profit (loss) for the period. This profit is equal to the change in the value of the net assets over the period (allowance being made for any contributions or withdrawals of assets by the owner). It may be noted that the same profit figure would be established if one took the difference between the totals of two inventories of the firm's net assets taken, respectively, at the beginning and at the end of the period, provided that the same valuations were used and the same allowance made for the owner's contributions and withdrawals. The method of profit calculation by means of successive inventories of assets and liabilities was widely used in the past. The surviving 16th-century records of the large-scale commercial, financial and mining enterprise of the Fugger family of Augsburg provide examples of this procedure.

The equality – Profit (Loss) = Change in Net Assets – evidently holds only if all the changes recorded in asset and liability accounts (other than the owner's contributions or withdrawals) are also recorded in
equity accounts that, in turn, are closed into the profit-and-loss account. In contemporary corporate financial accounting it is permissible to allow the counter-entries representing certain changes in asset values, depending upon the circumstances, to bypass the profit-and-loss account (for example, by recording these changes as debits or credits to one or other reserve account). This practice breaks the nexus between changes in net asset values and profits. It does, however, allow more ‘realistic’ values to be used in asset accounts where, otherwise, their use might produce ‘distortions’ in the profit figures that could mislead users such as investors and investment advisers. Both ‘realistic’ and ‘distortions’ are words that give rise to much debate in accounting circles. The double-entry recording system can accommodate the practice of bypassing the profit-and-loss account as comfortably as it can the alternative. The system itself imposes no discipline or constraint upon accountant or management – except the constraint that for each transaction or change recorded in the firm's accounting system, equal but offsetting debit and credit entries have to be made in accounts in the ledger.

The German economic historian, Werner Sombart, claimed that ‘capitalism without double-entry bookkeeping is simply inconceivable’, and that double-entry was one of the most significant inventions or creations of the human spirit. In similar vein, Oswald Spengler asserted that the creator of double-entry bookkeeping could take his place worthily beside his contemporaries Columbus and Copernicus. These scholars evidently attributed to the double-entry system a role that goes well beyond what one might think appropriate to ascribe to a system of organizing and arranging accounting data. In a nutshell, Sombart argued that, historically, the double-entry system opened up possibilities and provided stimuli that enabled capitalism to develop fully. It clarified the acquisitive ends of commerce and provided the rational basis on which this acquisition could be carried on. It provided the basis for the continued rational pursuit of profits, and virtually compelled its users to pursue the acquisition of wealth. It also enabled the firm or enterprise to be separated from its owners, thus facilitating the development of corporate enterprises.

These views are in their details either untenable or grossly exaggerated. To note only a few points: the profits of an enterprise and its capital employed can be calculated without double-entry bookkeeping; joint-stock companies, such as the Dutch East India Company, have existed and flourished without double-entry bookkeeping; 16th- and 17th-century merchants, like the Fugger, who did not use the system do not seem to have been any less acquisitive, rational and successful than those who did use the system; and the adoption of the double-entry system could not have changed, or even have reinforced, the temperament, commercial acumen, motivation or goals of those who adopted it for organizing their accounting records.

To reject grandiose claims made for double-entry bookkeeping is not to deny the more workaday usefulness of the system. A method or system for recording and classifying accounting data that has been used increasingly over a period of six centuries must indeed have substantial practical merit. Double entry is a useful and versatile method for organizing accounting data, its value increasing with the volume and complexity of the data to be organized. In turn, the efficient organization of data helps management at various levels in many ways, more notably in large organizations. But its contribution to efficiency does not proceed along the lines emphasized by Sombart.

Keywords

agricultural economics; climacteric (of 1896–1914); Cobb, C. W.; Cobb–Douglas functions; Douglas, P. H.; Phelps Brown, H.; real wage growth

Article

Born in 1892 in Salem, Massachusetts, Paul Douglas attended Bowdoin College in Maine (BA, 1913) and Columbia University (Ph.D., 1921). After holding a number of teaching posts between 1916 and 1920, he joined the faculty of the University of Chicago where he remained (apart from service in the Second World War) until 1948, when he became a United States Senator from Illinois. After his retirement from the Senate in 1966, he taught at the New School for Social Research for two years (1967–9).

Paul Douglas first became well known for his massive theoretical and factual studies (for example, 1930) of all the available information on wages in the United States from 1890. This work required laborious following up of old, obscure records, and repairing gaps in the available knowledge, such as domestic service wages. Douglas also collected information on prices so as to make an estimate of the movement of real wages.

In Britain there was almost complete cessation of the growth of real wages between 1896 and 1914. Understandably, it was a period of growing social tension. Sir Henry Phelps Brown called it the ‘climacteric’. We still do not really understand its cause; there was some sociological evidence about the deterioration of the quality of businessmen. D.H. Robertson found at least a partial explanation in economic causes, namely, that, of the two leading British export industries, cotton was produced under constant returns and coal under diminishing returns.

This problem remains of primary interest to economic historians, and naturally they enquire whether there is any evidence of a similar ‘climacteric’ in other countries. In Germany there was a slowing down of the rate of rise in real wages, but not very marked. Douglas's American data likewise do not show such a ‘climacteric’. Recent research, however, has thrown some doubt not on Douglas's wage data, but on his price data; and perhaps there was some slowing down of the rate of growth of real wages.
Douglas became famous to the whole economic world through the ‘Cobb–Douglas function’ (for example, 1934). Working in conjunction with Charles W. Cobb, a mathematician from Amherst College, and using Massachusetts State annual factory returns, Douglas in 1928 established the following relation: Let product be \( P \), labour input \( L \), capital input \( C \), and \( k \) a constant. Then \( P = kL^aC^b \).

(The same formula, with land in place of capital, had already been used by Wicksell – for example, 1900 – but he gave it neither theoretical nor empirical development.)

We may, if we wish, constrain \( a \) and \( b \) to add up to 1; but we get much the same results unconstrained. If \( a \) and \( b \) add up to more than 1 this is an indication of economies of scale (increasing returns) – a uniform increase in the quantities of inputs giving a more than proportionate increase in product.

Annual data, which many economists have been using, give results mainly dependent on fluctuations in the short-period business cycle – which is not what we want at all. It is only when we have data for such a long period as to make it possible to average out the business cycle that we can draw conclusions about productivity. This has been done by Solow in the United States, Aukrust in Norway, and Niitamo in Finland. In each case it was found, in the long run, that the product was rising much more rapidly than expected from inputs and their exponents. This difference is generally held to be due to technical advance, though some look for economies of scale. Some difficult but promising work by Denison further analyses the labour input by numerous categories, male and female, adult and juvenile, and various levels of education. These methods reduce the unknown factor – but it does not disappear.

Differentiating the Cobb–Douglas formula to obtain marginal productivities, then aggregate earnings of the factors should be proportional to \( a:b \) – assuming that each factor is remunerated according to its marginal productivity. When he first made this calculation (so he told me), Douglas fully expected the aggregate income of labour to be below that indicated by its marginal productivity. He was surprised, however, to find that it was almost exactly what was to be expected – about 75 per cent of the product.

The Cobb–Douglas formula has had abundant application in agricultural economics, especially for cross-section studies, where each farm may be considered an independent piece of evidence. Land is introduced as a factor, and also data for other inputs – fertilizers, insecticides, and so on – even (in one study in Sweden) the age of the farmer – a negative factor.

Douglas was very much a political economist. Organized labour in the United States did not attempt to form a political party of its own as in Britain, but instead played the two existing parties off against each other in demanding concessions. But in the 1920s this was not fully agreed. The other element in the population with a grievance against the current state of affairs was the farmers, and an attempt was made to form a Farmer–Labour political party. Douglas took an active part in these negotiations, and was national treasurer of the organization. But with the Roosevelt reforms of the 1930s the prospects of a Farmer–Labour party died away.

Chicago had acquired a worldwide reputation for corruption and crime; and the ruling Democratic Party considered that its ‘image’ would be improved by an upright professor of economics on the city council. Douglas assured me that some improvement had taken place, though less than was hoped for. Later, the despotic Mayor Daley achieved a real reduction in crime. But once I asked Douglas whether, if I wished to set up a milk distribution business in Chicago, he could guarantee my safety. He replied that, ‘regrettably’, he could not.

Douglas was a Quaker, and in the First World War applied for exemption from military service on religious grounds. But in the Second World War he felt very differently. In spite of his age, he obtained a commission in the marines through President Roosevelt's personal intervention, and took part in the
bloody landing on Iwojima. He sustained an injury to his hand which was with him for the rest of his life. From city councillor he advanced to become Senator for Illinois. On the very day that he arrived in Washington he found a vanload of furniture which had been offered to him as a gift. He sent it back. This episode prompted him to write a little book, *Ethics in Government* (1952). He saw no harm in the small presents customarily exchanged among businessmen and politicians – calendars, cigars, and so on – but instructed his staff to return any present valued at over four dollars.

Du Pont de Nemours, Pierre Samuel (1739–1817)

Peter Groenewegen

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
advisers; assignats; Du Pont de Nemours, P. S.; excise taxes; mathematical economics; Mercier de la Rivière, P.-P.; Mirabeau, V. R., Marquis de; Physiocracy; Quesnay, F.; silver; Turgot, A. R. J.

Article

Economic writer and editor. Born in Paris, he trained for various occupations including medicine and watch making. A pamphlet on taxation (1763) brought him in contact with Mirabeau and Quesnay, under whose guidance he wrote a work on the grain trade (1764). He also befriended Turgot, with whom he diligently corresponded until Turgot's death. From 1766 to late 1768 he edited the Journal de l'Agriculture in the Physiocratic cause, then the Ephémérides until 1772. During this period he also published Quesnay's economics under the title Physiocratie (Du Pont, 1767) and summarized Mercier (1767), adding material on the history of the new science (Du Pont, 1768). From the early 1770s he developed a career as economic adviser through correspondence with the King of Sweden and the Margrave of Baden; the correspondence with the latter was subsequently published (Knies, 1892). In 1774 he was appointed tutor to the Polish royal family. On becoming contrôleur-général, Turgot required his friend's assistance and Du Pont was back in Paris by early 1775. Financial compensation for loss of his royal tutorship enabled him to purchase landed property near Nemours. Turgot's dismissal from office in 1776 did not end Du Pont's career in giving official economic advice; a highlight of which is his influence on the 1786 Anglo–French Commercial Treaty. Du Pont was politically active in the French Revolution, serving from 1789 as Deputy for Nemours in the National Assembly and becoming its President during 1790; in 1794 to 1797 he was imprisoned for short periods. He migrated to the United States in 1799 but returned to Paris in 1802. From 1803 to 1810 he served in the Paris Chamber of Commerce, and in addition edited Turgot's works (Du Pont, 1808–11). In 1815 he returned to the United States and settled in Delaware, the town where his son Irenée had started the gunpowder factory from which the Du Pont chemical conglomerate developed, and where he died in 1817. Du Pont is now mainly remembered as a major propagator of Physiocracy, an early historian of economics, a pioneer in the use of diagrams in economic argument and, most importantly, as the editor of Quesnay and Turgot.

whose works he helped to preserve. An assessment of his work as economist needs to take all facets of his career into account, as the one full-length attempt at this (McLain, 1977) has in fact done. Virtually all Du Pont's economic work is characterized by dogmatic adherence to the Physiocracy developed by Quesnay and codified by Mercier de la Rivière. Turgot criticized this ‘servitude to the ideas of the master’ as totally inappropriate in matters of science (Schelle, 1913–23, vol. 2, p. 677). Despite such criticism Du Pont allowed his dogmatism to colour excursions into the history of economics (Du Pont, 1769) and, more importantly, his preparation of Turgot's works for the press (see Groenewegen, 1977), particularly his editions of the Reflections (Turgot, 1766). Two examples of his more novel contributions to economics can be given. One is his use of diagrams in explaining economic policy, which Theocharis (1961, p. 60) described as the first use of a diagram by a professional economist for ‘illustrating an economic argument set out in essentially dynamic time’, thereby making Du Pont (1774) ‘the earliest French contribution of importance in mathematical economics’. The problem analysed is the price effects of an excise reduction, the benefits of which are argued to accrue ultimately to the landowning class. The excise reduction's initial income effect on manufacturers and merchants allows them either to reduce their own prices or to pay higher prices for raw materials. By assuming this increased competition for raw materials to raise their price in each period by three-fourths of the increase in the preceding period, Du Pont shows how a new equilibrium price will be reached which transfers the benefits from excise reduction to the rural sector. His proof relies on the properties of diminishing geometrical progressions which also formed the basis for much of the analysis of the Tableau économique. Du Pont's analysis of the inflationary consequences from issuing assignats is a second example. Although much of this is similar to Turgot's (1749) analysis, some of it is of interest in explaining Smith's version of the specie mechanism to which Du Pont (1790, p. 28) explicitly refers. Issuing paper money by assignats makes silver superfluous as a circulating medium; this drives the metal out of the country because its only other use is to be sold abroad (Du Pont, 1790, p. 42), a specie mechanism like Smith's (1776, pp. 293–4) that is independent of relative price movements. Both examples of his more original economics relate to matters of economic policy and add force to the claim by McLain (1977, p. 255) that Du Pont represents ‘the first important case of a professional economist turned government policy-maker, a tradition in which he would be followed by [many] others…’.

dual economies

David Vines and Andrew Zeitlin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Dual economies have asymmetric sectors, the interaction between which influences the path of development. These are typically a rural, traditional, or agricultural sector on one hand, and an urban, modern, or industrial sector on the other. The relevant asymmetries are not merely technological but also include institutional, behavioural, and informational aspects. Modern treatments have grown out of the work of W. Arthur Lewis, whose model was based on the existence of surplus labour in agriculture. Subsequent authors have considered the implications of alternative assumptions for the development of a dual economy.

Article

Dual economies have asymmetric sectors, the interaction between which influences the path of development. W. Arthur Lewis introduced this idea in his paper, ‘Economic Development with Unlimited Supplies of Labour’ (Lewis, 1954), which earned him the Nobel Prize for Economics in 1979. That paper contains two theoretical models, both designed to explain the intrinsic problems of underdevelopment. When the prize was awarded, Ronald Findlay wrote that ‘a large part of … development economics … can be seen as an extended commentary on the meaning and ramifications [of this article]’ (Findlay, 1980, p. 64). Here we focus primarily on the first of Lewis's two models of
dual economies: The New Palgrave Dictionary of Economics

dualism – that of a single underdeveloped economy. We describe that model, trace the evolution of the ideas which grew from it, and discuss the continuing importance of these ideas in the study of economic development.

Long before Lewis wrote his article, there had been much thinking about ‘dual’ economies, conceived of as economies with both an industrial sector and an agricultural sector. Adam Smith and David Ricardo both focused on the interaction between these sectors during the Industrial Revolution; for Ricardo the outlook for industrial growth was ‘dismal’ because of diminishing returns in agriculture (see Hicks, 1965; Pasinetti, 1974). In the early 20th century, there was an extended discussion in the Soviet Union of the ‘scissors problem’, concerning the determination of the terms of trade between these two sectors. Evgeny Preobrazhensky (1924) argued that a decrease in the relative price of agricultural goods could be used to stimulate industrial investment; others replied that sufficient agricultural goods would not be available at lower relative prices and that these goods would need to be seized by force, something which the collectivization of agriculture made possible (see Sah and Stiglitz, 1984). And during the Great Leap Forward in China in the 1950s, Chairman Mao attempted to confiscate an increasing quantity of primary goods from the Chinese countryside in order to facilitate the development of urban manufacturing. These policies led to famine and to the deaths of approximately 30 million people. Thus both theorists and policymakers have long recognized that, in an economy with two very different sectors, growth prospects hinge on how these sectors interact.

In his Nobel Prize autobiography, Lewis (1979) writes that his interest was in the ‘fundamental forces determining the rate of economic growth’. But he was not satisfied with the neoclassical model of growth that was emerging at the time (Solow, 1956; Swan, 1956), out of the work of Roy F. Harrod (1939) and Evsey D. Domar (1945). That neoclassical framework aimed to provide a general theory of growth. But to Lewis it seemed inadequate because it did not deal with interactions between the industrial and the agricultural sectors: in Lewis's words, this model contained no discussion ‘of what determines the relative price of steel and coffee [namely, of industrial goods and agricultural goods]. The approach through marginal utility made no sense to me. And the Heckscher–Ohlin framework could not be used, since that assumes that trading partners have the same production functions, whereas coffee cannot be grown in most of the steel-producing countries.’ Furthermore, the neoclassical theory seemed inadequate to him for historical reasons: ‘[a]pparently, during the first fifty years of the industrial revolution, real wages in Britain remained more or less constant while profits and savings soared. This could [also] not be squared with the neoclassical framework, in which a rise in investment should raise wages and depress the rate of return on capital’ (Lewis, 1979).

Then, Lewis continues:

One day in August, 1952, walking down the road in Bangkok, it came to me suddenly that both problems have the same solution. Throw away the neoclassical assumption that the quantity of labour is fixed. An ‘unlimited supply of labour’ will keep wages down, producing cheap coffee in the first case and high profits in the second case. The result is a dual (national or world) economy, where one part is a reservoir of cheap labour for the other. The unlimited supply of labour derives ultimately from population pressure, so it is a phase in the demographic cycle. (Lewis, 1979, p. 397)
This key insight launched Lewis on the journey that led to his famous article. Spelling out the implications of his insight led him to use the term ‘dualism’ to describe economies in which there are differences between industrial and agricultural sectors that cannot be adequately explained by differences in production technologies or in factor endowments, in the manner normally used by economists.

The Lewis model

Lewis identified three such differences between industry and agriculture, which we term ‘asymmetries’ in this article (following Kanbur and McIntosh, 1987).

First, there are technological differences between the sectors. Labour is used in each sector. In agriculture it is combined with land in production, whereas industrial goods are produced by combining labour with reproducible capital. Moreover, industrial goods can be consumed or invested, whereas agricultural goods can only be consumed.

Second, there are organizational differences between the sectors. The large, rural agricultural sector functions on traditional lines and is primarily based on subsistence; industrial production happens in a modern, market-oriented sector, located in towns and cities. There is ‘an unlimited supply of labour, available at [a] subsistence wage’ (Lewis 1954, p. 139) to both sectors. Lewis interprets the word ‘subsistence’ broadly. The level of the wage is determined in some way by conventions in the underdeveloped agricultural sector. Lewis is non-committal as to whether wages in this sector are set according to actual subsistence needs, or living standards, or workers’ average product. The central idea is that workers are paid above their marginal product. Labour can be transferred from agricultural sector to the industrial sector by the migration of workers to towns and cities. The overall stock of labour in the economy is normally fixed in supply (though Lewis, like Ricardo, did sometimes allow for Malthusian features). Workers in the cities are paid not much more than the subsistence wage, although there may be a gap, as discussed below.

Third, and finally, there are differences in the behaviour of the actors in the two sectors. Capitalists in the industrial sector save all their profits, because they are ambitious. Workers save nothing, in either sector, because they are poor (Lewis describes them as not belonging to the ‘the saving class’ – 1954, p. 157). And landlords in agriculture are assumed to consume all their income, which comes to them to the extent that agricultural workers receive a wage below their average product.

The general story is this: the profits in the modern, capitalist, sector create a growing supply of savings. This finances the formation of an increasing stock of capital, which is used to employ more and more labour in the urban workforce.

We can explain the story in detail, using a simplified version of the model. To do this we make four sets of extreme assumptions. (a) There is ‘pure’ surplus labour, by which we mean that the marginal product of workers withdrawn from agriculture is zero. Wages initially consist only of agricultural goods, the level of wages per worker is exogenous, and workers are indifferent between working in industry and in agriculture at the same wage. (b) When one individual worker leaves agriculture and no longer needs to be rewarded there, then all the increase in the agricultural surplus (that is, all the increase in the total of food produced minus the total of wages paid to agricultural workers) accrues to landlords and is spent by them on consumption of industrial goods. (c) Industrial capitalists employ labour up to the point at which the marginal physical product of labour is equal to the cost of the wage, measured in industrial
goods. (d) All industrial profits are saved and then invested in industrial production. Given these assumptions, there are two steps to the argument. First, given assumptions (a), (c) and (d), the rate of growth depends negatively on the relative price of agricultural goods in terms of industrial goods. This is because an increase in food prices raises the cost of the wage per worker in terms of steel, causing less labour-intensive methods of production to be adopted, that is, causing production to become more capital intensive. As a result of this, any given amount of savings, and the accumulation of capital that it causes, will ‘go less far’ in employing labour in industry, and, as a result, industrial output will grow less rapidly. Second, assumptions (a) and (b) determine the relative price of agricultural goods, in the following way: the accumulation of capital in industry increases the demand for industrial workers, who must be transferred from agriculture. The relative price of agricultural goods will need to be high enough to induce the workers’ landlords to offer up those agricultural goods that they would have paid to the transferred workers but now receive as surplus, so as to receive industrial goods for consumption in exchange. Such trade enables workers to be paid in industry, where they now work. As Lewis (1954, p. 188) says, ‘the capitalists need the peasants’ food, and … the demand for food is inelastic’.

Clearly, the relative prices of industrial and agricultural goods, and the growth rate of the economy, are jointly determined in this process – as Lewis's intuition had suggested to him. And it will clearly be true that the relative price of agricultural goods will need to be less high – and so the rate of growth will be higher – the lower is the price of agricultural goods required for landlords to release their surplus in exchange for consumable industrial goods.

Note that the share of income that accrues to industrial capitalists will increase during the growth process, as the capitalist sector grows in size. This suggested to Lewis (1954, p. 155) that a growth process of this kind might help to solve what he called the ‘central problem’ of development: the need to raise the savings rate enough to enable rapid growth to take place. In this model it is necessary to transfer labour into industry, in order to increase the overall savings rate of the economy. This is due to the behavioural assumption that agricultural income is not saved; we revisit this assumption below. Interestingly – from today's point of view – Lewis thought that a savings rate of ten to twelve per cent might be sufficient to achieve the ‘rapid capital accumulation’ that he believed integral to the process of development (Lewis, 1954, p. 155). Note also that increasing inequality is a frequent, if not necessary, correlate to this rising savings share, at least in the early stages of development (see, for example, Fei et al., 1979). This story thus also provides an explanation of the ‘Kuznets curve’.

**Generalizations**

Lewis does sometimes enlist the extreme simplifications made above. They correspond most closely to those made by Gustav Ranis and John C. H. Fei (1961), who used them to explain, more formally than Lewis did, what they call the ‘first phase’ of economic development – a phase in which there is ‘pure’ surplus labour. But Lewis also hints at many ways in which these assumptions could be relaxed. Ranis and Fei, along with Dale W. Jorgenson (and many others), went on to consider the implications of dualism when there are sectoral asymmetries different from those outlined above. In what follows, we consider a number of these extensions.

The first, and most fundamental, generalization of Lewis's model was made by Ranis and Fei (1961), who demonstrated that the dualistic framework continued to give insight into the process of economic
growth even when the condition of pure surplus labour does not hold. They initiated a large body work on this question by examining the microeconomic foundations of surplus labour and exploring what occurs when these conditions come to an end. This occurs when a sufficient number of workers have been removed from agriculture for the marginal productivity of the remaining agricultural workers to become positive. As a result, agricultural output declines as further workers leave. (This may happen even if there is technological progress in agriculture, providing that this progress is not sufficient to fully compensate for lost labour.) Consequently, the marginal agricultural surplus per worker, which accrues to landlords as each worker leaves – and which is traded by landlords for industrial goods – begins to decline, even if the wage per worker (measured in terms of agricultural goods) is exogenous. This means that the cost of labour to industry, measured in terms of industrial goods, will begin to rise above the level described in the sketch above – thereby constraining the rate of growth. This is the first turning point identified by Ranis and Fei. It corresponds to the onset of Ricardo's 'dismal' diminishing returns. Ranis and Fei label what happens beyond this point as the 'second phase' of economic development. In that phase the economy is characterized by 'disguised unemployment', since labour in agriculture is still paid more than its marginal product.

Lewis himself was accused of not allowing for this possibility, even though he had written that the existence of zero marginal product is 'not… of fundamental importance to our analysis' (Lewis, 1954, p. 142). This accusation led to what Lewis later called an 'irrelevant and intemperate controversy' about the existence, or not, of 'pure' surplus labour (Lewis, 1972, p. 77). Ranis (2003, p. 8) agrees with Lewis's self-defence: in a retrospective assessment, he describes the postulation of a 'pure' labour surplus as a red herring. Amartya Sen (1966) helpfully clarifies the debate about this issue.

Growth becomes more difficult in this second stage of development. Recall that Lewis argues that the real wages per worker, and the level of welfare per worker, do not fall as growth proceeds. But growth is driven by the transfer of labour from agriculture to industry, which, in this second phase, causes agricultural output to fall. As a consequence of this the relative price of agricultural goods rises, and real wages can remain constant only if workers are able to substitute towards industrial goods in such a way as to avoid any damage to their welfare.

The agricultural sector as a constraint on growth

To highlight the essential role of such substitution, Mukesh Eswaran and Ashok Kotwal (1993) assume an extreme version of Engel's law. Consumers are assumed to spend all their income on food until they reach a particular threshold level of consumption, when they become sated with food. Beyond this point all further increases in consumption are devoted to industrial goods. At the same time they assume that labour always has a positive marginal product in agriculture. Under these assumptions, if workers remain so poor that they are not sated with food, then the transfer of labour across sectors – and therefore accumulation of industrial capital – becomes impossible. The inability of the poor to ‘eat shirts’ – an extreme version of what Ranis (2003) describes as the ‘product’ dimension of dualism – becomes a constraint on whether savings can lead to development. (And this constraint will bind quite independently of how high the marginal physical product of labour is in industry.) Any attempt to increase savings rates, in the manner desired by Lewis, so as to draw labour out of agriculture, would fail in these circumstances. The withdrawal of labour would lead to a reduction in the supply of food per
dual economies: The New Palgrave Dictionary of Economics

worker – the only thing that matters for workers’ real wages – and so to a shortage of food. That shortage would turn the terms of trade against industry, depressing industrial profits and savings until the downward pressure on the supply of food had been removed, or until growth has ceased. As a result, all the gains from any increase in industrial production would accrue, in the form of lower prices, to those who consume industrial goods, rather than enabling growth, as in the Lewis model. It is thus clear that an important influence on whether development can proceed under dualism is the ability to shift workers’ demands away from agricultural goods.

Of course, in a small, open, economy, the relative prices of tradables will be tied down, and the economy can respond to any developing shortage of food simply by exporting manufactures and importing food. That was Ricardo’s insight, over 100 years earlier, about the gains to Britain from the abolition of the Corn Laws; Lewis’s model of dualism in the world economy also incorporates such trade. But Lewis (1972, p. 94) cautions that there may be limits to this if export prices are not really exogenous, and if, instead, the country needs to cheapen its exports to pay for the imports of food – and other goods – that it will need as it grows. Perhaps partly because of this, Lewis (1954, p. 176) argues that a country which exhausts its surplus labour supply might instead export its savings, investing in industrial development in countries where the surplus labour condition continues to hold, and so enabling the output of manufactured goods to grow without driving down the rate of profit. In addition, the country might import labour from these countries. In this way Lewis's early contributions anticipated, and fed into, debates about the roles of outsourcing and immigration in contemporary globalization.

Jorgenson (1961) further develops the study of the dynamics of a dualistic economy in this second phase of development – when there is a positive marginal product of labour in agriculture and disguised unemployment. He incorporates a Malthusian perspective, by supposing that population growth is increasing in the amount of food consumed per capita, up to a biological ceiling that corresponds to the food-consumption threshold of Eswaran and Kotwal. This has the consequence that too rapid a rate of growth of population can cause a Malthusian trap by preventing the emergence of any significant agricultural surplus. Growth of manufacturing activity, such as that analysed by Lewis, can then be sustained only if technological progress in agriculture enables food production to outstrip population growth. (Capital accumulation in agriculture could have a similar effect in a model more general than that used by Jorgenson.) Only then can an agricultural surplus emerge, and grow, and so only then can labour progressively move away from agriculture. If this does not happen, then any increases in profits, savings and capital accumulation in industry become self-defeating, since they turn the terms of trade against industry and so bring down profits and savings, and bring growth to an end, in the way described two paragraphs above.

As stressed by Avinash Dixit (1973, p. 346), such a model focuses on ‘the constraint on growth imposed by the rate of release of labour from agriculture’, whereas in Lewis’s model the focus had been on the ability of capital accumulation in industry to soak up the surplus labour force in agriculture. Nevertheless, as Dixit notes, growth paths in the two models will produce similar outcomes. In particular, in both models one would observe an endogenous rise in the savings rate as development proceeds. And in both models, it may be the case that any attempt to foster growth in industry, by a ‘big push’ to save more, is self-defeating. (This can be true in Jorgenson's model, and as we saw above, it can also be true beyond the ‘first stage’ of growth in the Lewis model, if it is not possible to induce workers to substitute away from agricultural goods.) This is why Jorgenson thought of increases in savings rates as an outcome of development, not as a policy tool which can be used to promote development.
It is worth contrasting this view of potential ‘development traps’ with that which had been put forward in the 1940s by Paul Rosenstein-Rodan (1943), who built on his experience of eastern Europe. Rosenstein-Rodan’s viewpoint also came from thinking about the interaction between agriculture and industry; like Lewis, he argued that development could only come to an agricultural economy through a process of industrialization. This, he argued, is because only industrial capitalists could afford to pay for the large fixed costs that are necessary to enable them to produce goods in a modern way, with low marginal costs. But if most people live in an impoverished agricultural sector then this would constrain their incomes, and so would limit their demand for modern industrial goods. That might make it unprofitable to make the required investment, and so might thwart the process of development. Here, just as for Lewis, a shortage of savings can be the problem of development. But by contrast with Lewis, a big push might fix it, since, roughly speaking, if all capitalists invested at once and paid their workers higher wages, then the demand for industrial goods would grow, making the investment worthwhile. This insight gave birth to the other great analytical engine of development economics, subsequently formalized by Kevin M. Murphy, Andrei Shleifer and Robert W. Vishny (1989) and Kiminori Matsuyama (1991), and well explained by Paul Krugman (1993). Since the pecuniary externalities that allow an economy to escape from a development trap are accessible only in the ‘modern’ sector, asymmetries between sectors are also central to this view.

Further aspects of labour transfer

The Lewis model was also generalized to explain the gap between the wage paid in the rural sector and that paid in the urban sector and to explore the consequences of such a gap. Lewis himself (1954, p. 150) acknowledged the existence of a wage gap, and suggested that it may result from the psychological costs of lifestyle changes, from the need to reward skills accumulated in the urban sector, or from the ability of workers in cities to bargain for higher wages. (This is particularly relevant when we recognize that the urban sector includes government employment and some services.) Subsequent authors took up this question, arguing, for example, that wage premia may arise because they lead to greater productivity through effects on health or employee motivation (for example, Dasgupta and Ray, 1986; Shapiro and Stiglitz, 1984).

The consequences of such a gap, for the process of labour transfer from agriculture to industry, were set out in the celebrated work of John Harris and Michael P. Todaro (1970). It may be that a wage floor in the urban formal sector prevents the market from clearing there. If a wage floor operates, then workers who choose to leave the rural sector face the prospect of receiving an urban wage which is above that of the rural sector, if they get employed, but also face some probability of becoming unemployed. In the simplest version of this model, equilibrium occurs when labour migration equalizes expected income across sectors – an outcome in which the rural wage equals a weighted average of the incomes received by employed and unemployed urban workers, weighted according to the probability of unemployment in the urban sector. Even without this extreme outcome, there are important policy implications in such a model. The more elastic is labour supply to the urban sector with respect to expected income there, the greater the amount of urban unemployment that will be induced by any policies that increase urban wages. This incorporation of urban unemployment into the model also enables one to begin to discuss...
the growth of a third sector: the production of services in cities (see Fields, 1975). Roughly speaking, we can say that services get produced by (some of) those who migrate to cites, but do not get a job in manufacturing.

It is clear that the expansion of the industrial sector will ultimately take the economy beyond the second phase of economic development, in which there is disguised unemployment. This is because withdrawal of labour from agriculture will eventually reach the point at which the marginal product of the remaining labour rises to equality with the subsistence wage. Ranis and Fei call this a ‘second turning point’. At this point the marginal worker, offered a subsistence wage, can now instead offer his or her labour to a higher bidder. From then on the wage (measured in agricultural goods) will begin to rise in both sectors as growth continues. We can say that the ‘dualistic’ structure of the economy then comes to an end, in that the rural economy becomes ‘commercialized’. (Something similar, too, will happen in any services sector.) That leads one back to a labour-scarce economy, the analysis of which is better suited to neoclassical theory. A two-sector neoclassical growth model – something like the model of Hirofumi Uzawa (1961; 1963) – may be a better way to think about growth in these circumstances.

One key strand of the story of dualism that we have been telling is the assumption that capitalists save, but workers (and landlords) do not. Lewis’s explanation of this asymmetry is largely behavioural. But such differences in savings rates between the traditional and the modern sectors might also be explained institutionally, by means of credit-market imperfections. If a technological asymmetry precludes investment in rural areas, and if limited financial development means that rural residents lack access to investment opportunities in manufacturing, then the agricultural surplus will not be used directly to finance investment. Moreover, typical characterizations of credit-market imperfections highlight the moral hazard problems that persist in rural areas because the poor there are unable to provide the kind of collateral required for formal-sector loans. (Small rural landholdings are of limited use as collateral.) Such lack of collateral stands as a barrier to borrowing, even though loans might be used to facilitate growth by promoting education, or capital accumulation, or technical progress in agriculture. (See Ray, 1998, for a summary of these arguments.) By contrast, Abhijit Banerjee and Andrew Newman (1998) provide an alternative perspective, emphasizing a sectoral asymmetry in the informational dimensions of credit-market imperfections, and showing how this can affect the willingness of individual workers to migrate in a dualistic economy. They present a model in which there is access to credit for consumption in rural areas. Given that workers have limited collateral wherever they live, a crucial determinant of their access to credit is the amount of information that lenders have about prospective borrowers. In contrast with the relative anonymity of urban life, small communities of the rural sector may provide superior information about borrowers, and thus foster lending. Banerjee and Newman show that dualism, characterized in terms of this differential severity of information asymmetries, might lead to a suboptimal allocation of labour across sectors. By financing consumption in the rural sector, rural credit might actually provide an incentive for labour to remain there; this incentive could offset the relatively high wages of the modern sector and could thereby impede the development process. Their paper suggests – at the least – that the lens of asymmetric information can shed useful light on the development of such economies.

Defining characteristics of economic dualism
We conclude by noting that we have described a number of reasons for differences between the industrial and agricultural sectors of a developing economy. Just as in Lewis's original article, all these differences go beyond mere asymmetries in production technologies or factor endowments between the sectors. This is why, following Ravi Kanbur and James McIntosh (1987), we would not normally describe the two-sector growth models of Uzawa (1961; 1963) as models of dualism, even though in those models the two sectors have different factor intensities. Nor would we say that the two-sector Hecksher–Ohlin model of international trade is a model of a dualistic economy – even when its two sectors have different factor intensities, and even when the two sectors are labelled ‘agriculture’ and ‘industry’. Furthermore, although the specificity of factors to sectors appears central to Lewis's set-up (with land specific to agriculture and capital specific to industry), this feature does not seem to be sufficient to merit the label of ‘dualism’. Thus, for example, we would not regard the short-run version of the Heckscher–Ohlin trade model presented by J. Peter Neary (1978), with factors specific in each of the two sectors, as portraying a dualistic economy.

Instead, we would argue that the defining characteristic of modern theories of economic dualism lies – just as it did in Lewis's article – in a focus on sectoral asymmetries that are not simply technological. For Lewis, and for Ranis and Fei, there were organizational differences between sectors – in that wages were assumed to be determined by institutional factors in the agricultural sector – and behavioural differences between sectors – in that those in the rural sector were assumed to be unwilling to save, while capitalists were assumed to save everything. A focus on these features might imply that ‘pull’ factors drive labour transfer, and hence economic growth, in a dualistic economy. But since Lewis, economists studying economic development have explored alternative asymmetries between sectors and have reached different conclusions. The model of Eswaran and Kotwal, in which the defining asymmetries are product asymmetries – an assumption that all income is spent on agricultural goods until some threshold – highlights the need for labour productivity increases in agriculture to avoid stagnation of real wages. This is a need that persists even in the presence of rising productivity in industry. Jorgenson, who coupled such a view with a demonstration that Malthusian pressures can prevent income from ever rising above this threshold, showed clearly that growth can be constrained unless the ‘push’ factor of growth in agricultural technology is strong enough. Banerjee and Newman, by contrast, have emphasized that informational asymmetries between traditional and modern sectors can constrain the growth process.

We thus believe that, in the study of any particular economy, it is important to understand which asymmetries impose binding constraints on growth. Different constraints imply the need for different policies. But identifying the relevant asymmetries is even more important if we wish to remove these underlying constraints themselves. Joseph Stiglitz has proposed that we do just this, advocating what he calls ‘growth strategies based on duality's elimination’ (Stiglitz, 1999, p. 56). Much empirical work is necessary if we are to understand what such strategies might require.

Dual track liberalization is a reform strategy in which a market track is introduced while the plan track is maintained at the same time. Dual track liberation is Pareto improving in the sense that it makes some people better off without making anybody worse off. Because prices are liberalized at the margin, dual track liberalization can also achieve efficiency. China used the dual track reform strategy in liberalizing many markets such as the markets of agricultural goods, industrial goods, consumer goods, foreign exchange, and labour, as well as in creating special economic zones.

Article

Dual track liberalization is a reform strategy of market liberalization in which a market track is introduced while the plan track is maintained at the same time. Under the plan track, economic agents are assigned rights to and obligations for a fixed quantity of goods and services at fixed planned prices as specified in the pre-existing plan. Under the market track, economic agents can participate in the market at free market prices, provided that they fulfil their obligations under the pre-existing plan. The essential feature of the dual track strategy to market liberalization is that prices are liberalized at the margin while inframarginal plan prices and quotas are maintained for some time before being phased out. Although the dual track reform strategy is widely adopted in China during its transition from plan to market, it is also used in other countries. For example, when introducing new legislation, a ‘grandfathering’ clause is often adopted to protect existing interests, which is a form of the dual track approach to reform.

Analysis of dual track liberalization follows two lines of approach. The first focuses on its Pareto-improvement property, that is, dual track liberation makes nobody worse off while it makes somebody better off – and therefore it has a political advantage in implementing reforms. Most efficiency-improving market liberalization reforms potentially create winners and losers, despite the fact that, in theory, efficiency gains should be large enough to allow the potential losers to be compensated. For example, the single track approach to liberalization (that is, where all the prices are freed at once) in general cannot guarantee an outcome without losers. Dual track liberalization means that planned quantity continues to be delivered at plan price but any additional quantity can be sold freely in the market. With the dual track, the surpluses of the rationed users and the planned suppliers remain exactly the same. The purpose of maintaining the plan track is to provide implicit transfers to compensate potential losers from market liberalization by protecting status quo rents under the pre-existing plan. On the one hand, the introduction of the market track provides the opportunity for economic agents who participate in it to be better off. At the same time, the new users and suppliers outside the plan are also better off. Therefore, the intuitive appeal of dual track liberalization for reformers lies precisely in the fact that it represents a mechanism of the implementation of a reform without creating losers (Lau, Qian and Roland, 2000).

The second approach focuses on the efficiency property of dual track liberalization. Pareto-improvement property implies that it always improves efficiency. This is independent of other assumptions, for example, as to whether the market is competitive or not. In contrast, the single track approach to liberalization may improve efficiency under perfect competition, but may not improve efficiency if the market is monopolistic (Li, 1999). The more subtle and deeper point is that the dual track approach to liberalization may achieve
allocative efficiency, despite the fact that it appears inefficient, by maintaining the inefficient planned track. The fundamental reason is that the compensatory transfers, which are implicitly embodied in the planned track, are inframarginal, and thus the distortion can be avoided.

To see this we look at the special case where the pre-reform status quo features efficient rationing and efficient planned supply in the sense that the planned output is allocated to users with the highest willingness to pay and the planned supply is delivered by suppliers with the lowest marginal costs. Nevertheless, the price of the good is fixed at an artificially low level and the production quota is fixed below market equilibrium (Figure 1). When the market track is introduced into this setting, it is clear that the market equilibrium quantity and price would be identical to the case without the planned price and quota to start with. Therefore, dual track liberalization achieves efficiency. Notice that efficiency is achieved without making anyone worse off. Indeed, the rents enjoyed by the buyers under rationing (area A in Figure 1) are preserved under dual track liberalization, but would be lost under single track liberalization.

Figure 1
The case of efficient supply and efficient rationing
In a more general case of inefficient rationing and/or inefficient planned supply, efficiency can still be achieved provided market liberalization is full, in the sense that market resales of plan-allocated goods and market purchases by planned suppliers for fulfilling planned delivery quotas are permitted after the fulfilment of the obligations of planned suppliers and rationed users under the plan. This removes any inefficiency associated with the original planned prices and quotas and makes imputed rents under planning inframarginal. This type of transaction takes many forms in practice, for example, subcontracting by inefficient planned suppliers to more efficient non-planned suppliers, and labour reallocation when workers in inefficient enterprises keep the housing while taking a new job in more efficient firms. In both examples, after fulfilling the obligations under the plan (planned delivery of supply and welfare support through housing subsidies), the market track functions to undo the inefficiency of the plan track.

This above partial equilibrium analysis can be generalized to a general equilibrium mode (Lau, Qian, and Roland, 1997). Efficiency requires full market liberalization under which market resales, subcontracting, and market purchases for redelivery are all allowed. Indeed, the distinction between limited and full market liberalization is a major difference between Lau, Qian, and Roland (1997) and Byrd (1991), and others who have studied the dual track approach. If such resales and purchases are not allowed or cannot be achieved, then dual track liberalization is limited and efficiency in general cannot be achieved, although it can be improved. Of course, in the special case discussed above with efficient supply and efficient rationing, dual track with limited market liberalization is the same as dual track with full market liberalization. In general, dual track limited market liberalization need not be the same as dual track full market liberalization.

Sometimes dual track liberalization of the market takes the following sequential form: in a first stage, limited market liberalization is implemented, and then in a second stage full market liberalization is implemented. In the first stage, going from a centrally planned economy to limited market liberalization, Pareto improvement is clearly attained, but efficiency cannot be guaranteed. Specifically, limited market liberalization generally leads to inefficient overproduction due to market entry. In the second stage, when full liberalization is introduced, efficiency is attained but Pareto improvement may not be. This is because the second-stage full market liberalization implies efficiency, and thus there must be a production contraction and some people have to reduce production and are made worse off. Therefore, the sequential dual track liberalization may result in some opposition to further reforms after the first and before the second stage, while the dual track full market liberalization that is implemented in one stroke will not. Nevertheless, it is also clear that, even under the sequential dual track liberalization, there are no losers at the end of the second stage compared with the status quo before the reform.

The dual track approach to market liberalization is an example of reform making the best use of existing information and institutions. First, it utilizes efficiently the existing information embedded in the original plan (that is, existing rents distribution) and its implementation does not require additional information. Second, it also enforces the plan through the existing plan institutions and does not need additional institutions. Enforcement of the plan track is crucial for preserving pre-existing rents. However, contrary to common understanding of the relationship between state power and reform, state enforcement power is needed here not to implement an unpopular reform, but to carry out one that creates only winners, without losers.

Economists sometimes find dual track liberalization puzzling and counter-intuitive, for several reasons. First, economists are used to the law of one price: in a competitive setting, multiple prices entail inefficiency. However, in dual price liberalization, the planned price comes together with planned quantity, when they are fixed, they do not entail inefficiency, at least not additional inefficiency. Second, dual track resembles price control, which is associated with inefficiency and rent seeking. But dual track is not price control; on the contrary, it is a move towards price liberalization. An important difference between the plan track under dual track and price control is that the plan track embodies both fixed prices and fixed quantities; it is a package of price and quantity control, not just price control. Under pure price control, the government fixes only prices, but not quantities. Third, to reformers, dual track seems a partial reform and not a complete reform. This is true under dual track with limited market liberalization, but not true with full market liberalization. Although dual track with limited market liberalization does not achieve efficiency, it improves efficiency and makes nobody worse off.

Dual track liberalization requires enforcement of the rights and obligations under the plan track. In fact, enforcement of the plan track alone would prevent any decline in aggregate output. Can the plan track be enforced? With a collapsing government, it cannot. But enforcing the pre-existing plan is informationally much less demanding for the government than drawing up a new plan. Under central planning, the information requirement for drawing up a plan is huge. Enforcing a pre-existing plan is different. In fact, the dual track approach uses minimal additional information as compared with other possible compensation schemes that may be used with other approaches to reform. Compliance with the plan by economic agents depends on their expectations of the credibility of state enforcement. If state enforcement is not credible, then the economic agents will have no incentive to fulfil their plan obligations. If people think that they are not going to receive the plan-mandated deliveries at plan prices, they will not make the plan-mandated sales at the fixed plan prices. In that case, dual track liberalization degenerates to single track liberalization.

Lack of enforcement of the plan track may result in supply diversion as analysed by Murphy, Shleifer and Vishny (1992). These authors studied a partial reform model with the following two crucial assumptions: (i) suppliers are free to sell to all users, and (ii) buyers who are not covered by the plan can freely purchase inputs at any price, but buyers who are covered by the plan are not allowed to purchase inputs above the plan price. This partial reform model differs from the dual track liberalization model in an important respect: there is
no plan delivery quota enforced on the suppliers.
In their model, partial reform may lead to inefficient supply diversion to such an extent that the outcome can be worse than that without reform. Therefore, the partial reform is not only not Pareto improving, but also total welfare reducing. Consider the case where the initial condition is also characterized by efficient rationing and efficient supply as shown in Figure 1, where the planned price $P_p$ is below the market clearing level $P_m$. Then, after the partial liberalization as defined above, suppliers can sell the goods freely to the highest bidders. While the firms under the plan are forced to buy the good at price $P_p$, the firms outside the plan are free to buy the good at any price. Then they will bid the good for price $P_p + \varepsilon$ where $\varepsilon$ is a positive but small number. Because the firms under the plan are constrained to pay $P_p$, an amount will be diverted from them to those not covered by the plan.
Because the willingness to pay from those not covered by the plan is lower than those covered by the plan (by the assumption of efficient rationing), this kind of partial reform induces a net efficiency loss. While the sector not covered by the plan gains, the sector covered by the plan loses, and the total welfare effect is unambiguously negative. Although the assumption of efficient rationing and efficient supply under central planning is too strong, the result of inefficient supply diversion under partial reform remains valid with weaker conditions about initial rationing and supply.
So which model is more relevant? It depends on the quota enforcement capability of the government. A good enforcement capability makes the dual track liberalization model of Lau, Qian and Roland more relevant, while a poor enforcement would make the partial reform model of Murphy, Shleifer, and Vishny more relevant. The dual track liberalization model is motivated mainly by the practice in China, where enforcement has been reasonably good, while the partial reform model is mainly motivated by the experiences of the last years of the Soviet Union, when the state enforcement power diminished quickly.
In China's context, lack of quota enforcement sometimes takes the following form. The government may be unable to freeze the plan by creating new quotas with (below market equilibrium) planned price and giving windfall rents to some people who are politically connected. This may lead to corruption: firms find it easier to make profits by lobbying the government for allocating more input goods delivery at low planned prices, without the corresponding obligations to deliver low price outputs as under central planning. They then sell the goods at the market price to receive the windfall gains. This type of corruption is often attributed to the dual track approach to liberalization. Indeed, without the coexistence of the planned prices and market prices, the above form of corruption is not possible. By eliminating the two prices, such form of corruption would disappear. However, the essence of the problem is the failure in the enforcement of the original planned track. If the planned track is strictly enforced, no new quotas should be created. (On the other hand, full market liberalization allows for market arbitrage, which may increase the welfare of those who were allocated with goods at below-market prices. This is essential for achieving efficiency. The difference is that the potential rents are inherited from the previous regime in this case, not from a new creation.)

**Dual track liberalization in practice**

Studies of dual track liberalization focus mostly on China, although other cases, such as that of Mauritius, are also mentioned. The origin of the dual track can be traced to the 1950s when China had two prices for grain, the official price and negotiated price. However, dual track approach to market liberalization as a reform strategy was used only after 1979, first in the agricultural goods markets, and then in other markets (Byrd, 1991; Naughton, 1995; Lau, Qian and Roland, 2000).

**Agriculture goods.** The agricultural reform in China started with a dual track approach to market liberalization. Under that reform, the commune (and later the household) was assigned the responsibility to sell a fixed quantity of output to the state procurement agency as previously mandated under the plan at predetermined plan prices and to pay a fixed tax (often in kind) to the government. It also had the right (and obligation) to receive a fixed quantity of inputs, principally chemical fertilizers, from state-owned suppliers at predetermined plan prices. Subject to fulfilling these conditions, the commune was free to produce and sell whatever it considered profitable, and retain any profit. Moreover, the commune could purchase from the market grain (or other) output for resale to the state in fulfillment of its responsibility. There was thus a full market liberalization.

Between 1978 and 1988 state procurement of domestically produced grain remained essentially fixed, with 47.8 million tons in 1978 and 50.5 million tons in 1988. During that same period, total grain output increased by almost one-third. But the dual track approach to liberalization applied to agricultural products other than grain: between 1978 and 1990, the share of transactions at plan prices in all agricultural goods fell from 94 per cent to 31 per cent, when the agricultural output in China doubled. There was a huge supply response to the introduction of the market track.

**Industrial goods.** The most noticeable and often cited application of the dual track approach to liberalization is to industrial goods (Byrd, 1991; McMillan and Naughton, 1992). The Chinese government issued a document in May 1984 stipulating that there would be two forms of production in state-owned enterprises: planned and non-planned. Correspondingly, there were two types of material supplies for enterprises, namely, state allocation and free purchase. Prices of goods in the former were fixed by the state and prices of goods above quota quantity could be sold in the market at price within a range up to 20 per cent higher or lower than of the planned price. In February 1985, the 20 per cent price cap was removed and the dual track for industrial goods was formally in place (Wu and Zhao, 1987). As a result, the share of transactions at plan prices, in terms of output value, fell from 100 per cent before the reform to 45 per cent in 1990.

Coal and steel are the two important industrial commodities most tightly controlled under central planning, and both coal and steel markets were liberalized through the dual track approach. For coal, China's principal energy source, the planned delivery led to some slight increases in absolute terms during the 1980s, but the market track increased dramatically from 293 million tons to 628 million tons over the same period – the supply came mainly from small rural mines run by Township–Village Enterprises. As a result, the share of
dual track liberalization. The New Palgrave Dictionary of Economics

annual lump-sum subsidies for a period of three years, which was sufficient for them to purchase the pre-reform allocation of foreign exchange. Because at that time the share of

swap rate – were merged into a single, market rate. In this last step of foreign exchange reform, those organizations that used to receive cheap foreign exchange were provided with

compared to the potential cost of compensation in the early 1980s. The dual track exchange rate ended on 1 January 1994, when the two exchange rates – the official rate and the

food coupons (grain, meat, oil, and so on) were removed in the early 1990s with lump-sum compensation. But the cost of compensation was much smaller in relative terms as

goods, and only 7.2 per cent in total retail sales of consumer goods. However, this phasing-out of the plan track was generally accompanied by compensation. For example, urban

plan track will become a matter of little consequence to most potential losers, which in turn reduces the cost required for compensating them. In China, the

Phasing out the plan track

With rapid growth, the plan track will become a matter of little consequence to most potential losers, which in turn reduces the cost required for compensating them. In China, the

plan track in product markets was largely phased out during the 1990s. By 1996, the plan track was reduced to 16.6 per cent in agricultural goods, 14.7 per cent in industrial producer

consumer goods. Prior to the economic reform of 1979, most essential consumer goods and services for urban residents, such as grain, cooking oil, meat, electricity, housing, and the

monthly transport pass, were rationed with coupons at values lower than corresponding free market prices. With dual track liberalization, urban residents continued to have the right to

purchase grain, meat, electricity and housing at the same pre-reform prices and within the limits of the pre-reform rationed quantities, but, at the same time, they were also free to buy consumer goods from the free market at generally higher prices. The proportion of transactions at plan prices declined from 97 per cent in 1978 to only 30 per cent in 1990.

Foreign exchange. Under central planning, foreign exchange transactions were strictly controlled by the government at the official exchange rate. Exporters were required to surrender to the state all foreign exchange they earned at the official exchange rate, and importers were allocated with planned quotas of foreign exchange, also at the official exchange rate. Foreign visitors to China were required to use ‘foreign exchange certificates’, which were available at the official exchange rate. Starting from May 1988, China allowed trading of foreign exchange at Foreign Exchange Adjustment Centres (more commonly referred to as ‘swap centres’) at the rate determined by market supply and demand, called ‘swap rate’. This was the beginning of the dual track in the foreign exchange market. The swap rate was, not surprisingly, significantly higher than the official rate. The supply of foreign exchange in the swap markets was provided by exporters through the foreign exchange they were allowed to retain from net increases in their export earnings in relation to the base period. By the end of 1993, transactions at official exchange rates accounted only for about 20 per cent of the total; the rest were at the market rate.

Labour. As in many other centrally planned economies, the labour market in China was also distorted: most labour was allocated to unproductive, state-owned enterprises and few to the non-state sector. Dual track liberalization in the labour market takes two forms. In the first, the non-state sector (the liberalized sector) pays market wages and decides on hiring and firing. Between 1978 and 1994, employment in the non-state sector increased by 318.8 per cent, while employment in the state sector (including civil servants in government agencies and non-profit organizations) increased by only 50.5 per cent. Second, even within the state sector there are also two tracks. Beginning in 1980, while pre-existing employees maintained their permanent employment status, most new hires in the state sector were made under the more flexible contract system and often at lower effective wage rates. Employment in the plan track was virtually stationary – it declined from 87.14 million in 1983, on the eve of the introduction of economic reform in industry, to 83.61 million in 1994.

Special economic zones. Dual track liberalization can also have a geographical dimension: special economic zones are such examples. Although similar zones for processing exports can be seen in other Asian economies, special economic zones had a more profound effect in China because the whole country was still under central planning when they were created. Therefore, the purpose of special economic zones was more than for exporting; it was a strategy for market reform.

In 1980, China established four ‘special economic zones’, Shenzhen, Zhuhai and Shantou in Guangdong province and Xiamen in Fujian province. Most transactions relating to activities inside the zones were on the market track, including prices of input and output goods and wages of labour – at a time when the rest of the economy was still operating under central planning. The special economic zones were insulated from the rest of the economy to minimize the impact on and interaction with the rest of the economic system. Initially, firms inside the special economic zones had to import all their inputs and export all their outputs – thus creating no disruption to the domestic aggregate supply and demand. The principal purpose of this approach was to minimize the impact of new economic activities on the old-style domestic state-owned enterprises. Thus, once again, there were two tracks and the reform was Pareto improving.

In order for the special economic zones to work, merely creating them was not enough. One of the crucial conditions was the insulation of the non-liberalized sector from the liberalized sector so that the latter's existing rents could be maintained while the other sector was liberalized. Therefore, creation of special economic zones is a type of limited market liberalization. It is Pareto improving and efficiency enhancing, but cannot be fully efficient.

duality

Lawrence E. Blume
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article surveys duality in producer theory, consumer theory and welfare economics. As opposed to the usual analysis through first-order conditions for optimization, the various dualities are derived here from convex duality theory, using Fenchel transforms and subdifferentials.

Article

1 Introduction

The word ‘duality’ is often used to invoke a contrast between two related concepts, as when the informal, peasant, or agricultural sector of an economy is labelled as dual to the formal, or profit-maximizing, sector. In microeconomic analysis, however, ‘duality’ refers to connections between quantities and prices which arise as a consequence of the hypotheses of optimization and convexity. Connected to this duality are the relationship between utility and expenditure functions (and profit and production functions), primal and dual linear programs, shadow prices, and a variety of other economic concepts. In most textbooks, the duality between, say, utility and expenditure functions arises from a sleight of hand with the first-order conditions for optimization. These dual relationships, however, are not naturally a product of the calculus; they are rooted in convex analysis and, in particular, in different ways of describing a convex set. This article will lay out some basic duality theory from the point of view of convex analysis, as a remedy for the microeconomic theory textbooks the reader may have suffered.

2 Mathematical background

Duality in microeconomics is properly understood as a consequence of convexity assumptions, such as laws of diminishing marginal returns. In microeconomic models, many sets of interest are closed convex sets. The mathematics here is surveyed in convex programming. The urtext for this material is Rockafellar (1970).

Closed convex sets can be described in two ways: by listing their elements, the ‘primal’ description of the set, and by listing the closed half-spaces that contain it. A closed (upper) half-space in \( \mathbb{R}^n \) is a set of the form \( h_{p,a} = \{ x : p \cdot x \geq a \} \), where \( p \) is another \( n \)-dimensional vector, \( a \) is a number and \( p \cdot x \) is the inner product. The vector \( p \) is the normal vector to the half-spaces \( h_{p,a} \). Geometrically speaking, this is the set of points lying on or above the line \( p \cdot x = a \). The famous separation theorem for convex sets implies that every closed convex set is the intersection of the half-spaces containing it.

Suppose that \( C \) is a closed convex set, and that \( p \) is a vector in \( \mathbb{R}^n \). How do we find all the numbers \( a \) such that \( C \subset h_{p,a} \)? If there is
an \( x \in \mathbb{C} \) such that \( p \cdot x < a \), then \( a \) is too big. So the natural candidate is \( w = \inf_{x \in \mathbb{C}} p \cdot x \). If \( a > w \) there will be an \( x \in \mathbb{C} \) such that \( p \cdot x < a \) on the other hand, if \( a < w \), then \( p \cdot x > a \) for all \( x \in \mathbb{C} \). So the half-spaces \( h_{pa} \) for \( a \leq w \) are the closed half-spaces containing \( \mathbb{C} \).

This construction can be applied to functions. A concave function on \( \mathbb{R}^n \) is an \([ -\infty, \infty ) \) valued function \( f^\bullet \) such that the hypograph of \( f \), the set \( \text{hyp} f = \{(x, a) \in \mathbb{R}^{n+1} : a \leq f(x)\} \), is convex. If \( \text{hyp} f \) is closed, \( f \) is said to be upper semi-continuous (usc). The domain \( \text{dom} f \) of concave \( f \) is the set of vectors in \( \mathbb{R}^n \) for which \( f \) is finite-valued. Concave (and convex) functions are very well-behaved on the relative interiors of their effective domains. The relative interior \( \text{ri} \mathbb{C} \) of a convex set \( \mathbb{C} \) is the interior relative to the smallest affine set containing \( \mathbb{C} \) (see convex programming), and on \( \text{ri} \mathbb{C} \), \( f \) (concave or convex) is continuous.

Suppose that \( f \) is usc. The minimal level \( a \) such that \( h_{(p,-1)a} \) the hyperplane in \( \mathbb{R}^{n+1} \) with normal vector \((p, -1)\), contains \( \text{hyp} f \) is \( f^\bullet(p) = \inf_x p \cdot x - f(x) \). Why the normal vector \((p, -1)\)? Because the graph of the affine function \( x \mapsto f^\bullet(p) + px \) is a tangent line to \( f \), the graph of \( f \) lies everywhere beneath it, and no other line with the same slope and a smaller intercept has this property. The function \( f^\bullet(p) \) is the (concave) Fenchel transform or conjugate of \( f \), and is traditionally denoted \( f^\ast \). The construction of the preceding paragraph can be done just this way: the concave indicator function of a convex set \( C \) is the function \( \delta_C(x) \) which is 0 on \( C \) and \(-\infty \) otherwise, and \( \delta_C^\ast(p) = \inf_{x \in C} p \cdot x \). For any function \( f \), not necessarily usc or concave, the Fenchel transform \( f^\bullet \) is usc and concave. If \( f \) is in fact both usc and concave, then \( f^{\bullet\bullet} = f \). This fact is known as the conjugate duality theorem. Convex functions with range \([ -\infty, \infty ] \) are treated identically. The function \( f \) is convex if and only if \(-f \) is concave, but the definitions are handled slightly differently in order to preserve the intuition just described. The set \( \text{epi} f = \{(x, a) : a \geq f(x)\} \), and the convex Fenchel transform is defined differently: \( f^\bullet(p) = \sup_x p \cdot x - f(x) \). The convex indicator function of a convex set \( C \) is the function \( \delta_C^\ast(x) \) which is 0 on \( C \) and \(+\) otherwise; its (convex) conjugate is \( \delta_{C^\ast}(p) = \sup_x p \cdot x \). These facts are discussed in convex programming.

If concave functions have tangent lines, then they must have something like gradients. A vector \( p \) is a subgradient of \( f \) at \( x \) if \( f(x) + p \cdot (y - x) \leq f(y) \). If \( f \) has a unique subgradient at \( x \), then \( f \) is differentiable at \( x \) and \( p = \nabla f(x) \), and conversely. But the subgradient need not be unique: the set \( \partial f(x) \) of subgradients at \( x \) is the subdifferential of \( f \) at \( x \). The domain \( \text{dom} f \), \( \text{dom} f \), is the set of \( x \) such that \( f(x) > -\infty \). The subdifferential is non-empty for all \( x \) in its relative interior. It follows from the definition of concavity (and is proved in convex programming) that the subdifferential correspondence is monotonic: if \( p \in \partial f(x) \) and \( q \in \partial f(y) \), then \( (p-q) \cdot (x-y) \leq 0 \). If \( f \) is convex, then the inequality is reversed, and \( (p-q) \cdot (x-y) \geq 0 \). Finally, suppose \( f \) is usc and concave. Then so is its conjugate \( f^\bullet \), and their subdifferentials have an inverse relationship: if \( p \in \partial f(x) \) and only if \( x \in \partial f^\bullet(p) \).

3 Cost, profit and production

In the theory of the firm, profit functions and cost functions are alternative ways of describing the firms’ technology choices. A technology is described by a set of vectors \( F \in \mathbb{R}^N \). Each vector \( Z \in F \) is an input–output vector. We adopt the convention that negative coefficients correspond to input quantities and positive quantities correspond to outputs. Suppose that the first \( L \) goods are inputs and the last \( M = N - L \) are outputs, so that \( F \subseteq \mathbb{R}^L_- \times \mathbb{R}^M_+ \). It is convenient to assume free disposal, so that if \( (x, y) \in F \), and both \( x' \leq x \) and \( y' \leq y \) (more input and less output), then \((x', y') \in F \). Two important dual representations of the technology are the cost and profit functions. The profit function is \( \Pi(p, w) = \sup_{(x, y) \in F} p \cdot y + w \cdot x \) for \( p \in \mathbb{R}^L \) and \( w \in \mathbb{R}^M \), which is the conjugate of the convex indicator function of \( F \). The cost function too can be obtained through conjugacy. The set \( F(y) = \{(x, y) \in F\} \) is the set of all input bundles that produce \( y \). Then \( C(y, w) = -\sup_{x \in F(y)} w \cdot x \), that is, \( C(y, w) = -\delta F(y)^\ast \). Immediately the properties of the Fenchel transform imply that \( \Pi(p, w) \) is convex in its arguments and \( C(y, w) \) is concave in \( w \), the profit function is lsc and the cost function is usc. (This implies that both functions are continuous on the relative interior of their effective domains.) Cost and profit functions are also linear homogeneous. Doubling all prices doubles both costs and revenues.

Cost is also monotonic. If \( W^I < W^I \) for every input \( I \), then \( C(y, W^I) \leq C(y, W) \) and if \( W^I < W^I \) for all \( I \), then \( C(y, W^I) < C(y, W) \). The point of duality is that, if the technology is closed and convex, then cost profit functions each characterize the technology \( F \).

The conjugate duality theorem (see convex programming) implies that \( \Pi^\ast(x, y) = \delta F^\ast(x, y) = \delta C(x, y) \), the convex indicator...
function of $F$:

$$
\sup_{(p,w) \in \mathbb{R}^N} p \cdot x + w \cdot y - \pi(p, w) = \begin{cases} 
0 & \text{if } (x, y) \in F, \\
+\infty & \text{otherwise}.
\end{cases}
$$

If $F$ is closed and convex, then each $F(y)$ is convex. If $F$ is closed then $F(y)$ will also be closed. Then $\delta F(y)$ is concave and usc, so

$$
\sup_{w \in \mathbb{R}^+_+} w \cdot x + C(y, w) = \sup_{w \in \mathbb{R}^+_+} w \cdot \delta F(y)^*(w) = \delta F(y)(x).
$$

*Hotelling's lemma* is a famous result of duality theory. It says that the net supply function of good $i$ is the derivative of the profit function with respect to the price of good $i$. The usual proof is via the envelope theorem: the marginal change in profits from a change in price $p$ is the quantity of good $i$ times the change in the price plus the price of all goods times the changes in their respective quantities. But the quantity changes are second-order because the quantities solve the profit maximization first-order conditions, that price times the marginal change in quantities in technologically feasible directions is 0. Every advanced microeconomics text proves this. A result like this is true whenever the technology is convex, even if the technology is not smooth.

The convex version of Hotelling's lemma is a consequence of the inversion property of subdifferentials for concave and convex $f$; that $p \in \partial f(x)$ if and only if $x \in \partial f^*(p)$. See convex programming for a brief discussion.

*Hotelling's lemma:* $(x, y) \in \partial \pi(p, w)$ if and only if $(x, y)$ is profit-maximizing at prices $(p, w)$.

Hotelling's lemma is quickly argued. If $(x, y) \in \partial \pi(p, w) = \partial \delta F^*(p, w)$, then $(p, w) \in \partial \delta F^{**}(x, y) = \partial \delta F(x, y)$. Then $\delta F(x, y) + (p, w) \cdot ((x', y') - (x, y)) \leq \delta F(x', y')$ for all $(x', y')$. This implies that $x \in F$ and furthermore that $(p, w) \cdot ((x', y') - (x, y)) \leq 0$ for all $(x, y) \in F$, in other words, that $(x, y)$ is profit-maximizing at prices $(p, w)$. Conversely, suppose that $(x, y)$ is profit maximizing at prices $(p, w)$. Then $(p, w)$ satisfies the subgradient inequality of $\delta F$ at $(x, y)$, and so $(p, w) \in \partial \delta F$. Consequently,

$$(x, y) \in \partial \delta F^*(p, w) = \partial \pi(p, w).$$

The textbook treatment of duality observes that, if net supply is the first derivative of the profit function, then the own-price derivative of net supply must be the second own-partial derivative of profit with respect to price, and convexity of the profit function implies that this partial derivative should be positive, so net supply is increasing in price. The same fact follows in the convex framework from the monotonicity properties of the subgradients. Suppose that $(w, p)$ and $(w', p')$ are two price vectors, and suppose that $(x, y)$ and $(x', y')$ are two profit-maximizing production plans corresponding to the two price vectors. Then $(w - w', p - p')(x - x', y - y') \geq 0$. If the two price vectors are identical for all prices but, say, $p_k \neq p'_k$, then $(p_k - p'_k)(y_k - y'_k) \geq 0$, and net supply is non-decreasing in price. As with net supplies, some comparative statics of conditional factor demand with respect to input price changes follows from the monotonicity property of subgradients.

Another implication of profit function convexity and (twice continuous) differentiability is symmetry of the derivatives of net supply:
\[
\frac{\partial v_k}{\partial p_l} = \frac{\partial^2 \pi}{\partial p_k \partial p_l} = \frac{\partial^2 \pi}{\partial p_l \partial p_k} = \frac{\partial v_l}{\partial p_k}.
\]

The convex analysis version of this is that for any finite sequences of goods \(i, \ldots, l\),

\[
p_i \cdot (v_j - v_i) + p_j \cdot (v_k - v_j) + \cdots + p_l \cdot (v_l - v_i) \leq 0.
\]

This requirement, which has a corresponding expression in terms of differences in prices, is called cyclic monotonicity. All subdifferential correspondences are cyclicly monotone. The connection with symmetry is not obvious, but it helps to know that Rockafellar (1974) leaves as an exercise (and so do we) that cyclic monotonicity is a property of a linear transformation corresponding to an \(n \times n\) matrix \(M\) if and only if \(M\) is symmetric and positive semi-definite. Monotonicity is cyclic monotonicity for sequences of length 2.

The other famous result in duality theory for production is Shephard's lemma, which does for cost functions what Hotelling's lemma does for profit functions: conditional input demands are the derivatives of the cost functions. This is demonstrated in the same way, since the cost function and the indicator function for the set of inputs from which \(y\) is producable are both convex and have closed hypographs.

4 Utility and expenditure functions

A quasi-concave utility function \(U\) defined on the commodity space \(\mathbb{R}^n_+\) has upper contour sets, the sets \(R_u\) of consumptions bundles which have utility at least \(u\), which are convex. If \(u\) is usc, these sets are closed as well.

The expenditure function gives for each utility level \(u\) and price vector \(p\) the minimum cost of realizing utility \(u\) at prices \(\tilde{p} : \mathbb{E}(\tilde{p}, u) = \inf \{p : x : u(x) \geq u\}\). If the infimum is actually realized at a consumption bundle \(x\), then \(x\) is the Hicksian or compensated real income demand.

In terms of convex analysis, \(e(p, u)\) is the conjugate of the concave indicator function \(\varphi_u(x)\) of the set \(\mathbb{R}(u) = \{x : U(x) \geq u\}\), that is, \(e(p, u) = \varphi_u^\ast(p)\). Thus \(e(p, u)\) will be usc and concave in \(p\) for each \(u\). The expenditure function is also linearly homogeneous in prices. If prices double, then the least cost of achieving \(u\) will double as well.

The duality of utility and expenditure functions is that each can be derived from the other; they are alternative characterizations of preference. Since the concave indicator function \(\varphi_u(x)\) is closed and convex, \(e(\cdot, u) = \varphi_u^\ast(\cdot)\). For fixed \(u\), the Fenchel transform of the expenditure function is the concave indicator function of \(\mathbb{R}(u)\); \(\inf p : p \cdot x - e(p, u)\) is 0 if \(U(x) \geq u\) and \(-\infty\) otherwise. If \(x \in \mathbb{R}(u)\), then the cost of \(x\) at any price \(p\) can be no less than the minimum cost necessary to achieve utility \(u\). The gap between the cost of \(x\) and the cost of utility level \(u\) is made by taking ever smaller prices, and so its minimum is 0. Suppose that \(x\) is not in \(\mathbb{R}(u)\). The separation theorem for convex sets says there is a price \(p\) such that \(p \cdot x < \inf_{y \in \mathbb{R}(u)} p \cdot y\); there is a price at which \(x\) is cheaper than the cost of \(u\). Now, by taking ever larger multiples of \(p\), the magnitude of the gap can be made arbitrarily large, and so the value of the conjugate is \(-\infty\). Thus the conjugate is the concave indicator function of \(\mathbb{R}(u)\).

Among the most useful consequence of the duality between utility and expenditure functions is the relationship between derivatives of the expenditure function and the Hicksian, or compensated, demand. Hicksian demand. The compensated demand at prices \(p\) and utility \(u\) are those consumption bundles in \(\mathbb{R}(u)\) which minimize expenditure at prices \(p\). This result is just Shephard's lemma for expenditure functions:

**Hicks compensated demand:** Consumption bundle \(x\) is a Hicks compensated consumption bundle at prices \(p\) if and only if \(x \in \mathbb{E}(p, u)\). Furthermore, if \(x\) is demanded at prices \(p\) and utility \(u\), and \(y\) is demanded at prices \(q\) and the same utility \(u\), then \((p-q) \cdot (x-y) \leq 0\).

The downward-sloping property just restates the monotonicity property of the subdifferential correspondence. For the special case of changes in a single price, the statement is that demand is non-increasing in its own price.
5 Equilibrium and optimality

The equivalence between Pareto optima and competitive equilibria can also be viewed as an expression of duality. When preferences have concave utility representations, \textit{quasi-equilibrium} emerges from Lagrangean duality. Quasi-equilibrium entails feasibility, profit maximization, and expenditure minimization rather than utility maximization. That is, each trader's consumption allocation is expenditure minimizing for the level of utility it achieves. The now traditional route of Arrow (1952) and Debreu (1951) to the Second Welfare Theorem first demonstrates that a Pareto-optimal allocation can be regarded as a quasi-equilibrium for an appropriate set of prices. Under some additional conditions, the quasi-equilibrium is in fact a competitive equilibrium, wherein utility maximization on an appropriate budget set replaces expenditure minimization. Our concern here is with the first step on this path.

Suppose that each of \( I \) individuals has preferences represented by a concave utility function on \( \mathbb{R}^N \), and that production is represented, as in Section 3, by a closed and convex set \( F \) of feasible production plans. Suppose that \( 0 \in F \) (it is possible to produce nothing) and that the aggregate endowment \( \epsilon \) is strictly positive. Assume, too, that there is free disposal in production. Every Pareto optimum is the maximum of a Bergson–Samuelson social welfare function of the form \( \sum \mu_i \mu_i \) defined on the set of all consumption allocations. An allocation is a vector \((x, y)\) where \( x \in \mathbb{R}^N \) is a consumption allocation, a consumption bundle for each individual, and \( y \) is a production plan. The allocation is \textit{feasible} if \( y \in F \) and \( \epsilon = - \sum i \leq 0 \). A Lagrangean for this convex program is

\[
L(x, y, p) = \begin{cases} 
\sum \mu_i(x_i) + p \cdot (\epsilon + - \sum \lambda_i) & \text{if } x \in \mathbb{R}^N, \quad y \in F \text{ and } p \in \mathbb{R}^L, \\
+ \infty & \text{if } x \in \mathbb{R}^N, \quad y \in F \text{ and } p \not\in \mathbb{R}^L, \\
- \infty & \text{otherwise},
\end{cases}
\]

where \( p \) is the vector of Lagrange multipliers for the \( L \) goods constraints.

The possibility of \( 0 \) production and the strict positivity of the aggregate endowment guarantee that the set of feasible solutions satisfies Slater's condition, and so a saddlepoint \((x^*, y^*, p^*)\) exists; that is, \( \sup_{x, y} L(x, y, p^*) \leq L(x^*, y^*, p^*) \leq L(x^*, y^*, p) \) for all \( x \in \mathbb{R}^N, y \in F \) and \( p \in \mathbb{R}^L \). Then \((x^*, y^*)\) is Pareto optimal and \( p^* \) solves the dual problem \( \min_p \sup_{x,y} L(x, y, p) \). The interpretation of \((x^*, y^*, p^*)\) as a quasi-equilibrium comes from examining the dual problem. The dual problem can be rewritten as

\[
\inf_{p \in \mathbb{R}^L} \sup_{x \in \mathbb{R}^N, y \in F} L(x, y, p) = \inf_{p \in \mathbb{R}^L} \sum_{i \in \mathbb{R}^N} \mu_i(x_i) + p \cdot (\epsilon + - \sum x_i) = \inf_{p \in \mathbb{R}^L} \sum_{i \in \mathbb{R}^N} x_i \mu_i(x_i) - p \cdot x_i = \sup_{y \in \mathbb{R}^F} \left( \sum_{i \in \mathbb{R}^N} \mu_i(x_i) - p \cdot x_i \right)
\]

In the dual problem, the Lagrange multipliers can be thought of as goods prices. The Second Welfare Theorem interprets the optimal allocation as an equilibrium allocation using the Lagrange multipliers as equilibrium prices. To see this, look at the second line of (1). At prices \( p \), a production plan is chosen from \( y \) to maximize profits \( p \cdot y \), so the value of this term is \( \pi \). Each consumer is asked to solve

\[
\max_i \lambda_i \mu_i(x_i) - p \cdot x = \min_i x_i \lambda_i \mu_i(x_i) = \lambda_i \mu_i - \min_i x_i \lambda_i (u_i(x_i) - u_i^*)
\]
where \( u_i^* = u_i(x_i^*) \). The term being minimized is the Lagrangean for the problem of expenditure minimization, and so \( x_i^* \) is the Hicksian demand for consumer \( i \) at prices \( p \) and utility level \( u_i^* = u_i(x_i^*) \). Finally, the optimal allocation is feasible, and so \((x^*, y^*, p^*)\) is a quasi-equilibrium.

Given the observation about expenditure minimization, the saddle value of the Lagrangean is

\[
\sum_l \lambda_l u_l^* - e_l(p^*, u_j^*) + \tau(p^*)
\]

The planner chooses prices to minimize net surplus, which is the sum of profits from production and the excess of total Bergson–Samuelson welfare less the cost of the consumption allocation.

### 6 Historical notes

Duality ideas appeared very early in the marginal revolution. Antonelli, for instance, introduced the indirect utility function in 1886. The modern literature begins with Hotelling (1932), who provided us with Hotelling's lemma and cyclic monotonicity. Shephard (1953) was the first modern treatment of duality, making use of notions such as the support function and the separating hyperplane theorem.

The results on consumer and producer theory are surveyed more extensively in Diewert (1981), who also provides a guide to the early literature. In its focus on Fenchel duality, this review has not even touched on the duality between direct and indirect aggregators, such as utility and indirect utility, and topics that would naturally accompany this subject such as Roy's identity. Again, this is admirably surveyed in Diewert (1981).

Dühring was born on 12 January 1833 in Berlin and died on 21 September 1921 at Nowawes bei Potsdam. The son of a Prussian state official, Dühring studied law, philosophy and economics at the University of Berlin and practised law until blindness obliged him to abandon this career. He then became a *Privatdozent* at the University of Berlin, where he taught philosophy and economics from 1863 to 1877, and began to write voluminously on a wide range of subjects, from the natural sciences to philosophy, social theory and socialism, his aim being to construct a system of social reform based upon positive science. His system was expounded in a series of books on capital and labour (1865), the principles of political economy (1866), a critical history of philosophy (1869), a critical history of political economy and socialism (1871), and courses in political economy and philosophy (1873; 1875).

Dühring was an adherent of positivism, concerned in his philosophical works to expound a ‘strictly scientific world outlook’, in opposition particularly to the Hegelian dialectic. His economic writings emphasize the role of political factors in the development of capitalism, and he argued that social injustice is not caused primarily by the economic system, but by social and political circumstances, the remedy being to control the misuse of private property and capital (not abolish them) through workers’ organizations and state intervention.

Schumpeter (1954, pp. 509–10), praised Dühring's history of mechanics (1873), which was awarded an academic prize, suggested that he would retain a prominent place in the history of anti-metaphysical and positivist currents of thought, and noted that he made an important criticism of Marxist theory in his argument that political causes had played a major part in constituting the property relations of capitalist society. In other respects, however, Schumpeter considered that Dühring had made no significant contribution to economic theory.

Engels, in his well-known book (originally published as a series of articles), *Herr Eugen Dühring's Revolution in Science [Anti-Dühring]* (1877–8), which has done more than anything else to keep
Dühring's name alive, took a much more critical view, deriding his work as a prime example of the 'higher nonsense' which infected German academic life. His philosophical views were dismissed by Engels as 'vulgar materialism' and compared unfavourably with the 'revolutionary side' of Hegel's dialectics; and in the chapter of Anti-Dühring devoted to the history of political economy (largely written by Marx, but not published in full until the third edition of the book in 1894), Dühring was castigated for his superficiality and theoretical misconceptions. It was, however, the concern with Dühring's programme of social reform, and its possible baleful effect on the developing labour movement (Eduard Bernstein, for example, was initially impressed by Dühring's Cursus of 1873, though soon repelled by his anti-Semitism) that originally provoked Engels's articles, and was countered in the final section of the book (frequently reprinted later as a separate text under the title Socialism, Utopian and Scientific) by an exposition of Marxist socialism which became enormously influential.

It seems doubtful that Dühring occupies more than a minor place in the history of economic and social thought, except for this encounter with Marx and Engels, though Schumpeter (1954, p. 509) called him a 'significant thinker' and the entry in the Encyclopedia of the Social Sciences (1931, vol. 5, p. 273) described his writings as 'among the important intellectual achievements of the nineteenth century'.

dummy variables

Pietro Balestra
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The dummy-variable method is a useful device for introducing, into a regression analysis, information contained in qualitative or categorical variables, that is, in variables that are not conventionally measured on a numerical scale, such as race, sex, marital status, occupation, or level of education. It is a means for considering a specific scheme of parameter variation, in which the variability of the coefficients is linked to the causal effect of some precisely identified qualitative variable. But when the qualitative effects are generic, as in the cross-section time-series model, an interpretation in terms of random effects may seem more appealing.

Keywords

covariance model; cross-section time-series model; dummy variables; Engel curve; error component model; qualitative variables; random coefficient model

Article

In economics, as well as in other disciplines, qualitative factors often play an important role. For instance, the achievement of a student in school may be determined, among other factors, by his father's profession, which is a qualitative variable having as many attributes (characteristics) as there are professions. In medicine, to take another example, the response of a patient to a drug may be influenced by the patient's sex and the patient's smoking habits, which may be represented by two qualitative variables, each one having two attributes. The dummy-variable method is a simple and useful device for introducing, into a regression analysis, information contained in qualitative or categorical variables; that is, in variables that are not conventionally measured on a numerical scale. Such qualitative variables may include race, sex, marital status, occupation, level of education, region, seasonal effects, and so on. In some applications, the dummy-variable procedure may also be fruitfully applied to a quantitative variable such as age, the influence of which is frequently U-shaped. A system of dummy variables defined by age classes conforms to any curvature and consequently may lead to more significant results.
The working of the dummy-variable method is best illustrated by an example. Suppose we wish to fit an Engel curve for travel expenditure, based on a sample of \( n \) individuals. For each individual \( i \), we have quantitative information on his travel expenditures \( (y_i) \) and on his disposable income \( (x_i) \), both variables being expressed in logarithms. A natural specification of the Engel curve is:

\[
y_i = a + bx_i + u_i
\]

where \( a \) and \( b \) are unknown regression parameters and \( u_i \) is a non-observable random term. Under the usual classical assumptions (which we shall adopt throughout this presentation), ordinary least-squares produce the best estimates for \( a \) and \( b \).

Suppose now that we have additional information concerning the education level of each individual in the sample (presence or absence of college education). If we believe that the education level affects the travel habits of individuals, we should explicitly account for such an effect in the regression equation. Here, the education level is a qualitative variable with two attributes: college education; no college education. To each attribute, we can associate a dummy variable which takes the following form:

\[
d_{1i} = \begin{cases} 
1 & \text{if college education} \\
0 & \text{if no college education}
\end{cases}
\]

\[
d_{2i} = \begin{cases} 
1 & \text{if no college education} \\
0 & \text{if college education}
\end{cases}
\]

Inserting these two dummy variables in the Engel curve, we obtain the following expanded regression:  

**Specification I:**

\[
y_i = a_1 d_{1i} + a_2 d_{2i} + bx_i + u_i
\]

which may be estimated by ordinary least-squares. Alternatively, noting that \( d_{1i} + d_{2i} = 1 \) for all \( i \), we can write:
Specification II:

\[ y_i = a_2 + (a_1 - a_2)d_{i1} + bx_i + u_i \]

which, again, may be estimated by ordinary least-squares.

It is easy to see how the procedure can be extended to take care of a finer classification of education levels. Suppose, for instance, that we actually have \( s \) education levels (\( s \) attributes). All we require is that the attributes be exhaustive and mutually exclusive. We then have the two following equivalent specifications:

Specification I:

\[ y_i = a_1 d_{1i} + a_2 d_{2i} + \ldots + a_s d_{si} + bx_i + u_i \]

Specification II:

\[ y_i = a_s + (a_1 - a_s)d_{1i} + \ldots + (a_{s-1} - a_s)d_{s-1,i} + bx_i + u_i. \]

Obviously, the two specifications produce the same results but give rise to different inputs. Specification I includes all the \( s \) dummy variables but no constant term. In this case, the coefficient of \( d_{ji} \) gives the specific effect of attribute \( j \). Specification II includes \( s - 1 \) dummy variables and an overall constant term. The constant term represents the specific effect of the omitted attribute, and the coefficients of the different \( d_{ji} \) represent the contrast (difference) of the effect of the \( j \)th attribute with respect to the effect of the omitted attribute. (Note that it is not possible to include all dummy variables plus an overall constant term, because of perfect collinearity.)

It is important to stress that by the introduction of additive dummy variables, it is implicitly assumed that the qualitative variable affects only the intercept but not the slope of the regression equation. In our example, the elasticity parameter, \( b \), is the same for all individuals; only the intercepts differ from individual to individual depending on their education level. If we are interested in individual variation in slope, we can apply the same technique, as long as at least one explanatory variable has a constant coefficient over all individuals. Take the initial case of only two attributes. If the elasticity parameter varies according to the level of education, we have the following specification:

\[ y_i = a_1 d_{1i} + a_2 d_{2i} + b_1 d_{1i}x_i + b_2 d_{2i}x_i + u_i. \]
Simple algebra shows that ordinary least-squares estimation of this model amounts to performing two separate regressions, one for each class of individuals. If, however, the model contained an additional explanatory variable, say \( z_i \), with constant coefficient \( c \), by simply adding the term \( c z_i \) to the above equation, we would simultaneously allow for variation in the intercept and variation in the slope (for \( x \)).

The dummy variable model also provides a conceptual framework for testing the significance of the qualitative variable in an easy way. Suppose we wish to test the hypothesis of no influence of the level of education on travel expenditures. The hypothesis is true if the \( s \) coefficients \( a_i \) are all equal; that is, if the \( s - 1 \) differences \( \bar{a}_j - \bar{a}_s \), \( j = 1, \ldots, s - 1 \), are all zero. The test therefore boils down to a simple test of significance of the \( s - 1 \) coefficients of the dummy variables in Specification II. If \( s = 2 \), the \( t \)-test applied to the single coefficient of \( d_{1i} \) is appropriate. If \( s > 2 \), we may conveniently compute the following quantity:

\[
\frac{(SS_c - SS) / (s - 1)}{SS / (n - s - 1)}
\]

which is distributed as an \( F \)-variable with \( s - 1 \) and \( n - s - 1 \) degrees of freedom. In the above expression, \( SS \) is the sum of squared residuals for the model with the dummy variables (either Specification I or II), and \( SS_c \) is the sum of squared residuals for the model with no dummy variables but with an overall constant term.

In some economic applications the main parameter of interest is the slope parameter, the coefficients of the dummy variables being nuisance parameters. When, as in the present context, only one qualitative variable (with \( s \) attributes) appears in the regression equation, an easy computational device is available which eliminates the problem of estimating the coefficients of the dummy variables. To this end, it suffices to estimate, by ordinary least-squares, the simple regression equation:

**Specification III:**

\[
y_i^* = b x_i^* + u_i^*.
\]

where the quantitative variables (both explained and explanatory) for each individual are expressed as deviations from the mean over all individuals possessing the same attribute. For the dichotomous case presented in the beginning, for an individual with college education, we subtract the mean over all individuals with college education and likewise for an individual with no college education. Note, however, that the true number of degrees of freedom is not \( n - 1 \) but \( n - 1 - s \). The same procedure also applies when the model contains other quantitative explanatory variables. The interested reader may
consult Balestra (1982) for the conditions under which this simple transformation is valid in the context of generalized regression. The case of multiple qualitative variables (of the explanatory type) can be handled in a similar fashion. However, some precaution must be taken to avoid perfect collinearity of the dummy variables. The easiest and most informative way to do this is to include, in the regression equation, an overall constant term and to add for each qualitative variable as many dummy variables as there are attributes minus one. Take the case of our Engel curve and suppose that, in addition to the education level (only two levels for simplicity), the place of residence also plays a role. Let us distinguish two types of place of residence: urban and rural. Again, we associate to these two attributes two dummy variables, say $e_{1i}$ and $e_{2i}$. A correct specification of the model which allows for both qualitative effects is:

$$y_i = \beta_1 + \beta_2 d_{1i} + \beta_3 e_{1i} + \beta_4 x_1 + \epsilon_i.$$  

Given the individual's characteristics, the measure of the qualitative effects is straightforward, as shown in the following table:

<table>
<thead>
<tr>
<th>Urban</th>
<th>Rural</th>
</tr>
</thead>
<tbody>
<tr>
<td>College education</td>
<td>$a_1 + a_2 + a_3 a_1 + a_2$</td>
</tr>
<tr>
<td>No college education</td>
<td>$a_1 + a_3$</td>
</tr>
</tbody>
</table>

The specification given above for the multiple qualitative variable model corresponds to Specification II of the single qualitative variable model. Unfortunately, when there are two or more qualitative variables there is no easy transformation analogous to the one incorporated in Specification III, except under certain extraordinary circumstances (Balestra, 1982).

One such circumstance arises in connection with cross-section time-series models. Suppose that we have $n$ individuals observed over $t$ periods of time. If we believe in the presence of both an individual effect and a time effect, we may add to our model two sets of dummy variables, one corresponding to the individual effects and the other corresponding to the time effects. This is the so-called covariance model. The number of parameters to be estimated is possibly quite large when $n$ or $t$ or both are big. To avoid this, we may estimate a transformed model (with no dummies and no constant term) in which each quantitative variable (both explained and explanatory) for individual $i$ and time period $j$ is transformed by subtracting from it both the mean of the $i$th individual and the mean of the $j$th time period and by adding to it the overall mean. Note that, by this transformation, we lose $n + t - 1$ degrees of freedom. To conclude, the purpose of the preceding expository presentation has been to show that the dummy-variable method is a powerful and, at the same time, simple tool for the introduction of qualitative effects in regression analysis. It has found and will undoubtedly find numerous applications in empirical economic research. Broadly speaking, it may be viewed as a means for considering a specific scheme of parameter variation, in which the variability of the coefficients is linked to the causal effect of some precisely identified qualitative variable. But it is not, by any means, the only scheme available. For instance, when the qualitative effects are generic, as in the cross-section time-series model, one may question the validity of representing such effects by fixed parameters. An interpretation in terms of
random effects may seem more appealing. This type of consideration has led to the development of other
schemes of parameter variation such as the error component model and the random coefficient model.
A final remark is in order. In the present discussion, qualitative variables of the explanatory type only
have been considered. When the qualitative variable is the explained (or dependent) variable, the
problem of these limited dependent variables is far more complex, both conceptually and
computationally.

Dunlop, John Thomas (1914–2003)

Richard B. Freeman

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

business cycles; dispute resolution; Dunlop, J.; industrial relations; labour's share of income; marginal productivity theory; mediation; wage contours; wage determination

Article

John Dunlop was an extraordinary labour economist, Professor and Dean of the Faculty at Harvard University, Secretary of Labor of the United States, and mentor to students and practitioners in the world of labour. He was extraordinary because he was more than an economist and because he was driven by a moral vision of what economists and academics should do to make the world better. Labour economists and policymakers paid close attention to Dunlop's thoughts because he combined academic research with unparalleled practical experience in solving problems and building institutions. His academic writings, which include several classic articles as well as major books, reflect Dunlop's participation in events and direct observations of social behaviour.

Dunlop first attracted academic attention with his 1938 *Economic Journal* article on the movement of real and money wages over the business cycle, which forced Keynes to admit that the *General Theory* was wrong on this issue: real wages fall in recessions not in booms, contrary to simple marginal productivity analysis. Quite an achievement for a 24-year-old economist. Dunlop followed this with *Wage Determination Under Trade Unions* (1944), in which he modelled unions as optimizing organizations; with analyses of the cyclic variation of labour's share, with the concept of ‘wage contours’ that captured the notion that product markets influenced wages, and with numerous analysis of wage determination, labour relations, mediation and dispute resolution. Dunlop's book *Industrial Relations Systems* (1958) sought to develop a broader perspective on how labour relations fit into economics.

In the 1980s, concerned that labour economists were limited in their conceptual vision by narrow optimizing models and in their empirical analysis by extant government data-sets, Dunlop carped at them for failing to see what he could see in the labour market. Dunlop saw the labour market as pre-eminently a social institution to resolve labour problems, which should be analysed as such rather than
as a bourse. His mode of analysis was that of a naturalist, who looks at the world with his own eyes and experience, with direct knowledge of the institutions and practitioners, without trying to force observation into a narrow conceptual framework.

Dunlop's career spanned a wide variety of activities. Earning his AB (1935) and Ph.D. (1939) from Berkeley, he rose to become professor of economics at Harvard and Dean of the University (1970–3), when he helped stabilize the university during a period of student disorders, and Lamont University Professor (1970–2003). He worked for the National War Labor Board (1943–54); served as member or chair on various national panels with responsibility for resolving labour disputes; led labour-management committees in areas ranging from missile sites to apparel, the public sector, and health; served as Director of the Cost of Living Council (1973–4), and as Secretary of Labor of the United States (1975–6). From 1993 to 1994 he chaired the Commission on the Future of Worker–Management Relations, popularly known as the Dunlop Commission, which was given the charge ‘to recommend ways to improve labor–management cooperation and productivity’. The politics and economics of the time were not right, however, for bringing management and labour to a consensus on modernizing labour relations, so that much of the Commission's recommendations went unheeded. Dunlop approached his work – advising presidents and cabinet officials and telling academics about the real world and practitioners about academic theory – with one goal: to help solve problems. The moral principle that guided him – that academics should use their knowledge and skill to help solve problems faced by real people, by workers and firms, and governments – represents social science at its best.

Article

French engineer and economic theorist, born at Fossano, Piedmont, Italy on 18 May 1804, when this region was part of the French empire; died 5 September 1866 in Paris. After his parents returned to Paris in 1814, Dupuit continued his education in the secondary schools at Versailles, at Louis-le-Grand and at Saint-Louis, where he finished brilliantly by winning a physics prize in a large group of competitors. Accepted to the Ecole des Ponts et Chaussées in 1824, Dupuit soon distinguished himself as an engineer and, in 1827, was put in charge of an engineering district in the department of Sarthe, where he concentrated on roadway and navigation work. Dupuit's numerous and trenchant engineering studies on such topics as friction and highway deterioration, floods and hydraulics, and municipal water systems made him one of the most creative civil engineers of his day. Decorated for such contributions by the Legion of Honour in 1843, Dupuit ultimately became director-chief engineer in Paris in 1850 and Inspector-General of the Corps of Civil Engineers in 1855. No less profound were Dupuit's contributions to general economic analysis and to the economic evaluation of public works (cost–benefit analysis). In fact, Dupuit was the most illustrious contributor in the long French tradition of study, teaching and writing on economic topics at the Ecole des Ponts et Chaussées, whose professors and students included Isnard, Henri Navier, Charles Minard, Emile Cheysson and Charles Ellet.

Led by a desire to evaluate the economic or net benefits of public provision, Dupuit directed his considerable analytical gifts to the utility foundation of demand and to its relevance to the welfare benefits of public works. In three substantial papers appearing in the Annales des Ponts et Chaussées (1844; 1849) and the Journal des économistes (1853), Dupuit became the first non-adventitious expositor of the theory of marginal utility, of (a variant of) marginal cost pricing, of simple and discriminating monopoly theory, and of pricing principles of the firm where location is a factor in expressing demand.

The font of Dupuit's contribution is the construction of a marginal utility curve and the identification of it with the demand curve or courbe de consommation (see Figure 1). Figure 1
Arguing in the manner of Carl Menger, who later elaborated on the point, Dupuit showed that the marginal utility that an individual obtained from a homogeneous stock of goods is determined by the use to which the last units of the stock are put. In doing so, he clearly pointed out that the marginal utility of a stock or some particular good diminishes with increases in quantity and that each consumer attaches a different marginal utility to the same good according to the quantity consumed. The importance of Dupuit's invention rests in the fact that the psychological concept of diminishing marginal utility, and its ramifications, were carried over to the law of demand. With some, but not all, of the reservations and qualifications of Alfred Marshall, Dupuit identified the marginal utility curve with the demand curve, adding up the utility curves of individuals to obtain the market demand curve.

Dupuit (1844, p. 106) described his construction (see Figure 1), which applied to all goods, public and private, as follows:

If … along a line $Op$ the lengths $O{p'}$, $O{p''}$ … represent various prices for an article, and that … $p_n, p'_{n'}$, $p''_{n''}$ … represent the number of articles consumed corresponding to these prices, then it is possible to construct a curve $Nn' \quad n''$ $P$ which we shall call the curve of consumption. $ON$ represents the quantity consumed when the price is zero, and $OP$ the price at which consumption falls to zero.
The identification of marginal utility and demand, of course, sets up the demand curve as a welfare tool and Dupuit made specific calculations. A measure of the welfare produced by the good (utilité absolue) at quantity Or is the definite integral of the demand curve between O and r. Given that Op is the (average) cost of producing quantity Or, consumers earn a surplus (utilité relative) equal to absolute utility (OrnP) less costs of production (Ornp). (Relative utility (pnP) is none other than Marshall's consumers' surplus without all the reservations that Marshall attached to the concept.) Importantly, Dupuit identified area rNn as lost utility (utilité perdue). Under competitive conditions this loss was inevitable due to the opportunity cost of resources. Under a monopoly structure, for example, if, in Figure 1, Op were a monopoly price with zero production costs assumed, utilité perdue would be a loss to society – the ‘deadweight’ loss associated with excise taxes, tariffs or monopoly. Further, Dupuit advanced the theorem that the loss in utility was proportional to the square of the tax of price above marginal cost. This theorem, with attendant analysis, formed the base for large areas of neoclassical welfare economics, including the taxation studies of F.Y. Edgeworth and the marginal cost pricing argument of Harold Hotelling.

From this theoretical base, Dupuit investigated an impressive number of pricing systems and market models (1849). While Dupuit was an ardent and stubborn defender of laissez faire in most markets (1861), he was equally concerned that public works, provided or regulated by government as a last resort, should produce the maximum amount of utility possible. Thus tools such as marginal cost pricing find their theoretical foundations in the writings of Dupuit. Although Dupuit did not provide an explicit formulation of the principle, one of his bridge examples and other statements strongly suggest the possibilities of such a technique to maximize welfare, but as a long-run proposition.

Dupuit analysed, independently of Cournot, who was apparently unknown to him, the profit-maximizing behaviour of the simple monopolist. He saw monopoly at the apex of a range of problems regarding the production of total welfare, being unconcerned about the ‘distribution’ of welfare between producers and consumers. His point was that the amount of ‘absolute utility’ (or what could be called net benefit) was lessened by monopoly profit maximization. This led him to defend the private practice of price discrimination and to produce an economic theory of discrimination. Price discrimination could exist, in Dupuit's view, with differences in ‘buyer estimates’, with the ability to segment markets either naturally or artificially, and with some degree of monopoly power. The motive was profit maximization, and although Dupuit discussed the effects of discrimination on price and revenue, he was primarily interested in the fact, as was Joan Robinson later, that discrimination could affect the size of the welfare benefit. This view was expanded to include the impact of price discrimination of welfare when buyers were spatially distributed (1849; 1854).

In the matter of policy, Dupuit recommended that tools be carefully fit to specific problems. If industries were to be collectivized or regulated by government, Dupuit proposed the maximization of net benefit under the constraint of covering total costs of production. The recovery of total cost might be achieved through regulated or constrained price discrimination or through a cost-based single price technique. However, Dupuit can hardly be credited with espousing an enlarged role for government or government intervention. A firm adherent of Smith's dictums concerning minimal government, Dupuit believed that free and open competition, along with vigorous antitrust or anticartel enforcement, would ensure optimal provisions in most cases, including transportation. Indeed, in the process of analysing the welfare principles of public works pricing, Dupuit discovered (in an uncommonly complete manner) some of the critical welfare-maximizing properties of a generalized competitive system.

durable goods markets and aftermarkets

Michael Waldman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

There is an extensive literature on durable-goods markets that starts with the work of Akerlof, Coase, and Swan in the early 1970s. In this entry I survey the literature by starting with the three theoretical building blocks of time inconsistency, adverse selection, and substitutability between new and used units. I then focus on our understanding of three important real-world issues. These are whether firms choose optimal durability levels, whether firms have incentives to eliminate second-hand markets, and reasons for leasing. The article also provides an extensive discussion of aftermarket monopolization.

Article

Durable goods are goods whose useful lifetime spans multiple periods. This article surveys the extensive literature on durable-goods markets and aftermarkets. I begin with the main theoretical ideas, then turn to specific real-world issues such as durability choice and leasing, discuss aftermarket monopolization and then end with a brief conclusion. (A more in-depth survey appears in Waldman, 2003.)

Three theoretical building blocks

Much of our understanding of durable-goods markets derives from three theoretical contributions. The
first is Coase’s (1972) insight concerning time inconsistency. To see the basic logic, consider Bulow’s (1982) formalization: a durable-goods monopolist sells its output in each of two periods and cannot commit in the first period to second-period actions. Bulow shows that, because in the second period the firm does not internalize how its actions affect the value of used units, its output is higher than under commitment. First-period purchasers anticipate this, pay less for new units and thus lower overall monopoly profitability.

Coase’s insight has spawned a large literature. One branch of this literature focuses on the Coase conjecture, that is, the idea that in an infinite-period setting time inconsistency causes price to drop immediately to marginal cost. A second branch identifies tactics such as leasing that firms can employ to reduce or possibly avoid time inconsistency. Finally, a third branch applies time inconsistency to other issues, including new-product introductions and repurchase prices.

The second major theoretical contribution is Akerlof’s (1970) adverse-selection argument. This paper helped start the asymmetric-information revolution, but was not initially thought of as an important contribution to durable-goods theory. However, the paper’s main example concerns second-hand markets. In Akerlof’s model buyers have higher valuations than sellers, so efficiency requires that all units be traded. Further, each seller is privately informed of his own unit’s quality. The result is a single price that reflects average quality, and sellers with high-quality units keep them because prices do not reflect actual quality, that is, trade is below the efficient level. (In Akerlof’s analysis there is no trade, but this result is not robust.)

A small empirical literature looks for evidence of adverse selection in durable-goods markets. Most of these papers find some support. For example, Bond (1982) considers the used pickup truck market and finds support for adverse selection for older trucks, while Genesove (1993) finds some supporting evidence in used-car dealer auctions. More recently, Gilligan (2004) finds supporting evidence in business aircraft.

In terms of durable-goods theory, Akerlof’s contribution was ignored for almost 30 years. Starting with Hendel and Lizzeri (1999a), however, a number of papers have extended Akerlof’s analysis. There are three basic findings. First, Akerlof’s main results continue to hold when new units are incorporated into the analysis. Second, because adverse selection in the used-unit market reduces the willingness to pay of new-unit buyers, firms will market new units in a manner that reduces adverse selection. Third, as discussed in detail later, new-unit leasing can be important for reducing adverse selection. The third major theoretical contribution is that there is a close analogy between the product-line pricing problem and the durable-goods monopoly problem. This analogy is described in Waldman (1996).

Consider Mussa and Rosen (1978), which analyses the product-line pricing problem of a non-durable-goods monopolist. The monopolist sells units of varying qualities to consumers who have heterogeneous valuations on quality. Because the substitutability between units links the various prices, the monopolist lowers below efficient levels the quality level sold to all but the highest-valuation group.

Now consider a durable-goods monopolist who controls the quality of a unit at every age. Further, assume heterogeneity in consumers’ valuations for quality and a frictionless second-hand market. Then, if the firm can commit, quality choices are as above. That is, new-unit quality is efficient. But, because of the linkages between the various prices, all used-unit qualities are below efficient levels. As discussed later, a number of recent papers use this result to analyse various real-world issues concerning durable goods.
Three real-world issues

Optimal durability choice

A much debated issue is whether a durable-goods monopolist chooses socially optimal durability. Swan (1970; 1971) considers models that satisfy the once standard assumption that a unit is a bundle of ‘service units’, so some number of used units is a perfect substitute for a new unit. Swan's steady-state analysis shows durability choice to be socially optimal because the firm produces the steady-state flow of service units at minimum cost. (Swan's analysis corrected the conclusions of earlier papers that had concluded that in such settings the monopolist would choose inefficiently low durability levels.)

A large literature investigates the robustness of Swan's conclusions. There are two major findings. The first employs time inconsistency. Bulow (1986) moves away from Swan's assumption of steady-state behaviour by considering a model similar to his earlier one, but now allows endogenous durability choice. He shows that time inconsistency provides a rationale for a durable-goods monopolist to choose less than the socially-optimal durability level. The logic is that durability is what leads to time inconsistency, so reducing durability below the efficient level reduces time inconsistency and thus increases profitability.

The second major finding appears in Waldman (1996) and Hendel and Lizzeri (1999b), which drop the service units assumption and instead assume that new and used units vary in quality and that durability choice controls the speed of quality deterioration. The earlier discussion immediately translates into an incentive for the firm to choose less than the socially optimal durability level. That is, in this setting the incentive for the monopolist to sell output whose used-unit quality is below the efficient level translates into durability below the efficient level. (In Hendel and Lizzeri's analysis durability choice can be above, below, or equal to the first-best level, but it is always below the second-best level defined by actual outputs.)

Eliminating second-hand markets

Do durable-goods producers with market power have incentives to eliminate second-hand markets? For example, do textbook publishers introduce new editions in order to kill off the market for used books? Until recently, the standard argument, found, for example, in Swan (1980), was that, since the new-unit price reflects prices the product will sell for on the second-hand market in subsequent periods, the producer has no such incentive.

Two recent arguments show that this result is, in fact, quite limited. The first, which builds on the discussion above, appears in Waldman (1996; 1997) and Hendel and Lizzeri (1999b). The idea is that, because substitutability between new and used units means the price of a used unit on the second-hand market limits the amount the firm can charge for new units, the firm sometimes eliminates the second-hand market or similarly reduces used-unit availability in order to raise the new-unit price. In particular, this is more likely when consumers of used units have low valuations for the firm's product. This is both because little revenue is lost by not serving such consumers and because serving them means a low used-unit price and thus a lower new-unit price. (A number of earlier papers find similar results starting with...
durable goods markets and aftermarkets: The New Palgrave Dictionary of Economics

The second argument, found initially in Waldman (1993), employs time inconsistency. As discussed, the early literature on time inconsistency focused on output choice. My 1993 paper shows time inconsistency also applies to actions such as new-product introductions that make used units unavailable because they become obsolete. The difference between this argument and the one above concerns commitment. Above it is assumed the firm can commit, so the firm eliminates the second-hand market only when it is profitable to do so. In contrast, here commitment is not assumed, so the firm may eliminate the second-hand market even though this lowers overall profitability.

A related empirical analysis appears in Iizuka (2004), which shows that the market share of used textbooks is an important determinant of whether or not a publisher introduces a new edition. This is consistent with new editions being used at least partly to eliminate second-hand markets, although Iizuka does not distinguish between the two possibilities described above for why a firm might want to do this. In future research, it might be possible to identify which argument is at work by focusing on how the decision to introduce new editions affects overall profitability.

**Reasons for leasing**

A number of reasons have been identified for why durable-goods producers frequently lease. (A reason I do not discuss is that there are sometimes tax advantages associated with leasing.) One reason, initially discussed in Coase (1972) and Bulow (1982), is that time inconsistency lowers profitability when a firm sells output because it chooses actions in later periods that inefficiently lower the value of used units. When the firm leases, however, it retains ownership of those units so the incentive to take inefficient actions disappears.

A second reason is also related to a previous discussion. As discussed in Waldman (1997) and Hendel and Lizzeri (1999b), when used-unit prices serve as important constraints on the new-unit price, leasing can be used to eliminate second-hand markets or at least reduce used-unit availability. The logic is that leasing allows a firm to eliminate the second-hand market by allowing the firm to retire returned used units. My 1997 paper shows this formally and argues that it is consistent with classic cases concerning the use of a lease-only policy such as United Shoe in the shoe machinery market, IBM in the computer market, and Xerox in the copier market. (One might argue that leasing is not needed because a firm can sell and then use high repurchase prices to purchase and retire used units. My 1997 paper shows this strategy is inferior to leasing because of time inconsistency.)

Finally, leasing is a response to adverse selection. This argument appears in Hendel and Lizzeri (2002) and Johnson and Waldman (2003). These papers show that, whether the new-unit market is monopolistic or competitive, in a world of asymmetric information leasing in the new-unit market can arise because it means used units are returned to the seller(s), which, in turn, avoids or at least reduces adverse selection in the used-unit market. The two papers develop different variants of the argument and show it is consistent with various empirical findings concerning the automobile market.

**Aftermarket monopolization**

Aftermarket monopolization is behaviour that stops alternative producers from selling aftermarket
products to the firm's customers. The focus on this subject started after the US Supreme Court's 1992 decision in the case *Eastman Kodak Company v. Image Technical Services*. Aftermarkets are common with durable goods, where aftermarkets refer to markets for complementary products such as maintenance and upgrades. I consider three possibilities: (a) hold-up rationales; (b) price discrimination and efficiency rationales; and (c) other strategic rationales.

### Hold-up

There are two distinct hold-up arguments, each of which focuses on aftermarket monopolization by competitive producers. In both, the firm prohibits other firms from selling the aftermarket product – for example, maintenance – and then exploits the locked-in positions of its customers in pricing the product. The result is a standard deadweight loss due to the high aftermarket price, although no transfer between the consumers and the firm since competition in the primary market means firms earn zero profits overall. In the ‘costly-information’ version, consumers ignore the aftermarket price when purchasing the primary product. In the ‘lack-of-commitment’ version, developed in Borenstein, Mackie-Mason and Netz (1995), consumers correctly anticipate the aftermarket price but, because firms cannot commit, time inconsistency causes firms to monopolize the aftermarket and inefficiently raise the aftermarket price after consumers are locked in. (A third hold-up theory is the ‘surprise’ theory. In this argument consumers are surprised by the aftermarket monopolization. Some discussions of this theory describe a transfer between the consumers and the firm, but it is unclear why competition does not result in zero profits, in which case the surprise and costly-information theories are equivalent.)

### Price discrimination and efficiency rationales

For various reasons, such as that many buyers in the relevant industries are sophisticated firms for which the costly-information argument is implausible, attention has shifted towards other arguments many of which have either neutral or positive social-welfare implications. One such argument is the price discrimination argument that appears in Chen and Ross (1993) and Klein (1993). Suppose the primary-good producer has market power. Then the firm may monopolize the aftermarket in order to raise the aftermarket price and in this way price discriminate by charging a high aggregate price to the high-volume/high-valuation consumers. From a social-welfare standpoint, this argument has neutral implications since an improved ability to price discriminate can either raise or lower social welfare. (Klein argues that this argument applies even when firms are competitive, although not perfectly competitive.) A plausible efficiency rationale follows from Schmalensee's (1974) argument that, given a durable-goods monopolist (which means new units priced above marginal cost) and a competitive maintenance market (which means maintenance is priced at cost), consumers will sometimes inefficiently maintain rather than replace used units. Tirole (1988) shows this can lead to aftermarket monopolization in a durable-goods monopoly setting because having a monopoly in both markets allows the firm to avoid the inefficiency and thus increases its profits. More recently, Morita and Waldman (2005) and Carlton and Waldman (2006) show that the argument extends to aftermarkets other than maintenance, and to competitive durable-goods markets given

http://www.dictionaryofeconomics.com.proxy.library.csi....edu/article?id=pde2008_D000240&goto=B&result_number=428 2008-12-31 0:05:05
switching costs. In the latter case the inefficient substitution problem arises even with competition because switching costs create market power at the time of the maintenance/replacement decision. Interestingly, because competitive sellers earn zero profits in equilibrium, when aftermarket monopolization eliminates the distortion, both social welfare and consumer welfare increase.

Strategic rationales

There is an extensive literature on strategic rationales for the tying of complementary products. Since the tying of primary and aftermarket products is one potential way to achieve aftermarket monopolization, much of this literature is relevant to aftermarket monopolization. Whinston (1990) shows that, if the primary good is not essential, tying may force the exit of an alternative producer of the complementary good and in this way increase the firm's profits by monopolizing the segment of the complementary-good market for which the primary good is not required.

In contrast, in Carlton and Waldman (2002) tying is sometimes used to preserve a monopoly in the primary-good market. They consider two-period settings in which a single potential entrant can enter the complementary market in either period but the primary market only in the second. In the presence of fixed costs of entry or network externalities, the primary-good monopolist sometimes ties in order to preserve its primary-good monopoly in the second period. For example, with entry costs tying stops the alternative producer from entering the complementary market in the first period. In turn, because of a possible inability to cover entry costs, the outcome can be no entry in either market in either period.

A third argument appears in Carlton and Waldman (2005). Whinston shows that in one-period settings there is never an incentive to tie if the monopolist's primary product is essential. Carlton and I show that in durable-goods settings, given the presence of complementary-good upgrades and switching costs, tying can be optimal even when the primary product is essential. The basic logic is that some profits are realized in later periods in the sale or lease of the upgraded complementary good, and the only way the monopolist can ensure it captures those profits is by tying and becoming the sole producer of the complementary good.

Conclusion

Starting in the early 1970s with the work of Akerlof, Coase and Swan, significant progress has been made in our understanding of durable-goods markets. In this entry I have surveyed this literature as well as the literature on the related issue of aftermarkets. Although I have referred throughout to various empirical papers, durable-goods markets is a topic for which theory is far ahead of empirical investigation. In the future I expect to see work that extends the theory in various important ways, but also empirical work that tests the validity of the various theoretical approaches that have been explored since the early 1970s.

Durbin–Watson statistic

James G. MacKinnon

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Durbin–Watson statistic; linear regression models; Monte Carlo test; ordinary least squares (OLS) estimator; serial correlation; testing; DW Statistic

Article

The well-known Durbin–Watson, or DW, statistic, which was proposed by Durbin and Watson (1950; 1951), is used for testing the null hypothesis that the error terms of a linear regression model are serially independent.

Consider the linear regression model with AR(1) errors,

\[ y_t = X_t \beta_0 + u_t, \quad u_t = \rho u_{t-1} + \epsilon_t, \quad \epsilon_t \sim \text{IID}(0, \sigma^2). \]  

(1)

Here the scalar \( y_t \) is an observation on a dependent variable, \( X_t \) is a \( 1 \times k \) vector of observations on independent variables that may be treated as fixed, and \( \beta \) is a \( k \)-vector of parameters to be estimated. There are \( n \) observations, and we wish to test the null hypothesis that \( \rho = 0 \), under which the model (1) reduces to

\[ y_t = X_t \beta_0 + u_t, \quad u_t \sim \text{IID}(0, \sigma^2), \]  

(2)
for which the ordinary least squares (OLS) estimator is efficient. This estimator is usually written as
\[ \hat{b} = (X'X)^{-1}X'y, \]
where the \( n \times k \) matrix \( X \) has \( t \)th row \( X_t \) and the \( n \)-vector \( y \) has \( t \)th element \( y_t \).

The Durbin–Watson \( d \) statistic for testing (2) against (1) is solely a function of the OLS residuals \( \hat{u}_t = y_t - X_t \hat{b} \). It is defined as
\[ d = \frac{\sum_{t=2}^{n} (\hat{u}_t - \hat{u}_{t-1})^2}{\sum_{t=1}^{n} \hat{u}_t^2}. \]

It is easy to see that \( d \) is approximately equal to \( 2 - 2\hat{\rho} \), where \( \hat{\rho} \) is the OLS estimate of \( \rho \) in a regression of \( \hat{u}_t \) on \( \hat{u}_{t-1} \). Thus \( d \) will be approximately equal to 2 if the residuals do not display any serial correlation, and it will be less (greater) than 2 whenever \( \hat{\rho} \) is more than a little bit greater (less) than 0.

The exact distribution of the DW statistic

The DW statistic can be written as a ratio of quadratic forms in the \( n \)-vector \( \hat{u} \) of OLS residuals, the \( t \)th element of which is \( \hat{u}_t \). Specifically,
\[ d = \frac{\hat{u}'A\hat{u}}{\hat{u}'\hat{u}}, \]

where \( A \) is the \( n \times n \) matrix
\[ \frac{1}{2} \begin{bmatrix} 1 & -1 & 0 & 0 & \cdots & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & \cdots & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & \cdots & 0 & -1 & 1 \end{bmatrix} \]
Durbin and Watson (1950) actually considered a number of statistics that can be written in the form of (4) for different choices of the matrix $A$ and chose to focus on $d$ for reasons of computational and theoretical convenience. Because both the numerator and the denominator are proportional to $\sigma^2$, $d$ is invariant to $\sigma$.

The exact distribution of $d$ depends on $X$ and the distribution of the $u_t$. When the error terms are i.i.d. normal, Durbin and Watson (1951) tabulated bounds on the critical values for tests based on $d$ against the one-sided alternative that $\sigma > 0$. These bounds, denoted $d_L$ and $d_U$, depend on the sample size and the number of regressors. We can reject the null hypothesis when $d < d_L$, cannot reject it when $d < d_U$, and can draw no firm conclusion when $d_L < d < d_U$. To test against the alternative that $\sigma < 0$, we would replace $d$ by $4 - d$ and use the same procedure.

The original Durbin–Watson tables have been extended by various authors, notably Savin and White (1977). However, since $d_U - d_L$ can be quite large, tests based on the bounds often have indeterminate outcomes. It is much better to perform exact tests conditional on $X$, and this is easy to do with modern computing technology. There are two approaches.

The first approach is to calculate an exact $P$ value for $d$ using one of several methods for calculating the distribution of a ratio of quadratic forms in normal random variables. The method of Imhof (1961) is probably the best known of these, but the more recent method of Ansley, Kohn and Shively (1992) is faster. If a suitable computer program is readily available, this approach is the best one.

An alternative approach is to perform a Monte Carlo test. As can be seen from (4), the statistic $d$ depends only on the vector $u$ and the matrix $X$, since $\hat{u} = M_{X} u$, where $M_{X} = I - X(X'X)^{-1}X'$. Because of its invariance to $\sigma$, $d$ does not depend on any unknown parameters. This implies that a Monte Carlo test will be exact.

To perform a Monte Carlo test at level $\alpha$, we first choose $B$ such that $\alpha(B + 1)$ is an integer (999 is often a reasonable choice) and generate $B$ vectors $\mathbf{u}^*_j$, each of which is multivariate standard normal. Each of the $\mathbf{u}^*_j$ is regressed on $X$ to calculate a vector of residuals $M_{X} \mathbf{u}^*_j$, which is then used to compute a simulated test statistic $\mathbf{d}^*_j$ according to (3). We can then calculate simulated $P$ values for a one-tailed test against either $\sigma > 0$ or $\sigma < 0$ or for a two-tailed test. For example, the simulated $P$ value for a one-tailed test against $\sigma > 0$ is

$$P^*(d) = \frac{1}{B} \sum_{j=1}^{B} I(d^*_j < d),$$

where $I(\cdot)$ is the indicator function that is equal to 1 when its argument is true and equal to 0 otherwise.
We reject the null hypothesis whenever $P^*(d) < \alpha$. For more on the calculation of $P$ values for bootstrap and Monte Carlo tests, see Davidson and MacKinnon (2006).

**Limitations of the DW statistic**

The Durbin–Watson statistic is valid only when all the regressors can be treated as fixed. It is not valid, even asymptotically, when $X_t$ includes a lagged dependent variable or any variable that depends on lagged values of $y_t$. Because $\hat{\rho}$ is biased towards 0 when $X_t$ includes a lagged dependent variable, $d$ is biased towards 2 in this case. Thus, a test based on the DW statistic will tend to under-reject when the null hypothesis is false.

Numerous procedures have been proposed for testing for serial correlation in models that include lagged dependent variables. The simplest is to rerun regression (2), with the addition of the lagged residuals from that regression. The test statistic is then the $t$ statistic on the lagged residuals. This procedure, which is due to Durbin (1970) and Godfrey (1978), does not yield an exact test and should be bootstrapped when the sample size is small.

Of course, since the finite-sample distribution of the DW statistic depends on the distribution of the $u_t$, we cannot expect to obtain an exact test even when the $X_t$ are exogenous if the normality assumption is not a good one. In principle, we could bootstrap $d$ by using re-sampled residuals instead of multivariate standard normal vectors for the $u^*_j$. This would probably work very well in most cases, but it would not actually yield an exact test.

Dutch disease

Thorvaldur Gylfason
From The New Palgrave Dictionary of Economics Online, 2008
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article outlines the ‘Dutch disease’, the fear of de-industrialization first seen in the Netherlands in the wake of the appreciation of the Dutch guilder following the discovery of natural gas deposits in the North Sea around 1960. It considers its symptoms, and asks whether it is indeed a ‘disease’ with negative economic implications. It also briefly reviews some cases of Dutch disease, and the case of Norway, which appears to have successfully avoided it.

Keywords

de-industrialization; Dutch disease; oil

Article

Dutch disease, in the original sense of the term, refers to the fears of de-industrialization that gripped the Netherlands in the wake of the appreciation of the Dutch guilder following the discovery of natural gas deposits in the North Sea around 1960. The appreciation of the guilder following the gas export boom hurt the profitability of manufacturing and service exports. Total exports from the Netherlands decreased markedly relative to Gross Domestic Product (GDP) during the 1960s. The growth of petroleum exports in the 1960s hurt other exports disproportionately. Many feared dire consequences for Dutch manufacturing. The problem proved short-lived, however. From the late 1960s onward, exports of goods and services have increased from less than 40 per cent of GDP to more than 70 per cent, a high export ratio by world standards. The expected de-industrialization did not materialize, but the name stuck. It can be said that, being neither Dutch nor a disease, the Dutch disease is a double misnomer. But when a disease bears the name of the first patient diagnosed with it, it would seem a bit harsh to require the patient to remain sick for the name to stick.

Is it a disease? Some view it as matter of one sector benefiting at the expense of others, without seeing any macroeconomic or social damage done. Others view the Dutch disease as an ailment, pointing to the potentially harmful consequences of the resulting reallocation of resources – from high-tech, high-skill intensive service industries to low-tech, low-skill intensive primary production, for example – for economic growth and diversification.

Symptoms

An overvalued currency was the first symptom associated with the Dutch disease, but later several other symptoms came to light. Figure 1 illustrates how an oil export boom lifts the equilibrium real exchange rate at which total exports of goods, services, and capital match total imports. In the figure, non-oil exports decline from A to C and hence by less than oil exports increase, so that total exports rise from A to B. For total exports to decline the import schedule would have to shift to the left (for instance through capital inflow) by an amount that exceeds the increase in oil exports, measured by the distance between B and C.

Figure 1

How an oil export boom crowds out nonoil exports.
Natural resource discoveries and dependence tend to go hand in hand with booms and busts: the prices and supplies of raw materials and related commodities fluctuate a great deal in world markets. Fish stocks, for example, are notoriously volatile. Oil wells are drilled, and then go dry, and mines are depleted. The resulting fluctuations in export earnings trigger exchange rate volatility, perhaps no less so under fixed exchange rates than under floating rates. Unstable currencies create uncertainty, which tends to hurt exports and imports as well as foreign investment. Further, the Dutch disease can strike even in countries that do not have a national currency of their own (as, for instance, in Greenland, which uses the Danish kroner and depends on fish). In this case, the natural-resource-based industry is able to pay higher wages and also higher interest rates than other industries, thus making it difficult for the latter to stay competitive. This problem can become particularly acute in countries with centralized wage bargaining (or with oligopolistic banking systems, for that matter) where the natural-resource-intensive industries set the tone in nation-wide wage negotiations and dictate wage settlements which other industries can ill afford. In one or all of these ways, the Dutch disease tends to reduce the level of total exports or skew the composition of exports away from manufacturing and service exports which could be particularly conducive to economic growth over time. Exports of capital, including inward foreign direct investment, may also suffer.

The Netherlands recovered quickly from the Dutch disease, and has seen a persistent upward trend in its total exports relative to GDP since the mid-1960s. On the other hand, in Norway, the world's third largest oil exporter after Saudi Arabia and Russia, total exports have risen slowly relative to GDP, to a level well below that of the Netherlands (45 per cent in Norway in 2005 compared with 71 per cent in the Netherlands), even if the Dutch economy is almost three times as large as that of Norway. Also, the share of manufactured exports in merchandise exports was 68 per cent in the Netherlands in 2005 compared with 17 per cent in Norway. Exports and manufacturing are good for growth. Openness to trade invigorates imports of goods and services, capital, technology, ideas and know-how. The Dutch disease matters mainly because of its potentially harmful consequences for economic growth.

Channels

Experience seems to suggest six main channels of transmission from heavy natural resource dependence to sluggish economic growth. At the top of the list is the Dutch disease. In second place, huge natural resource rents, especially in conjunction with ill-defined property rights, imperfect or missing markets, and lax legal structures, may lead to rent-seeking behaviour that diverts resources away from more socially fruitful economic activity. The struggle for resource rents may lead to a concentration of economic and political power in the hands of elites which, once in power, use the rent to placate their political supporters and thus secure their hold on power, with stunted or weakened democracy and slow growth as a result. Extensive rent seeking -- in other words, seeking to make money from market distortions -- can breed corruption, thus reducing both economic efficiency and social equality.

Third, natural resource abundance may imbue people with a false sense of security and lead governments to lose sight of the need for growth-friendly economic management, including free trade, foreign investment, bureaucratic efficiency and good institutions, including democracy. Incentives to create wealth through good policies and institutions may wane because of the relatively effortless ability to extract wealth from the soil or the sea. Fourth, abundant natural resources may likewise weaken incentives to accumulate human capital, even if the rent stream from the resources may enable nations to give a high priority to education. Fifth, natural resource abundance may blunt private and public incentives to save and invest in real capital no less than in human capital, and thereby weaken financial institutions and reduce economic growth. Sixth, natural resource wealth is a fixed factor of production that hampers economic growth potential by causing a growing labour force and a growing stock of capital to run into diminishing returns.

In sum, an abundance of natural capital, if not well managed, may erode or reduce the quality of human, physical, social, financial, and foreign capital, and thus stand in the way of rapid economic growth. Manna from heaven can be a mixed blessing. Consider the attitudes of individuals to their own and to other people's money. A person's respect for money tends to vary inversely with his or her distance from the effort expended to make the money. For example, loot tends to be invested with less forethought than honest wages. The same argument applies to unrequited foreign aid. An influx of aid tends to increase the real exchange rate, thereby hurting exports as in Figure 1. Import restrictions exacerbate the appreciation of the currency, hurting exports further. The figure suggests that aid needs to be accompanied by trade liberalization to avoid currency appreciation and its consequences.

Cases

The list of natural-resource-abundant countries beset by economic and political difficulties is a long one. Take Libya. Without its oil export revenues, Libya (population 6 million) would hardly have had the means to purchase 700 military aircraft, submarines and helicopters to pursue the foreign ambitions of Colonel Gaddafi, in power since 1969. In Equatorial Guinea, following oil discoveries, the purchasing power of per capita GDP increased by a factor of six or seven from 1990 to 2005, while life expectancy plunged from 46 years to 42. One child in five dies before reaching its fifth birthday. More than a half of the population of 500,000 lives on less than a dollar a day. President Mbsagzo has ruled the country with an iron fist since 1979, usurping the country's oil wealth for himself and his family and cronies. The readiness of the rest of the world to import oil from Equatorial Guinea, and thus to buy stolen goods, is an integral part of the problem because a people's right to its natural resources is a human right proclaimed in primary documents of international law and enshrined in many national constitutions. Article 1 of the International Covenant on Civil and Political Rights states that 'All people may, for their own ends, freely dispose of their natural wealth and resources.' Neither Libya nor Equatorial Guinea exports any manufactures to speak of.

The list of countries afflicted by various symptoms of the Dutch disease could be extended to include Iran, Iraq, Mexico, Nigeria, Russia, Saudi Arabia, Sudan and Venezuela, among several others. Some other countries have managed to avoid such afflictions. A prime example is Norway, where, before the first drop of oil emerged, the oil and gas reserves within Norwegian jurisdiction were defined by law as common property resources, thereby clearly establishing the legal rights of the Norwegian people to the resource rents. On this legal basis, the government has absorbed about 80 per cent of the resource rent over the years, having learnt the hard way in the 1970s to use a relatively small portion of the total to meet current fiscal needs. Most oil revenue is set aside in the state petroleum fund, recently renamed the pension fund to reflect its intended use. The government laid down economic as well as ethical principles (commandments) to guide the use and exploitation of the oil and gas for the benefit of current and future generations of Norwegians. The main political parties share an understanding that the national economy needs to be shielded from an excessive influx of oil money to avoid overheating and waste. The Central Bank (Norges Bank), which was granted increased independence from the government in 2001, manages the fund (currently around US$400 billion or $85,000 per Norwegian) on behalf of the Ministry of Finance. This arrangement maintains a distance between politicians and the fund. Almost 40 years after discovering their oil, the Norwegians have a smaller central government than Denmark, Finland and Sweden next door.

Norway's tradition of democracy since long before the advent of oil has probably helped immunize the country from the ailments that afflict most other oil-rich nations. Large-scale rent seeking has been averted in Norway, investment performance has been adequate, and the country's education record is excellent. Even so, some (weak) signs of the Dutch disease can be detected, notably sluggish exports and foreign direct investment and the absence of a large, vibrant high-tech manufacturing sector as in Sweden and Finland. Norway's lack of interest in joining the European Union can also be viewed in this light.

Then there is Botswana. Having managed its diamonds quite well and used the rents to support rapid growth, Botswana has become the richest country in Africa, measured by the purchasing power of per capita GDP. Its rapid growth since 1965 has been accompanied by political stability and a steady advance of democracy. Unlike Sierra Leone's alluvial diamonds, which are easy to mine by shovel and pan, and easy to loot, Botswana's kimberlite diamonds lie deep in the ground and can only be mined with large hydraulic shovels and other sophisticated equipment. They are therefore not very lootable. This difference probably helped Botswana succeed while Sierra Leone failed, and so, most likely, did South African involvement in Botswana's diamond industry.

- oil and the macroeconomy

Bibliography

How to cite this article

**Dutch Disease**
dutch disease, in the original sense of the term, refers to the fears of de-industrialization that gripped the Netherlands in the wake of the appreciation of the Dutch guilder following the discovery of natural gas deposits in the North Sea around 1960. The appreciation of the guilder following the gas export boom hurt the profitability of manufacturing and service exports. Total exports from the Netherlands decreased markedly relative to Gross Domestic Product (GDP) during the 1960s. The growth of petroleum exports in the 1960s hurt other exports disproportionately. Many feared dire consequences for Dutch manufacturing. The problem proved short-lived, however. From the late 1960s onward, exports of goods and services have increased from less than 40 per cent of GDP to more than 70 per cent, a high export ratio by world standards. The expected de-industrialization did not materialize, but the name stuck. It can be said that, being neither Dutch nor a disease, the Dutch disease is a double misnomer. But when a disease bears the name of the first patient diagnosed with it, it would seem a bit harsh to require the patient to remain sick for the name to stick.

Is it a disease? Some view it as matter of one sector’s benefiting at the expense of others, without seeing any macroeconomic or social damage done. Others view the Dutch disease as an ailment, pointing to the potentially harmful consequences of the resulting reallocation of resources – from high-tech, high-skill intensive service industries to low-tech, low-skill intensive primary production, for example – for economic growth and diversification.

**Symptoms**
An overvalued currency was the first symptom associated with the Dutch disease, but later several other symptoms came to light. Figure 1 illustrates how an oil export boom lifts the equilibrium real exchange rate at which total exports of goods, services, and capital match total imports. In the figure, nonoil exports decline from A to C and hence by less than oil exports increase, so that total exports rise from A to B. For total exports to decline the import schedule would have to shift to the left (e.g., through capital inflow) by an amount that exceeds the increase in oil exports, measured by the distance between B and C.

![Figure 1](image)

Natural resource discoveries and dependence tend to go hand in hand with booms and busts: the prices and supplies of raw materials and related commodities fluctuate a great deal in world markets. Fish stocks, for example, are notoriously volatile. Oil wells are drilled, and then go dry, and mines are depleted. The resulting fluctuations in export earnings trigger exchange rate volatility, perhaps no less so under fixed exchange rates than under floating rates. Unstable currencies create uncertainty that tends to hurt exports and imports as well as foreign investment. Further, the Dutch disease can strike even in countries that do not have a national currency of their own (as, for instance, in Greenland that uses the Danish krone and depends on fish). In this case, the natural-resource-based industry is able to pay higher wages and also higher interest rates than other industries, thus making it difficult for the latter to stay competitive. This problem can become particularly acute in countries with centralized wage bargaining (or with oligopolistic banking systems, for that matter) where the natural-resource-intensive industries set the tone in nation-wide wage negotiations and dictate wage settlements that other industries can ill afford. In one or all of these ways, the Dutch disease tends to reduce the level of total exports or skew the composition of exports away from manufacturing and service exports that may be particularly conducive to economic growth over time. Exports of capital, including inward foreign direct investment, may also suffer.

The Netherlands recovered quickly from the Dutch disease, and have seen a persistent
upward trend in their total exports relative to GDP since the mid-1960s. On the other hand, in Norway, the world’s third largest oil exporter after Saudi Arabia and Russia, total exports have risen slowly relative to GDP to a level well below that of the Netherlands (45 per cent in Norway in 2005 compared with 71 per cent in the Netherlands), even if the Dutch economy is almost three times as large as that of Norway. Also, the share of manufactured exports in merchandise exports was 68 per cent in the Netherlands in 2005 compared with 17 per cent in Norway. Exports and manufacturing are good for growth. Article

This article studies a new class of models which synthesize the two traditions of general equilibrium with non-clearing markets and imperfect competition on the one hand, and dynamic stochastic general equilibrium (DSGE) models on the other hand. Although this line of models is still recent, it has clearly become in a short time a central paradigm of modern macroeconomics. The reasons are at least threefold. The first is that it displays solid microeconomic foundations. This is quite natural since from the two constituent fields above this one inherited a strong general equilibrium framework where all agents (households or firms) maximize their respective objectives subject to well defined constraints. The second is that it is a highly synthetic theory, which combines in a unified framework general equilibrium, non-clearing markets, imperfect competition, growth theory and rational expectations, so that it can appeal to macroeconomists with very different backgrounds. The third reason is empirical. A key motivation for DSGE models is to compare the ‘statistics’ generated by these models with the real-world ones. In that respect the addition of non-clearing markets and imperfect competition has led to substantial progress in matching these statistics, and this has certainly been an important factor in the success of these models. Now such a wide synthesis did not come all at once. So we begin by recalling briefly a little bit of history and some of the antecedents of the field.

We then present a series of models with explicit solutions. These will demonstrate analytically how the introduction of non-clearing markets allows us to substantially improve the ability of DSGE to reproduce a number of macroeconomic facts.
At the time when many of the developments leading to these models were initiated, there was a profound split between microeconomics and macroeconomics. On the one hand microeconomics, in its general equilibrium version, was dominated by Walras’s (1874) model, as developed by Arrow and Debreu (1954), Arrow (1963), and Debreu (1959). In these models all adjustments are carried out via fully flexible prices, and agents never experience any quantity constraint. On the other hand in the standard macroeconomic model in the Keynes (1936) and Hicks (1937) tradition, as exemplified by the IS–LM model, there are price and wage rigidities, unemployment is present and most adjustments are carried out through variations in real income, a quantity, not a price.

Confronted with this inconsistency, the strategies of macroeconomists turned out to be quite diverse and they took two different routes.

**General equilibrium with non-clearing markets**

On the one hand, a first set of authors aimed at achieving a synthesis between the then existing microeconomics and macroeconomics. This was achieved by generalizing the traditional general equilibrium model, by introducing non-clearing markets, introducing quantity signals into demand and supply functions, and endogenizing prices in a framework of imperfect competition.

Patinkin (1956) and Clower (1965) showed that the presence of quantity constraints in non-clearing markets would drastically modify the demands for labour and goods, an insight further emphasized by Leijonhufvud (1968). Barro and Grossman (1971; 1976) combined these insights into a fixprice macromodel. Drèze (1975) and Bénassy (1975; 1982) constructed full general equilibrium concepts with price rigidities, where price movements are partially replaced by endogenous quantity constraints. Bénassy (1976) linked these concepts with general equilibrium under imperfect competition à la Negishi (1961). This link was furthered with the construction of a full general equilibrium concept of objective demand curve based on quantity constraints (Bénassy, 1988; see also Gabszewicz and Vial, 1972, for a Cournotian view). All these developments are reviewed in the dictionary entry ‘non clearing markets in general equilibrium’.

**Dynamic market clearing macroeconomics**

A second set of authors achieved consistency between microeconomics and macroeconomics by importing into macroeconomics the basic assumption of the then dominant general equilibrium microeconomic models, market clearing. At the same time they paid strong attention to the issues of dynamics and expectations. A central part of these developments was the use of ‘rational expectations’ in the sense of Muth (1961). This was an important addition, as in the Keynesian system it was sometimes difficult to disentangle the results due to price or wage rigidity from those due to incorrect expectations. Rational expectations allowed the suppression of the second type of results. It appeared also that, even with rational expectations and market clearing, it was possible to build rigorous models displaying fluctuations (Lucas, 1972; Kydland and Prescott, 1982; Long and Plosser, 1983).

**Non-Walrasian cycles**

Starting in the mid-1980s authors began combining elements of the two paradigms described above, achieving the synthesis that is the subject of this article. Svensson (1986) studies a dynamic stochastic general equilibrium monetary economy subject to supply and demand shocks. Prices are preset one period in advance by monopolistically competitive firms, so we have both imperfect competition and sticky prices. Because of price presetting the model has multiple regimes.

Various types of rigidities have been then introduced in dynamic models, leading to different patterns of cycles. Andersen (1994) reviews various causes and consequences of price and wage rigidities. A first type of rigidities is ‘real’ rigidities, which create an endogenous non-competitive wedge between various prices. As an example, monopolistic competition à la Dixit and Stiglitz (1977) introduces a markup between marginal cost and price. In this class Danthine and Donaldson (1990) introduce efficiency wages, Danthine and Donaldson (1991; 1992) introduce implicit contracts in the vein of Azariadis (1975), Baily (1974) and Gordon (1974). Rotemberg and Woodford (1992; 1995) study imperfect competition.

Models with nominal rigidities study situations where the nominal prices themselves (and not relative prices) are sluggish. Several devices have been used. The first, following the early works on wage and price contracts by Gray (1976), Fischer (1977), Phelps and Taylor (1977), Taylor (1979; 1980) and Calvo (1983), assumes that there is a system of contracts expiring at deterministic or stochastic dates. For that reason they are called ‘time dependent’. Such contracts have been integrated in DSGE models by Cho (1993), Cho and Cooley (1995), Bénassy (1995; 2002; 2003a; 2003b), Yun (1996), Cho, Cooley and Planeuf (1997), Andersen (1998), Jeanne (1998), Ascani (2000), Chari, Kehoe and McGrattan (2000), Collard and Ertz (2000), Ascani and Rankin (2002), Huang and Liu (2002), Smets and Wouters (2003) and Christiano, Eichenbaum and Evans (2005), to name only a few.

Another type of price rigidity, called ‘state dependent’, is based on costs of changing prices. Two specifications are favoured in the literature: quadratic costs of changing prices.
dynamic models with non-clearing markets: The New Palgrave Dictionary of Economics

(Rotemberg, 1982a; 1982b), which have been implemented, for example, in Hairault and Portier (1993), and fixed costs of changing prices (Barro, 1972), often renamed ‘menu costs’. Clearly these costs should be interpreted as surrogates for other unspecified causes, and identifying these causes is a challenge that faces this line of research.

Now most of the contributions of this field are based on numerical evaluations of various models. So we present next a number of models with explicit solutions which will make clear why this line of models has been successful in solving problems that were difficult to solve in market-clearing models.

An analytical illustration

We shall now show in this section in a series of explicitly solved models how the introduction of nominal rigidities in DSGE models allows to considerably improve the capacities of these models to reproduce the dynamic evolutions of actual economies.

We first present a basic model and compute as a reference its Walrasian equilibrium and dynamics. Then we introduce a first nominal rigidity, one-period wage contracts. This improves some correlations, but cannot create strong persistence as in reality. We next introduce multi-periodic wage contracts, and show that this allows us to obtain a persistent response of output to demand shocks. Finally, simultaneous rigidities of wages and prices are considered, and we show that one can obtain in this way with fairly realistic values of the parameters a persistent and hump-shaped response of both output and inflation.

The basic model

We study a dynamic monetary economy à la Sidrauski (1967) and Brock (1975), where goods are exchanged against money at the (average) price $P_t$ and work against money at the (average) wage $W_t$. There are two types of agents: households and firms. Firms have a simple technology:

$$y_t = Z_t N_t$$

(1)

where $N_t$ is the quantity of labour used by firms and $Z_t$ a technological shock common to all firms. Note that we do not introduce capital in this model. Because its rate of depreciation is low, it would not add much to our argument, and would substantially complicate the results and exposition.

The representative household works $N_t$, consumes $C_t$, and ends period $t$ with a quantity of money $M_t$. It maximizes the expectation of its discounted utility:

$$U = E_0 \sum_{t=0}^{\infty} \beta^t \left[ \log C_t + \omega \log \frac{M_t}{P_t} - \frac{\xi N_t^\gamma}{\gamma} \right].$$

(2)

At the beginning of period $t$ the household faces a monetary shock à la Lucas (1972), whereby the quantity of money $M_{t-1}$ coming from $t-1$ is multiplied by $\mu_t$, so that its budget constraint for period $t$ is:

$$C_t + \frac{M_t}{P_t} = W_t N_t + \frac{\mu_t M_{t-1}}{P_t}.$$
There are thus two shocks in this economy, the technology shock \( Z_t \) and the monetary shock \( \mu_t = M_t / M_{t-1} \). As an illustration we shall use below the following traditional processes (in all that follows lower-case letters represent the logarithm of the variable represented by the corresponding uppercase letter):

\[
m_t - m_{t-1} = \frac{\epsilon_{mt}}{1 - \delta l} Z_t = \frac{\epsilon_{mt}}{1 - \delta l}
\]

(4)

where \( \epsilon_{zt} \) and \( \epsilon_{mt} \), the innovations in \( z_t \) and \( m_t \), are uncorrelated white noises with:

\[
\text{var}(\epsilon_{zt}) = \sigma_z^2 \text{var}(\epsilon_{mt}) = \sigma_m^2.
\]

(5)

Walrasian dynamics

As a benchmark we shall study here the case where both labour and goods markets are in Walrasian equilibrium in each period, as in the first traditional real business cycle (RBC) models, and we shall see how this economy reacts to technological and monetary shocks. Solving the model we find that money holdings are a multiple of consumption:

\[
\frac{M_t}{P_t \xi_t} = \frac{\omega}{1 - \beta}
\]

(6)

and that employment \( N_t \) is constant:

\[
N_t = N = (\omega / \xi)^{1/\nu}.
\]

(7)

Using (1) and (7) we find (we eliminate some irrelevant constant terms):

\[
n_t = n\gamma_t = Z_t + \alpha n \omega_t - \rho_t = \gamma_t - n.
\]

(8)
Although we will not do any real calibration in this article, we can note at this stage a few issues that posed a problem to researchers in the RBC domain.

First, real wages are much too pro-cyclical in this Walrasian model. From (8) we see that the real wage–output correlation is equal to 1. Even though this correlation is lower than 1 in calibrated models where \( N_t \) varies, it is always quite above what is observed in real economies.

A second problem concerns the inflation–output correlation, a problem related to the literature on the Phillips curve. Whereas it is generally considered that this correlation is positive, the above Walrasian model yields a negative correlation:

\[
\text{cov}(\Delta P_t, \gamma_t) = -\frac{\sigma^2}{1 + \Phi} < 0.
\]  
(9)

Finally, an important and recurrent critique of RBC-type models has been that they do not generate any internal propagation mechanism, and that the only persistence in output movements is that already present in the exogenous process of technological shocks \( z_t \) (see, for example, Cogley and Nason, 1993; 1995). This appears here in eq. (8), where the dynamics of output \( \gamma_t \) is exactly the same as that of the technological shock \( z_t \).

We shall now introduce wage contracts, first lasting one period, and then multi-period overlapping contracts, and we shall see that the above problems find a natural solution in this framework.

**Single period wage contracts**

Let us thus assume (Bénassy, 1995, and Bénassy, 2002, for microfoundations), that the wages are predetermined at the beginning of each period at the expected value of the Walrasian wage (in logarithms), and that at this contractual wage the households supply the quantity of work demanded by firms (this type of contract was introduced by Gray, 1976).

Combining (6) and \( C_t = \gamma_t \) we find that the Walrasian wage \( \gamma_t^* \) is, up to an unimportant constant, equal to \( m_t \), so that the preset wage \( w_t \) is given by:

\[
w_t = E_{t-1} \gamma_t^* = E_{t-1} m_t
\]  
(10)

where \( E_{t-1} m_t \) is the expectation of \( m_t \) formed at the beginning of period \( t \), before shocks are known.

The difference with the Walrasian case is that employment \( N_t \) is now variable and demand determined. Equations (8) become:

\[
\gamma_t = z_t + \alpha n_t w_t - p_t = \gamma_t - n_t
\]  
(11)

while \( n_t = n \) is replaced by (10). So we first obtain the level of employment in period \( t \):

\[
n_t = n + m_t - E_{t-1} m_t = n + \varepsilon_{t+1}
\]
since \( m_t - m_{t-1} = \epsilon_t \). Contrarily to what happened in the Walrasian version of the model, unanticipated monetary shocks now have an impact on the level of employment, and therefore output. We shall now use the preceding formulas to show that the hypothesis of preset wages allows to substantially improve some correlations relative to the Walrasian model.

Let us start with the real wage which, in the Walrasian model, has a much too high positive correlation with output. Let us combine (11) and (12), to obtain the values of output and real wage:

\[
\gamma_t = z_t + \alpha \epsilon_t, \\
\rho_t = z_t - (1 - \alpha) \epsilon_t. 
\]

(13)

We see that supply shocks create a positive correlation between the real wage and output. However, monetary shocks create a negative correlation. Our model thus allows us to combine this last characteristic, typical of traditional Keynesians models, with the usual results of RBC models. If one considers the technological and monetary shocks (4), one obtains the following correlation:

\[
\text{corr}(w_t, \gamma_t) = \frac{\sigma^2_w - (1 - \phi^2) \alpha (1 - \alpha) \sigma^2_m}{\left[\left(\sigma^2_w + (1 - \phi^2) \alpha^2 \sigma^2_m\right)^{1/2} \left[\sigma^2_w + (1 - \phi^2) (1 - \alpha)^2 \sigma^2_m\right]^{1/2}\right]^{1/2}}. 
\]

(14)

We see that the real-wage–output correlation is equal to 1 if there are only technological shocks. But this correlation diminishes as soon as there are monetary shocks, and it can even become negative. One can thus reproduce the correlations observed in reality by adequate combinations of technological and monetary shocks.

Let us now consider the relation between inflation and output, which are generally considered to be positively correlated, at least in Keynesian tradition. If we assume again the monetary and technological shocks (4), we find:

\[
\text{Covariance}(\Delta \rho_t, \gamma_t) = \alpha (1 - \alpha) \sigma^2_m - \frac{\sigma^2_w}{1 + \phi}. 
\]

(15)

Formula (15) shows us that the positive covariance (and thus correlation) between inflation and output is linked to the presence of demand shocks, and that the sign of this correlation may change if there are sufficiently strong technological shocks.

So we just saw that one-period contracts allow us to improve some important correlations. We now naturally ask a question already posed for the standard RBC model: is the response to shocks, and in particular to demand shocks, sufficiently persistent? Let us recall eq. (13):

\[
\gamma_t = z_t + \alpha \epsilon_t. 
\]
We see that monetary shocks now have an immediate effect on output (and employment), but that, starting with the second period, the effect of these shocks is completely dampened. One-period contracts allow us to solve the puzzle raised by some correlations, but certainly not the persistence problem. We shall see in the next two sections that multi-periodic contracts allow us to solve that problem.

Multi-period wage contracts

The models that we have examined so far share with traditional RBC models the defect of having an extremely weak internal propagation mechanism. In particular, the response of output to monetary demand shocks is almost entirely transitory. But several empirical studies (see, for example, Christiano, Eichenbaum and Evans, 1999; 2005) have pointed out that in reality the response to monetary shocks not only was persistent but also had a hump-shaped response function. We shall now introduce multi-period wage contracts in rigorous stochastic dynamic models, and show that they allow us to reproduce these features. Models with such multi-period wage or price contracts have been studied notably by Yun (1996), Andersen (1998), Jeanne (1998), Ascari (2000), Chari, Kehoe and McGrattan (2000), Collard and Ertz (2000), and Bénassy (2002; 2003a; 2003b).

In order to make our demonstration analytically, we use a contract, inspired by Calvo (1983) and developed in Bénassy (2002; 2003a), which has three advantages: (a) the average duration of contracts can take any value from zero to infinity, (b) an analytical solution can be found with both wage and price contracts, and (c) it has explicit microfoundations.

In this framework, in each period $s$, a contract is made for wages at period $t$. As in the Gray contract, the contract wage is the expectation of the market-clearing wage in period $t$. So if we denote as $x_{st}$ the contract wage made in $s$ for period $t$:

$$x_{st} = \mathbb{E}_s(w^*_t).$$

(17)

Now, as in Calvo (1983), each wage contract has a probability $\gamma$ to stay unchanged, and a probability $1 - \gamma$ to be broken. If the contract is broken, a new contract is immediately renegotiated on the basis of current period information. So for $\gamma = 0$, wages are totally flexible, for $\gamma = 1$ they are totally rigid.

It is easy to compute the average duration of these contracts. The probability for a contract to be still valid $j$ periods after the date it was concluded is equal to $(1 - \gamma)^j$. The expected duration of the contract is thus:

$$\sum_{j=0}^{\infty} (1 - \gamma)^j \gamma^j = \frac{\gamma}{1 - \gamma}.$$

(18)

We thus see that varying $\gamma$ from 0 to 1 the average duration of the contract varies from zero to infinity.

The average wage $w_t$ is the mean of past $x_{st}$’s weighted by the probability for the corresponding contract to be still in effect. Because of the law of large numbers, and since the probability of survival of wage contracts is $\gamma$, the proportion of contracts coming from period $s \leq t$ is $(1 - \gamma)^{t - s}$. Therefore, the average wage in the economy is given by:
If we now solve the model with the shocks (4) we find that the dynamics of employment is characterized by (Bénassy, 2002; 2003a):

\[ \psi_t = (1 - \gamma) \sum_{s=-\infty}^{t} \gamma^{s-t} c_{s,t}. \]  

(19)

where \( L \) is the lag operator: \( L^j X_t = X_{t-j} \). The response of output is deduced from that of employment through:

\[ n_t = n + \frac{\gamma \sigma \rho}{(1 - \gamma L) (1 - \gamma \rho L)} Y_{n \rho} \]  

(20)

where \( L \) is the lag operator: \( L^j X_t = X_{t-j} \). The response of output is deduced from that of employment through:

\[ y_t = \alpha n_t + z_t \]  

(21)

Formula (20) shows clearly that, contrarily to the case of one-period contracts, the response to a monetary shock can be quite persistent. We can have an idea of the temporal profile of this response by computing the response function of output and employment to a monetary shock. The value of \( \rho \) most often found in the literature is \( \rho = 0.5 \). As for \( \gamma \), we saw above (formula 18) that the average duration of wage contracts is equal to \( \gamma / (1 - \gamma) \). One considers generally that the average duration of wage contracts is about one year (see, for example, Taylor, 1999), which corresponds to \( \gamma = 4 / 5 \). Figure 1 shows the response of employment (output is derived via 21) to a monetary shock for \( \gamma = 4 / 5 \).
We see that the response function displays persistence in the effects of monetary shocks, and has even a hump-shaped response. If we plot, however, the response function of inflation, we find that it is steadily decreasing after the initial jump, whereas it seems to have a delayed hump-shaped response in reality.

**Wage and price multi-periodic contracts**

We shall now enlarge our model by considering simultaneously wage and price multi-periodic contracts (see Bénassy, 2003b, for such a model with explicit microfoundations). Numerically solved models with both wage and price multi-periodic contracts are found in Christiano, Eichenbaum and Evans (2005), Huang and Liu (2002), Smets and Wouters (2003).

Wage contracts are exactly the same as in the preceding section: each contract is maintained with probability $\gamma$, or renegotiated with probability $1 - \gamma$. Symmetrically, price contracts are maintained with probability $\varphi$, or break down and are renegotiated with probability $1 - \varphi$. The average price $p_t$ is given by:
where \( q_{st} \) is the price contract negotiated in period \( s \) for period \( t \). Using again the shock processes (4), and taking \( \psi = 1 \), we find the following dynamics for output and inflation:

\[
\xi_t = z_t - \frac{\psi \xi_{tt}}{1 - \psi L} + \frac{\alpha Y \xi_{tt}}{(1 - \gamma L)(1 - \gamma L)} + \frac{\psi \xi_{tt}}{(1 - \psi L)(1 - \psi L)} - \frac{\alpha Y \psi \xi_{tt}}{(1 - \gamma \psi L)(1 - \gamma \psi L)}
\]

\[
\pi_t = (1 - L) \rho_t = (1 - L) (\xi_t - \gamma_t).
\]

As in the preceding section we take as an illustration \( \alpha = 2 / 3, \phi = 1 / 2 \) and \( \gamma = 4 / 5 \) (one-year wage contracts). As for prices, we want to take a rather low duration of contracts, so we shall take \( \psi = 1 / 2 \) (one quarter). Simulations show that in that case we obtain a persistent and hump-shaped response for both output and inflation. So we see that with only reasonable nominal rigidities we obtain some realistic response functions. Clearly the adjunction of ‘real’ rigidities would allow to reproduce even better the actual dynamic macroeconomic patterns.

dynamic models with non-clearing markets: The New Palgrave Dictionary of Economics

dynamic programming

John Rust
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews the history and theory of dynamic programming (DP), a recursive method of solving sequential decision problems under uncertainty. It discusses computational algorithms for the numerical solution of DP problems, and an important limitation in our ability to solve realistic large-scale dynamic programming problems, the ‘curse of dimensionality’. It also summarizes recent research in complexity theory that delineates situations where the curse can be broken (allowing us to solve DPs using fast polynomial time algorithms), and situations where it is insuperable. The literature on econometric estimation and testing of DP models is reviewed, as is another ‘scientific limit to knowledge’, namely, the identification problem.

Article

1 Introduction

Dynamic programming is a recursive method for solving sequential decision problems (hereafter abbreviated as SDP). Also known as backward induction, it is used to find optimal decision rules in ‘games against nature’ and subgame perfect equilibria of dynamic multi-agent games, and competitive equilibria in dynamic economic models. Dynamic programming has enabled economists to formulate and solve a huge variety of problems involving sequential decision-making under uncertainty, and as a result it is now widely regarded as the single most important tool in economics. Section 2 provides a brief history of dynamic programming. Section 3 discusses some of the main theoretical results underlying dynamic programming, and its relation to game theory and optimal control theory. Section 4 provides a brief survey of numerical dynamic programming. Section 5 surveys the experimental and econometric literature that uses dynamic programming to construct empirical models economic behaviour.

2 History

The earliest reference to the use of the method of backward induction to solve decision problems appears to be Arthur Cayley’s 1875 solution to the secretary problem (I am grateful to Arthur F. Veinott Jr. for alerting me to this). In the mid-1940s a number of different researchers in economics and statistics appear to have independently discovered backward induction as a way to solve SDPs involving risk or uncertainty. Von Neumann and Morgenstern, in their seminal work on game theory (1944), used backward induction to find what we now call subgame perfect equilibria of extensive form games. (‘We proceed to discuss the game Γ by starting with the last move $M_v$ and then going backward from there through the moves $M_{v−1}, \ldots,M_0$: 1944, p. 126.) Abraham Wald, who is credited with the invention of statistical decision theory, extended this theory to sequential decision-making in his 1947 book Sequential Analysis. Wald generalized the
problem of gambler’s ruin from probability theory and introduced the sequential probability ratio test that minimizes the expected number of observations in a sequential generalization of the classical hypothesis test. However, the role of backward induction is less obvious in Wald’s work. It was more clearly elucidated in the 1949 paper by Arrow, Blackwell and Girshick. They studied a generalized version of the statistical decision problem and formulated and solved it in a way that is a readily recognizable application of modern dynamic programming. Following Wald, they characterized the optimal rule for making a statistical decision (for example, accept or reject a hypothesis), accounting for the costs of collecting additional observations. In the section ‘The Best Truncated Procedure’ they show how the optimal rule can be approximated ‘Among all sequential procedures not requiring more than N observations …’ and solve for the optimal truncated sampling procedure ‘by induction backwards’ (1949, p. 217).

Other early applications of backward induction include the work of Pierre Massé (1945, p. 196) on statistical hydrology and the management of reservoirs, and Dvoretsky, Kiefer and Wolfowitz’s (1952) analysis of optimal inventory policy. Richard Bellman is widely credited with recognizing the common structure underlying SDPs, and showing how backward induction can be applied to solve a huge class of SDPs under uncertainty. Most of Bellman’s work in this area was done at the RAND Corporation, starting in 1949. It was there that he invented the term ‘dynamic programming’ that is now the generally accepted synonym for backward induction. Bellman (1984, p. 159) explained that he invented the name ‘dynamic programming’ to hide the fact that he was doing mathematical research at RAND under a Secretary of Defense who ‘had a pathological fear and hatred of the term, research’. He settled on ‘dynamic programming’ because it would be difficult give it a ‘pejorative meaning’ and because ‘It was something not even a Congressman could object to’.

3 Theory

Dynamic programming can be used to solve for optimal strategies and equilibria of a wide class of SDPs and multiplayer games. The method can be applied both in discrete time and continuous time settings. The value of dynamic programming is that it is a ‘practical’ (that is, constructive) method for finding solutions to extremely complicated problems. However, continuous time problems involve technicalities that I wish to avoid in this survey. If a continuous time problem does not admit a closed-form solution, the most commonly used numerical approach is to solve an approximate discrete time version of the problem or game, since under very general conditions one can find a sequence of discrete time DP problems whose solutions converge to the continuous time solution the time interval between successive decisions tends to zero (Kushner, 1990). I start by describing how dynamic programming is used to solve single agent ‘games against nature’. The approach can be extended to solve multiplayer games, dynamic contracts, principal–agent problems, and competitive equilibria of dynamic economic models. See recursive competitive equilibrium.

3.1 Sequential decision problems

There are two key variables in any dynamic programming problem: a state variable s_t, and a decision variable d_t (the decision is often called a ‘control variable’ in the engineering literature). These variables can be vectors in \( \mathbb{R}^n \), but in some cases they might be infinite-dimensional objects. For example, in Bayesian decision problems, one of the state variables might be a posterior distribution for some unknown quantity \( \Theta \). In general, this posterior distribution lives in an infinite dimensional space of all probability distributions on \( \Theta \). In heterogeneous agent equilibrium problems state variables can also be distributions. The state variable evolves randomly over time, but the agent’s decisions can affect its evolution. The agent has a utility or payoff function \( U(s_1, d_1, \ldots, s_T, d_T) \) that depends on the realized states and decisions from period \( t = 1 \) to the horizon \( T \). In some cases \( T = \infty \), and we say the problem is infinite horizon. In other cases, such as a life-cycle decision problem, \( T \) might be a random variable, representing a consumer’s date of death. As we will see, dynamic programming can be adapted to handle either of these possibilities. Most economic applications presume a discounted, time-separable objective function, that is, \( U \) has the form

\[
U(s_1, d_1, \ldots, s_T, d_T) = \sum_{t=1}^{T} \beta_t U_t(s_t, d_t)
\]

where \( \beta_t \) is known as a discount factor that is typically presumed to be in the \((0, 1)\) interval, and \( U_t(s_t, d_t) \) is the agent’s period \( t \) utility (payoff) function. Discounted utility and profits are typical examples of time separable payoff functions studied in economics. However, the method of dynamic programming does not require time separability, and so I will describe it without imposing this restriction.

We model the uncertainty underlying the decision problem via a family of history and decision-dependent conditional probabilities \( \{ p_t(s_t | H_{t-1}) \} \) where \( H_{t-1} = (s_1, d_1, \ldots, s_{t-1}, d_{t-1}) \) denotes the history, that is the realized states and decisions from the initial date \( t=1 \) to date \( t=T \). Note that this includes all deterministic SDPs as a special case where the transition probabilities \( p_t \) are degenerate. In this case we can represent the ‘law of motion’ for the state variables by deterministic functions \( s_{t+1} = f(s_t, d_t) \). This implies that in the most general case, \( (s_t, d_t) \), evolves as a history dependent stochastic process. Continuing the ‘game against nature’ analogy, it will be helpful to think of \( \{ p_t(s_t | H_{t-1}) \} \) as constituting a ‘mixed strategy’ played by ‘nature’ and the agent’s optimal
strategy as a 'best response' to nature's strategy.

The final item we need to specify is the timing of decisions. Assume that the agent selects \( d_t \) after observing \( s_t \), which is ‘drawn’ from the distribution \( p(s_t | H_{t-1}) \). The alternative case where \( d_t \) is chosen before \( s_t \) is realized can also be handled, but requires a small change in the formulation of the problem. The agent’s choice of \( d_t \) is restricted to a state-dependent constraint (choice) set \( D_t \) \((H_{t-1}, s_t)\). We can think of \( D_t \) as the generalization of a ‘budget set’ in standard static consumer theory. The choice set could be a finite set, in which case we refer to the problem as discrete choice, or \( D_t \) could be a subset of \( R^k \) with non-empty interior, then we have a continuous choice problem. In many cases, there is a mixture of types of choices, which we refer to as discrete-continuous choice problems. An example is commodity price speculation; see for example Hall and Rust (2006), where a speculator has a discrete choice of whether or not to order his inventory and a continuous decision of how much of the commodity to order. Another example is retirement: a person has a discrete decision of whether to retire and a continuous decision of how much to consume.

**Definition:** A (single agent) sequential decision problem (SDP) consists of (1) a utility function \( U \), (2) a sequence of choice sets \( \{D_t\} \), and (3) a sequence of transition probabilities \( \{pt(s_t | H_{t-1})\} \)

where we assume that the process is initialized at some given initial state \( s_1 \).

In order to solve this problem, we have to make assumptions about how the decision-maker evaluates alternative risky strategies. The standard assumption is that the decision-maker maximizes expected utility. Backward induction does not necessarily result in optimal strategies for non-expect utility maximizers, except for certain classes of recursive preferences. As the name implies, an expected utility maximizer makes decisions that maximize their ex ante expected utility. However, since information unfolds over time, it is generally not optimal to pre-commit to any fixed sequence of actions \((d_1, …, d_T)\). Instead, the decision-maker can generally obtain higher expected utility by adopting a history-dependent strategy or decision rule \((\delta_1, ..., \delta_T)\). This is a sequence of functions such that for each time \( t \) the realized decision is a function of all available information. In the engineering literature, a decision rule that does not depend on evolving information is referred to as an open-loop strategy, whereas one that does is referred to as a closed-loop strategy. In deterministic control problems, the closed-loop and open-loop strategies are the same since both are simple functions of time. However in stochastic control problems, open-loop strategies are a strict subset of closed-loop strategies. Under our timing assumptions the information available at time \( t \) is \((H_{t-1}, s_t)\), so we can write \( d_t = \delta(H_{t-1}, s_t) \). By convention we set \( H_0 = \emptyset \) so that the available information for making the initial decision is just \( s_1 \). A decision rule is feasible if it also satisfies \( \delta(H_{t-1}, s_t) \in D_t(H_{t-1}, s_t) \) for all \((s_t, H_{t-1})\). Each feasible decision rule can be regarded as a ‘lottery’ whose payoffs are utilities, the expected value of which corresponds to expected utility associated with the decision rule. An optimal decision rule \( \delta^* = (\delta_1^*, …, \delta_T^*) \) is simply a feasible decision rule that maximizes the decision-maker's expected utility

\[
\delta^* = \max_{\delta \in \mathcal{F}} \mathbb{E} \{ U(\{ \tilde{H}_t, \tilde{d}_t \} \} \}
\]

where \( \mathcal{F} \) denotes the class of feasible history-dependent decision rules, and \( \{ \tilde{H}_t, \tilde{d}_t \} \) denotes the stochastic process induced by the decision rule \( \delta = (\delta_1, …, \delta_T) \). Problem (2) can be regarded as a static, ex ante version of the agent’s problem. In game theory, (2) is referred to as the normal form or the strategic form of a dynamic game, since the dynamics are suppressed and the problem has the superficial appearance of a static optimization problem or game in which an agent’s problem is to choose a best response, either to nature (in the case of single agent decision problems) or to other rational opponents (in the case of games). The strategic formulation of the agent’s problem is quite difficult to solve since the solution is a sequence of history-dependent functions \( \delta^* = (\delta_1^*, …, \delta_T^*) \) for which standard finite dimensional constrained optimization techniques (for example, the Kuhn–Tucker th) are inapplicable. (If we consider problems where all states can assume only a finite number of values, it is possible to apply standard finite dimensional Kuhn–Tucker constrained optimization methods, but if the state variables can assume a continuum of possible values, the programming problem becomes an infinite dimensional programming problem for which optimal control and dynamic programming methods are more appropriate. See Luenberger, 1969, for a more thorough discussion of how Lagrange multipliers and Kuhn–Tucker methods can be extended to problems where decisions are infinite-dimensional objects. These methods are usually applied in deterministic context, and there is a specialized literature on optimal control for solving such problems.) See Pontryagin's principle of optimality.

### 3.2 Solving sequential decision problems by backward induction

To carry out backward induction, we start at the last period, \( T \), and for each possible combination \((H_{T-1}, s_T)\) we calculate the time \( T \) value function and decision rule (we will discuss how backward induction can be extended to cases where \( T \) is random or where \( T = \infty \) shortly).

\[
V_T(\{H_{T-1}, s_T\}) = \max_{d_T \in D_T(\{H_{T-1}, s_T\})} \mathbb{E} \{ U(\{H_{T-1}, s_T, d_T\}) \}
\]
where we have written $U(H_{T-1}, s_T, d_T)$ instead of $U(s_1, d_1, \ldots, s_T, d_T)$ since $H_{T-1} = (s_1, d_1, \ldots, s_{T-1}, d_{T-1})$. Next we move backward one time period to time $T-1$ and compute

\[
V_{T-1}(H_{T-2}, s_{T-1}) = \max_{d_{T-1} \in D(T-1, H_{T-2}, s_{T-1})} E\{V_T(H_{T-2}, s_{T-1}, d_{T-1}, s_{T-1}, d_{T-1})|H_{T-2}, s_{T-1}, d_{T-1}\}
\]

(4)

where the integral in eq. (4) is the formula for the conditional expectation of $V_T$, where the expectation is taken with respect to the random variable $s_T$ whose value is not known as of time $T-1$. We continue the backward induction recursively for time periods $T-2, T-3, \ldots$ until we reach time period $t=1$. The equation for the value function $V_t$ in an arbitrary period $t$ is defined recursively by an equation that is now commonly called the Bellman equation

\[
V_t(H_{t-1}, s_t) = \max_{d_t \in D_t(H_{t-1}, s_t)} E\{V_{t+1}(H_{t-1}, s_t, d_t, s_{t+1}|H_{t-1}, s_t, d_t)|H_{t-1}, s_t, d_t\}
\]

(5)

The decision rule $\delta_t$ is defined by the value of $d_t$ that attains the maximum in the Bellman equation for each possible value of $(H_{t-1}, s_t)$

\[
\delta_t(H_{t-1}, s_t) = \arg\max_{d_t \in D_t(H_{t-1}, s_t)} E\{V_{t+1}(H_{t-1}, s_t, d_t, s_{t+1}|H_{t-1}, s_t, d_t)|H_{t-1}, s_t, d_t\}
\]

(6)

Backward induction ends when we reach the first period, in which case, as we will now show, the function $V_1(s_1)$ provides the expected value of an optimal policy, starting in state $s_1$ implied by the recursively constructed sequence of decision rules $\delta = (\delta_1, \ldots, \delta_T)$.
3.3 The principle of optimality

The key idea underlying why backward induction produces an optimal decision rule is called

The principle of optimality: an optimal decision rule \( \delta^* = (\delta_1^*, \ldots, \delta_T^*) \) has the property that given any \( t \in \{1, \ldots, T\} \) and any history \( H_{t-1} \) in the support of the controlled process \( \{\tilde{s}_t, d_t\}_{\xi^*} \), \( \delta^* \) remains optimal for the 'subgame' starting at time \( t \) and history \( H_{t-1} \). That is, \( \delta^* \) maximizes the "continuation payoff" given by the conditional expectation of utility from period \( t \) to \( T \), given history \( H_{t-1} \):

\[
\delta^* = \arg \max_{\delta} \mathbb{E}(U((s_{t}, d_{t})_{\xi})|H_{t-1}).
\]

In game theory, the principle of optimality is equivalent to the concept of a subgame perfect equilibrium in an extensive form game. When all actions and states are discrete, the stochastic decision problem can be diagrammed as a game tree. The principle of optimality, which in game theory is equivalent to the concept of a subgame perfect equilibrium, guarantees that if \( \delta^* \) is an optimal strategy (or equilibrium strategy) for the overall game tree, then it must also be an optimal strategy for every subgame, or, more precisely, all subgames that are reached with positive probability from the initial node.

It should now be evident why there is a need for the qualification 'for all \( H_{t-1} \) in the support of \( \{\tilde{s}_t, d_t\}_{\xi^*} \) in the statement of the principle of optimality. There are some subgames that are never reached with positive probability under an optimal strategy. Thus, it is easy to construct alternative optimal decision rules that do not satisfy the principle of optimality because they involve taking suboptimal decisions on 'zero probability subgames'. Since these subgames are never reached, such modifications do not jeopardize \textit{ex ante} optimality. However we cannot be sure \textit{ex ante} which subgames will be irrelevant \textit{ex post} unless we carry out the full backward induction process. Dynamic programming results in strategies that are optimal in every possible subgame, even those which will never be reached when the strategy is executed. Since backward induction results in a decision rule \( \delta^* \) that is optimal for all possible subgames, it is intuitively clear that \( \delta^* \) is optimal for the game as a whole, that is, it is a solution to the \textit{ex ante} strategic form of the optimization problem (2).

For a formal proof of this result for games against nature (with appropriate care taken to ensure measurability and existence of solutions), see Gihman and Skorohod (1979). If in addition to 'nature' we extend the game tree by adding another rational expected utility maximizing player, then backward induction can be applied in the same way to solve this alternating move dynamic game. Assume that player 1 moves first, then player 2, then nature, and so on. Dynamic programming results in a pair of strategies for both players. Nature still plays a 'mixed strategy' that could depend on the entire previous history of the game, including all the previous moves of both players. The backward induction process ensures that each player can predict the future choices of their opponent, not only in the succeeding move but in all future stages of the game. The pair of strategies \((\delta^1, \delta^2)\) produced by dynamic programming are mutual best responses, as well as being best responses to nature's moves. Thus, these strategies constitute a Nash equilibrium. They actually satisfy a stronger condition: they are Nash equilibrium strategies in every possible subgame of the original game, and thus are subgame-perfect (Selten, 1975). Subgame-perfect equilibria exclude 'implausible equilibria' based on incredible threats. A standard example is an incumbent's threat to engage in a price war if a potential entrant enters the market. This threat is incredible if the incumbent would not really find it advantageous to engage in a price war (resulting in losses for both firms) if the entrant called its bluff and entered the market. Thus the set of all Nash equilibria to dynamic multiplayer games is strictly larger than the subset of subgame-perfect equilibria, a generalization of the fact that, in single agent decision problems, the set of optimal decision rules includes ones which take suboptimal decisions on subgames that have zero chance of being reached for a given optimal decision rule. Dynamic programming ensures that the decision-maker would never mistakenly reach any such subgame, similar to the way subgame perfection ensures that a rational player would not be fooled by an incredible threat.

3.4 Dynamic programming for stationary, Markovian, infinite-horizon problems

The complexity of dynamic programming arises from the exponential growth in the number of possible histories as the number of possible values for the state variables, decision variables, and/or number of time periods \( T \) increases. For example, in a problem with \( N \) possible values for \( s_t \) and \( D \) possible values for \( d_t \) in each period \( t \), there are \([ND]^T\) possible histories, and thus the required number of calculations to solve a general \( T \) period, history-dependent dynamic programming problem is \( O([ND]^T) \). Bellman and Dreyfus (1962) referred to this exponential growth in the number of calculations as the curse of dimensionality. In the next section, I will describe various strategies for dealing with this problem, but an immediate solution is to restrict attention to time separable Markovian decision problems. These are problems where the payoff function \( U \) is additively separable as in eq. (1), and where both the choice sets \( \{d_t\} \) and the transition probabilities \( \{p_t\} \) depend only on the contemporaneous state variable \( s_t \) and not on the entire previous history \( H_{t-1} \). We say a conditional distribution \( p_t \) satisfies the Markov property if it depends on the previous history only via the most recent values, that is, if \( p_t(s_t|H_{t-1}) = p_t(s_t|s_{t-1}, d_{t-1}) \). In this case backward induction becomes substantially easier. For example, in this case the dynamic
Dynamic programming optimizations have to be performed only at each of the \( N \) possible values of the state variable at each time \( t \), so only \( O(NDT) \) calculations are required to solve a time \( T \) period time separable Markovian problem instead of \( O([ND]T) \) calculations when histories matter. This is part of the reason why, even though time non-separable utilities and non-Markovian forms of uncertainty may be more general, most dynamic programming problems that are solved in practical applications are both time separable and Markovian.

SDPs with random horizons \( \bar{T} \) can be solved by backward induction provided there is some finite time \( T \) satisfying \( P_{\bar{T} \leq T} = 1 \). In this case, backward induction proceeds from the maximum possible value \( \bar{T} \) and the survival probability \( \rho_t = P\{T > \bar{T} \} \) is used as to capture the probability that the problem will continue for at least one more period. The Bellman equation for the discounted, time-separable utility with uncertain lifetime is

\[
V_t(s_t) = \max_{d \in D_t(s_t)} \{ u_t(s_t, d) + \rho_t \beta EV_{t+1}(s_t, d) \}
\]

where

\[
\delta_t(s_t) = \arg\max_{d \in D_t(s_t)} \{ u_t(s_t, d) + \rho_t \beta EV_{t+1}(s_t, d) \}
\]

(8)

\[
EV_{t+1}(s, d) = \int_{s}^{s'} V_{t+1}(s', d) \rho_{t+1}(s'|s, d)
\]

(9)

In many problems there is no finite upper bound \( \bar{T} \) on the horizon. These are called infinite horizon problems and they occur frequently in economics. For example, SDPs used to model decisions by firms are typically treated as infinite horizon problems. It is also typical in infinite horizon problems to assume stationarity. That is, the utility function \( u(s, d) \), the constraint set \( D(s) \), the survival probability \( \rho \), and the transition probability \( P(\cdot|s, d) \) do not explicitly depend on time \( t \). In such cases, it is not hard to show the value function and the optimal decision rules are also stationary, and satisfy the following version of Bellman's equation

\[
V(s) = \max_{d \in D(s)} \{ u(s, d) + \beta EV(s, d) \}
\]

\[
\delta(s) = \arg\max_{d \in D(s)} \{ u(s, d) + \beta EV(s, d) \}
\]

(10)
where

\[ \mathbb{V}(s, \alpha) = \int_s V(s') \rho(s' || s, \alpha). \] (11)

This is a fully recursive definition of \( V \), and as such there is an issue of existence and uniqueness of a solution. In addition, it is not obvious how to carry out backward induction, since there is no 'last' period from which to begin the backward induction process. However, under relatively weak assumptions one can show there is a unique \( V \) satisfying the Bellman equation, and the implied decision rule in eq. (10) is an optimal decision rule for the problem. Further, this decision rule can be approximated by solving an approximate finite horizon version of the problem by backward induction.

For example, suppose that \( u(s, d) \) is a continuous function of \( (s, d) \), the state space \( S \) is compact, the constraint sets \( D(s) \) are compact for each \( s \in S \), and the transition probability \( \rho(s' || s, d) \) is weakly continuous in \( (s, d) \) (that is, \( \mathbb{E}[s', d] = \int_s W(s') \rho(s' || s, d) \) is a continuous function of \( (s, d) \) for each continuous function \( W: S \rightarrow \mathbb{R} \)). Blackwell (1965a; 1965b), Denardo (1967) and others have proved that, under these sorts of assumptions, \( V \) is the unique fixed point to the Bellman operator \( \Gamma: \mathcal{B} \rightarrow \mathcal{B} \), where \( \mathcal{B} \) is the Banach space of continuous functions on \( S \) under the supremum norm, and \( \Gamma \) is given by

\[ \Gamma(W)(s) = \max_{d \in D(s)} \left[ u(s, d) + \rho \beta \int_s W(s') \rho(s' || s, d) \right]. \] (12)

The existence and uniqueness of \( V \) is a consequence of the contraction mapping th, since \( \Gamma \) can be shown to satisfy the contraction property,

\[ \| \Gamma W - \Gamma V \| \leq \alpha \| W - V \|. \] (13)

where \( \alpha \in (0,1) \) and \( \| W \| = \sup_{s \in S} | W(s) | \). In this case, \( \alpha = \rho \beta \), so the Bellman operator will be a contraction mapping if \( \rho \beta \in (0,1) \).

The proof of the optimality of the decision rule \( \delta \) in eq. (10) is somewhat more involved. Using the Bellman equation (10), we will show that (see eq. (34) in section 4),

\[ V(s) - u(s, \delta(s)) + \rho \beta \int_s V(s') \rho(s' || s, \delta(s)) - \mathbb{E} \left[ \sum_{t=0}^{\infty} \left[ \rho \beta \right]^t u(s_t, \delta(s_t)) \big| s_0 = s \right] \] (14)

that is, \( V \) is the value function implied by the decision rule \( \delta \). Intuitively, the boundedness of the utility function, combined with discounting of future utilities, \( \rho \beta \in (0,1) \), implies that if we truncate the infinite horizon problem to a finite horizon problem, the error in doing so would be arbitrarily small when \( T \) is sufficiently large. Indeed, this is the key to understanding how to find approximately optimal decision rules to infinite horizon SDPs: we approximate the infinite horizon decision rule \( \delta \) by solving an approximate finite horizon version of the problem by dynamic programming. The validity of this approach can be formalized using a well-known property of contraction mappings, namely, that the method of successive approximations starting from any initial guess \( W \) converges to the fixed point of \( \Gamma \), that is
\[ \lim_{T \to \infty} V_T - \Gamma^T(W) - V \forall W \in \mathcal{B}, \quad (15) \]

where \( \Gamma^tW \) denotes \( t \) successive iterations of the Bellman operator \( \Gamma \).

\[ \begin{align*}
V_0 &= \Gamma^0(W) = W \\
V_1 &= \Gamma^1(W) \\
&\vdots \\
V_T &= \Gamma^T(W) = \Gamma^{T-1}(\Gamma^{T-2}(\ldots(\Gamma^1(W)))) \\
(16) 
\end{align*} \]

If \( W = 0 \) (that is the zero function in \( B \)), then \( V_T = \Gamma^T(0) \) is simply the period \( t = 1 \) value function resulting from the solution of a \( T \) period dynamic programming problem. Thus, this result implies that the optimal value function \( V_T \) for a \( T \)-period approximation to the infinite horizon problem converges to \( V \) as \( T \to \infty \). Moreover, the difference in the two functions satisfies the bound

\[ \|V_T - V\| \leq \frac{|\rho\beta|^T \|W\|}{1 - \|\rho\beta\|}. \quad (17) \]

Let \( \delta_{1,T}, \delta_{2,T}, \ldots, \delta_{T,T} \) be the optimal decision rule to the \( T \) period problem. It can be shown that, if we follow this decision rule up to period \( T \) and then use \( \delta_{1,T} \) in every period after \( T \), the resulting decision rule is approximately optimal in the sense that the value function for this infinite horizon problem also satisfies inequality (17), and thus can be made arbitrarily small as \( T \) increases.

In many cases in economics the state space \( S \) has no natural upper bound. An example might be where \( s_t \) denotes an individual’s wealth at time \( t \), or the capital stock of the firm. If the unboundedness of the state space results in unbounded payoffs, the contraction mapping argument must be modified since the Banach space structure under the supremum norm no longer applies to unbounded functions. Various alternative approaches have been used to prove existence of optimal decision rules for unbounded problems. One is to use an alternative norm (for example, a weighted norm) and demonstrate that the Banach space/contraction mapping argument still applies. However, there are cases where there are no natural weighted norms, and the contraction mapping property cannot hold since the Bellman equation can be shown to have multiple solutions. The most general conditions under which the existence and uniqueness of the solution \( V \) to the Bellman equation and the optimality of the implied stationary decision rule \( \delta \) has been established is in Bhattacharya and Majumdar (1989). However, as I discuss in the next section, considerable care must be taken in solving unbounded problems numerically.

4 Numerical dynamic programming and the curse of dimensionality

The previous section showed that dynamic programming is a powerful tool that has enabled us to formulate and solve a wide range of economic models involving sequential decision-making under uncertainty – at least ‘in theory’. Unfortunately, the cases where dynamic programming results in analytical, closed-form solutions are rare and often rather fragile in the sense that small changes in the formulation of a problem can destroy the ability to obtain an analytical solution. However even though most problems do not have analytical solutions, the theorems in the previous section guarantee the existence of solutions, and these solutions can be calculated (or approximated) by numerical methods. Since the 1980s, faster computers and better numerical methods have made dynamic programming a tool of substantial practical value by significantly expanding the range of problems that can be solved. In particular, it has led to the development of a large and rapidly growing literature on econometric estimation and testing of ‘dynamic structural models’ that I will discuss in the next section.

However, there are still many difficult challenges that prevent us from formulating and solving models that are as detailed and realistic as we might like, a problem that is especially acute in
empirical applications. The principal challenge is what Bellman and Dreyfus (1962) called the curse of dimensionality. We have already illustrated this problem in Section 3.4: for history-dependent SDPs with a finite horizon \( T \) and a finite number of states \( N \) and actions \( D \), dynamic programming requires \( O((ND)^T) \) operations to find a solution. Thus it appears that the time required to compute a solution via dynamic programming increases exponentially fast with the number of possible decisions or states in a dynamic programming problem. Fortunately, computer power (for example, operations per second) has also been growing exponentially fast, a consequence of Moore’s Law and other developments in information technology, such as improved communications and massive parallel processing. Bellman and Dreyfus (1962) carried out calculations on RAND’s ‘Johnniac’ computer (named in honour of Jon von Neumann, whose work contributed to the development of the first electronic computers) and reported that this machine could do 12,500 additions per second. Nowadays, in 2007, a typical laptop computer can do over a billion operations per second and we now have supercomputers that are approaching a thousand trillion operations per second – a level known as a ‘petaflop’. In addition to faster ‘hardware’, research on numerical methods has resulted in significantly better ‘software’ that has had a huge impact on the spread of numerical dynamic programming and on the range of problems we can solve. In particular, algorithms have been developed that succeed in ‘breaking’ the curse of dimensionality, enabling us to solve in polynomial time classes of problems that were previously believed to be solvable only in exponential time. The key to breaking the curse of dimensionality is the ability to recognize and exploit special structure in an SDP problem. We have already illustrated an example of this in Section 3.4: if the SDP is Markovian and utility is time separable, a finite horizon, finite state SDP can be solved by dynamic programming in only \( O(NDT) \) operations, compared to the \( O((ND)^T) \) operations that are required in the general history-dependent case. There is only enough space here to discuss several of the most commonly used and most effective numerical methods for solving different types of SDPs by dynamic programming. I refer the reader to Puterman (1994), Rust (1996) and Judd (1998) for more in-depth surveys on the literature on numerical dynamic programming. See computational methods in econometrics.

Naturally, the numerical method that is appropriate or ‘best’ depends on the type of problem being solved. Different methods are applicable depending on whether the problem has (a) finite versus infinite horizon, \( (b) \) finite versus continuous-valued state and decision variables, and \( (c) \) single versus multiple players. In finite horizon problems, backward induction is the essentially the only approach, although as we will see there are many different choices about how to most efficiently do it – especially in discrete problems where the number of possible values for the state variables is huge (for example, chess) or in problems with continuous state variables. In the latter case, it is clearly not possible to carry out backward induction for every possible history (or value of the state variable at stage \( t \) if the problem is Markovian and time separable), since there are infinitely many (indeed a continuum) of them. In these cases, it is necessary to interpolate the value function, whose values are only explicitly computed at a finite number of points in the state space. I use the term ‘grid’ to refer to the finite number of points in the state space where the backward induction calculations are actually performed. Grids might be lattices (that is, regularly spaced sets of points formed as Cartesian products of unidimensional grids for each of the continuous state variables), or they may be quasi-random grids formed by randomly sampling the state space from some probability distribution, or by generating deterministic sequences of points such as low discrepancy sequences. The reason why one might choose a random or low-discrepancy grid instead of regularly spaced lattice is to break the curse of dimensionality, as I discuss shortly. Also, in many cases it is advantageous to refine the grid over the course of the backward induction process, starting out with an initial ‘coarse’ grid with relatively few points and subsequently increasing the number of points in the grid as the backward induction progresses. I will have more to say about such multigrid and adaptive grid methods when I discuss solution of infinite horizon problems below.

Once a particular grid is chosen, the backward induction process is carried out in the way it would be normally be done in a finite state problem. On the assumption that the problem is Markovian and the utility is time separable and there are \( n \) grid points \( \{s_1, \ldots, s_n\} \), this involves the following calculation at each grid point \( s_i \), \( i = 1, \ldots, n \)

\[
V_t(s_i) = \max_{d \in D_t(s_i)} \{ u(d, s_i) + \rho \hat{E}V_{t+1}(s_i, d) \},
\]

(18)

where \( \hat{E}V_{t+1}(s_i, d) \) is a numerical estimate of the conditional expectation of next period’s value function. I will be more specific below about which numerical integration methods are appropriate, but at this point it suffices to note that they are all simple weighted sums of values of the value function at \( t+1, V_{t+1}(s) \). We can now see that, even if the actual backward induction calculations are carried out only at the \( n \) grid points \( \{s_1, \ldots, s_n\} \), we will still have to do numerical integration to compute \( \hat{E}V_{t+1}(s_i, d) \) and the latter calculation may require values of \( V_{t+1}(s) \) at points \( s \) off the grid, that is at points \( s \) \( \notin \{s_1, \ldots, s_n\} \). This is why some form or interpolation (or in some cases extrapolation) is typically required. Almost all methods of interpolation can be represented as weighted sums of the value function at its known values \( \{V_{t+1}(s_1), \ldots, V_{t+1}(s_n)\} \) at the \( n \) grid points, which were calculated by backward induction at the previous stage. Thus, we have

\[
\hat{V}_{t+1}(s) = \sum_{j=1}^{n} \gamma_j(s) V_{t+1}(s_j),
\]

(19)
where \( w_i(s) \) is a weight assigned to the \( i^{th} \) grid point that depends on the point \( s \) in \( qst \). These weights are typically positive and sum to 1. For example in multilinear interpolation or simplicial interpolation the \( w_i(s) \) weights are those that allow \( s \) to be represented as a convex combination of the vertices of the smallest lattice hypercube containing \( s \). Thus, the weights \( w_i(s) \) will be zero for all \( i \) except the immediate neighbours of the point \( s \). In other cases, such as kernel density and local linear regression, the weights \( w_i(s) \) are generally non-zero for all \( i \), but the weights will be highest for the grid points \( \{ s_1, \ldots, s_n \} \) which are the nearest neighbours of \( s \). An alternative approach can be described as curve fitting. Instead of attempting to interpolate the calculated values of the value function at the grid points, this approach treats these values as a data-set and estimates parameters \( \Theta \) of a flexible functional form approximation to \( V_{t+1}(s) \) by nonlinear regression.

Using the estimated \( \hat{\Theta}_{t+1} \) from this nonlinear regression, we can ‘predict’ the value of \( V_{t+1}(s) \) at any \( s \in S \)

\[
\hat{V}_{t+1}(s) = f(s, \hat{\Theta}_{t+1}).
\]

A frequently used example of this approach is to approximate \( V_{t+1}(s) \) as a linear combination of \( K \) ‘basis functions’ \( \{ b_1(s), \ldots, b_K(s) \} \). This implies that \( f(s, \Theta) \) takes the form of a linear regression function

\[
f(s, \Theta) = \sum_{k=1}^{K} \beta_k b_k(s),
\]

and \( \hat{\Theta}_{t+1} \) can be estimated by ordinary least squares. Neural networks are an example where \( f \) depends on \( \Theta \) in a nonlinear fashion. Partition \( \Theta \) into subvectors \( \Theta = (\gamma, \lambda, \alpha) \), where \( \gamma \) and \( \lambda \) are vectors in \( R^J \), and \( \alpha = (\alpha_1, \ldots, \alpha_J) \), where each \( \alpha_j \) has the same dimension as the state vector \( s \). Then the neural network \( f \) is given by

\[
f(s, \Theta) = f(s, \gamma, \lambda, \alpha) = \sum_{j=1}^{J} \gamma_j \varphi(\lambda_j + \langle s, \alpha_j \rangle)
\]

where \( \langle s, \alpha_j \rangle \) is the inner product between \( s \) and the conformable vector \( \alpha_j \), and \( \varphi \) is a ‘squashing function’ such as the logistic function \( \varphi(x) = \exp(x) / (1 + \exp(x)) \). Neural networks are known to be ‘universal approximators’ and require relatively few parameters to provide good approximations to nonlinear functions of many variables. For further details on how neural networks are applied, see the book by Bertsekas and Tsitsiklis (1996) on Neuro-Dynamic Programming.

All these methods require extreme care for problems with unbounded state spaces. By definition, any finite grid can cover only a small subset of the state space in this case, and thus any of the methods discussed above would require extrapolation of the value function to predict its values in regions where there are no grid points, and thus ‘data’ on what its proper values should be. Not only may mistakes that lead to incorrect extrapolations in these regions lead to errors in the regions where there are no grid points, but the errors can ‘unravel’ and also lead to considerable errors in approximating the value function in regions where we do have grid points. Attempts to ‘compactify’ an unbounded problem by arbitrarily truncating the state space may also lead to inaccurate solutions, since the truncation is itself an implicit form of extrapolation (for example, some assumption needs to be made to do what to do when state variables approach the ‘boundary’ of the state space: do we assume a ‘reflecting boundary’, an ‘absorbing boundary’, and so on?). For example in life-cycle optimization problems, there is no natural upper bound on wealth, even if it is true that there is only a finite amount of wealth in the entire economy. We can always ask the qst, if a person had wealth near the ‘upper bound’, what would happen to next period wealth if he invested some of it? Here we can see that, if we extrapolate the value function by assuming that the value function is bounded in wealth, this means that by definition there is no incremental return
to saving as we approach the upper bound. This leads to lower saving, and this generally leads to errors in the calculated value function and decision rule far below the assumed upper bound. There is no good general solution to this problem except to solve the problem on a much bigger (bounded) state space than one would expect to encounter in practice, in the hope that extrapolation-induced errors in approximating the value function die out the further one is from the boundary. This property should hold for problems where the probability that the next period state will hit or exceed the ‘truncation boundary’ gets small the farther the current state is from this boundary.

When a method for interpolating/extrapolating the value function has been determined, a second choice must be made about the appropriate method for numerical integration in order to approximate the conditional expectation of the value function \( EV_{t+1}(s, d) \) given by

\[
EV_{t+1}(s, d) = \int_{S} V_{t+1}(s') \rho_{t+1}(s|s, d).
\]

(23)

There are two main choices here: (1) deterministic quadrature rules or (2) (quasi-) Monte Carlo methods. Both methods can be written as weighted averages of form

\[
\hat{EV}_{t+1}(s, d) = \sum_{i=1}^{N} w_i(s, d) V_{t+1}(a_i),
\]

(24)

where \( w_i(s, d) \) are weights, and \( a_i \) are quadrature abscissae. Deterministic quadrature methods are highly accurate (for example, an \( N \)-point Gaussian quadrature rule is constructed to exactly integrate all polynomials of degree \( 2N-1 \) or less), but become unwieldy in multivariate integration problems when product rules (tensor products of unidimensional quadrature) are used. Any sort of deterministic quadrature method can be shown to be subject to the curse of dimensionality in terms of worst-case computational complexity (see Traub and Werschulz, 1998). For example, if \( N=O(1/\varepsilon^d) \) quadrature points are necessary to approximate a univariate integral within \( \varepsilon \), then in a \( d \)-dimensional integration problem \( N^d = O(1/\varepsilon^d) \) quadrature points would be necessary to approximate the integral with an error of \( \varepsilon \), which implies that computational effort to find an \( \varepsilon \)-approximation increases exponentially fast in the problem dimension \( d \). Using the theory of computational complexity, one can prove that any deterministic integration procedure is subject to the curse of dimensionality, at least in terms of a ‘worst case’ measure of complexity. The curse of dimensionality can disappear if one is willing to adopt a Bayesian perspective and place a ‘prior distribution’ over the space of possible integrands and consider an ‘average case’ instead of a ‘worst case’ notion of computational complexity.

Since multivariate integration is a ‘sub-problem’ that must be solved in order to carry out dynamic programming when there are continuous state variables (indeed, dynamic programming in principle involves infinitely many integrals in order to calculate \( EV_{t+1}(s, d) \), one for each possible value of \( (s, d) \)), if there is a curse of dimensionality associated with numerical integration of a single multivariate integral, then it should also not be surprising that dynamic programming is also subject to the same curse. There is also a curse of dimensionality associated with global optimization of nonconvex objective functions of continuous variables. Since optimization is also a sub-problem of the overall dynamic programming problem, this constitutes another reason why dynamic programming is subject to a curse of dimensionality. Under the standard worst case definition of computational complexity, Chow and Tsitsiklis (1989) proved that no deterministic algorithm can succeed in breaking the curse of dimensionality associated with a sufficiently broad class of dynamic programming problems with continuous state and decision variables. This negative result dashes the hopes of researchers dating back to Bellman and Dreyfus (1962), who conjectured that there might be sufficiently clever deterministic algorithms that can overcome the curse of dimensionality.

However, there are examples of random algorithms that can circumvent the curse of dimensionality. Monte Carlo integration is a classic example. Consider approximating the (multidimensional) integral in eq. (23) by using random quadrature abscissae \( \{a_i\} \) that are \( N \) independent and identically distributed (IID) draws from the distribution \( \rho_{t+1}(s|s, d) \) and uniform quadrature weights equal to \( w_i(s, d) = 1/N \). Then the law of large numbers and the central limit theorem imply that the Monte Carlo integral \( \hat{EV}_{t+1}(s, d) \) converges to the true conditional expectation \( EV_{t+1}(s, d) \) at rate \( 1/\sqrt{N} \) regardless of the dimension of the state space \( d \). Thus a random algorithm, Monte Carlo integration, succeeds in breaking the curse of dimensionality of multivariate integration. Unfortunately, randomization does not succeed in breaking the curse of dimensionality associated with general nonconvex optimization problems with continuous multidimensional decision variables \( d \) (see Nemirovsky and Yudin, 1983).

However, naive application of Monte Carlo integration will not necessarily break the curse of dimensionality of the dynamic programming problem. The reason is that a form of uniform
convergence (as opposed to pointwise) convergence of the conditional expectations $\hat{EV}_{t+1}(s, d)$ to $EV_{t+1}(s, d)$ is required in order to guarantee that the overall backward induction process converges to the true solution as the number of Monte Carlo draws, $N$, gets large. To get an intuition why, note that if separate IID sets of quadrature abscissae $\{\xi_i\}$ where drawn for each $(s, d)$ point that we wish to evaluate the Monte Carlo integral $\hat{EV}_{t+1}(s, d)$ at, the resulting function would be an extremely ‘choppy’ and irregular function of $(s, d)$ instead of $(s_i, d)$. In particular, if $\xi_i$ for each possible value of $(s, d)$ where drawn for each $(s, d)$, the second important feature is that the resulting function remains fixed for the duration of the backward induction. Then we begin ordinary backward induction calculations, at each stage $t$ computing $V_t(\xi_i)$ at each of the $N$ random grid points, and using the self-approximating formula (25) to calculate the conditional expectation of the period $t+1$ value function using only the $N$ stored values $\langle V_{t+1}(\xi_1), \ldots, V_{t+1}(\xi_N) \rangle$ from the previous stage of the backward induction. See Keane and Wolpin (1994) for an alternative approach, which combines Monte Carlo integration with the curve-fitting approaches discussed above. Note that the Keane and Wolpin approach will not generally succeed in breaking the curse of dimensionality since it requires approximation of functions of $s$ variables which is also subject to a curse of dimensionality, as is well known from the literature on nonparametric regression.

There are other subclasses of SDPs for which it is possible to break the curse of dimensionality. For example, the family of linear quadratic/Gaussian (LQG) can be solved in polynomial time using highly efficient matrix methods, including efficient methods for solving the matrix Ricatti equation which is used to compute the Kalman filter for Bayesian LQG problems (for example, problems where agents only receive a noisy signal of a state variable of interest, and they update their beliefs about the unknown underlying state variable via Bayes rule). Now consider stationary, infinite horizon Markovian decision problems. As noted in Section 3.4, there is no ‘last’ period from which to begin the backward induction process. However, if the utility function is time separable and discounted, then, under fairly general conditions, it will be possible to approximate the solution arbitrarily closely by solving a finite horizon version of the problem, where the horizon $T$ is chosen sufficiently large. As we noted in Section 3.4, this is equivalent to solving for $V$, the fixed point to the contraction mapping $V = \Gamma(V)$ by the method of successive approximations, where $\Gamma$ is the Bellman operator defined in eq. (12) of Section 3.4.

$$V_{t+1} = \Gamma(V_t).$$ (26)
Since successive approximations converges at a geometric rate, with errors satisfying the upper bound in eq. (17), this method can converge at an unacceptably slow rate when the discount factor is close to 1. A more effective algorithm in such cases is *Newton's method* whose iterates are given by

\[
V_{t+1} = V_t - (I - \Gamma' \langle \Gamma \rangle)^{-1} [V_t - \Gamma \langle V \rangle],
\]

(27)

where \( \Gamma' \) is the *Gateaux* or *directional derivative* of \( \Gamma \), that is, it is the linear operator given by

\[
\Gamma' \langle \Gamma \rangle (W) = \lim_{t \to 0} \frac{\Gamma(W + \rho t) - \Gamma(W)}{t}.
\]

(28)

Newton's method converges *quadratically* independent of the value of the discount factor, as long as it is less than 1 (to guarantee the contraction property and the existence of a fixed point). In fact, Newton's method turns out to be equivalent to the method of *policy iteration* introduced by Howard (1960). Let \( \delta \) be any stationary decision rule, that is, a candidate policy. Define the policy-specific conditional expectation operator \( E_{\delta} \) by

\[
E_{\delta} V(s) = \int_s V(s') \rho(s' | s, \delta(s)).
\]

(29)

Given a value function \( V_t \), let \( \delta_{t+1} \) be the decision rule implied by \( V_t \), that is

\[
\delta_{t+1} = \arg \max_{d \in D(s)} \left[ \nabla \langle s, d \rangle + \rho \beta \int_s V_t(s') \rho(s' | s, \delta(s)) \right].
\]

(30)

It is not hard to see that the value of policy \( \delta_{t+1} \) must be at least as high as \( V_t \), and for this reason, eq. (30) is called the *policy improvement step* of the policy iteration algorithm. It is also not hard to show that

\[
\Gamma' \langle V_t \rangle (W) = -\rho \beta E_{\delta_{t+1}} W(s),
\]

(31)

and this implies that the Newton iteration, eq. (27), is numerically identical to *policy iteration*.
where $\delta_{t+1}$ is given in eq. (30). Equation (32) is called the policy valuation step of the policy iteration algorithm since it calculates the value function implied by the policy $\delta_{t+1}$. Note that, since $E_\delta$ is an expectation operator, it is linear and satisfies $\|E_\delta\| \leq 1$, and this implies that the operator $[1 - \rho \beta E_\delta]$ is invertible and has the following geometric series expansion

$$[1 - \rho \beta E_\delta]^{-1} = \sum_{j=0}^{\infty} [\rho \beta]^j E_\delta^j,$$

where $E_\delta^j$ is the $j$ step ahead expectations operator. Thus, we see that

$$[1 - \rho \beta E_\delta]^{-1} u(s, \delta(s)) = \sum_{j=0}^{\infty} [\rho \beta]^j E_\delta^j u(s, \delta(s)) - E_\delta \left( \sum_{i=0}^{\infty} [\rho \beta]^i u(s_0, \delta(s_0)) \right) \delta_0 - s_0,$$

so that value function $V_t$ from the policy iteration (32) corresponds to the expected value implied by policy (decision rule) $\delta_{t+1}$.

If there are an infinite number of states, the expectations operator $E_\delta$ is an infinite-dimensional linear operator, so it is not feasible to compute an exact solution to the policy iteration eq. (32). However if there are a finite number of states (or an infinite state space is discretized to a finite set of points, as per the discussion above), then $E_\delta$ is an $N \times N$ transition probability matrix, and policy iteration is feasible using ordinary matrix algebra, requiring at most $O(N^3)$ operations to solve a system of linear equations for $V_t$ at each policy valuation step. Further, when there are a finite number of possible actions as well as states, there are only a finite number of possible policies $|D|^S$, where $|D|$ is the number of possible actions and $|S|$ is the number of states, and policy iteration can be shown to converge in a finite number of steps, since the method produces an improving sequences of decision rules, that is $V_t \leq V_{t+1}$. Thus, since there is an upper bound on the number of possible policies and policy iteration cannot cycle, it must converge in a finite number of steps. The number of steps is typically quite small, far fewer than the total number of possible policies. Santos and Rust (2004) show that the number of iterations can be bounded independent of the number of elements in the state space $|S|$. Thus, policy iteration is the method of choice for infinite horizon problems for which the discount factor is sufficiently close to 1. However, if the discount factor is far enough below 1, then successive approximations can be faster since policy iteration requires $O(N^3)$ operations per iteration whereas successive approximations requires $O(N^2)$ operations per iteration. At most $T(\varepsilon, \beta)$ successive approximation iterations are required to compute an $\varepsilon$ -approximation to an infinite horizon Markovian decision problem with discount factor $\beta$, where $T(\varepsilon, \beta) = \log((1 - \beta) \varepsilon) / \log(\beta)$. Roughly speaking, if $T(\varepsilon, \beta) < N$, then successive approximations are faster than policy iteration. Successive approximations can be accelerated by a number of means discussed in Puterman (1994) and Rust (1996). Multigrid algorithms are also effective: these methods begin backward induction with a coarse grid with relatively few grid points $N$, and then as iterations proceed, the number of grid points is successively increased, leading to finer and finer grids as the backward induction starts to converge. Thus, computational time is not wasted early on in the backward induction iterations when the value function is far from the true solution. Adaptive grid methods are also highly effective in many problems: these methods can automatically detect regions in the state space where there is higher curvature in the value function, and in these regions more grid points are added in order to ensure that the value function is accurately approximated, whereas in regions where the value function is ‘flatter’ grid points can be removed, so as to direct computational resources to the regions of the state space where there is the highest payoff in terms of accurately approximating the value function. See Grüne and Semmler (2004) for more details and an interesting application of adaptive grid algorithms.

I conclude this section with a discussion of several other alternative approaches to solving stationary infinite horizon problems that can be extremely effective relative to ‘discretization’ methods when the number of grid points $N$ required to obtain a good approximation becomes very large. Recall the curve-fitting approach discussed above in finite horizon SDPs: we approximate the value
function \( V \) by a parametric function as
\[
V_\theta(s) = f(s, \theta)
\]
for some flexible functional form \( f \), where \( \theta \) are treated as unknown parameters to be ‘estimated’. For infinite horizon SDPs, our goal is to find parameter values \( \hat{\theta} \) so that the implied value function satisfies the Bellman equation as well as possible. One approach to doing this, known as the minimum residual method, is a direct analogue of nonlinear least squares: if \( \theta \) is a vector with \( K \) components, we select \( N \geq K \) points in the state space (potentially at random) and find \( \hat{\theta} \) that minimizes the squared deviations or residuals in the Bellman equation
\[
\hat{\theta} = \arg\min_{\theta \in \mathbb{R}^K} \sum_{i=1}^{N} \left[ \hat{\Gamma}(V_\theta)(s_i) - V_\theta(s_i) \right]^2, 
\quad (35)
\]
where \( \hat{\Gamma} \) denotes an approximation to the Bellman operator, where some numerical integration and optimization algorithm are used to approximate the true expectation operator and maximization in the Bellman equation (12). Another approach, called the collocation method, finds \( \hat{\theta} \) by choosing \( K \) grid points in the state space and setting the residuals at those \( K \) points to zero:
\[
\begin{align*}
V_\theta(s_1) &= \hat{\Gamma}(V_\theta)(s_1) \\
V_\theta(s_2) &= \hat{\Gamma}(V_\theta)(s_2) \\
& \vdots \\
V_\theta(s_K) &= \hat{\Gamma}(V_\theta)(s_K). 
\end{align*}
\quad (36)
\]
Another approach, called parametric policy iteration, carries out the policy iteration algorithm in eq. (32) above, but, instead of solving the linear system (32) for the value function \( V_t \) at each policy valuation step, they approximately solve this system by finding \( \hat{\theta}_t \) that solves the regression problem
\[
\theta_t = \arg\min_{\theta \in \mathbb{R}^K} \sum_{i=1}^{N} \left[ V_{\theta_t}(s_i) - u(s_i, \delta_t(s_i)) - \rho \mathbb{E}_{s'} V_{\theta_t}(s') \right]^2. 
\quad (37)
\]
Other than this, policy iteration proceeds exactly as discussed above. Note that, due to the linearity of the expectations operator, the regression problem above reduces to an ordinary linear regression problem when \( V_\theta \) is approximated as a linear combination of basis functions as in (21) above.
There are variants of the minimum residual and collocation methods that involve parameterizing the decision rule rather than the value function. These methods are frequently used in problems where the control variable is continuous, and construct residuals from the Euler equation – a functional equation for the decision rule that can in certain classes of problems be derived from the first-order necessary condition for the optimal decision rule. These approaches then try to find \( \hat{\theta} \) so that the Euler equation (as opposed to the Bellman equation) is approximately satisfied, in the sense of minimizing the squared residuals (minimum residual approach) or setting the residuals to zero at \( K \) specified points in the state space (collocation method). See Judd (1998) for further discussion of these methods and a discussion of strategies for choosing the grid points necessary to implement the collocation or minimum residual method.
There is a variety of other iterative stochastic algorithms for approximating solutions to dynamic programming problems that have been developed in the computer science and ‘artificial intelligence’ literatures on reinforcement learning. These methods include Q-learning, temporal difference learning, and real time dynamic programming. The general approach in all these methods is to iteratively update an estimate of the value function, and recursive versions of Monte Carlo integration methods are employed in order to avoid doing numerical integrations to calculate conditional expectations. Using methods adapted from the literature on stochastic approximation, it is possible to prove that these methods converge to the true value function in the limit.
as the number of iterations tends to infinity. A key assumption underlying the convergence proofs is that there is sufficient stochastic noise to ensure that all possible decisions and decision nodes are visited ‘indefinitely often’. The intuition of why such an assumption is necessary follows from the discussion in Section 3: suppose that at some state \( s \) an initial estimate of the value function for decision that is actually optimal happens to be so low that the action is deemed to be ‘nonoptimal’ relative to the initial estimate. If the agent does not ‘experiment’ sufficiently, and thus fails to choose suboptimal decisions infinitely often, the agent may fail to learn that the initial estimated value was an underestimate of the true value, and therefore the agent might never learn that the corresponding action really is optimal. There is a trade-off between learning and experimentation, of course. The literature on ‘multi-armed bandits’ (Gittins, 1979) shows that a fully rational Bayesian decision-maker will generally not find it optimal to experiment infinitely often. As a result such an agent can fail to discover actions that are optimal in an \textit{ex post} sense. However, this does not contradict the fact that their behaviour is optimal in an \textit{ex ante} sense: rather, it is a reflection that learning and experimentation is a costly activity, and thus it can be optimal to be incompletely informed, a result that has been known as early as Wald (1947). A nice feature of many of these methods, particularly the real time dynamic programming developed in Barto, Bradtke and Singh (1995), is that these methods can be used in ‘real time’, that is, we do not have to ‘calculate’ the optimal decision rule in ‘offline’ mode. All these algorithms result in steady improvement in performance with experience. Methods similar to these have been used to produce highly effective strategies in extremely complicated problems. An example is IBM’s ‘Deep Blue’ computer chess strategy, which has succeeded in beating the world’s top human chess player, Garry Kasparov. However, the level of computation and repetition necessary to ‘train’ effective strategies is hugely time consuming, and it is not clear that any of these methods succeed in breaking the curse of dimensionality. For further details on this literature, see Bertsekas and Tsitsiklis (1996). Pakes (2001) applies these methods to approximate Markov perfect equilibria in games with many players. All types of stochastic algorithms have the disadvantage that the approximate solutions can be ‘jagged’ and there is always at least a small probability that the converged solution can be far from the true solution. However, they may be the only feasible option in many complex, high-dimensional problems where deterministic algorithms (for example, the Pakes and McGuire, 1994, algorithm for Markov perfect equilibrium) quickly become intractable due to the curse of dimensionality.

5 Empirical dynamic programming and the identification problem

The developments in numerical dynamic programming described in the previous section paved the way for a new, rapidly growing literature on empirical estimation and testing of SDPs and dynamic games. This literature began to take shape in the late 1970s, with contributions by Sargent (1978) on estimation of dynamic labour demand schedules in a linear quadratic framework, and Hansen and Singleton (1982), who developed a generalized method of moment estimation strategy for a class of continuous choice SDPs using the Euler equation as an orthogonality condition. About the same time, a number of papers appeared that provided different strategies for estimation and inference in \textit{dynamic discrete choice models} including Gotz and McCall’s (1980) model of retirements of air force pilots, Wolpin’s (1984) model of a family’s decision whether or not to have a child, Pakes’s (1986) model of whether or not to renew a patent, and Rust’s (1987) model of whether or not to replace a bus engine. Since 1987, hundreds of different empirical applications of dynamic programming models have been published. For surveys of this literature see Eckstein and Wolpin (1989), Rust (1994), and the very readable book by Adda and Cooper (2003) – which also provides accessible introductions to the theory and numerical methods for dynamic programming. The remainder of this section will provide a brief overview of estimation methods and a discussion of the identification problem.

In econometrics, the term \textit{structural estimation} refers to a class of methods that tries to go beyond simply summarizing the behaviour of economic agents by attempting to infer their underlying \textit{preferences} and \textit{beliefs}. This is closely related to the distinction between the \textit{reduced-form} of an economic model and the underlying \textit{structure} that ‘generates’ it. (Structural estimation methods were first developed at the Cowles Commission at Yale University, starting with attempts to structurally estimate the linear simultaneous equations model, and models of investment by firms. Frisch, Haavelmo, Koopmans, Marschak, and Tinbergen were among the earliest contributors to this literature.) The reason why one would want to do structural estimation, which is typically far more difficult (for example, computationally intensive) than reduced-form estimation, is having knowledge of underlying structure enables us to conduct \textit{hypothetical/counterfactual policy experiments}. Reduced-form estimation methods can be quite useful and yield significant insights into behaviour, but they are limited to summarizing behaviour under the status quo. However, they are inherently limited in their ability to forecast how individuals change their behaviour in response to various changes in the environment, or in \textit{policies} (for example, tax rates, government benefits, regulations, laws, and so on) that \textit{change the underlying structure} of agents’ decision problems. As long as it is possible to predict how different policies change the underlying structure, we can use dynamic programming to re-solve agents’ SDPs under the alternative structure, resulting in corresponding decision rules that represent predictions of how their behaviour (and welfare) will change in response to the policy change.

The rationale for structural estimation was recognized as early as Marschak (1953); however, his message appears to have been forgotten until the issue was revived in Lucas’s (1976) critique of the limitations of reduced-form methods for policy evaluation. An alternative way to do policy evaluation is via \textit{randomized experiments} in which subjects are randomly assigned to the \textit{treatment group} (where the ‘treatment’ is some alternative policy of interest) and the \textit{control group} (who continue with the policy under the status quo). By comparing the outcomes in the treatment and control groups, we can assess the behavioural and welfare impacts of the policy change. However, human experiments can be very time consuming and expensive to carry out, whereas ‘computational experiments’ using a structural model are very cheap and can be conducted extremely rapidly. The drawback of the structural approach, though, is the issue of \textit{credibility} of the structural model. If the structural model is \textit{misspecified}, it can generate incorrect forecasts of the impact of a policy change. There are numerous examples of how structural models can be used to make policy predictions: see Todd and Wolpin (2005) for an example that compares the prediction of a structural model with the results of a randomized experiment, where the structural model is estimated using subjects from the control group, and \textit{out-of-sample predictions} are made to predict the behavioural response by subjects in the treatment group. They show that the structural model results in accurate predictions of how the treatment group subjects responded to the policy change.

I illustrate the main econometric methods for structural estimation of SDPs in the case of a stationary infinite horizon Markovian decision problem, although all the concepts extend in a straightforward fashion to finite horizon, nonstationary and non-Markovian problems. Estimation requires a specification of the \textit{data generating process}. Assume we observe \( N \) agents, and we
observe agent i from time period $i_i$ (or via appropriate re-indexing, from $t=1, \ldots, T_i$). Assume observations of each individual are independently distributed realizations from the controlled process $\{x_i, d_i\}$. However, while we assume that we can observe the decisions made by each agent, it is more realistic to assume that we only observe a subset of the agent's state $s_i$. If we partition $s_i = (x_i, \epsilon_i)$, assume that the econometrician observes $x_i$ but not $\epsilon_i$, so this latter component of the state vector constitutes an unobserved state variable. Then the reduced-form of the SDP is the decision rule $d = \delta(x_i, \epsilon_i).

\begin{equation}
\text{(38)}
\end{equation}

since the decision rule embodies all the behavioural content of the SDP model. The structure $\Lambda$ consists of the objects $\Lambda = \{\beta, \rho, u(s, d), \varphi(\delta|s, d)\}$. Equation (10) specifies the mapping from the structure $\Lambda$ into the reduced form, $\delta$. The data-set consists of $\{(x_i, \delta_i), t = 1, \ldots, T_i, i = 1, \ldots, N\}$. The econometric problem is to infer the underlying structure $\Lambda$ from our data on the observed states and decisions by a set of individuals. Although the decision rule is potentially a complicated nonlinear function of unobserved state variables in the reduced-form eq. (38), it is often possible to consistently estimate the decision rule under weak assumptions as $N \rightarrow \infty$, or as $T_i \rightarrow \infty$ if the data consists only of a single agent or a small number of agents $i$ who are observed over long intervals. Thus, the decision rule $\delta$ can be treated as a known function for purposes of a theoretical analysis of identification. The identification problem is the qst, under what conditions is the mapping from the underlying structure $\Lambda$ to the reduced form 1 to 1 (that is invertible)? If this mapping is 1 to 1, we say that the structure is identified since in principle it can be inverted to uniquely determine the underlying structure $\Lambda$. In practice, we construct an estimator $\hat{\Lambda}$ based on the available data and show that $\hat{\Lambda}$ converges to the true underlying structure $\Lambda$ as $N \rightarrow \infty$ and/or $T_i \rightarrow \infty$ for each $i$.

Unfortunately, rather strong a priori assumptions on the form of agents' preferences and beliefs are required in order to guarantee identification of the structural model. Rust (1994) and Magnac and Thesmar (2002) have shown that an important subclass of SDPs, discrete decision processes (DDPs), are nonparametrically unidentified. That is, if we are unwilling to make any parametric functional form assumptions about preferences or beliefs, then in general there are infinitely many different structures $\Lambda$ consistent with any reduced form $\delta$. In more direct terms, there are many different ways to rationalize any observed pattern of behaviour as being ‘optimal’ for different configurations of preferences and beliefs. It is likely that these results extend to continuous choice problems, since it is possible to approximate a continuous decision process (CDP) by a sequence of DDPs with expanding numbers of elements in their choice sets. Further, for dynamic games, Ledyard (1986) has shown that any undominated strategy profile can be a Bayesian equilibrium for some set of preferences and beliefs. Thus, the hypothesis of optimality or equilibrium per se does not have testable empirical content: further a priori assumptions must be imposed in order for SDP models to be identified and result in empirically testable restrictions on behaviour.

There are two main types of identifying assumptions that have been made in the literature to date: (a) parametric functional form assumptions on preferences $u(s,d)$ and components of agents' beliefs $\varphi(\delta|s,d)$ that involve unobserved state variables $\epsilon$ and (b) rational expectations. Rational expectations states that an agent's subjective beliefs $\varphi(\delta|s,d)$ coincide with objective probabilities that can be estimated from data. Of course, this restriction is useful only for those components of $s, x$, that the econometrician can actually observe. In addition, there are other more general functional restrictions that can be imposed to help identify the model. One example is monotonicity and shape restrictions on preferences (for example, concavity and monotonicity of the utility function), and another example is independence or conditional independence assumptions about variables entering agents' beliefs. I will provide specific examples below; however, it should be immediately clear why these additional assumptions are necessary.

For example, consider the two parameters $\rho$ (the agent's subjective survival probability) and $\beta$ (the agent's subjective discount factor). We have seen in Section 3 that only the product $\rho \beta$ enter the SDP model, and not $\rho$ and $\beta$ separately. Thus, at most the product $\rho \beta$ can be identified, but without further assumptions it is impossible to separately identify the subjective survival probability $\rho$ from the subjective discount factor $\beta$ since both affect an agent's behaviour in a symmetrical fashion. However, we can separately identify $\rho$ and $\beta$ if we assume that an individual has rational survival expectations, that is, that their subjective survival probability $\rho$ coincides with the ‘objective’ survival probability. Then we can estimate $\rho$ ‘outside’ the SDP model, using data on the lifetime distributions of similar types of agents, and then $\beta$ can be identified if other restrictions are imposed to guarantee that the product $\rho \beta$ is identified. However, it can be very difficult to make precise inferences about agents' discount factors in many problems, and it is easy to think of models where there is heterogeneity in survival probabilities and discount factors, and unobserved variables affecting one's beliefs about them (for example, family characteristics such as a predisposition for cancer, and so on, that are observed by an agent but not by the econometrician) where identification is problematic.

There are two main approaches for conducting inference in SDPs: (a) maximum likelihood and (b) ‘simulation estimation’. The latter category includes a variety of similar methods such as indirect inference (Gourieroux and Monfort, 1997), simulated method of moments (McFadden, 1989; Gallant and Tauchen, 1996), simulated maximum likelihood and method of simulated scores (see simulation-based estimation), and simulated minimum distance (Hall and Rust, 2006). To simplify the discussion I will define these initially for single agent SDPs and at the end discuss how these concepts naturally extend to dynamic games. I will illustrate maximum likelihood and show how a likelihood can be derived for a class of DDDPs; however, for CDDPs, it is typically much more difficult to derive a likelihood function, especially when there are issues of censoring, or problems involving mixed discrete and continuous choice. In such cases simulation estimation is often the only feasible way to do inference.
For discrete decision processes, assume that the utility function has the following parametric, *additively separable* representation

\[ u(x, \varepsilon, d) = u(x, d, \theta_1) + \varepsilon(d)(\text{AS}). \quad (39) \]

where \( \varepsilon = \{ \varepsilon(d) | d \in D(x) \} \), and \( \varepsilon(d) \) is interpreted as an unobserved component of utility associated with choice of alternative \( d \in D(x) \). Further, suppose that the transition density \( p(x', \varepsilon | x, \varepsilon, d) \) satisfies the following *conditional independence assumption*

\[ p(x', \varepsilon | x, \varepsilon, d) = p(x'|x, \varepsilon, d, \theta_2) q(\varepsilon', \theta_3)(\text{CI}). \quad (40) \]

The CI assumption implies that \( \{ \varepsilon \} \) is an IID ‘noise’ process that is independent of \( \{ x, d \} \). Thus all of the serially correlated dynamics in the state variables are captured by the observed component of the state vector \( x_t \). If, in addition, \( q(\varepsilon, \theta_3) \) is a distribution with unbounded support with finite absolute first moments, one can show that the following *conditional choice probabilities* exist

\[ P(d|x, \theta) = \int_{\varepsilon} \left[ \alpha - \beta(x, \varepsilon, \theta) \right] q(\varepsilon) d\varepsilon, \quad (41) \]

where \( \theta = (\alpha, \beta, \theta_1, \theta_2, \theta_3) \) constitute the vector of unknown parameters to be estimated. (Identification of fully parametric models is a ‘generic’ property, that is, if there are two different parameters \( \theta \) that produce the same conditional choice probability \( P(d|x, \theta) \) for all \( x \) and \( d \in D(x) \) – and thus led to the same limiting expected log-likelihood – small perturbations in the parameterization will ‘almost always’ result in a nearby model for which \( \theta \) is uniquely identified.) In general, the parametric functional form assumptions, combined with the assumption of rational expectations and the AS and CI assumptions, are sufficient to identify the unknown parameter vector \( \theta^* \). \( \theta^* \) can be estimated by maximum likelihood, using the *full information* likelihood function \( L_f \) given by

\[ L_f(\theta(x_i, d_i), t = 1, \ldots, T, i = 1, \ldots, N) = \prod_{i=1}^{N} \prod_{t=2}^{T_j} P(d_{i,t} | x_{i,t}, \theta) \times P(x_{i,t} | x_{i,t-1}, d_{i,t-1}, \theta_2). \quad (42) \]

A particularly tractable special case is where \( q(\varepsilon, \theta_3) \) has a *multivariate extreme value distribution* where \( \theta_3 \) is a common scale parameter (linearly related to the standard deviation) for each variable in this distribution (see McFadden, Daniel; logit models of individual choice for the exact formula for this density). This specification leads to a dynamic generalization of the *multinomial logit model*

\[ P(d|x, \theta) = \frac{\exp\{\nu(x, d, \theta) / \theta_3\}}{\sum_{d' \in D(x)} \exp\{\nu(x, d', \theta) / \theta_3\}}. \]
where \( \nu(x, d, \theta) \) is the expected, discounted utility from taking action \( d \) in observed state \( x \) given by the unique fixed point to the following *smoothed Bellman equation*

\[
\nu(x, d, \theta) = u(x, d, \theta_1) + \rho \mathbb{E}_{x'} \left[ \sum_{d' \in D(x')} \exp\left\{ \nu(x', d', \theta) / \theta_2 \right\} \times \pi(x'|x, d, \theta_2) \, dx' \right].
\]

Define \( \Gamma_\theta \) by

\[
\Gamma_\theta(W) (x, d) = u(x, d, \theta_1) + \rho \mathbb{E}_{x'} \left[ \sum_{d' \in D(x')} \exp\left\{ W(x', d', \theta) / \theta_2 \right\} \times \pi(x'|x, d, \theta_2) \, dx' \right].
\]

It is not hard to show that under weak assumptions \( \Gamma_\theta \) is a contraction mapping, so that \( \nu(x, d, \theta) \) exists and is unique. Maximum likelihood estimation can be carried out using a nested *fixed point* maximum likelihood algorithm consisting of an ‘outer’ optimization algorithm to search for a value of \( \theta \) that maximizes \( \mathcal{L}_f(\theta) \), and an ‘inner’ fixed point algorithm that computes \( \nu_\theta = \Gamma_\theta(\nu_\theta) \) each time the outer optimization algorithm generates a new trial guess for \( \theta \). The implicit function theorem guarantees that \( \nu_\theta \) is a smooth function of \( \theta \). See Aguirregabiria and Mira (2004) for an ingenious alternative that ‘swaps’ the order of the inner and outer algorithms of the nested fixed-point algorithm resulting in significant computational speedups. See also Rust (1988) for further details on the nested fixed-point algorithm and the properties of the maximum likelihood estimator, and Rust (1994) for a survey of alternative less efficient but computationally simpler estimation strategies.

As noted above, econometric methods for CDPs, that is, problems where the decision variable is continuous (such as firm investment decisions, price settings, or consumption/savings decisions) are harder, since there is no tractable, general specification for the way unobservable state variables to enter the decision rule that result in a *nondegenerate* likelihood function (that is, where the likelihood \( \mathcal{L}(\theta) \) is non-zero for any data-set and any value of \( \theta \)). For this reason, maximum likelihood estimation of CDPs is rare, outside certain special subclasses, such as linear quadratic CDPs (Hansen and Sargent, 1980; Sargent, 1981). However, simulation-based methods of inference can be used in a huge variety of situations where a likelihood is difficult or impossible to derive. These methods have a great deal of flexibility, a high degree of generality, and often permit substantial computational savings. In particular, generalizations of McFadden’s (1989) *method of simulated moments* (MSM) have enabled estimation of a wide range of CDPs. The MSM estimator minimizes a quadratic form between a set of moments constructed from the data, \( h_N \) and a vector of *simulated moments* \( s(\theta) \), that is

\[
h_N - \frac{1}{N} \sum_{i=1}^{N} h_i \left( x_{it}, d_{it} \right) - s(\theta) \rightarrow 0.
\]
moments’ (that is, functionals of the data that the econometrician is trying to ‘match’), where \( K \) is the dimension of \( \Theta \), \( \{x_{it}, d_{it}\} \) are the data, and \( \{q^j_\Theta(\theta), \delta^j_\Theta(\theta)\}, j=1, \ldots, S \) are IID realizations of the controlled process. The estimate \( \hat{\Theta} \) is given by

\[
\hat{\Theta} = \underset{\Theta \in \mathbb{R}^K}{\arg\min} \left[ W_N [ h_N - h_N, S(\Theta)] \right],
\]

where \( W_N \) is a \( J \times J \) positive–definite weighting matrix. The most efficient choice for \( W_N \) is \( W_N = \left[ \hat{\Sigma}_N \right]^{-1} \) where \( \hat{\Sigma}_N \) is the variance-covariance matrix formed from the vector of sample moments \( h_N \). Simulation estimators require a nested fixed-point algorithm since each time the outer minimization algorithm tries a new trial value for \( \Theta \), the inner fixed point problem must be called to solve the CDP problem, using the optimal decision rule \( q^j_\Theta(\theta) = \delta(x_{it}, d_{it}, \theta) \) to generate the simulated decisions, and the transition density \( p(x_{it+1} | x_{it}, d_{it}, \theta) \) to generate \( j=1, \ldots, S \) IID realizations for a simulated panel each potential value of \( \Theta \). (It is important to simulate using ‘common random numbers’ that remain fixed as \( \Theta \) varies over the course of the estimation, in order to satisfy the stochastic equicontinuity conditions necessary to establish consistency and asymptotic normality of the simulation estimator.)

Simulation methods are extremely flexible for dealing with a number of data issues such as attrition, missing data, censoring and so forth. The idea is that, if we are willing to build a stochastic model of the data ‘problem’, we can account for it in the process of simulating the behavioural model. For example, Hall and Rust (2006) develop a dynamic model of commodity price speculation in the steel market. An object of interest is to estimate the stochastic process governing wholesale steel prices; however, there is no public commodity market where steel is traded and prices are recorded on a daily basis. Instead, Hall and Rust observe only the actual wholesale prices of a particular steel trader, who records wholesale prices only on the days he actually buys steel in the wholesale market. Since the speculator makes money by ‘buying low and selling high’, the set of observed wholesale prices are endogenously sampled, and failure to account for this can lead to incorrect inferences about wholesale prices – a dynamic analogue of sample selection bias. However, in a simulation model it is easy to censor the simulated data in the same way it is censored in the actual data, that is, by discarding simulated wholesale prices on days where no simulated purchases are made. Hall and Rust show that even though moments based on the observed (censored) data are ‘biased’ estimates, the simulated moments are biased in exactly the same fashion, so minimizing the distance between actual and simulated biased moments nevertheless results in consistent and asymptotically normal estimates of the parameters of the wholesale price process and other parameters entering the speculator’s objective function.

Simulation methods have also enabled the use of Bayesian methods, resulting in methods of inference that do not require asymptotic approximations, although they generally use Markov chain Monte Carlo methods to generate simulated draws from a distribution that approximates the exact finite sample posterior distribution for the parameters of interest (see for example, Lancaster, 1997; Imai, Jain and Ching, 2005; Nourets, 2006).

The most recent literature has extended the methods for estimation of single-agent SDPs to multi-agent dynamic games. For example, Rust (1994) described applications of dynamic discrete choice models to multiple-agent discrete dynamic games. The unobserved state variables \( \varepsilon_{it} \) entering any particular agent’s payoff function are assumed to be unobserved both by the econometrician and by the other players in the game. The Bayesian–Nash equilibria of this game can be represented as a vector of conditional choice probabilities \( \{P_{1}(d_{it} | x_{it}), \ldots, P_{n}(d_{it} | x_{it})\} \), one for each player, where \( P_{i}(d_{it} | x_{it}) \) represents the econometrician’s and the other players’ beliefs about the probability player \( i \) will take action \( d_{it} \), ‘integrating out’ over the unobservable states variable \( \varepsilon_{it} \) affecting player \( i \)’s decision at time \( t \) similar to eq. (41) for single-agent problems. If one adapts the numerical methods for Markov–perfect equilibrium described in Section 4, it is possible to compute Bayesian–Nash equilibria of discrete dynamic games using nested fixed-point algorithms. While it is relatively straightforward to write down the likelihood function for the game, actual estimation via a straightforward application of full information maximum likelihood is extremely computationally demanding since it requires a doubly nested fixed point algorithm (that is, an ‘outer’ algorithm to search over \( \Theta \) to maximize the likelihood, and then an inner algorithm to solve the dynamic game for each value of \( \Theta \), but this inner algorithm is itself a nested fixed-point algorithm). Alternative, less computationally demanding estimation methods have been proposed by Aguirregabiria and Mira (2007), Bajari and Hong (2006), Bajari, Benkard and Levin (2007), and Pesendorfer and Schmidt-Dengler (2003). This research is at the current frontier of development in numerical and empirical applications of dynamic programming.

Besides econometric methods, which are applied for structural estimation for actual agents in their ‘natural’ settings, an alternative approach is to try to make inferences about agents’ preferences and beliefs (and even their ‘mode of reasoning’) for artificial SDPs in a laboratory setting. The advantage of a laboratory experiment is experimental control over preferences and beliefs. The
ability to control these aspects of decision-making can enable much tighter tests of theories of decision-making. For example, Binmore et al. (2002) structured a laboratory experiment to determine whether individuals do backward induction in one- and two-stage alternating offer games, and ‘find systematic violations of backward induction that cannot be explained by payoff-interdependent preferences’ (2002, p. 49).

6 Comments

There has been tremendous growth in research related to dynamic programming since the 1940s. The method has evolved into the main tool for solving sequential decision problems, and research related to dynamic programming has led to fundamental advances in theory, numerical methods and econometrics. As we have seen, while dynamic programming embodies the notion of rational decision-making under uncertainty, there is mixed evidence as to whether it provides a good literal description of how human beings actually behave in comparable situations. Although human reasoning and decision-making is undoubtedly both more complex and more ‘frail’ and subject to foibles and limitations than the idealized notion of ‘full rationality’ that dynamic programming embodies, the discussion of the identification problem shows that, if we are given sufficient flexibility about how to model individual preferences and beliefs, there exist SDPs whose decision rules provide arbitrarily good approximations to individual behaviour. Thus, dynamic programming can be seen as a useful ‘first approximation’ to human decision-making, but it will undoubtedly be superseded by more descriptively accurate psychological models. Indeed, in the future one can imagine behavioural models that are not derived from some a priori axiomatization of preferences, but will result from empirical research that will ultimately deduce human behaviour from yet even deeper ‘structure’, that is the very underlying neuroanatomy of the human brain.

Even if dynamic programming is unlikely to be a descriptively accurate model of human decision-making, it will probably still remain highly relevant for the foreseeable future as the embodiment of rational decision-making. There are well-defined problems, for example, profit maximization or cost minimization, where there is agreement on the objective function to be maximized or minimized, and where there will be a demand for dynamic programming methods to find the optimal profit- or cost-minimizing strategies. There are many examples of this in the operations research literature. Practical applications include optimal inventory management (Hall and Rust, 2006) and optimal harvesting of timber (Paarsch and Rust, 2007).

Some observers such as Kurzweil (2005) predict that in the not too distant future (for example, approximately 2050) a singularity will occur, ‘during which the pace of technological change will be so rapid, its impact so deep, that human life will be irreversibly transformed’ (2005, p. 7). The singularity is a complex of accelerating improvements in computer hardware and software, and a merger of machine- and biological-based intelligence that will blur the distinction between ‘artificial intelligence’ and human intelligence, that will overcome many of current limitations of the human brain and human reasoning: ‘By the end of this century, the nonbiological portion of our intelligence will be trillions and trillions of times more powerful than unaided human intelligence’ (2005, p. 9). Dynamic programming will undoubtedly continue to be a critical tool in this brave new world.

Whether this prognosis will ever come to pass, or come to pass as soon as Kurzweil forecast, is debatable; but it does suggest that there will be continued interest in and research on dynamic programming. However, the fact that reasonably broad classes of dynamic programming problems are subject to a curse of dimensionality suggests that it may be too optimistic to think that human rationality will soon be superseded by ‘artificial rationality’. While there are many complicated problems that we would like to solve by dynamic programming in order to understand what ‘fully rational’ behaviour actually looks like in specific situations, the curse of dimensionality still limits us to very simple ‘toy models’ that only very partially and simplistically capture the myriad of details and complexities we face in the real world. Although we now have a number of examples where artificial intelligence based on principles from dynamic programming outstrips human intelligence, for example computerized chess, all these cases are for very specific problems in very narrow domains. I believe that it will be a long time before technological progress in computation and algorithms produce truly general-purpose ‘intelligent behaviour’ that can compete successfully with human intelligence in widely varying domains and in the immensely complicated situations that we operate in every day. Despite all our psychological frailties and limitations, there is an important unanswered question of ‘how do we do it?’, and more research is required to determine if human behaviour is simply suboptimal, or whether the human brain uses some powerful implicit ‘algorithm’ to circumvent the curse of dimensionality that digital computers appear to be subject to for solving problems such as SDPs by dynamic programming. For a provocative theory that deep principles of quantum mechanics can enable human intelligence to transcend computational limitations of digital computers, see Penrose (1989).

Easterlin hypothesis

Diane J. Macunovich and Richard A. Easterlin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The economic and social fortunes of a birth cohort tend to vary as a function of that cohort's relative size, approximated by the crude birth rate surrounding the cohort's birth. Effects have been observed on young men's earnings and unemployment rates, college enrolment rates, marriage and divorce, fertility, crime, and suicide rates. These effects have been found to be asymmetrical about the peak of a baby boom, and the original hypothesis has been extended to suggest a wide range of effects on the economy as a whole, from GDP growth rate, through interest rates and stock market performance, to measures of productivity.

Article

The Easterlin, or ‘relative cohort size’, hypothesis as originally formulated posits that, other things constant, the economic and social fortunes of a cohort (those born in a given year) tend to vary as a function of its relative size, approximated by the crude birth rate surrounding the cohort's birth (Easterlin, 1987). This hypothesis has since been extended to suggest a wider range of effects on the economy as a whole (Macunovich, 2002).

Although cohort size effects were originally expected to be symmetrical around the peak of the baby boom, which in the United States entered the labour market around 1980, it is now thought that they are tempered by aggregate demand effects and by feedback effects from adjustments made by young adults on the ‘leading edge’ of a baby boom. As a result, cohorts – and the economy generally – on the ‘leading
Easterlin hypothesis: The New Palgrave Dictionary of Economics

edge of a baby boom fare much better than those on the ‘trailing edge’, when all else is equal. The ultimate effects of changing relative cohort size are hypothesized to fall into these three categories:

1. Direct or first-order effects of relative cohort size on male relative income (the earnings of young men relative to their aspirations); male unemployment and hours worked; men's and women's college wage premium (the extra earnings of a college graduate relative to those of a secondary school graduate); and levels of income inequality generally.

2. Second-order effects operating through male relative income, especially the demographic adjustments people make in response to changing relative income, such as changes in women's labour force participation and their occupational choices; men's and women's college enrolment rates; marriage and divorce; fertility; crime, drug use, and suicide rates; out-of-wedlock childbearing and the incidence of female-headed families; and living arrangements.

3. Third-order effects on the economy of changing relative cohort size and the resulting demographic adjustments, such as changes in average wage growth; the overall demand for goods and services in the economy and hence the growth rate of the economy; inflation, interest rates, and savings rates; stock market performance; industrial structure; measures of gross domestic product (GDP); and productivity measures.

The three categories of effect are discussed first in this article, followed by a consideration of feedback effects and a discussion of empirical evidence.

First-order effects

The linkage between higher birth rates and adverse social and economic effects arises from ‘crowding mechanisms’ operating within three major social institutions, the family, school and the labour market. Within the family, a sustained upsurge in the birth rate is likely to entail an increase in the average number of siblings, higher average birth order, and a shorter average birth interval, and there is a substantial literature in psychology, sociology and economics linking child development negatively to one or more of these magnitudes (Ernst and Angst, 1983; Heer, 1985). The negative effects that have been investigated range over a wide variety of phenomena. With regard to mental health, for example, there is evidence that problem behaviours such as fighting, breaking rules, and delinquency are associated with increased family size. Adverse effects on morbidity and mortality of children have been found to be associated with increased family size and shorter birth spacing. A negative association between IQ and number of siblings has been found in a number of studies, and, with IQ controlled for, between educational attainment and family size. The principal mechanism underlying such developments is likely to be the dilution of parental time and energy per child and family economic resources per child, associated with increased family size.

The family mechanisms just discussed imply that, on average, a larger cohort is likely to perform less well in school. But even in the absence of any adverse effects within the family, a large cohort is likely to experience crowding in schools, which reduces average educational performance (Freeman, 1976). At any given time the human and physical capital stock comprising the school system tends to be either fixed in amount or to expand at a fairly constant rate, so that a surge in entrants into the school system
Easterlin hypothesis: The New Palgrave Dictionary of Economics
tends to be accompanied by a reduction in physical facilities and teachers per student. In the United
States, school planning decisions are divided among numerous local governments and private
institutions, and expansion has tended to occur in reaction to, rather than in anticipation of, a large
cohort's entry. Moreover, even when expansion occurs it is usually not accompanied by maintenance of
curriculum standards, partly because of the diminishing pool of qualified teachers available to supply the
needs of educational expansion.
The experience of a large cohort both in the family and in school is likely, in turn, to leave the cohort
less well prepared, on reaching adulthood, for success in the labour market. But even if there were no
prior effects, the entry of a large proportion of young and relatively inexperienced workers into the
labour market creates a new set of crowding phenomena, because the expansion of complementary
factor inputs is unlikely to be commensurate with that of the youth labour force. Additions to physical
capital stock tend to be dominated by considerations other than the relative supply of younger workers,
and the growth in older, experienced, workers is largely governed by prior demographic conditions.
Growth in the relative supply of younger workers results, in consequence, in a deterioration of their
relative wage rates, unemployment conditions and upward job mobility (Welch, 1979). The adverse
effects of labour market crowding tend to reinforce those of crowding within the school and family. For
example, the deterioration in relative wage rates of the young translates into lower returns to education
and consequent adverse impact on school drop-out rates and college enrolment (Freeman, 1976). Also,
problems encountered in finding a good job may reinforce feelings of inadequacy or frustration already
stirred up by some prior experiences at home or in school, and lead to lower labour force participation
among young men.

Second-order effects

The relative economic standing of successive generations at a given point in time may be altered
systematically by fluctuations in relative cohort size. If parents’ living levels play an important role in
setting their children's material aspirations, as socialization theory leads one to believe, then an increase
in the shortfall of children's wage rates relative to parents will cause the children to feel relatively
derived and under greater pressure to keep up. The importance of relative status influences of this type
in affecting attitudes or behaviour has been widely recognized in social science theory (Duesenberry,
1949).
Confronted with the prospect of a deterioration in its living level relative to that of its parents, a large
young adult cohort may make a number of adaptations in an attempt to preserve its comparative
standing. Foremost among these are changes in behaviour related to family formation and family life
(Macunovich and Easterlin, 1990; McNown and Rajbhandary, 2003). To avoid the financial pressures
associated with family responsibilities, marriage may be deferred. If marriage occurs, wives are more
likely to work and to put off childbearing. If a wife bears children, she is more likely to couple labour
force participation with childrearing, and to have a smaller number of children more widely spaced
(Macunovich, 2002; Jeon and Shields 2005).
The process of demographic adjustment to changing relative income can best be thought of in terms of
ex ante and ex post income; that is, the disposable per capita income of individuals prior to and then
following the adjustments. Analyses of baby boom cohorts in the United States have found that a

The Easterlin hypothesis suggests that the large size of the baby boomer cohort had significant economic impacts. Notably, the individual earning potential of baby boomers relative to their parents was significantly lower than that of pre-boom cohorts relative to their parents. However, after making the necessary demographic adjustments, the boomers managed to bring their per capita disposable income on par with that of their parents (Easterlin, Macdonald, and Manucovich, 1990).

Other reactions to the psychological stresses induced by large cohort size may be viewed as socially dysfunctional. Feelings of inadequacy and frustration, for example, may lead to disproportionate consumption of alcohol and drugs, mental depression, and, at the extreme, a higher rate of suicide (Pampel, 2001; Stockard and O'Brien, 2002). Feelings of bitterness, disappointment, and rage may induce a higher incidence of crime (O'Brien, Stockard, and Isaacson, 1999). Within marriage, the stresses of conflicting work and motherhood roles for women, and feelings of inadequacy as a breadwinner for men, are likely to result in a higher incidence of divorce (Macunovich, 2002). In the political sphere, the disaffection felt by a large cohort because of its lack of success may make it more responsive to the appeals of those who are politically alienated (O'Brien and Gwartney-Gibbs, 1989).

**Third-order effects**

The second-order effects described in the previous section will, through reduced marriage rates and increased divorce and female labour force participation rates, reduce the proportion of households with stay-at-home spouses, which increases the tendency to purchase market replacements for the goods and services traditionally produced by women in the home. The result is a ‘commoditization’ of many goods and services that used to be produced in the home. They are now exchanged in the market – and thus counted in official measures of GDP and productivity – whereas previously they were part of the excluded ‘non-market’ economy.

This commoditization of goods and services causes measures of industrial structure to skew strongly toward services and retail, away from agriculture and manufacturing, creating low-wage service jobs. In addition, the influx of inexperienced young workers as members of a large birth cohort – both men and women – into the labour market exacerbates any decline in productivity growth by changing the composition of the workforce to one dominated by inexperienced and therefore lower-productivity workers. This decline in relative wages of younger workers resulting from their oversupply would lead employers to substitute cheaper labour for more expensive capital, thus lowering the young workers’ productivity still further by providing those low-wage workers with less productivity-enhancing machinery and technology.

Although some analysts maintain that the potential age structure effect of the baby boomers on personal savings is not large enough to explain the full drop in US national savings rates since the 1980s, studies of this phenomenon to date have focused only on the behaviour of the baby boomers themselves. However, one might argue that the baby boomers have affected the propensity to save in age groups other than their own. For example, because boomers’ earnings were depressed and they experienced an inflated housing market when they went to buy homes (both the effects of their own large cohort size), many parents of baby boomers drew on their own savings in order to help with down payments.

When the age structure of children is permitted to affect consumption and savings, a very strong age-related pattern of expenditures and saving can be identified. Children induce savings on the part of their...
Easterlin hypothesis: The New Palgrave Dictionary of Economics

parents between the ages of five and 16, possibly in anticipation of later educational expenses. When the relationships identified in this way are combined with the changing age distribution in the US population during the 20th century, they produce a savings rate that fluctuates by plus or minus 25 per cent around the mean, simply as a result of changing age structure (Macunovich, 2002).

Similarly, a strong effect has been identified of changing age structure (measured simply as the proportion of young to old in the population) on real interest rates and inflation, because of differential patterns of savings and consumption with age (McMillan and Baesel, 1990). A higher proportion of young adults in a population will produce lower aggregate savings levels – and hence higher interest rates. In this model, today's lower interest and inflation rates are the result of the ageing of the baby boomers, as they begin to acquire assets for their retirement years. The converse of this phenomenon – the potential ‘meltdown’ effect of a retiring baby boom on financial markets, asset values and interest rates – has been described as well (Schieber and Shoven, 1994).

Some research has estimated a strong effect of age structure on housing prices in the United States, with the entry of the baby boom into the housing market causing the severe house price inflation of the 1970s and 1980s, and the entry of the baby bust causing house price deflation (Mankiw and Weil, 1989). Although some have disputed the magnitude of the effect estimated there, most researchers have confirmed its existence. A later study, for example, found significant effects of detailed (single year) age structure in the adult population on all forms of consumption, including housing demand, and on money demand (Fair and Dominguez, 1991).

These potential effects on aggregate demand, savings rates, interest rates and inflation suggest that there might have been a connection between changing age structure and macroeconomic fluctuations in the United States and elsewhere during the 20th century. When the population of young adults is expanding, the resultant growth in demand for durable goods creates confidence in investors, while an unexpected slowdown in the growth rate of young adults could cause cutbacks in production and investment in response to inventory buildups, with a snowball effect throughout the economy. There was a close correspondence in the United States in the 20th century between ‘turnaround points’ of growth in the key age group of 15–24, and significant economic dislocations in 1908, 1929, 1938 and 1974. Similarly, there was a correlation between age structure and economic performance in industrialized nations in the 1930s, and in both industrialized and developing nations since the 1980s, with the ‘Asian Tigers’ some of the most recent examples (Macunovich, 2002).

Feedback effects on the relationship between relative cohort size and relative income

Easterlin's original statements recognized the potential effects of outside influences on the relative cohort size mechanism (Easterlin, 1987). However, the dynamic nature of the mechanism – the fact that many of these other factors would, in fact, be secondary and tertiary results of changing relative cohort size, and thus endogenous in any empirical application – has not been fully appreciated in most analyses to date. As a result, it is often concluded that the hypothesis may have been relevant in the post-Second World War period up to about 1980, but that it fails to extend beyond one full cycle to apply to the period since 1980.

The aggregate demand effect of changing relative cohort size, discussed in the previous section, is hypothesized to contribute significantly to the observed asymmetry in relative cohort size effects on
Easterlin hypothesis: The New Palgrave Dictionary of Economics

male relative income. Although cohorts on the leading edge of a baby boom experience declining wages relative to those of older workers, they do so in an economy experiencing strong growth in aggregate demand resulting from the increasing relative cohort size among young adults. Cohorts on the lagging edge of a baby boom, however, enter a labour market weakened by the economic slump resulting from a transition from expanding to contracting relative cohort size.

Similarly, as one of the secondary effects of changing relative cohort size discussed earlier, female labour force participation is hypothesized to have increased in response to declining male relative income as the leading edge of the baby boom entered the labour market. If, as hypothesized, these young women also increased their levels of educational attainment in anticipation of future labour market participation, they would have in many cases competed directly with the male members of their cohort and exacerbated the effects of relative cohort size on male relative income. This effect would have been greatest for cohorts on the lagging edge of the boom – those who should have benefited from declining relative cohort size. It is important in empirical analyses to recognize the potential endogeneity of these other factors, rather than treat relative cohort size effects as ‘contingent’ on exogenous changes in female labour force participation, educational attainment and wages. Wage analyses based on relative cohort size which control for a cohort’s position in the US baby boom – and thus allow for aggregate demand and female labour force changes – can explain most of the observed change in young men’s entry level wages and in their returns to experience and education (Macunovich, 2002).

Empirical analyses

Empirically, the most important application of the hypothesis has been to explain the varying experience of young adults in the United States since the Second World War. There is, however, some evidence of its relevance to the experience of developed countries more generally in this period (Korenman and Neumark, 2000; Pampel, 2001; Stockard and O’Brien, 2002; Jeon and Shields, 2005), and perhaps as a mechanism leading to fertility decline during the demographic transition in developing countries (Macunovich, 2002).

Overall, however, empirical analyses testing various aspects of the Easterlin hypothesis have produced fairly mixed results. By 2007 there have been two comprehensive analyses of the literature on the Easterlin hypothesis, and one meta-analysis of 19 studies completed between 1976 and 2002. The meta-analysis (Waldorf and Byun, 2005) focused on the age structure–fertility link, and concluded that analytical problems contribute to an apparent lack of empirical support for the Easterlin hypothesis. Most significant among these were the failure to recognize the endogeneity of an income variable when combined with a relative cohort size variable, and the use of very broad age groups in defining relative cohort size.

The first of the literature reviews considered a broad range of topics, including labour market experience and education; marriage, fertility and divorce; and crime, suicide and alienation. It concluded:

[T]he evidence for the Easterlin effect proves mixed at best and plain wrong at worst… Aggregate data support the hypothesis more than individual level data, period-specific or time-series data support the hypothesis more than cohort-specific data, experiences from 1945–1980 support the hypothesis more than the years since 1980, and trends in the
United States support the hypothesis more than trends in European nations. (Pampel and Peters, 1995, p. 189)

The second literature review evaluated 76 published analyses focused solely on fertility, and concluded:

With an equal number of micro- and macro-level analyses using North American data (twenty-two), the ‘track record’ of the hypothesis is the same in both venues, with fifteen providing significant support in each case. The literature suggests unequivocal support for the relativity of the income concept in fertility but is less clear regarding the source(s) of differences in material aspirations, and suggests that the observed relationship between fertility and cohort size has varied across countries and time periods due to the effects of additional factors not included in most models. (Macunovich, 1998, p. 53)

This review suggests that, because of data limitations and idiosyncratic interpretations of the hypothesis by individual researchers, many of the studies with unfavourable findings have been only peripherally related to the Easterlin hypothesis.

Conclusion

Since the early 1980s, demographic concepts have encroached modestly on economic theory, as evidenced by the appearance of life cycle, overlapping generations and vintage models. The cohort size hypothesis might be viewed as another in this sequence. Its roots, however, extend beyond economics, reaching out into sociology, demography and psychology, and it seeks to encompass a wider range of attitudinal and behavioural phenomena than is traditionally considered economic.

Article

Eckstein was an entrepreneur who moved a whole technology from the research community into the marketplace. Until he founded Data Resources, Inc., macroeconometric models were research vehicles and not vehicles for aiding business decision making. Under his direction Data Resources came to dominate the marketplace for this type of information, but more importantly it changed the nature of the game. To be taken seriously after his innovation, all economic forecasts had to be buttressed with econometric equations and no large firm would attempt to begin its decision-making processes without an understanding of the national and international economic forecasts emanating from such models.

Born in Ulm, Germany, in 1927, Dr Eckstein fled to England in 1938 and came to the United States in 1939. He graduated from Stuyvesant High School in New York City and served in the United States Army Signal Corps from 1946 to 1947. He received an AB degree from Princeton University in 1951 and a Ph.D. from Harvard University in 1955.

In 1968, he and Donald B. Marron founded Data Resources, Inc., which has grown into the largest economic information company in the world. The firm became a subsidiary of McGraw-Hill, Inc. in 1979. He directed the development of the Data Resources Model of the US economy, and was responsible for its forecasting operations.

As an immigrant to the United States from Nazi Germany, Otto Eckstein wanted to contribute something to America's future success. Better economic policies that would lead to a higher American standard of living were not an abstraction to him. They were the centre of his professional life.

His professional career began with the analysis of large scale multi-year water resources projects and how one might better allocate national resources in such projects. In the late 1950s he was the principal intellectual director of a Joint Economic Committee study on how the United States might break out of what was then seen as the stagnation of the mid-1950s. His study on growth, full employment and price stability laid the basis for the successful economic policies that were followed in the first two-thirds of
the 1960s. But he went on to implement those intellectual foundations as a member of the President's Council of Economic Advisers under President Johnson. No one who knew the enthusiasm of Otto Eckstein for studying, teaching, and practising economics could thereafter think of economics as the dismal science.

Ecological economics is the study of the interactions and co-evolution in time and space of human economies and the ecosystems in which human economies are embedded. It uncovers the links and feedbacks between human economies and ecosystems, and so provides a unified picture of ecology and economy. The link between ecology and human economies has been manifested in the development of resource management or bio-economic models, in which the main focus has been on fishery or forestry management where the impact of humans on ecosystems is realized through harvesting. More closed links have been developed, however, as both disciplines evolve.

Article

Ecology can be regarded as the study of living species such as animals, plants and microorganisms, and the relations among them and their natural environment. In this context, an ecosystem includes these species and their non-living environment, their interactions, and their evolution in time and space (see, for example, Roughgarden, May and Levin, 1989). Economics, meanwhile, is the study of how human societies use scarce resources to produce commodities and to distribute them among their members. The need for an interdisciplinary approach – ‘ecological economics’ – stems from the fact that natural ecosystems and human economies are closely linked. In the process of production and consumption, human beings use ecosystems and their services, influence their evolution, and are the recipients of
feedbacks originating from their actions upon ecosystems. As Kenneth Boulding (1965) notes in his classic paper ‘Earth as a space ship’, which can be regarded as a landmark in the emergence of ecological economics, ‘Man is finally going to have to face the fact that he is a biological system living in an ecological system, and that his survival power is going to depend on his developing symbiotic relationships of a closed-cycle character with all the other elements and populations of the world of ecological systems.’

Thus, ecological economics can be regarded as the study of the interactions and co-evolution in time and space of human economies and the ecosystems in which human economies are embedded. This implies that the task of ecological economics is to bridge the gap between economy and ecology by uncovering the links and the feedbacks between human economies and ecosystems, and by using these links and feedbacks to provide a unified picture of ecology and economy and their interactions and co-evolution. In a sense, ecological economics aims at linking ecological models and economic models in order to provide insights into complex and interrelated phenomena stemming from and affecting both ecosystems and human economies.

The natural link between ecology and human economies has been manifested in the traditional development of resource management or bio-economic models (for example, Clark, 1990), in which the main focus has been on fishery or forestry management where the impact of humans on ecosystems is realized through harvesting. More close links have been developed, however, as both disciplines evolve. Common methodological approaches may also be encountered in ecology and economics. Optimality behaviour, which is fundamental in economics, has also been used to provide insights into the structure of ecological systems, in the context of optimal foraging behaviour, species competition, or net energy maximization by organisms (for example, Tschirhart, 2000; Tilman, Polasky and Lehman, 2005) with the purpose of founding macro-behaviours in ecosystems – such as those emerging from population dynamics – on micro-foundations.

In the same context, the classical phenomenological-descriptive approach to species competition based on Lotka–Volterra systems has recently been complemented by mechanistic resource-based models of species competition for limiting resources (Tilman, 1982; 1988). This approach has obvious links to competition among economic agents for limited resources. Furthermore, by linking the functioning of natural ecosystems with the provision of useful services to humans, or by using concepts such as ecosystems productivity, insurance from the genetic diversity of ecological systems against catastrophic events, or development of new products using genetic resources existing in natural ecosystems (Heal, 2000), new insights into the fundamental issues of the valuation of ecosystems or the valuation of biodiversity have been derived. (Examples of useful services to humans include provisioning services, such as food, water, fuel, genetic material; regulation services, such as climate regulation, disease regulation; and cultural services and supporting services, such as soil formation, nutrient cycling; see Millennium Ecosystem Assessment, 2005.)

Ecological models

The traditional bio-economic models (Clark, 1990), which describe the evolution of the population or the biomass of species when harvesting takes place, have formed the building blocks of ecological-economic modelling. These models can be extended along various lines to provide a more realistic
picture of ecosystems (for a detailed analysis, see Murray, 2003) and help build meaningful ecological-economic models. To start with, let \( x(t) \) denote the biomass of a certain species at time \( t \). Then evolution of the biomass is described by an ordinary differential equation

\[
\frac{dx(t)}{dt} = \text{birth} - \text{natural death} + \text{migration} - \text{harvesting}.
\]  

(1)

In the analysis of population models it is common, unless it is a specific case, to set the migration rate at zero, and to represent the natural rate of population growth (birth-natural death) by a function \( F(x) \). The most common specification of this function is the famous logistic function, which is

\[ F(x) = r x (1 - x / K). \]

In this function \( r \) is a positive constant called intrinsic growth rate and \( K \) is the carrying capacity of the environment which depends on factors such as resource availability or environmental pollution. If we denote by \( h(t) \) the rate of harvesting of the species biomass by humans, the population model becomes:

\[
\frac{dx(t)}{dt} = F(x) - h(t), \quad x(0) = x_0.
\]  

(2)

If \( h(t) = F(x) \), the population remains constant and the harvesting rate corresponds to sustainable yield. Harvesting rate is usually modelled as population dependent or \( h = q E x \), where \( q \) is a positive constant, referred to as a catchability coefficient in fishery models, and \( E \) is harvesting effort. Human activities can affect the species population, in addition to harvesting, by affecting parameters such as the intrinsic growth rates or the carrying capacity. For example, if the stock of environmental pollution of a certain pollutant (such as phosphorus in a lake) in a natural ecosystem is denoted by \( P \), with dynamics described by

\[
\frac{dP(t)}{dt} = g(s(t), P(t)), \quad P(0) = P_0.
\]  

(3)

where \( s(t) \) is the rate of emissions (such as phosphorus loadings), and the pollutant affects parameters of the population model, then the combined model will be (3) along with
If the catchability coefficient is affected by technical change, then it can be expressed by a function of time as \( q(t) \). In this case (4) is not autonomous. Alternatively \( q \) can be a function of technological variables like R&D evolving in the economic module.

The population model (2) can be generalized to age-structured populations and multi-species populations. In multi-species populations the Lotka–Volterra predator–prey models are classic. If we denote the prey population by \( x(t) \) and the predator population by \( y(t) \) and ignore harvesting for the moment to simplify things, the model can be written as

\[
\frac{dx(t)}{dt} = r(x) \left[ 1 - \frac{x}{K} \right] - q \frac{dx}{dt}, \quad r'(P) < 0, \quad K'(P) < 0. \tag{4}
\]

Alternatively \( q \) can be a function of technological variables like R&D evolving in the economic module.

A more general multi-species model with \( J \) prey and \( J \) predators can be written, for \( i = 1, ..., J \), as

\[
\frac{dx_i(t)}{dt} = a_i - \sum_{j=1}^{J} \beta_{ij} y_j, \quad x_i(0) = x_{i0} \tag{7}
\]

where \( R(x) \) is a function called the \textit{predation term}, which can be specified as \( \gamma x / (x^2 + \delta^2) \), \( \gamma, \delta > 0 \).
where all parameters are positive constants. An even more general model of interacting populations can be obtained by the generalized Kolmogorov model where the evolution of each species biomass is described by:

\[
\frac{dx_i(t)}{dt} = x_i f_i(x_1, x_2, x_3, \ldots) \quad i = 1, 2, 3, \ldots
\]

(9)

In the mechanistic resource-based models of species competition emerging from the work of Tilman (for example, Tilman, 1982; 1988), species compete for limiting resources. (For the use of this model in ecological-economic modelling, see Brock and Xepapadeas, 2002; Tilman, Polasky and Lehman, 2005.) In these models the growth of a species depends on the limiting resource, and interactions among species take place through the species’ effects on the limiting resource. Let \( \mathbf{x} = (x_1, \ldots, x_n) \) be the vector of species biomasses and \( R \) the amount of the available limiting resource. Then a mechanistic resource-based model with a single limiting factor in a given area and \( i = 1, \ldots, n \) species can be described by the following equations:

\[
\frac{\dot{x}_i}{x_i} = g_i(R) - a_i x_i(0) = x_i(0)
\]

(10)

\[
\dot{R} = S - aR - \sum_{i=1}^{n} w_i x_i \dot{g}_i(R)
\]

(11)
where \( g_i(R) \) is resource-related growth, \( d_i \) is the species’ natural death rate, \( S \) is the amount of resource supplied, \( a \) is the natural resource removal rate (leaching rate), and \( w_i \) is specific resource consumption by species \( i \). The main result in this framework relates to an exclusion principle stating that, in a landscape free of disturbances, the species with the lowest resource requirement in equilibrium will competitively displace all other species, driving the system to a monoculture. Species coexistence and polycultures in equilibrium can be supported in a system with more than one limiting resource, or even in single resource systems if there is temperature-dependent growth and temperature variation in the ecosystem, spatial or temporal variations in resource ratios, differences in local palatabilities and local abundance of herbivores.

In addition to the temporal variation captured by the models described above an important characteristic of ecosystems is that of spatial variation. Biological resources tend to disperse in space under forces promoting ‘spreading’ or ‘concentrating’ (Okubo, 2001); these processes, along with intra- and inter-species interactions, induce the formation of spatial patterns for species. A central concept in modelling the dispersal of biological resources is that of diffusion. Diffusion is defined as a process whereby the microscopic irregular movement of particles such as cells, bacteria, chemicals, or animals results in some macroscopic regular motion of the group. Biological diffusion is based on random walk models which, when coupled with population growth equations, lead to general reaction-diffusion systems (see, for example, Okubo and Levin, 2001; Murray, 2003). When only one species is examined, the coupling of classical diffusion with a logistic growth function leads to the so-called Fisher–Kolmogorov equation, which can be written as

\[
\frac{\partial x(z, t)}{\partial t} = F(x(z, t)) + D_x \frac{\partial^2 x(z, t)}{\partial z^2}
\]  

where \( x(z, t) \) denotes the concentration of the biomass at spatial point \( z \) at time \( t \). The biomass grows according to a standard growth function \( F(x) \) which determines the resource's kinetics but also disperses in space with a constant diffusion coefficient \( D_x \). (Nonlinear reaction diffusion equations are associated with propagating wave solutions.) In general, a diffusion process in an ecosystem tends to produce a uniform population density, that is, spatial homogeneity. Thus it might be expected that diffusion would ‘stabilize’ ecosystems where species disperse and humans intervene through harvesting. There, is however, one exception, known as ‘diffusion induced instability’ or ‘diffusive instability’. It was Alan Turing (1952) who suggested that under certain conditions reaction-diffusion systems can generate spatially heterogeneous patterns. This is the so-called ‘Turing mechanism’ for generating diffusion instability. With two interacting species evolving according to

\[
\frac{\partial x(z, t)}{\partial t} = F(x, y) + D_x \frac{\partial^2 x(z, t)}{\partial z^2}
\]

if in the absence of diffusion \((D_x = D_y = 0)\) the system tends to a spatially uniform stable steady state, then under certain conditions, depending on the relationship \(D_x/D_y\), spatially heterogeneous patterns can emerge due to diffusion-induced instability.

Spatial variations in ecological systems can also be analysed in terms of meta-population models. A meta-population is a set of local populations occupying isolated patches which are connected by migrating individuals. Meta-population dynamics can be developed for single or many species (Levin, 1974). For the single species case the dynamics become

\[
\frac{dx}{dt} = F(x)x + Dx
\]

(15)

where \(x = (x_1, \ldots, x_l)\) is a column vector of species densities, \(F\) has its \(i\)th row depending on the \(i\)th row of \(x\), and \(D = [d_{ij}]\) is a connectivity matrix, where \(d_{ij}\) is the rate of movement from patch \(j\) to patch \(i\) \((j \neq i)\). Thus dynamics are local with the exception of movements from one patch to the other.

A more general model encompassing \(i = 1, \ldots, n\) species competing for \(j = 1, \ldots, l\) limiting resources, with density-dependent growth and interactions across patches \(c = 1, \ldots, C\) in a given landscape, can be written as

\[
\frac{\dot{x}_{ic}}{x_{ic}} = F_{ic}(x_c, x_{-c}) g_{ic}(R_c, d_{ic}), \quad \forall i, c
\]

(16)
where \( \mathbf{R}_c, \mathbf{x}_c \) are respectively vectors of resources and species outside patch \( c \).

(For a detailed analysis, see Brock and Xepapadeas, 2002.) A more general set-up can be obtained in the context of co-evolutionary models which describe the interactions between population (or biomass) dynamics and mutation (or trait dynamics). Antagonistic co-evolution of species on the one hand and pests or parasites or the other can be described by the so-called Red Queen hypothesis (see, for example, Van Valen, 1973, and Kawecki, 1998). According to this hypothesis, parasites evolve ceaselessly in response to perpetual evolution of species’ (or hosts’) resistance. The co-evolution of the parasites’ ability to attack (virulence) and the hosts’ resistance is expected to indicate persistent fluctuations of resistance and virulence. In this context the Red Queen hypothesis generates a continuous need for variation, resulting in a limit cycle or other non-point attractor in trait space dynamics, which are called Red Queen races. Red Queen cycles are observed in a slow time scale, since trait dynamics are assumed to evolve slowly, in contrast to the population, host-parasite, dynamics which are assumed to evolve fast (see Dieckmann and Law, 1996).

A simple co-evolutionary model can be developed in a system with one harvested (‘useful’) species or host species whose biomass is denoted by \( x \) and a parasite denoted by \( y \), where the abundance of \( x \) and \( y \) depends on the evolution of two characteristics or traits denoted by \( d \) and \( \gamma \) (see, for example, the Red Queen dynamic models developed by Krakauer and Jansen, 2002), where \( d \) affects the fitness of \( x \) and \( \gamma \) affects the fitness of \( y \).

Let the growth rates of \( x \) and the pathogen \( y \) be given by

\[
g_x = \frac{\dot{x}}{x} = (s - r x - \gamma Q(d, \gamma))
\]

(18)

\[
g_y = \frac{\dot{y}}{y} = (\kappa Q(d, \gamma) - \delta).
\]

(19)
If we measure fitness by growth rates, then \( \frac{\partial Q(d, \gamma)}{\partial d} < 0 \), so that an increase in \( d \) increases fitness of \( x \). In the same way, \( \frac{\partial Q(d, \gamma)}{\partial \gamma} > 0 \) for an increase in \( \gamma \) to increase fitness of \( y \). In equilibrium of the fast population system where \( \dot{x} = \dot{y} = 0 \), it holds that

\[
\dot{x} = \frac{\delta}{Q(d, \gamma)}, \quad \dot{y} = \frac{s - r\dot{x}}{Q(d, \gamma)}, \quad s \geq r\dot{x}.
\] (20)

On the assumption of constant mutation rates \( \mu_d \) and \( \mu_\gamma \), the evolutionary dynamics for the traits \( d \) and \( \gamma \), when population dynamics have reached the asymptotically stable steady state, are given by

\[
\dot{d} = -\mu_d \dot{\gamma} \dot{y} \frac{\partial Q(d, \gamma)}{\partial d}
\] (21)

\[
\dot{\gamma} = \mu_\gamma \dot{\gamma} \dot{y} \frac{\partial Q(d, \gamma)}{\partial \gamma}.
\] (22)

See Krakauer and Jansen (2002) who, by considering the slow time scale trait dynamics, show that the equilibrium point \((d^*, \gamma^*)\): \( \dot{d} = \dot{\gamma} = 0 \) is not attracting; the dynamics spiral away from this point. This behaviour is the oscillatory, Red Queen dynamics.

**Ecological-economic modelling**

The ecological models developed above are the cornerstones of the development of meaningful ecological-economic models. The impact of humans on the population of species can be realized through direct harvesting \( h \) as described in (1) and (2). This type of impact can be easily incorporated into the more general population dynamic models by selecting the harvested species. Human influence can also be realized in an indirect way by having the environmental carrying capacity affected by environmental
pollution generated in the non-harvesting sector of the economy, as in (3) and (4), or by having technological considerations affecting catchability coefficients. It is also possible that external environmental conditions which are anthropogenic, such as global warming, can make some parameters associated with population dynamics or mutation dynamics change slowly. This can be modelled in (21) and (22) by considering $\mu_d$ and $\mu_\gamma$ as slow varying parameters, defined as $\mu_d(\varepsilon, t)$ and $\mu_\gamma(\varepsilon, t)$, where $0 < \varepsilon \ll 1$ is the adiabatic parameter. This slowly varying system could be used to model slow anthropogenic impacts on ecosystem structure.

However, the size and the severity of the impact of human economies in ecosystems depend on the way in which variables, such as harvesting or other variables which can be chosen by humans (such as emissions, investment in harvesting capacity) and which influence the evolution of ecosystems, are actually chosen. These variables can be regarded as control variables, and the way in which they are chosen affects the evolution of ecological variables, such as species biomasses or traits, which can be considered as the state variables of the problem.

The typical approach in economics is to associate the choice of the control variables with optimizing behaviour. Thus, the control variables are chosen so that a criterion function is optimized, and the economic problem of ecosystem management – where management means choice of control variables – is defined as a formal optimal control problem. In this problem the objective is the optimization of the criterion function subject to the constraints imposed by the structure of the ecosystem. These constraints, which provide the transition equations of the optimal control problem, are the dynamic equations of the ecological models described in the previous section.

The solution of the ecological-economic model, provided it exists, will determine the paths of the state and the control variables and the steady state of the system, which will determine the long-run equilibrium values of the ecological populations as well as the approach dynamics to the steady state. In this context, managed ecological systems which are predominantly nonlinear could exhibit dynamic behaviour characterized by multiple, locally stable and unstable steady states, limit cycles, or the emergence of hysteresis, bifurcations or irreversibilities.

The way in which the objective function is set up and the ecological constraints which are taken into account determine the solution of the ecological-economic model. In principle, a socially optimal solution can be distinguished from a privately optimal solution. The socially optimal solution corresponds to the so-called problem of the social planner, where the objective function takes into account not only benefits from harvesting certain resources of the ecological system, which corresponds to harvesting commercially valuable biomass, but in addition a wide spectrum of flows of services generated by the whole ecosystem. These include, as described above, regulation, cultural or supporting services, existence values, or benefits associated with productivity or insurance gains. If $V(h(t))$ denotes harvesting benefits at time $t$ associated with harvesting vector $h$, and $U(x(t))$ denotes the flow of benefits associated with ecosystem service generated by species biomasses existing in the ecosystem and not removed by harvesting, then the total flow of benefit is $V(h(t)) + U(x(t))$. In this formulation, the $V(\cdot)$ and $U(\cdot)$ functions are usually assumed to be monotonically increasing and concave. In a more general setup, the total benefit function can be non-separable, defined as $u(h(t), x(t))$.

The objective can then be written as:
\[
\max_{\mathbf{h}(t)} \int_0^{\infty} e^{-\rho t} \left[ V(\mathbf{h}(t)) + U(\mathbf{x}(t)) \right] dt
\]

(23)

where $\rho \geq 0$ is a discount rate. It should be noted that in principle benefits associated with $V(\mathbf{h}(t))$ can be estimated using market data, while benefits associated with $U(\mathbf{x}(t))$ are hard to estimate because markets for the larger part of the spectrum of ecosystem services are missing. (Valuation of ecosystem services is an open question. For details, see, for example, Bingham et al., 1995.) The social optimum corresponds to the maximization of (23), subject to the constraints imposed by the ecological system. For example, if we use the generalized model of resource competition, the constraints are:

\[
\frac{\dot{\mathbf{x}}_c}{\dot{\mathbf{x}}_c} = F_{ic}(\mathbf{x}_c, \mathbf{x}_{-c}) g_{ic}(\mathbf{R}_c, d_{ic}) - h_{io} \quad \forall i, c
\]

(24)

\[
\dot{\mathbf{R}}_{jc} = S_{jc}(\mathbf{R}_c, \mathbf{R}_{-c}) - D_{jc}(\mathbf{x}_c, \mathbf{x}_{-c}, \mathbf{R}_c, \mathbf{R}_{-c}), \quad \forall j, c.
\]

(25)

A solution $(\mathbf{h}^*(t), \mathbf{x}^*(t))$ is regarded as the socially optimal solution. The privately optimal solution is distinguished from the socially optimal by the fact that only harvesting benefits enter the objective function. The assumption is that management is carried out by a ‘small’ profit-maximizing private agent that ignores the general flows of ecosystem services. In this case, the private agents do not take into account externalities associated with their management practices on ecosystem service flow and $U(\mathbf{x}(t)) \equiv 0$. Market externalities associated with the definition of $V(\mathbf{h})$ could relate to imperfections in the markets for the harvested commodities, or to property rights-related externalities, as the well known ‘tragedy of the commons’ emerging in the harvesting of open access resources.

In general the privately optimal solution $(\mathbf{h}^0(t), \mathbf{x}^0(t))$ will deviate from the socially optimal solution. Another type of externality can be associated with strategic behaviour in resource harvesting if more than one private agent harvests the resource. If $l = 1, \ldots, L$ harvesters are present, then the biomass equation (24) for patch $c$ becomes
In this case the privately optimal solution can be obtained as an open loop or feedback Nash equilibrium. Privately optimal solutions can also be distinguished from the socially optimal by the extent to which the ecological constraints are taken into account. For example, if resource dynamics or trait dynamics are not taken into account in the optimization problem, the management rule will deviate from the social optimum. Furthermore, since all the ecological constraints are operating, there will be discrepancies between the perceived evolution of ecosystems under management that ignores certain constraints, and the actual evolution of the ecosystem. Brock and Xepapadeas (2003), show that, by ignoring genetic constraints associated with the development of resistance to genetically modified organisms, the actual system loses any productivity advantage because of resistance development. These discrepancies might be a cause for surprises in ecosystem management. For example, with reference to the co-evolutionary model (18) – (22), profit-maximizing decisions which ignore evolution might steer the system to a certain steady state on a fast time scale, but then the underlying trait dynamics might move the system in slow time to another attractor.

The deviations between the private solution and the social optimum provide a basis for regulation which is similar to the rationale behind the regulation of environmental externalities. Regulation could take the form, in general spatial models of ecosystem management, of species-specific and site-specific taxes on harvesting, or equivalent quota and zoning systems.

Ecological inference is a general statistical problem where a response variable is not available at the subject level because summary statistics are reported for groups only. It consists of merging information from different databases which are not linked to each other at the record level. We consider an election scenario where in each electoral precinct the fraction of voting-age people who turn out to vote, the fraction of black population and the number of voting-age people are observed. The proportions of blacks and of whites who vote are unobserved because electoral results and census data are not linked.

aggregation; ecological inference; likelihood; Markov chain Monte Carlo methods; method of bounds; nonparametric models; statistical approaches

Article

1 The ecological inference problem

For expository purposes, we discuss only an important but simple special case of ecological inference, and adopt the running example and notation from King (1997: ch. 2). The basic problem has two observed variables ($T_i$ and $X_i$) and two unobserved quantities of interest ($\beta_i^b$ and $\beta_i^w$) for each of $p$ observations. Observations represent aggregate units, such as geographic areas, and each individual-level variable within these units is dichotomous.

To be more specific, in Figure 1 we observe for each electoral precinct $i$ the fraction of voting age people who turnout to vote ($T_i$) and who are black ($X_i$), along with the number of voting age people ($N_i$). The quantities of interest, which remain unobserved because of the secret ballot, are the proportions of blacks who vote ($\beta_i^b$) and whites who vote ($\beta_i^w$). The proportions $\beta_i^b$ and $\beta_i^w$ are not observed because $T_i$ and $X_i$ are from different data sources (electoral results and census data, respectively) and record linkage is impossible (and illegal), and so the cross-tabulation cannot be computed.

Figure 1

Notation for Precinct $i$. Note: The goal is to estimate the quantities of interest, $\beta_i^b$ (the fraction of blacks who vote) and $\beta_i^w$ (the fraction of whites who vote), from the aggregate variables $X_i$ (the fraction of voting age people who are black) and $T_i$ (the fraction of people who vote), along with $N_i$ (the known number of voting age people).
### Race of Voting decision

<tr>
<td>White</td>
<td>$\beta_i^w$</td>
<td>$1 - \beta_i^w$</td>
</tr>
</tbody>
</table>

Also of interest are the district-wide fractions of blacks and whites who vote, which are respectively

$$b^b = \frac{\sum_{j=1}^{p} N_j X_j \beta_i^b}{\sum_{j=1}^{p} N_j X_j}$$

and

$$b^w = \frac{\sum_{j=1}^{p} N_j (1 - X_j) \beta_i^w}{\sum_{j=1}^{p} N_j (1 - X_j)}$$. 

$X_i$ and $1 - X_i$
These are weighted averages of the corresponding precinct-level quantities. Some methods aim to estimate only $B^b$ and $B^w$ without giving estimates of $B^b_i$ and $B^w_i$ for all $i$.

2 Deterministic and statistical approaches

The ecological inference literature before King (1997) was bifurcated between supporters of the method of bounds, originally proposed by Duncan and Davis (1953), and supporters of statistical approaches, proposed even before Ogburn and Goltra (1919) but first formalized into a coherent statistical model by Goodman (1953; 1959). (For the historians of science among us: although these two monumental articles were written by two colleagues and friends in the same year and in the same department and university – the Department of Sociology at the University of Chicago – the principal did not discuss their work prior to completion. Even by today's standards, nearly a half century after their publication, the articles are models of clarity and creativity.) Although Goodman and Duncan and Davis moved on to other interests following their seminal contributions, most of the ecological inference literature in the five decades since 1953 was an ongoing war between supporters of these two key approaches, and often without the usual academic decorum.

2.1 Extracting deterministic information: the method of bounds

The purpose of the method of bounds and its generalizations is to extract deterministic information, known with certainty, about the quantities of interest. The intuition behind these quantities is simple. For example, if a precinct contained 150 African-Americans and 87 people in the precinct voted, then how many of the 150 African-American actually cast their ballot? We do not know exactly, but bounds on the answer are easy to obtain: in this case, the answer must lie between 0 and 87. Indeed, conditional only on the data being correct, $[0, 87]$ is a 100 per cent confidence interval. Intervals like this are sometimes narrow enough to draw meaningful inferences, and sometimes they are too wide, but the ability to provide (non-trivial) 100 per cent confidence intervals in even some situations is quite rare in any statistical field.

In general, before any data are seen, the unknown parameters $B^b_i$ and $B^w_i$ are each bounded on the unit interval. Once we observe $T_i$ and $X_i$ they are bounded more narrowly, as:

$$
B^b_i = \left[ \max \left( 0, \frac{T_i - X_i}{X_i} \right), \min \left( T_i, 1 \right) \right] \\
B^w_i = \left[ \max \left( 0, \frac{T_i - X_i}{1 - X_i} \right), \min \left( \frac{T_i}{1 - X_i}, 1 \right) \right].
$$

Deterministic bounds on the district-level quantities $B^b$ and $B^w$ are weighted averages of these precinct-level bounds. The bounds then indicate that the parameters in each case fall within these deterministic bounds with certainty, and in practice they are almost always narrower than $[0,1]$. Whether they are narrow enough in any one application depends on the nature of the data.

2.2 Extracting statistical information: Goodman’s regression

Leo Goodman’s (1953; 1959) approach is very different from, but just as important as, Duncan and Davis’s. He looked at the same data and focused on the statistical information. His approach examines variation in the marginals ($X_i$ and $T_i$) over the precincts to attempt to reason back to the district-wide fractions of blacks and whites who vote, $B^b$ and $B^w$. The outlines of this approach and the problems with it have been known at least since Ogburn and Goltra (1919). For example, if in precincts with large proportions of black citizens we observe that many people do not vote, then it may seem reasonable to infer that blacks turn out at lower rates than whites. Indeed, it often is reasonable, but not always. The problem is that it could instead be the case that the whites who happen to live in heavily black precincts are the ones who vote less frequently, yielding the opposite ecological inference to the individual-level truth.
What Goodman accomplished was to formalize the logic of the approach in a simple regression model, and to give the conditions under which estimates from such a model are unbiased. To see this, note first that the accounting identity

\[ T_i = X_i \beta_i^b + (1 - X_i) \beta_i^w \]  

(4)

holds exactly. Then he showed that a regression of \( T_i \) on \( X_i \) and \((1 - X_i)\) with no constant term could be used to estimate \( B^b \) and \( B^w \), respectively. The key assumption necessary for unbiasedness that Goodman identified is that the parameters and \( X_i \) be uncorrelated: \( \text{Cov}(\beta_i^b, X_i) = \text{Cov}(\beta_i^w, X_i) = 0 \). In the example, the assumption is that blacks vote in the same proportions in homogeneously black areas as in more integrated areas. Obviously, this is true sometimes and it is false other times. (King, 1997: ch. 3, showed that Goodman's assumption was necessary but not sufficient. To have unbiasedness, it must also be true that the parameters and \( N_i \) are uncorrelated.)

As Goodman recognized, when this key assumption does not hold, estimates from the model will be biased. Indeed, they can be very biased, outside the deterministic bounds, and even outside the unit interval. This technique has been used extensively since the 1950s, and impossible estimates occur with considerable frequency (some estimates range to a majority of real applications; Achen and Shively, 1995).

2 Extracting both deterministic and statistical information: King's EI approach

From 1953 until 1997, the only two approaches used widely in practice were the method of bounds and Goodman’s regression. King’s (1997) idea was that the insights from these two conflicting literatures in fact do not conflict with each other; the sources of information are largely distinct and can be combined to improve inference overall and synergistically. The idea is to combine the information from the bounds, applied to both quantities of interest for each and every precinct, with a statistical approach for extracting information within the bounds. The amount of information in the bounds depends on the data-set, but for many data-sets it can be considerable. For example, if precincts are spread uniformly over a scatterplot of \( X_i \) by \( T_i \), the average bounds on \( \beta_i^b \) and \( \beta_i^w \) are narrowed from \([0,1]\) to less than half of that range – hence eliminating half of the ecological inference problem with certainty. This additional information also helps make the statistical portion of the model far less sensitive to assumptions than previous statistical methods which exclude the information from the bounds.

To illustrate these points, we first present all the information available without making any assumptions, thus extending the bounds approach as far as possible. As a starting point, the left graph in Figure 2 provides a scatterplot of a sample data set as observed, \( X_i \) horizontally by \( T_i \) vertically. Each point in this figure corresponds to one precinct, for which we would like to estimate the two unknowns. We display the unknowns in the right graph of the same figure; any point in the right graph portrays values of the two unknowns, \( \beta_i^b \) which is plotted horizontally, and \( \beta_i^w \) which is plotted vertically. Ecological inference involves locating, for each precinct, the one point in this unit square corresponding to the true values of \( \beta_i^b \) and \( \beta_i^w \), since values outside the square are logically impossible.

Figure 2

Two views of the same data. Note: The left graph is a scatterplot of the observables, \( X_i \) by \( T_i \). The right graph displays this same information as a tomography plot of the quantities of interest, \( \beta_i^b \) by \( \beta_i^w \). Each precinct \( i \) that appears as a point in the left graph is a line (rather than a point because of information lost due to aggregation) in the right graph. For example, precinct 52 appears as the dot with a little square around it in the left graph and the dark line in the right graph. Source: The data are from King (1997: Figures 5.1 and 5.5).
To map the knowns onto the unknowns, King begins Goodman’s accounting identity from eq. (4). From this equation, which holds exactly, King solves for one unknown in terms of the other:

\[ \beta_i^w = \left( \frac{T_i}{1 - X_i} \right) \beta_i^b, \]

which shows that \( \beta_i^w \) is a linear function of \( \beta_i^b \), where the intercept and slope are known (since they are functions of the data, \( X_i \) and \( T_i \)).

King then maps the knowns from the left graph onto the right graph by using the linear relationship in eq. (5). A key point is that each dot on the left graph can be expressed, without assumptions or loss of information, as what King called a ‘tomography’ line within the unit square in the right graph. It is precisely the information lost due to aggregation that causes us to have to plot an entire line (on which the true point must fall) rather than the goal of one point for each precinct on the right graph. In fact, the information lost is equivalent to having a graph of the \( \beta_i^b \) by \( \beta_i^w \) points but having the ink smear, making the points into lines and partly but not entirely obscuring the correct positions of the \( (\alpha_i^b, \beta_i^w) \) points. (King also showed that the ecological inference problem is mathematically equivalent to the ill-posed ‘tomography’ problem of many medical imaging procedures, such as CAT and PET imaging.)
What does a tomography line tell us? Before we know anything, we know that the true point must lie somewhere within the unit square. After $X_i$ and $T_i$ are observed for a precinct, we also know that the true point must fall on a specific line represented by eq. (5) and appearing in the tomography plot in Figure 2. In many cases narrowing the region to be searched for the true point from the entire square to the one line in the square can provide a significant amount of information. To see this, consider the point enclosed in a box in the left graph, and the corresponding dark line in the right graph. This precinct, number 52, has observed values of $X_{52} = 0.88$ and $T_{52} = 0.19$. As a result, substituting into eq. (5) gives $\beta^w_{i,52} = 1.58 - 7.33 \beta^b_i$, which when plotted appears as the dark line on the right graph. This particular line tells us that, in our search for the true point on the right graph, we can eliminate with certainty all area in the unit square except that on the line, which is clearly an advance over not having the data. Translated into the quantities of interest, this line tells us (by projecting the line downward to the horizontal axis) that, wherever the true point falls on the line, $\beta^b_i$ must fall in the relatively narrow bounds of $[0.07, 0.21]$. Unfortunately, in this case, $\beta^w_i$ can only be bounded (by projecting to the left) to somewhere within the entire unit interval. More generally, lines that are relatively steep, like this one, tell us a great deal about $\beta^b_i$ and little about $\beta^w_i$. Tomography lines that are relatively flat give narrow bounds on $\beta^w_i$ and wide bounds on $\beta^b_i$. Lines that cut off the bottom left (or top right) of the figure give narrow bounds on both quantities of interest.

If the only information available to learn about the unknowns in precinct $i$ is $X_i$ and $T_i$, a tomography line like that in Figure 2 exhausts all this available information. This line immediately tells us the known bounds on each of the parameters, along with the precise relationship between the two unknowns, but it is not sufficient to narrow in on the right answer any further. Fortunately, additional information exists in the other observations in the same data set ($X_j$ and $T_j$ for all $j$) which, under the right assumptions, can be used to learn more about $\beta^b_i$ and $\beta^w_i$ in our precinct of interest.

In order to borrow statistical strength from all the precincts to learn about $\beta^b_i$ and $\beta^w_i$ in precinct $i$, some assumptions are necessary. The simplest version of King’s model (that is, the one most useful for expository purposes) requires three assumptions, each of which can be relaxed in different ways.

First, the set of $(\beta^b_i, \beta^w_i)$ points must fall in a single cluster within the unit square. The cluster can fall anywhere within the square; it can be widely or narrowly dispersed or highly variable in one unknown and narrow in the other; and the two unknowns can be positively, negatively, or not at all correlated over $i$. An example that would violate this assumption would be two or more distinct clusters of $(\beta^b_i, \beta^w_i)$ points, as might result from subsets of observations with fundamentally different data generation processes (such as from markedly different regions). The specific mathematical version of this one-cluster assumption is that $\beta^b_i$ and $\beta^w_i$ follow a truncated bivariate normal density

$$
\text{TN}(\beta^b_i, \beta^w_i|\varnothing, \Sigma) - N(\beta^b_i, \beta^w_i|\varnothing, \Sigma) \frac{\text{1}(\beta^b_i, \beta^w_i)}{R(\varnothing, \Sigma)},
$$

where the kernel is the untruncated bivariate normal,

$$
N(\beta^b_i, \beta^w_i|\varnothing, \Sigma) = (2\pi)^{-1/2} |\Sigma|^{-1/2} \exp \left[-\frac{1}{2} (\beta^b_i - \varnothing)^{\prime} \Sigma^{-1} (\beta^b_i - \varnothing) \right].
$$
and $1(\beta^b_i, \beta^w_i)$ is an indicator function that equals 1 if $\beta^b_i \in [0, 1]$ and $\beta^w_i \in [0, 1]$ and zero otherwise. The normalization factor in the denominator, $R(\psi, \Sigma)$, is the volume under the untruncated normal distribution above the unit square:

$$
R(\psi, \Sigma) = \int_0^1 \int_0^1 N(\beta^b, \beta^w | \psi, \Sigma) \, d\beta^b \, d\beta^w
$$

When divided into the untruncated normal, this factor keeps the volume under the truncated distribution equal to 1. The parameters of the truncated density, which we summarize as

$$
\psi = \begin{cases} 
\beta^b, \beta^w, \sigma^b, \sigma^w, \rho \\
\psi, \Sigma
\end{cases}
$$

are on the scale of the untruncated normal (and so, for example, $\beta^b$ and $\beta^w$ need not be constrained to the unit interval even though $\beta^b_i$ and $\beta^w_i$ are constrained by this density). The second assumption, which is necessary to form the likelihood function, is the absence of spatial autocorrelation: conditional on $X_i$, $T_i$ and $T_j$ are mean independent. Violations of this assumption in empirically reasonable (and even some unreasonable) ways do not seem to induce much if any bias.

The final, and by far the most critical, assumption is that $X_i$ is independent of $\beta^b_i$ and $\beta^w_i$. The three assumptions together produce what has come to be known as King's 'basic' EI model. (The use of EI to name this method comes from the name of his software, available at http://GKing.Harvard.edu/) King also generalizes this assumption, in what has come to be known as the 'extended' EI model, by allowing the truncated normal parameters to vary as functions of measured covariates, $Z^b_i$ and $Z^w_i$, giving:

$$
\psi_i = \begin{cases} 
\beta^b_i Z^b_i, \beta^w_i Z^w_i, \sigma^b_i, \sigma^w_i, \rho \\
\psi_i, \Sigma
\end{cases}
$$

where $\alpha^b$ and $\alpha^w$ are parameter vectors to be estimated along with the original model parameters and that have as many elements as $Z^b_i$ and $Z^w_i$ have columns. This relaxes the mean independence assumptions to:

$$
E(\beta^b_i | X_i, Z_i) = E(\beta^b_i | Z_i) E(\beta^w_i | X_i, Z_i) = E(\beta^w_i | Z_i).
$$

Note that this extended model also relaxes the assumptions of truncated bivariate normality, since there is now a separate density being assumed for each observation. Because the
bounds, which differ in width and information content for each \( i \), generally provide substantial information, even \( X_i \) can be used as a covariate in \( Z_i \). (The recommended default setting in EI includes \( X_i \) as a covariate with a prior on its coefficient.) In contrast, under Goodman's regression, which does not include information in the bounds, including \( X_i \) leads to an unidentified model (King, 1997: sec. 3.2).

These three assumptions – one cluster, no spatial autocorrelation, and mean independence between the regressor and the unknowns conditional on \( X_i \) and \( Z_i \) – enable one to compute a posterior (or sampling) distribution of the two unknowns in each precinct. A fundamentally important component of EI is that the quantities of interest are not the parameters of the likelihood but instead come from conditioning on \( T_i \) and producing a posterior for \( \beta_i^b \) and \( \beta_i^w \) in each precinct. Failing to condition on \( T_i \) and examining the parameters of the truncated bivariate normal only makes sense if the model holds exactly and so is much more model-dependent than King's approach. Since the most important problem in ecological inference modelling is precisely model misspecification, failing to condition on \( T \) assumes away the problem without justification. This point is widely regarded as a critical step in applying the EI model (Adolph and King, with Herron and Shotts, 2003).

When bounds are narrow, EI model assumptions do not matter much. But, for precincts with wide bounds on a quantity of interest, inferences can become model dependent. This is especially the case with ecological inference problems precisely because of the loss of information due to aggregation. In fact, this loss of information can be expressed by noting that the joint distribution of \( \beta_i^b \) and \( \beta_i^w \) cannot be fully identified from the data without some untestable assumptions. To be precise, distributions with positive mass over any curve or combination of curves that connects the bottom left point \( (\hat{\beta}_i^b = 0, \hat{\beta}_i^w = 0) \) to the top right point \( (\hat{\beta}_i^b = 1, \hat{\beta}_i^w = 1) \) of a tomography plot cannot be rejected by the data (King, 1997: 191). Other features of the distribution are estimable. This fundamental indeterminacy is, of course, a problem because it prevents pinning down the quantities of interest with certainty, but it can also be something of an opportunity since different distributional assumptions can lead to the same estimates, especially since only those pieces of the distributions above the tomography lines are used in the final analysis.

4 Alternative approaches to ecological inference

In the continuing search for more information to bring to bear on ecological inferences, King, Rosen and Tanner (1999) extend King's (1997) model another step. They incorporate King's main advance of combining deterministic and statistical information but begin modelling a step earlier at the individuals who make up the counts. They also build a hierarchical Bayesian model, using easily generalizable Markov chain Monte Carlo (MCMC) technology (Tanner, 1996).

To define the model formally, let \( T_i' \) denote the number of voting age people who turn out to vote. At the top level of the hierarchy they assume that \( T_i' \) follows a binomial distribution with probability equal to \( \beta_i = X_i \beta_i^b + (1 - X_i) \beta_i^w \) and count \( N_i \). Note that at this level it is assumed that the expectation of \( T_i' \), rather than \( T_i' \), is equal to \( X_i \beta_i^b + (1 - X_i) \beta_i^w \). In other words, King (1997) models \( T_i \) as a continuous proportion, whereas King, Rosen, and Tanner (1999) recognize the inherently discrete nature of the counts of voters that go into computing this proportion. The two models are connected, of course, since \( T_i/N_i \) approaches \( T_i \) as \( N_i \) gets large.

The connection to King's tomography line can be seen in the contribution of the data from precinct \( i \) to the likelihood, which is

\[
(11) \quad \left( X_i \beta_i^b + (1 - X_i) \beta_i^w \right) T_i' \left( 1 - X_i \beta_i^b - (1 - X_i) \beta_i^w \right) (N_i - T_i').
\]

By taking the logarithm of this contribution to the likelihood and differentiating with respect to \( \beta_i^b \) and \( \beta_i^w \). King, Rosen and Tanner show that the maximum of (11) is not a unique point, but rather a line whose equation is given by the tomography line in eq. (5). Thus, the log-likelihood for precinct \( i \) looks like two playing cards leaning against each other. As long as \( T_i \) is fixed and bounded away from 0.5 (and \( X_i \) a fixed known value between 0 and 1), the derivative at this point is seen to increase with \( N_i \) that is, the pitch of the playing cards increases with the sample size. In other words, for large \( N_i \), the log-likelihood for precinct \( i \) degenerates from a surface defined over the unit square into a single playing card standing perpendicular to the unit square and oriented along the corresponding tomography line.

At the second level of the hierarchical model, \( \beta_i^b \) is distributed as a beta density with parameters \( c_b \) and \( d_b \) and \( \beta_i^w \) follows an independent beta with parameters \( c_w \) and \( d_w \). While \( \beta_i^b \)
and $\beta^{D}$ are assumed a priori independent, they are a posteriori dependent. At the third and final level of the hierarchical model, the unknown parameters $c_{b}$, $d_{b}$, $c_{w}$ and $d_{w}$ follow an exponential distribution with a large mean.

A key advantage of this model is that it generalizes immediately to arbitrarily large $R \times C$ tables. This approach was pursued by Rosen et al. (2001), who also provided a much faster method of moment-based estimator. For an application, see King et al. (2003).

ecological inference: The New Palgrave Dictionary of Economics

Abstract

As a unified discipline, econometrics is still relatively young and has been transforming and expanding very rapidly. Major advances have taken place in the analysis of cross-sectional data by means of semiparametric and nonparametric techniques. Heterogeneity of economic relations across individuals, firms and industries is increasingly acknowledged and attempts have been made to take it into account either by integrating out its effects or by modelling the sources of heterogeneity when suitable panel data exist. The counterfactual considerations that underlie policy analysis and treatment valuation have been given a more satisfactory foundation. New time-series econometric techniques have been developed and employed extensively in the areas of macroeconometrics and finance. Nonlinear econometric techniques are used increasingly in the analysis of cross-section and time-series observations. Applications of Bayesian techniques to econometric problems have been promoted largely by advances in computer power and computational techniques. The use of Bayesian techniques has in turn provided the investigators with a unifying framework where the tasks of forecasting, decision making, model evaluation and learning can be considered as parts of the same interactive and iterative process, thus providing a basis for ‘real time econometrics’.

1 What is econometrics?

Broadly speaking, econometrics aims to give empirical content to economic relations for testing economic theories, forecasting, decision making, and for *ex post* decision/policy evaluation. The term ‘econometrics’ appears to have been first used by Pawel Ciompa as early as 1910, although it is Ragnar Frisch who takes the credit for coining the term, and for establishing it as a subject in the sense in which
it is known today (see Frisch, 1936, p. 95, and Bjerkholt, 1995). By emphasizing the quantitative aspects of economic relationships, econometrics calls for a ‘unification’ of measurement and theory in economics. Theory without measurement can have only limited relevance for the analysis of actual economic problems; while measurement without theory, being devoid of a framework necessary for the interpretation of the statistical observations, is unlikely to result in a satisfactory explanation of the way economic forces interact with each other. Neither ‘theory’ nor ‘measurement’ on its own is sufficient to further our understanding of economic phenomena.

As a unified discipline, econometrics is still relatively young and has been transforming and expanding very rapidly since an earlier version of this article was published in the first edition of *The New Palgrave: A Dictionary of Economics* in 1987 (Pesaran, 1987a). Major advances have taken place in the analysis of cross-sectional data by means of semiparametric and nonparametric techniques. Heterogeneity of economic relations across individuals, firms and industries is increasingly acknowledged, and attempts have been made to take them into account either by integrating out their effects or by modelling the sources of heterogeneity when suitable panel data exists. The counterfactual considerations that underlie policy analysis and treatment evaluation have been given a more satisfactory foundation. New time series econometric techniques have been developed and employed extensively in the areas of macroeconometrics and finance. Nonlinear econometric techniques are used increasingly in the analysis of cross-section and time-series observations. Applications of Bayesian techniques to econometric problems have been given new impetus largely thanks to advances in computer power and computational techniques. The use of Bayesian techniques has in turn provided the investigators with a unifying framework where the tasks of forecasting, decision making, model evaluation and learning can be considered as parts of the same interactive and iterative process; thus paving the way for establishing the foundation of ‘real time econometrics’. See Pesaran and Timmermann (2005a).

This article attempts to provide an overview of some of these developments. But to give an idea of the extent to which econometrics has been transformed over the past decades we begin with a brief account of the literature that pre-dates econometrics, and discuss the birth of econometrics and its subsequent developments to the present. Inevitably, our accounts will be brief and non-technical. Readers interested in more details are advised to consult the specific entries provided in the *New Palgrave* and the excellent general texts by Maddala (2001), Greene (2003), Davidson and MacKinnon (2004), and Wooldridge (2006), as well as texts on specific topics such as Cameron and Trivedi (2005) on microeconometrics, Maddala (1983) on econometric models involving limited-dependent and qualitative variables, Arellano (2003), Baltagi (2005), Hsiao (2003), and Wooldridge (2002) on panel data econometrics, Johansen (1995) on cointegration analysis, Hall (2005) on generalized method of moments, Bauwens, Lubrano and Richard (2001), Koop (2003), Lancaster (2004), and Geweke (2005) on Bayesian econometrics, Bosq (1996), Fan and Gijbels (1996), Horowitz (1998), Härdle (1990), Härdle and Linton (1994) and Pagan and Ullah (1999) on nonparametric and semiparametric econometrics, Campbell, Lo and MacKinlay (1997) and Gourieroux and Jasiak (2001) on financial econometrics, Granger and Newbold (1986), Lütkepohl (1991) and Hamilton (1994) on time series analysis.

2 Quantitative research in economics: historical backgrounds
Empirical analysis in economics has had a long and fertile history, the origins of which can be traced at least as far back as the work of the 16th-century political arithmeticians such as William Petty, Gregory King and Charles Davenant. The political arithmeticians, led by Sir William Petty, were the first group to make systematic use of facts and figures in their studies. They were primarily interested in the practical issues of their time, ranging from problems of taxation and money to those of international trade and finance. The hallmark of their approach was undoubtedly quantitative, and it was this which distinguished them from their contemporaries. Although the political arithmeticians were primarily and understandably preoccupied with statistical measurement of economic phenomena, the work of Petty, and that of King in particular, represented perhaps the first examples of a unified quantitative–theoretical approach to economics. Indeed Schumpeter in his *History of Economic Analysis* (1954, p. 209) goes as far as to say that the works of the political arithmeticians ‘illustrate to perfection, what Econometrics is and what Econometricians are trying to do’.

The first attempt at quantitative economic analysis is attributed to Gregory King, who was the first to fit a linear function of changes in corn prices on deficiencies in the corn harvest, as reported in Charles Davenant (1698). One important consideration in the empirical work of King and others in this early period seems to have been the discovery of ‘laws’ in economics, very much like those in physics and other natural sciences.

This quest for economic laws was, and to a lesser extent still is, rooted in the desire to give economics the status that Newton had achieved for physics. This was in turn reflected in the conscious adoption of the method of the physical sciences as the dominant mode of empirical enquiry in economics. The Newtonian revolution in physics, and the philosophy of ‘physical determinism’ that came to be generally accepted in its aftermath, had far-reaching consequences for the method as well as the objectives of research in economics. The uncertain nature of economic relations began to be fully appreciated only with the birth of modern statistics in the late 19th century and as more statistical observations on economic variables started to become available.

The development of statistical theory in the hands of Galton, Edgeworth and Pearson was taken up in economics with speed and diligence. The earliest applications of simple correlation analysis in economics appear to have been carried out by Yule (1895; 1896) on the relationship between pauperism and the method of providing relief, and by Hooker (1901) on the relationship between the marriage rate and the general level of prosperity in the United Kingdom, measured by a variety of economic indicators such as imports, exports, and the movement in corn prices. Benini (1907), the Italian statistician was the first to make use of the method of multiple regression in economics. But Henry Moore (1914; 1917) was the first to place the statistical estimation of economic relations at the centre of quantitative analysis in economics. Through his relentless efforts, and those of his disciples and followers Paul Douglas, Henry Schultz, Holbrook Working, Fred Waugh and others, Moore in effect laid the foundations of ‘statistical economics’, the precursor of econometrics. The monumental work of Schultz, *The Theory and the Measurement of Demand* (1938), in the United States and that of Allen and Bowley, *Family Expenditure* (1935), in the United Kingdom, and the pioneering works of Lenoir (1913), Wright (1915; 1928), Working (1927), Tinbergen (1929–30) and Frisch (1933) on the problem of ‘identification’ represented major steps towards this objective. The work of Schultz was exemplary in the way it attempted a unification of theory and measurement in demand analysis; while the work on identification highlighted the importance of ‘structural estimation’ in econometrics.
and was a crucial factor in the subsequent developments of econometric methods under the auspices of the Cowles Commission for Research in Economics. Early empirical research in economics was by no means confined to demand analysis. Louis Bachelier (1900), using time-series data on French equity prices, recognized the random walk character of equity prices, which proved to be the precursor to the vast empirical literature on market efficiency hypothesis that has evolved since the early 1960s. Another important area was research on business cycles, which provided the basis of the later development in time-series analysis and macroeconometric model building and forecasting. Although, through the work of Sir William Petty and other early writers, economists had been aware of the existence of cycles in economic time series, it was not until the early 19th century that the phenomenon of business cycles began to attract the attention it deserved. Clement Juglar (1819–1905), the French physician turned economist, was the first to make systematic use of time-series data to study business cycles, and is credited with the discovery of an investment cycle of about 7–11 years duration, commonly known as the Juglar cycle. Other economists such as Kitchin, Kuznets and Kondratieff followed Juglar's lead and discovered the inventory cycle (3–5 years duration), the building cycle (15–25 years duration) and the long wave (45–60 years duration), respectively. The emphasis of this early research was on the morphology of cycles and the identification of periodicities. Little attention was paid to the quantification of the relationships that may have underlain the cycles. Indeed, economists working in the National Bureau of Economic Research under the direction of Wesley Mitchell regarded each business cycle as a unique phenomenon and were therefore reluctant to use statistical methods except in a nonparametric manner and for purely descriptive purposes (see, for example, Mitchell, 1928; Burns and Mitchell, 1947). This view of business cycle research stood in sharp contrast to the econometric approach of Frisch and Tinbergen and culminated in the famous methodological interchange between Tjalling Koopmans and Rutledge Vining about the roles of theory and measurement in applied economics in general and business cycle research in particular. (This interchange appeared in the August 1947 and May 1949 issues of the *Review of Economics and Statistics.*)

3 The birth of econometrics

Although, quantitative economic analysis is a good three centuries old, econometrics as a recognized branch of economics began to emerge only in the 1930s and the 1940s with the foundation of the Econometric Society, the Cowles Commission in the United States, and the Department of Applied Economics (DAE) in Cambridge, England. (An account of the founding of the first two organizations can be found in Christ, 1952; 1983, while the history of the DAE is covered in Stone, 1978.) This was largely due to the multidisciplinary nature of econometrics, comprising of economic theory, data, econometric methods and computing techniques. Progress in empirical economic analysis often requires synchronous developments in all these four components. Initially, the emphasis was on the development of econometric methods. The first major debate over econometric method concerned the applicability of the probability calculus and the newly developed sampling theory of R.A. Fisher to the analysis of economic data. Frisch (1934) was highly sceptical of the value of sampling theory and significance tests in econometrics. His objection was not, however, based on the epistemological reasons that lay behind Robbins's and Keynes's criticisms of econometrics.
He was more concerned with the problems of multicollinearity and measurement errors which he believed were pervasive in economics; and to deal with the measurement error problem he developed his confluence analysis and the method of ‘bunch maps’. Although used by some econometricians, notably Tinbergen (1939) and Stone (1945), the bunch map analysis did not find much favour with the profession at large. Instead, it was the probabilistic rationalizations of regression analysis, advanced by Koopmans (1937) and Haavelmo (1944), that formed the basis of modern econometrics.

Koopmans did not, however, emphasize the wider issue of the use of stochastic models in econometrics. It was Haavelmo who exploited the idea to the full, and argued for an explicit probability approach to the estimation and testing of economic relations. In his classic paper published as a supplement to *Econometrica* in 1944, Haavelmo defended the probability approach on two grounds. First, he argued that the use of statistical measures such as means, standard errors and correlation coefficients for inferential purposes is justified only if the process generating the data can be cast in terms of a probability model. Second, he argued that the probability approach, far from being limited in its application to economic data, because of its generality is in fact particularly suited for the analysis of ‘dependent’ and ‘non-homogeneous’ observations often encountered in economic research.

The probability model is seen by Haavelmo as a convenient abstraction for the purpose of understanding, or explaining or predicting, events in the real world. But it is not claimed that the model represents reality in all its details. To proceed with quantitative research in any subject, economics included, some degree of formalization is inevitable, and the probability model is one such formalization. The attraction of the probability model as a method of abstraction derives from its generality and flexibility, and the fact that no viable alternative seems to be available. Haavelmo's contribution was also important as it constituted the first systematic defence against Keynes's (1939) influential criticisms of Tinbergen's pioneering research on business cycles and macroeconometric modelling. The objective of Tinbergen's research was twofold: first, to show how a macroeconometric model may be constructed and then used for simulation and policy analysis (Tinbergen, 1937); second, ‘to submit to statistical test some of the theories which have been put forward regarding the character and causes of cyclical fluctuations in business activity’ (Tinbergen, 1939, p. 11). Tinbergen assumed a rather limited role for the econometrician in the process of testing economic theories, and argued that it was the responsibility of the ‘economist’ to specify the theories to be tested. He saw the role of the econometrician as a passive one of estimating the parameters of an economic relation already specified on a priori grounds by an economist. As far as statistical methods were concerned, he employed the regression method and Frisch's method of confluence analysis in a complementary fashion. Although Tinbergen discussed the problems of the determination of time lags, trends, structural stability and the choice of functional forms, he did not propose any systematic methodology for dealing with them. In short, Tinbergen approached the problem of testing theories from a rather weak methodological position. Keynes saw these weaknesses and attacked them with characteristic insight (Keynes, 1939). A large part of Keynes's review was in fact concerned with technical difficulties associated with the application of statistical methods to economic data. Apart from the problems of the ‘dependent’ and ‘non-homogeneous’ observations mentioned above, Keynes also emphasized the problems of misspecification, multicollinearity, functional form, dynamic specification, structural stability, and the difficulties associated with the measurement of theoretical variables. By focusing his attack on Tinbergen's attempt at testing economic theories of business cycles, Keynes almost totally ignored the practical significance of Tinbergen's work for econometric model building and policy analysis (for more
In his own review of Tinbergen's work, Haavelmo (1943) recognized the main burden of the criticisms of Tinbergen's work by Keynes and others, and argued the need for a general statistical framework to deal with these criticisms. As we have seen, Haavelmo's response, despite the views expressed by Keynes and others, was to rely more, rather than less, on the probability model as the basis of econometric methodology. The technical problems raised by Keynes and others could now be dealt with in a systematic manner by means of formal probabilistic models. Once the probability model was specified, a solution to the problems of estimation and inference could be obtained by means of either classical or of Bayesian methods. There was little that could now stand in the way of a rapid development of econometric methods.

4 Early advances in econometric methods

Haavelmo's contribution marked the beginning of a new era in econometrics, and paved the way for the rapid development of econometrics, with the likelihood method gaining importance as a tool for identification, estimation and inference in econometrics.

4.1 Identification of structural parameters

The first important breakthrough came with a formal solution to the identification problem which had been formulated earlier by Working (1927). By defining the concept of ‘structure’ in terms of the joint probability distribution of observations, Haavelmo (1944) presented a very general concept of identification and derived the necessary and sufficient conditions for identification of the entire system of equations, including the parameters of the probability distribution of the disturbances. His solution, although general, was rather difficult to apply in practice. Koopmans, Rubin and Leipnik (1950) used the term ‘identification’ for the first time in econometrics, and gave the now familiar rank and order conditions for the identification of a single equation in a system of simultaneous linear equations. The solution of the identification problem by Koopmans (1949) and Koopmans, Rubin and Leipnik (1950) was obtained in the case where there are a priori linear restrictions on the structural parameters. They derived rank and order conditions for identifiability of a single equation from a complete system of equations without reference to how the variables of the model are classified as endogenous or exogenous. Other solutions to the identification problem, also allowing for restrictions on the elements of the variance–covariance matrix of the structural disturbances, were later offered by Wegge (1965) and Fisher (1966).

Broadly speaking, a model is said to be identified if all its structural parameters can be obtained from the knowledge of its implied joint probability distribution for the observed variables. In the case of simultaneous equations models prevalent in econometrics, the solution to the identification problem depends on whether there exists a sufficient number of a priori restrictions for the derivation of the structural parameters from the reduced-form parameters. Although the purpose of the model and the focus of the analysis on explaining the variations of some variables in terms of the unexplained variations of other variables is an important consideration, in the final analysis the specification of a minimum number of identifying restrictions was seen by researchers at the Cowles Commission to be
the function and the responsibility of ‘economic theory’. This attitude was very much reminiscent of the
approach adopted earlier by Tinbergen in his business cycle research: the function of economic theory
was to provide the specification of the econometric model, and that of econometrics to furnish
statistically optimal methods of estimation and inference. More specifically, at the Cowles Commission
the primary task of econometrics was seen to be the development of statistically efficient methods for
the estimation of structural parameters of an a priori specified system of simultaneous stochastic
equations.

More recent developments in identification of structural parameters in context of semiparametric models
is discussed below in Section 12. See also Manski (1995).

4.2 Estimation and inference in simultaneous equation models

Initially, under the influence of Haavelmo’s contribution, the maximum likelihood (ML) estimation
method was emphasized as it yielded consistent estimates. Anderson and Rubin (1949) developed the
limited information maximum likelihood (LIML) method, and Koopmans, Rubin and Leipnik (1950)
proposed the full information maximum likelihood (FIML). Both methods are based on the joint
probability distribution of the endogenous variables conditional on the exogenous variables and yield
consistent estimates, with the former utilizing all the available a priori restrictions and the latter only
those which related to the equation being estimated. Soon, other computationally less demanding
estimation methods followed, both for a fully efficient estimation of an entire system of equations and
for a consistent estimation of a single equation from a system of equations.

The two-stage least squares (2SLS) procedure was independently proposed by Theil (1954; 1958) and
Basmann (1957). At about the same time the instrumental variable (IV) method, which had been
developed over a decade earlier by Reiersol (1941; 1945), and Geary (1949) for the estimation of errors-in-variables models, was generalized and applied by Sargan (1958) to the estimation of simultaneous
equation models. Sargan’s generalized IV estimator (GIVE) provided an asymptotically efficient
technique for using surplus instruments in the application of the IV method to econometric problems,
and formed the basis of subsequent developments of the generalized method of moments (GMM)
estimators introduced subsequently by Hansen (1982). A related class of estimators, known as k-class
estimators, was also proposed by Theil (1958). Methods of estimating the entire system of equations
which were computationally less demanding than the FIML method were also advanced. These methods
also had the advantage that, unlike the FIML, they did not require the full specification of the entire
system. These included the three-stage least squares method due to Zellner and Theil (1962), the iterated
instrumental variables method based on the work of Lyttkens (1970), Brundy and Jorgenson (1971), and
Dhrymes (1971) and the system k-class estimators due to Srivastava (1971) and Savin (1973). Important
contributions have also been made in the areas of estimation of simultaneous nonlinear equations
(Amemiya, 1983), the seemingly unrelated regression equations (SURE) approach proposed by Zellner
(1962), and the simultaneous rational expectations models (see Section 7.1 below).

Interest in estimation of simultaneous equation models coincided with the rise of Keynesian economics
in early 1960s, and started to wane with the advent of the rational expectations revolution and its
emphasis on the GMM estimation of the structural parameters from the Euler equations (first-order
optimization conditions). See Section 7 below. But, with the rise of the dynamic stochastic general equilibrium models in macroeconometrics, a revival of interest in identification and estimation of nonlinear simultaneous equation models seems quite likely. The recent contribution of Fernandez-Villaverde and Rubio-Ramirez (2005) represents a start in this direction.

4.3 Developments in time series econometrics

While the initiative taken at the Cowles Commission led to a rapid expansion of econometric techniques, the application of these techniques to economic problems was rather slow. This was partly due to a lack of adequate computing facilities at the time. A more fundamental reason was the emphasis of the research at the Cowles Commission on the simultaneity problem almost to the exclusion of other econometric problems. Since the early applications of the correlation analysis to economic data by Yule and Hooker, the serial dependence of economic time series and the problem of nonsense or spurious correlation that it could give rise to had been the single most important factor explaining the profession's scepticism concerning the value of regression analysis in economics. A satisfactory solution to the spurious correlation problem was therefore needed before regression analysis of economic time series could be taken seriously. Research on this topic began in the mid-1940s at the Department of Applied Economics (DAE) in Cambridge, England, as a part of a major investigation into the measurement and analysis of consumers’ expenditure in the United Kingdom (see Stone et al., 1954). Although the first steps towards the resolution of the spurious correlation problem had been taken by Aitken (1934–5) and Champernowne (1948), the research in the DAE introduced the problem and its possible solution to the attention of applied economists. Orcutt (1948) studied the autocorrelation pattern of economic time series and showed that most economic time series can be represented by simple autoregressive processes with similar autoregressive coefficients. Subsequently, Cochrane and Orcutt (1949) made the important point that the major consideration in the analysis of stationary time series was the autocorrelation of the error term in the regression equation and not the autocorrelation of the economic time series themselves. In this way they shifted the focus of attention to the autocorrelation of disturbances as the main source of concern. Although, as it turns out, this is a valid conclusion in the case of regression equations with strictly exogenous regressors, in more realistic set-ups where the regressors are weakly exogenous the serial correlation of the regressors is also likely to be of concern in practice. See, for example, Stambaugh (1999).

Another important and related development was the work of Durbin and Watson (1950; 1951) on the method of testing for residual autocorrelation in the classical regression model. The inferential breakthrough for testing serial correlation in the case of observed time-series data had already been achieved by von Neumann (1941; 1942), and by Hart and von Neumann (1942). The contribution of Durbin and Watson was, however, important from a practical viewpoint as it led to a bounds test for residual autocorrelation which could be applied irrespective of the actual values of the regressors. The independence of the critical bounds of the Durbin–Watson statistic from the matrix of the regressors allowed the application of the statistic as a general diagnostic test, the first of its type in econometrics. The contributions of Cochrane and Orcutt and of Durbin and Watson marked the beginning of a new era in the analysis of economic time-series data and laid down the basis of what is now known as the ‘time-series econometrics’ approach.
5 Consolidation and applications

The work at the Cowles Commission on identification and estimation of the simultaneous equation model and the development of time series techniques paved the way for widespread application of econometric methods to economic and financial problems. This was helped significantly by the rapid expansion of computing facilities, advances in financial and macroeconomic modelling, and the increased availability of economic data-sets, cross section as well as time series.

5.1 Macroeconometric modelling

Inspired by the pioneering work of Tinbergen, Klein (1947; 1950) was the first to construct a macroeconometric model in the tradition of the Cowles Commission. Soon others followed Klein's lead. Over a short space of time macroeconometric models were built for almost every industrialized country, and even for some developing and centrally planned economies. Macroeconometric models became an important tool of ex ante forecasting and economic policy analysis, and started to grow in both size and sophistication. The relatively stable economic environment of the 1950s and 1960s was an important factor in the initial success enjoyed by macroeconometric models. The construction and use of large-scale models presented a number of important computational problems, the solution of which was of fundamental significance, not only for the development of macroeconometric modelling but also for econometric practice in general. In this respect advances in computer technology were clearly instrumental, and without them it is difficult to imagine how the complicated computational problems involved in the estimation and simulation of large-scale models could have been solved. The increasing availability of better and faster computers was also instrumental as far as the types of problems studied and the types of solutions offered in the literature were concerned. For example, recent developments in the area of microeconometrics (see Section 10 below) could hardly have been possible if it were not for the very important recent advances in computing facilities.

5.2 Dynamic specification

Other areas where econometrics witnessed significant developments included dynamic specification, latent variables, expectations formation, limited dependent variables, discrete choice models, random coefficient models, disequilibrium models, nonlinear estimation, and the analysis of panel data models. Important advances were also made in the area of Bayesian econometrics, largely thanks to the publication of Zellner's textbook (1971), which built on his earlier work including important papers with George Tiao. The Seminar on Bayesian Inference in Econometrics and Statistics (SBIES) was founded shortly after the publication of the book, and was key in the development and diffusion of Bayesian ideas in econometrics. It was, however, the problem of dynamic specification that initially received the greatest attention. In an important paper, T. Brown (1952) modelled the hypothesis of habit persistence in consumer behaviour by introducing lagged values of consumption expenditures into an otherwise static Keynesian consumption function. This was a significant step towards the incorporation of dynamics in applied econometric research, and allowed the important distinction to be made between the
short-run and the long-run impacts of changes in income on consumption. Soon other researchers followed Brown's lead and employed his autoregressive specification in their empirical work.

The next notable development in the area of dynamic specification was the distributed lag model. Although the idea of distributed lags had been familiar to economists through the pioneering work of Irving Fisher (1930) on the relationship between the nominal interest rate and the expected inflation rate, its application in econometrics was not seriously considered until the mid-1950s. The geometric distributed lag model was used for the first time by Koyck (1954) in a study of investment. Koyck arrived at the geometric distributed lag model via the adaptive expectations hypothesis. This same hypothesis was employed later by Cagan (1956) in a study of demand for money in conditions of hyperinflation, by Friedman (1957) in a study of consumption behaviour and by Nerlove (1958a) in a study of the cobweb phenomenon. The geometric distributed lag model was subsequently generalized by Solow (1960), Jorgenson (1966) and others, and was extensively applied in empirical studies of investment and consumption behaviour. At about the same time Almon (1965) provided a polynomial generalization of I. Fisher's (1937) arithmetic lag distribution which was later extended further by Shiller (1973). Other forms of dynamic specification considered in the literature included the partial adjustment model (Nerlove, 1958b; Eisner and Strotz, 1963) and the multivariate flexible accelerator model (Treadway, 1971) and Sargan's (1964) work on econometric time series analysis which formed the basis of error correction and cointegration analysis that followed next. Following the contributions of Champernowne (1960), Granger and Newbold (1974) and Phillips (1986) the spurious regression problem was better understood, and paved the way for the development of the theory of cointegration. For further details see Section 8.3 below.

5.3 Techniques for short-term forecasting

Concurrent with the development of dynamic modelling in econometrics there was also a resurgence of interest in time-series methods, used primarily in short-term business forecasting. The dominant work in this field was that of Box and Jenkins (1970), who, building on the pioneering works of Yule (1921; 1926), Slutsky (1927), Wold (1938), Whittle (1963) and others, proposed computationally manageable and asymptotically efficient methods for the estimation and forecasting of univariate autoregressive-moving average (ARMA) processes. Time-series models provided an important and relatively simple benchmark for the evaluation of the forecasting accuracy of econometric models, and further highlighted the significance of dynamic specification in the construction of time-series econometric models. Initially univariate time-series models were viewed as mechanical 'black box' models with little or no basis in economic theory. Their use was seen primarily to be in short-term forecasting. The potential value of modern time-series methods in econometric research was, however, underlined in the work of Cooper (1972) and Nelson (1972) who demonstrated the good forecasting performance of univariate Box–Jenkins models relative to that of large econometric models. These results raised an important question about the adequacy of large econometric models for forecasting as well as for policy analysis. It was argued that a properly specified structural econometric model should, at least in theory, yield more accurate forecasts than a univariate time-series model. Theoretical justification for this view was provided by Zellner and Palm (1974), followed by Trivedi (1975), Prothero and Wallis (1976), Wallis
6 A new phase in the development of econometrics

With the significant changes taking place in the world economic environment in the 1970s, arising largely from the breakdown of the Bretton Woods system and the quadrupling of oil prices, econometrics entered a new phase of its development. Mainstream macroeconometric models built during the 1950s and 1960s, in an era of relative economic stability with stable energy prices and fixed exchange rates, were no longer capable of adequately capturing the economic realities of the 1970s. As a result, not surprisingly, macroeconometric models and the Keynesian theory that underlay them came under severe attack from theoretical as well as from practical viewpoints. While criticisms of Tinbergen's pioneering attempt at macroeconometric modelling were received with great optimism and led to the development of new and sophisticated estimation techniques and larger and more complicated models, the disenchantment with macroeconometric models in 1970s prompted a much more fundamental reappraisal of quantitative modelling as a tool of forecasting and policy analysis.

At a theoretical level it was argued that econometric relations invariably lack the necessary ‘microfoundations’, in the sense that they cannot be consistently derived from the optimizing behaviour of economic agents. At a practical level the Cowles Commission approach to the identification and estimation of simultaneous macroeconometric models was questioned by Lucas and Sargent and by Sims, although from different viewpoints (Lucas, 1976; Lucas and Sargent, 1981; Sims, 1980). There was also a move away from macroeconometric models and towards microeconometric research with greater emphasis on matching of econometrics with individual decisions.

It also became increasingly clear that Tinbergen's paradigm where economic relations were taken as given and provided by ‘economic theorist’ was not adequate. It was rarely the case that economic theory could be relied on for a full specification of the econometric model (Leamer, 1978). The emphasis gradually shifted from estimation and inference based on a given tightly parameterized specification to diagnostic testing, specification searches, model uncertainty, model validation, parameter variations, structural breaks, and semiparametric and nonparametric estimation. The choice of approach often governed by the purpose of the investigation, the nature of the economic application, data availability, computing and software technology.

What follows is a brief overview of some of the important developments. Given space limitations there are inevitably significant gaps. These include the important contributions of Granger (1969), Sims (1972) and Engle, Hendry and Richard (1983) on different concepts of ‘causality’ and ‘exogeneity’, the literature on disequilibrium models (Quandt, 1982; Maddala, 1983; 1986), random coefficient models (Swamy, 1970; Hsiao and Pesaran, 2008, unobserved time series models (Harvey, 1989), count...
regression models (Cameron and Trivedi, 1986; 1998), the weak instrument problem (Stock, Wright and Yogo, 2002), small sample theory (Phillips, 1983; Rothenberg, 1984), econometric models of auction pricing (Hendricks and Porter, 1988; Laffont, Ossard and Vuong, 1995).

7 Rational expectations and the Lucas critique

Although the rational expectations hypothesis (REH) was advanced by Muth in 1961, it was not until the early 1970s that it started to have a significant impact on time-series econometrics and on dynamic economic theory in general. What brought the REH into prominence was the work of Lucas (1972; 1973), Sargent (1973), Sargent and Wallace (1975) and others on the new classical explanation of the apparent breakdown of the Phillips curve. The message of the REH for econometrics was clear. By postulating that economic agents form their expectations endogenously on the basis of the true model of the economy, and a correct understanding of the processes generating exogenous variables of the model, including government policy, the REH raised serious doubts about the invariance of the structural parameters of the mainstream macroeconometric models in the face of changes in government policy. This was highlighted in Lucas's critique of macroeconometric policy evaluation. By means of simple examples Lucas (1976) showed that in models with rational expectations the parameters of the decision rules of economic agents, such as consumption or investment functions, are usually a mixture of the parameters of the agents’ objective functions and of the stochastic processes they face as historically given. Therefore, Lucas argued, there is no reason to believe that the ‘structure’ of the decision rules (or economic relations) would remain invariant under a policy intervention. The implication of the Lucas critique for econometric research was not, however, that policy evaluation could not be done, but rather than the traditional econometric models and methods were not suitable for this purpose. What was required was a separation of the parameters of the policy rule from those of the economic model. Only when these parameters could be identified separately given the knowledge of the joint probability distribution of the variables (both policy and non-policy variables) would it be possible to carry out an econometric analysis of alternative policy options.

There have been a number of reactions to the advent of the rational expectations hypothesis and the Lucas critique that accompanied it.

7.1 Model consistent expectations

The least controversial reaction has been the adoption of the REH as one of several possible expectations formation hypotheses in an otherwise conventional macroeconometric model containing expectational variables. In this context the REH, by imposing the appropriate cross-equation parametric restrictions, ensures that ‘expectations’ and ‘forecasts’ generated by the model are consistent. In this approach the REH is regarded as a convenient and effective method of imposing cross-equation parametric restrictions on time series econometric models, and is best viewed as the ‘model-consistent’ expectations hypothesis. There is now a sizeable literature on solution, identification, and estimation of linear RE models. The canonical form of RE models with forward and backward components is given by
where $y_t$ is a vector of endogenous variables, $E(\cdot | F_t)$ is the expectations operator, $F_t$ the publicly available information at time $t$, and $w_t$ is a vector of forcing variables. For example, log-linearized version of dynamic general equilibrium models (to be discussed) can all be written as a special case of this equation with plenty of restrictions on the coefficient matrices $A$ and $B$. In the typical case where $w_t$ are serially uncorrelated and the solution of the RE model can be assumed to be unique, the RE solution reduces to the vector autoregression (VAR)

$$y_t = \Phi y_{t-1} + Gw_t$$

where $\Phi$ and $G$ are given in terms of the structural parameters:

$$B\Phi^2 - \Phi + A = 0, \quad \text{and} \quad G = (I - B\Phi)^{-1}.$$

The solution of the RE model can, therefore, be viewed as a restricted form of VAR popularized in econometrics by Sims (1980) as a response in macroeconometric modelling to the rational expectations revolution. The nature of restrictions is determined by the particular dependence of $A$ and $B$ on a few ‘deep’ or structural parameters. For general discussion of solution of RE models see, for example, Broze, Gouriéroux and Szafarz (1985) and Binder and Pesaran (1995). For studies of identification and estimation of linear RE models see, for example, Hansen and Sargent (1980), Wallis (1980), Wickens (1982) and Pesaran (1981; 1987b). These studies show how the standard econometric methods can in principle be adapted to the econometric analysis of rational expectations models.

### 7.2 Detection and modelling of structural breaks

Another reaction to the Lucas critique has been to treat the problem of ‘structural change’ emphasized by Lucas as one more potential econometric ‘problem’. Clements and Hendry (1998; 1999) provide a taxonomy of factors behind structural breaks and forecast failures. Stock and Watson (1996) provide extensive evidence of structural break in macroeconomic time series. It is argued that structural change can result from many factors and need not be associated solely with intended or expected changes in policy. The econometric lesson has been to pay attention to possible breaks in economic relations. There now exists a large body of work on testing for structural change, detection of breaks (single as well as multiple), and modelling of break processes by means of piece-wise linear or non-linear dynamic models.
VAR macroeconometrics

8.1 Unrestricted VARs

The Lucas critique of mainstream macroeconometric modelling also led some econometricians, notably Sims (1980; 1982), to doubt the validity of the Cowles Commission style of achieving identification in econometric models. Sims focused his critique on macroeconometric models with a vector autoregressive (VAR) specification, which was relatively simple to estimate; and its use soon became prevalent in macroeconometric analysis. The view that economic theory cannot be relied on to yield identification of structural models was not new and had been emphasized in the past, for example, by Liu (1960). Sims took this viewpoint a step further and argued that in presence of rational expectations a priori knowledge of lag lengths is indispensable for identification, even when we have distinct strictly exogenous variables shifting supply and demand schedules (Sims, 1980, p. 7). While it is true that the REH complicates the necessary conditions for the identification of structural models, the basic issue in the debate over identification still centres on the validity of the classical dichotomy between exogenous and endogenous variables (Pesaran, 1981). In the context of closed-economy macroeconometric models where all variables are treated as endogenous, other forms of identification of the structure will be required. Initially, Sims suggested a recursive identification approach where the matrix of contemporaneous effects was assumed to be lower (upper) triangular and the structural shocks orthogonal. Other non-recursive identification schemes soon followed.

8.2 Structural VARs

One prominent example was the identification scheme developed in Blanchard and Quah (1989), who distinguished between permanent and transitory shocks and attempted to identify the structural models through long-run restrictions. For example, Blanchard and Quah argued that the effect of a demand shock on real output should be temporary (that is, it should have a zero long-run impact), while a supply shock should have a permanent effect. This approach is known as ‘structural VAR’ (SVAR) and has been used extensively in the literature. It continues to assume that structural shocks are orthogonal, but uses a mixture of short-run and long-run restrictions to identify the structural model. In their work Blanchard and Quah considered a bivariate VAR model in real output and unemployment. They assumed real output to be integrated of order 1, or $I(1)$, and viewed unemployment as an $I(0)$, or a stationary variable. This allowed them to associate the shock to one of the equations as permanent, and the shock to the other equation as transitory. In more general settings, such as the one analysed by Gali (1992) and Wickens and Motto (2001), where there are $m$ endogenous variables and $r$ long-run or...
cointegrating relations, the SVAR approach provides \( m(m - r) \) restrictions which are not sufficient to fully identify the model, unless \( m = 2 \) and \( r = 1 \) which is the simple bivariate model considered by Blanchard and Quah (Pagan and Pesaran, 2007). In most applications additional short-term restrictions are required. More recently, attempts have also been made to identify structural shocks by means of qualitative restrictions, such as sign restrictions. Notable examples include Canova and de Nicolo (2002), Uhlig (2005) and Peersman (2005).

The focus of the SVAR literature has been on impulse response analysis and forecast error variance decomposition, with the aim of estimating the time profile of the effects of monetary policy, oil price or technology shocks on output and inflation, and deriving the relative importance of these shocks as possible explanations of forecast error variances at different horizons. Typically such analysis is carried out with respect to a single model specification, and at most only parameter uncertainty is taken into account (Kilian, 1998). More recently the problem of model uncertainty and its implications for impulse response analysis and forecasting have been recognized. Bayesian and classical approaches to model and parameter uncertainty have been considered. Initially, Bayesian VAR models were developed for use in forecasting as an effective shrinkage procedure in the case of high-dimensional VAR models (Doan, Litterman and Sims, 1984; Litterman, 1985). The problem of model uncertainty in cointegrating VARs has been addressed in Garratt et al. (2003b; 2006), and Strachan and van Dijk (2006).

8.3 Structural cointegrating VARs

This approach provides the SVAR with the decomposition of shocks into permanent and transitory and gives economic content to the long-run or cointegrating relations that underlie the transitory components. In the simple example of Blanchard and Quah this task is trivially achieved by assuming real output to be I(1) and the unemployment rate to be an I(0) variable. To have shocks with permanent effects some of the variables in the VAR must be non-stationary. This provides a natural link between the SVAR and the unit root and cointegration literature. Identification of the cointegrating relations can be achieved by recourse to economic theory, solvency or arbitrage conditions (Garratt et al., 2003a). Also there are often long-run over-identifying restrictions that can be tested. Once identified and empirically validated, the long-run relations can be embodied within a VAR structure, and the resultant structural vector error correction model identified using theory-based short-run restrictions. The structural shocks can be decomposed into permanent and temporary components using either the multivariate version of the Beveridge and Nelson (1981) decompositions, or the one more recently proposed by Garratt, Robertson and Wright (2006).

Two or more variables are said to be cointegrated if they are individually integrated (or have a random walk component), but there exists a linear combination of them which is stationary. The concept of cointegration was first introduced by Granger (1986) and more formally developed in Engle and Granger (1987). Rigorous statistical treatments followed in the papers by Johansen (1988; 1991) and Phillips (1991). Many further developments and extensions have taken place with reviews provided in Johansen (1995), Juselius (2006) and Garratt et al. (2006). The related unit root literature is reviewed by Stock (1994) and Phillips and Xiao (1998).
For policy analysis macroeconometric models need to be based on decisions by individual households, firms and governments. This is a daunting undertaking and can be achieved only by gross simplification of the complex economic interconnections that exists across millions of decision-makers worldwide. The dynamic stochastic general equilibrium (DSGE) modelling approach attempts to implement this task by focusing on optimal decisions of a few representative agents operating with rational expectations under complete learning. Initially, DSGE models were small and assumed complete markets with instantaneous price adjustments, and as a result did not fit the macroeconomic time series (Kim and Pagan, 1995). More recently, Smets and Wouters (2003) have shown that DSGE models with sticky prices and wages along the lines developed by Christiano, Eichenbaum and Evans (2005) are sufficiently rich to match most of the statistical features of the main macroeconomic time series. Moreover, by applying Bayesian estimation techniques, these authors have shown that even relatively large models can be estimated as a system. Bayesian DSGE models have also shown to perform reasonably well in forecasting as compared with standard and Bayesian vector autoregressions. It is also possible to incorporate long-run cointegrating relations within Bayesian DSGE models. The problems of parameter and model uncertainty can also be readily accommodated using data-coherent DSGE models. Other extensions of the DSGE models to allow for learning, regime switches, time variations in shock variances, asset prices, and multi-country interactions are likely to enhance their policy relevance (Del Negro and Schorfheide, 2004; Del Negro et al., 2005; An and Schorfheide, 2007; Pesaran and Smith, 2006). Further progress will also be welcome in the area of macroeconomic policy analysis under model uncertainty, and robust policymaking (Brock and Durlauf, 2006; Hansen and Sargent, 2007).

Model and forecast evaluation

While in the 1950s and 1960s research in econometrics was primarily concerned with the identification and estimation of econometric models, the dissatisfaction with econometrics during the 1970s caused a shift of focus from problems of estimation to those of model evaluation and testing. This shift has been part of a concerted effort to restore confidence in econometrics, and has received attention from Bayesian as well as classical viewpoints. Both these views reject the ‘axiom of correct specification’ which lies at the basis of most traditional econometric practices, but they differ markedly as how best to proceed. It is generally agreed, by Bayesians as well as by non-Bayesians, that model evaluation involves considerations other than the examination of the statistical properties of the models, and personal judgements inevitably enter the evaluation process. Models must meet multiple criteria which are often in conflict. They should be relevant in the sense that they ought to be capable of answering the questions for which they are constructed. They should be consistent with the accounting and/or theoretical structure within which they operate. Finally, they should provide adequate representations of the aspects of reality with which they are concerned. These criteria and their interaction are discussed in Pesaran and Smith (1985b). More detailed breakdowns of the criteria of model evaluation can be found in Hendry and Richard (1982) and McAleer, Pagan, and Volker (1985). In econometrics it is, however, the criterion of ‘adequacy’ which is emphasized, often at the expense of relevance and consistency.
The issue of model adequacy in mainstream econometrics is approached either as a model selection problem or as a problem in statistical inference whereby the hypothesis of interest is tested against general or specific alternatives. The use of absolute criteria such as measures of fit/parsimony or formal Bayesian analysis based on posterior odds are notable examples of model selection procedures, while likelihood ratio, Wald and Lagrange multiplier tests of nested hypotheses and Cox's centred log-likelihood ratio tests of non-nested hypotheses are examples of the latter approach. The distinction between these two general approaches basically stems from the way alternative models are treated. In the case of model selection (or model discrimination) all the models under consideration enjoy the same status and the investigator is not committed a priori to any one of the alternatives. The aim is to choose the model which is likely to perform best with respect to a particular loss function. By contrast, in the hypothesis-testing framework the null hypothesis (or the maintained model) is treated differently from the remaining hypotheses (or models). One important feature of the model-selection strategy is that its application always leads to one model being chosen in preference to other models. But, in the case of hypothesis testing, rejection of all the models under consideration is not ruled out when the models are non-nested. A more detailed discussion of this point is given in Pesaran and Deaton (1978).

Broadly speaking, classical approaches to the problem of model adequacy can be classified depending on how specific the alternative hypotheses are. These are the general specification tests, the diagnostic tests, and the non-nested tests. The first of these, pioneered by Durbin (1954) and introduced in econometrics by Ramsey (1969), Wu (1973), Hausman (1978), and subsequently developed further by White (1981; 1982) and Hansen (1982), are designed for circumstances where the nature of the alternative hypothesis is kept (sometimes intentionally) rather vague, the purpose being to test the null against a broad class of alternatives. (The pioneering contribution of Durbin, 1954, in this area has been documented by Nakamura and Nakamura, 1981.) Important examples of general specification tests are Ramsey's regression specification error test (RESET) for omitted variables and/or misspecified functional forms, and the Durbin–Hausman–Wu test of misspecification in the context of measurement error models and/or simultaneous equation models. Such general specification tests are particularly useful in the preliminary stages of the modelling exercise.

In the case of diagnostic tests, the model under consideration (viewed as the null hypothesis) is tested against more specific alternatives by embedding it within a general model. Diagnostic tests can then be constructed using the likelihood ratio, Wald or Lagrange multiplier (LM) principles to test for parametric restrictions imposed on the general model. The application of the LM principle to econometric problems is reviewed in the papers by Breusch and Pagan (1980), Godfrey and Wickens (1982), and Engle (1984). An excellent review is provided in Godfrey (1988). Examples of the restrictions that may be of interest as diagnostic checks of model adequacy include zero restrictions, parameter stability, serial correlation, heteroskedasticity, functional forms, and normality of errors. The distinction made here between diagnostic tests and general specification tests is more apparent than real. In practice some diagnostic tests such as tests for serial correlation can also be viewed as a general test of specification. Nevertheless, the distinction helps to focus attention on the purpose behind the tests and the direction along which high power is sought.

The need for non-nested tests arises when the models under consideration belong to separate parametric families in the sense that no single model can be obtained from the others by means of a suitable limiting process. This situation, which is particularly prevalent in econometric research, may arise when models
differ with respect to their theoretical underpinnings and/or their auxiliary assumptions. Unlike the
general specification tests and diagnostic tests, the application of non-nested tests is appropriate when
specific but rival hypotheses for the explanation of the same economic phenomenon have been
advanced. Although non-nested tests can also be used as general specification tests, they are designed
primarily to have high power against specific models that are seriously entertained in the literature.
Building on the pioneering work of Cox (1961; 1962), a number of such tests for single equation models
and systems of simultaneous equations have been proposed (Pesaran and Weeks, 2001).
The use of statistical tests in econometrics, however, is not a straightforward matter and in most
applications does not admit of a clear-cut interpretation. This is especially so in circumstances where test
statistics are used not only for checking the adequacy of a given model but also as guides to model
construction. Such a process of model construction involves specification searches of the type
emphasized by Leamer (1978) and presents insurmountable pre-test problems which in general tend to
produce econometric models whose ‘adequacy’ is more apparent than real. As a result, in evaluating
econometric models less reliance should be placed on those indices of model adequacy that are used as
guides to model construction, and more emphasis should be given to the performance of models over
other data-sets and against rival models.
A closer link between model evaluation and the underlying decision problem is also needed. Granger
and Pesaran (2000a; 2000b) discuss this problem in the context of forecast evaluation. A recent survey
of forecast evaluation literature can be found in West (2006). Pesaran and Skouras (2002) provide a
review from a decision-theoretic perspective.
The subjective Bayesian approach to the treatment of several models begins by assigning a prior
probability to each model, with the prior probabilities summing to 1. Since each model is already
endowed with a prior probability distribution for its parameters and for the probability distribution of
observable data conditional on its parameters, there is then a complete probability distribution over the
space of models, parameters, and observable data. (No particular problems arise from non-nesting of
models in this framework.) This probability space can then be augmented with the distribution of an
object or vector of objects of interest. For example, in a macroeconomic policy setting the models could
include VARs, DSGEs and traditional large-scale macroeconomic models, and the vector of interest
might include future output growth, interest rates, inflation and unemployment, whose distribution is
implied by each of the models considered. Implicit in this formulation is the conditional distribution of
the vector of interest conditional on the observed data. Technically, this requires the integration (or
marginalization) of parameters in each model as well as the models themselves. As a practical matter
this usually proceeds by first computing the probability of each model conditional on the data, and then
using these probabilities as weights in averaging the posterior distribution of the vector of interest in
each model. It is not necessary to choose one particular model, and indeed to do so would be suboptimal.
The ability to actually carry out this simultaneous consideration of multiple models has been enhanced
greatly by recent developments in simulation methods, surveyed in Section 16 below; recent texts by
(2006) specifically outline these methods in the context of economic forecasting.

10 Microeconometrics: an overview
Partly as a response to the dissatisfaction with macroeconometric time-series research and partly in view of the increasing availability of micro data and computing facilities, since the mid-1980s significant advances have been made in the analysis of micro data. Important micro data-sets have become available on households and firms especially in the United States in such areas as housing, transportation, labour markets and energy. These data sets include various longitudinal surveys (for example, University of Michigan Panel Study of Income Dynamics, and Ohio State National Longitudinal Study Surveys), cross-sectional surveys of family expenditures, population and labour force surveys. This increasing availability of micro-data, while opening up new possibilities for analysis, has also raised a number of new and interesting econometric issues primarily originating from the nature of the data. The errors of measurement are likely to be important in the case of some micro data-sets. The problem of the heterogeneity of economic agents at the micro level cannot be assumed away as readily as is usually done in the case of macro data by appealing to the idea of a ‘representative’ firm or a ‘representative’ household.

The nature of micro data, often being qualitative or limited to a particular range of variations, has also called for new econometric models and techniques. Examples include categorical survey responses (‘up’, ‘same’ or ‘down’), and censored or truncated observations. The models and issues considered in the microeconometric literature are wide ranging and include fixed and random effect panel data models (for example, Mundlak, 1961; 1978), logit and probit models and their multinominal extensions, discrete choice or quantal response models (Manski and McFadden, 1981), continuous time duration models (Heckman and Singer, 1984), and microeconometric models of count data (Hausman, Hall and Griliches, 1984; Cameron and Trivedi, 1986).

The fixed or random effect models provide the basic statistical framework and will be discussed in more detailed below. Discrete choice models are based on an explicit characterization of the choice process and arise when individual decision makers are faced with a finite number of alternatives to choose from. Examples of discrete choice models include transportation mode choice (Domenich and McFadden, 1975), labour force participation (Heckman and Willis, 1977), occupation choice (Boskin, 1974), job or firm location (Duncan 1980), and models with neighbourhood effects (Brock and Durlauf, 2002).

Limited dependent variables models are commonly encountered in the analysis of survey data and are usually categorized into truncated regression models and censored regression models. If all observations on the dependent as well as on the exogenous variables are lost when the dependent variable falls outside a specified range, the model is called truncated, and, if only observations on the dependent variable are lost, it is called censored. The literature on censored and truncated regression models is vast and overlaps with developments in other disciplines, particularly in biometrics and engineering.

Maddala (1983, ch. 6) provides a survey.

The censored regression model was first introduced into economics by Tobin (1958) in his pioneering study of household expenditure on durable goods, where he explicitly allowed for the fact that the dependent variable, namely, the expenditure on durables, cannot be negative. The model suggested by Tobin and its various generalizations are known in economics as Tobit models and are surveyed in detail by Amemiya (1984), and more recently in Cameron and Trivedi (2005, ch. 14). Continuous time duration models, also known as survival models, have been used in analysis of unemployment duration, the period of time spent between jobs, durability of marriage, and so on. Application of survival models to analyse economic data raises a number of important issues resulting primarily from the non-controlled
experimental nature of economic observations, limited sample sizes (that is, time periods), and the heterogeneous nature of the economic environment within which agents operate. These issues are clearly not confined to duration models and are also present in the case of other microeconometric investigations that are based on time series or cross-section or panel data.

Partly in response to the uncertainties inherent in econometric results based on non-experimental data, there has also been a significant move towards social experimentation, and experimental economics in general. A social experiment aims at isolating the effects of a policy change (or a treatment effect) by comparing the consequences of an exogenous variation in the economic environment of a set of experimental subjects known as the ‘treatment’ group with those of a ‘control’ group that have not been subject to the change. The basic idea goes back to the early work of R.A. Fisher (1928) on randomized trials, and has been applied extensively in agricultural and biomedical research. The case for social experimentation in economics is discussed in Burtless (1995). Hausman and Wise (1985) and Heckman and Smith (1995) consider a number of actual social experiments carried out in the United States, and discuss their scope and limitations.

Experimental economics tries to avoid some of the limitations of working with observations obtained from natural or social experiments by using data from laboratory experiments to test economic theories by fixing some of the factors and identifying the effects of other factors in a way that allows ceteris paribus comparisons. A wide range of topics and issues are covered in this literature, such as individual choice behaviour, bargaining, provision of public goods, theories of learning, auction markets, and behavioural finance. A comprehensive review of major areas of experimental research in economics is provided in Kagel and Roth (1995).

These developments have posed new problems and challenges in the areas of experimental design, statistical methods and policy analysis. Another important aspect of recent developments in microeconometric literature relates to the use of microanalytic simulation models for policy analysis and evaluation to reform packages in areas such as health care, taxation, social security systems, and transportation networks. Cameron and Trivedi (2005) review the recent developments in methods and application of microeconometrics. Some of these topics will be discussed in more detail below.

11 Econometrics of panel data

Panel data models are used in many areas of econometrics, although initially they were developed primarily for the analysis of micro behaviour, and focused on panels formed from cross-section of \( N \) individual households or firms surveyed for \( T \) successive time periods. These types of panels are often referred to as ‘micropans’. In social and behavioural sciences they are also known as longitudinal data or panels. The literature on micro-panels typically takes \( N \) to be quite large (in hundreds) and \( T \) rather small, often less than ten. But more recently, with the increasing availability of financial and macroeconomic data, analyses of panels where both \( N \) and \( T \) are relatively large have also been considered. Examples of such data-sets include time series of company data from Datastream, country data from International Financial Statistics or the Penn World Table, and county and state data from national statistical offices. There are also pseudo panels of firms and consumers composed of repeated cross sections that cover cross-section units that are not necessarily identical but are observed over relatively long time periods. Since the available cross-section observations do not (necessarily) relate to
the same individual unit, some form of grouping of the cross-section units is needed. Once the grouping criteria are set, the estimation can proceed using fixed effects estimation applied to group averages if the number of observations per group is sufficiently large; otherwise possible measurement errors of the group averages also need to be taken into account. Deaton (1985) pioneered the econometric analysis of pseudo panels. Verbeek (2008) provides a recent review.

Use of panels can enhance the power of empirical analysis and allows estimation of parameters that might not have been identified using the time or the cross-section dimensions alone. These benefits come at a cost. In the case of linear panel data models with a short time span the increased power is usually achieved under assumptions of parameter homogeneity and error cross-section independence. Short panels with autocorrelated disturbances also pose a new identification problem, namely, how to distinguished between dynamics and state dependence (Arellano, 2003, ch. 5). In panels with fixed effects the homogeneity assumption is relaxed somewhat by allowing the intercepts in the panel regressions to vary freely over the cross-section units, but continues to maintain the error cross-section independence assumption. The random coefficient specification of Swamy (1970) further relaxes the slope homogeneity assumption, and represents an important generalization of the random effects model (Hsiao and Pesaran, 2007). In micro-panels where \( T \) is small cross-section dependence can be dealt with if it can be attributed to spatial (economic or geographic) effects. Anselin (1988) and Anselin, Le Gallo and Jayet (2007) provide surveys of the literature on spatial econometrics. A number of studies have also used measures such as trade or capital flows to capture economic distance, as in Conley and Topa (2002), Conley and Dupor (2003), and Pesaran, Schuermann and Weiner (2004).

Allowing for dynamics in panels with fixed effects also presents additional difficulties; for example, the standard within-group estimator will be inconsistent unless \( T \to \infty \) (Nickell, 1981). In linear dynamic panels the incidental parameter problem (the unobserved heterogeneity) can be resolved by first differencing the model and then estimating the resultant first-differenced specification by instrumental variables or by the method of transformed likelihood (Anderson and Hsiao, 1981; 1982; Holtz-Eakin, Newey and Rosen, 1988; Arellano and Bond, 1991; Hsiao, Pesaran and Tahmiscioglu, 2002). A similar procedure can also be followed in the case of short \( T \) panel VARs (Binder, Hsiao and Pesaran, 2005).

But other approaches are needed for nonlinear panel data models. See, for example, Honoré and Kyriazidou (2000) and review of the literature on nonlinear panels in Arellano and Honoré (2001). Relaxing the assumption of slope homogeneity in dynamic panels is also problematic, and neglecting to take account of slope heterogeneity will lead to inconsistent estimators. In the presence of slope heterogeneity Pesaran and Smith (1995) show that the within-group estimator remains inconsistent even if both \( N \) and \( T \to \infty \). A Bayesian approach to estimation of micro dynamic panels with random slope coefficients is proposed in Hsiao, Pesaran and Tahmiscioglu (1999).

To deal with general dynamic specifications, possible slope heterogeneity and error cross-section dependence, large \( T \) and \( N \) panels are required. In the case of such large panels it is possible to allow for richer dynamics and parameter heterogeneity. Cross-section dependence of errors can also be dealt with using residual common factor structures. These extensions are particularly relevant to the analysis of purchasing power parity hypothesis (O’Connell, 1998; Imbs et al., 2005; Pedroni, 2001; Smith et al., 2004), output convergence (Durlauf, Johnson and Temple, 2005; Pesaran, 2007b), the Fisher effect (Westerlund, 2005), house price convergence (Holly, Pesaran and Yamagata, 2006), regional migration...
econometrics: The New Palgrave Dictionary of Economics (Fachin, 2006), and uncovered interest parity (Moon and Perron, 2007). The econometric methods developed for large panels has to take into account the relationship between the increasing number of time periods and cross-section units (Phillips and Moon, 1999). The relative expansion rates of \( N \) and \( T \) could have important consequences for the asymptotic and small sample properties of the panel estimators and tests. This is because fixed \( T \) estimation bias tend to magnify with increases in the cross-section dimension, and it is important that any bias in the \( T \) dimension is corrected in such a way that its overall impact disappears as both \( N \) and \( T \to \infty \), jointly.

The first generation panel unit root tests proposed, for example, by Levin, Lin and Chu (2002) and Im, Pesaran and Shin (2003) allowed for parameter heterogeneity but assumed errors were cross-sectionally independent. More recently, panel unit root tests that allow for error cross-section dependence have been proposed by Bai and Ng (2004), Moon and Perron (2004) and Pesaran (2007a). As compared with panel unit root tests, the analysis of cointegration in panels is still at an early stage of its development. So far the focus of the panel cointegration literature has been on residual-based approaches, although there has been a number of attempts at the development of system approaches as well (Pedroni, 2004). But once cointegration is established the long-run parameters can be estimated efficiently using techniques similar to the ones proposed in the case of single time-series models. These estimation techniques can also be modified to allow for error cross-section dependence (Pesaran, 2007a). Surveys of the panel unit root and cointegration literature are provided by Banerjee (1999), Baltagi and Kao (2000), Choi (2006) and Breitung and Pesaran (2008).

The micro and macro panel literature is vast and growing. For the analysis of many economic problems, further progress is needed in the analysis of nonlinear panels, testing and modelling of error cross-section dependence, dynamics, and neglected heterogeneity. For general reviews of panel data econometrics, see Arellano (2003), Baltagi (2005), Hsiao (2003) and Wooldridge (2002).

### 12 Nonparametric and semiparametric estimation

Much empirical research is concerned with estimating conditional mean, median, or hazard functions. For example, a wage equation gives the mean, median or, possibly, some other quantile of wages of employed individuals conditional on characteristics such as years of work experience and education. A hedonic price function gives the mean price of a good conditional on its characteristics. The function of interest is rarely known a priori and must be estimated from data on the relevant variables. For example, a wage equation is estimated from data on the wages, experience, education and, possibly, other characteristics of individuals. Economic theory rarely gives useful guidance on the form (or shape) of a conditional mean, median, or hazard function. Consequently, the form of the function must either be assumed or inferred through the estimation procedure.

The most frequently used estimation methods assume that the function of interest is known up to a set of constant parameters that can be estimated from data. Models in which the only unknown quantities are a finite set of constant parameters are called ‘parametric’. A linear model that is estimated by ordinary least squares is a familiar and frequently used example of a parametric model. Indeed, linear models and ordinary least squares have been the workhorses of applied econometrics since its inception. It is not difficult to see why. Linear models and ordinary least squares are easy to work with both analytically and computationally, and the estimation results are easy to interpret. Other examples of widely used
parametric models are binary logit and probit models if the dependent variable is binary (for example, an indicator of whether an individual is employed or whether a commuter uses automobile or public transit for a trip to work) and the Weibull hazard model if the dependent variable is a duration (for example, the duration of a spell of employment or unemployment).

Although parametric models are easy to work with, they are rarely justified by theoretical or other a priori considerations and often fit the available data badly. Horowitz (2001), Horowitz and Savin (2001), Horowitz and Lee (2002), and Pagan and Ullah (1999) provide examples. The examples also show that conclusions drawn from a convenient but incorrectly specified model can be very misleading. Of course, applied econometricians are aware of the problem of specification error. Many investigators attempt to deal with it by carrying out a specification search in which several different models are estimated and conclusions are based on the one that appears to fit the data best. Specification searches may be unavoidable in some applications, but they have many undesirable properties. There is no guarantee that a specification search will include the correct model or a good approximation to it. If the search includes the correct model, there is no guarantee that it will be selected by the investigator's model selection criteria. Moreover, the search process invalidates the statistical theory on which inference is based.

Given this situation, it is reasonable to ask whether conditional mean and other functions of interest in applications can be estimated nonparametrically, that is, without making a priori assumptions about their functional forms. The answer is clearly ‘yes’ in a model whose explanatory variables are all discrete. If the explanatory variables are discrete, then each set of values of these variables defines a data cell. One can estimate the conditional mean of the dependent variable by averaging its values within each cell. Similarly, one can estimate the conditional median cell by cell.

If the explanatory variables are continuous, they cannot be grouped into cells. Nonetheless, it is possible to estimate conditional mean and median functions that satisfy mild smoothness conditions without making a priori assumptions about their shapes. Techniques for doing this have been developed mainly in statistics, beginning with Nadaraya's (1964) and Watson's (1964) nonparametric estimator of a conditional mean function. The Nadaraya–Watson estimator, which is also called a kernel estimator, is a weighted average of the observed values of the dependent variable. More specifically, suppose that the dependent variable is \( Y \), the explanatory variable is \( X \), and the data consist of observations \( \{ Y_i, X_i : i = 1, \ldots, n \} \). Then the Nadaraya–Watson estimator of the mean of \( Y \) at \( X = x \) is a weighted average of the \( Y_i \)'s. \( Y_i \)'s corresponding to \( X_i \)'s that are close to \( x \) get more weight than do \( Y_i \)'s corresponding to \( X_i \)'s that are far from \( x \). The statistical properties of the Nadaraya–Watson estimator have been extensively investigated for both cross-sectional and time-series data, and the estimator has been widely used in applications. For example, Blundell, Browning and Crawford (2003) used kernel estimates of Engel curves in an investigation of the consistency of household-level data and revealed preference theory. Hausman and Newey (1995) used kernel estimates of demand functions to estimate the equivalent variation for changes in gasoline prices and the deadweight losses associated with increases in gasoline taxes. Kernel-based methods have also been developed for estimating conditional quantile and hazard functions.

There are other important nonparametric methods for estimating conditional mean functions. Local linear estimation and series or sieve estimation are especially useful in applications. Local linear estimation consists of estimating the mean of \( Y \) at \( X = x \) by using a form of weighted least squares to fit a linear model to the data. The weights are such that observations \( \{ Y_i, X_i \} \) for which \( X_i \) is close to \( x \)
receive more weight than do observations for which \( X_i \) is far from \( x \). In comparison with the Nadaraya–Watson estimator, local linear estimation has important advantages relating to bias and behaviour near the boundaries of the data. These are discussed in the book by Fan and Gijbels (1996), among other places.

A series estimator begins by expressing the true conditional mean (or quantile) function as an infinite series expansion using basis functions such as sines and cosines, orthogonal polynomials, or splines. The coefficients of a truncated version of the series are then estimated by ordinary least squares. The statistical properties of series estimators are described by Newey (1997). Hausman and Newey (1995) give an example of their use in an economic application.

Nonparametric models and estimates essentially eliminate the possibility of misspecification of a conditional mean or quantile function (that is, they consistently estimate the true function), but they have important disadvantages that limit their usefulness in applied econometrics. One important problem is that the precision of a nonparametric estimator decreases rapidly as the dimension of the explanatory variable \( X \) increases. This phenomenon is called the ‘curse of dimensionality’. It can be understood most easily by considering the case in which the explanatory variables are all discrete. Suppose the data contain 500 observations of \( Y \) and \( X \). Suppose, further, that \( X \) is a \( K \)-component vector and that each component can take five different values. Then the values of \( X \) generate \( 5^k \) cells. If \( K = 4 \), which is not unusual in applied econometrics, then there are 625 cells, or more cells than observations. Thus, estimates of the conditional mean function are likely to be very imprecise for most cells because they will contain few observations. Moreover, there will be at least 125 cells that contain no data and, consequently, for which the conditional mean function cannot be estimated at all. It has been proved that the curse of dimensionality is unavoidable in nonparametric estimation. As a result of it, impractically large samples are usually needed to obtain acceptable estimation precision if \( X \) is multidimensional.

Another problem is that nonparametric estimates can be difficult to display, communicate, and interpret when \( X \) is multidimensional. Nonparametric estimates do not have simple analytic forms. If \( X \) is one- or two-dimensional, then the estimate of the function of interest can be displayed graphically, but only reduced-dimension projections can be displayed when \( X \) has three or more components. Many such displays and much skill in interpreting them can be needed to fully convey and comprehend the shape of an estimate.

A further problem with nonparametric estimation is that it does not permit extrapolation. For example, in the case of a conditional mean function it does not provide predictions of the mean of \( Y \) at values of \( x \) that are outside of the range of the data on \( X \). This is a serious drawback in policy analysis and forecasting, where it is often important to predict what might happen under conditions that do not exist in the available data. Finally, in nonparametric estimation it can be difficult to impose restrictions suggested by economic or other theory. Matzkin (1994) discusses this issue.

The problems of nonparametric estimation have led to the development of so-called semiparametric methods that offer a compromise between parametric and nonparametric estimation. Semiparametric methods make assumptions about functional form that are stronger than those of a nonparametric model but less restrictive than the assumptions of a parametric model, thereby reducing (though not eliminating) the possibility of specification error. Semiparametric methods permit greater estimation precision than do nonparametric methods when \( X \) is multidimensional. Semiparametric estimation results are usually easier to display and interpret than are nonparametric ones, and provide limited
In econometrics, semiparametric estimation began with Manski's (1975; 1985) and Cosslett's (1983) work on estimating discrete-choice random-utility models. McFadden had introduced multinomial logit random utility models. These models assume that the random components of the utility function are independently and identically distributed with the Type I extreme value distribution. (The Type I extreme value distribution and density functions are defined, for example, in eqs (3.1) and (3.2) Maddala, 1983, p. 60.) The resulting choice model is analytically simple but has properties that are undesirable in many applications (for example, the well-known independence-of-irrelevant-alternatives property). Moreover, estimators based on logit models are inconsistent if the distribution of the random components of utility is not Type I extreme value. Manski (1975; 1985) and Cosslett (1983) proposed estimators that do not require a priori knowledge of this distribution. Powell's (1984; 1986) least absolute deviations estimator for censored regression models is another early contribution to econometric research on semiparametric estimation. This estimator was motivated by the observation that estimators of (parametric) Tobit models are inconsistent if the underlying normality assumption is incorrect. Powell's estimator is consistent under very weak distributional assumptions.

Semiparametric estimation has continued to be an active area of econometric research. Semiparametric estimators have been developed for a wide variety of additive, index, partially linear, and hazard models, among others. These estimators all reduce the effective dimension of the estimation problem and overcome the curse of dimensionality by making assumptions that are stronger than those of fully nonparametric estimation but weaker than those of a parametric model. The stronger assumptions also give the models limited extrapolation capabilities. Of course, these benefits come at the price of increased risk of specification error, but the risk is smaller than with simple parametric models. This is because semiparametric models make weaker assumptions than do parametric models, and contain simple parametric models as special cases.

Semiparametric estimation is also an important research field in statistics, and it has led to much interaction between statisticians and econometricians. The early statistics and biostatistics research that is relevant to econometrics was focused on survival (duration) models. Cox's (1972) proportional hazards model and the Buckley and James (1979) estimator for censored regression models are two early examples of this line of research. Somewhat later, C. Stone (1985) showed that a nonparametric additive model can overcome the curse of dimensionality. Since then, statisticians have contributed actively to research on the same classes of semiparametric models that econometricians have worked on.

13 Theory-based empirical models

Many econometric models are connected to economic theory only loosely or through essentially arbitrary parametric assumptions about, say, the shapes of utility functions. For example, a logit model of discrete choice assumes that the random components of utility are independently and identically distributed with the Type I extreme value distribution. In addition, it is frequently assumed that the indirect utility function is linear in prices and other characteristics of the alternatives. Because economic theory rarely, if ever, yields a parametric specification of a probability model, it is worth asking whether theory provides useful restrictions on the specification of econometric models, and whether models that are consistent with economic theory can be estimated without making non-theoretical parametric
assumptions. The answers to these questions depend on the details of the setting being modelled. In the case of discrete-choice, random-utility models, the inferential problem is to estimate the distribution of (direct or indirect) utility conditional on observed characteristics of individuals and the alternatives among which they choose. More specifically, in applied research one usually is interested in estimating the systematic component of utility (that is, the function that gives the mean of utility conditional on the explanatory variables) and the distribution of the random component of utility. Discrete choice is present in a wide range of applications, so it is important to know whether the systematic component of utility and the distribution of the random component can be estimated nonparametrically, thereby avoiding the non-theoretical distributional and functional form assumptions that are required by parametric models. The systematic component and distribution of the random component cannot be estimated unless they are identified. However, economic theory places only weak restrictions on utility functions (for example, shape restrictions such as monotonicity, convexity, and homogeneity), so the classes of conditional mean and utility functions that satisfy the restrictions are large. Indeed, it is not difficult to show that observations of individuals’ choices and the values of the explanatory variables, by themselves, do not identify the systematic component of utility and the distribution of the random component without making assumptions that shrink the class of allowed functions.

This issue has been addressed in a series of papers by Matzkin that are summarized in Matzkin (1994). Matzkin gives conditions under which the systematic component of utility and the distribution of the random component are identified without restricting either to a finite-dimensional parametric family. Matzkin also shows how these functions can be estimated consistently when they are identified. Some of the assumptions required for identification may be undesirable in applications. Moreover, Manski (1988) and Horowitz (1998) have given examples in which infinitely many combinations of the systematic component of utility and distribution of the random component are consistent with a binary logit specification of choice probabilities. Thus, discrete-choice, random-utility models can be estimated under assumptions that are considerably weaker than those of, say, logit and probit models, but the systematic component of utility and the distribution of the random component cannot be identified using the restrictions of economic theory alone. It is necessary to make additional assumptions that are not required by economic theory and, because they are required for identification, cannot be tested empirically.

Models of market-entry decisions by oligopolistic firms present identification issues that are closely related to those in discrete-choice, random utility models. Berry and Tamer (2006) explain the identification problems and approaches to resolving them.

The situation is different when the economic setting provides more information about the relation between observables and preferences than is the case in discrete-choice models. This happens in models of certain kinds of auctions, thereby permitting nonparametric estimation of the distribution of values for the auctioned object. An example is a first-price, sealed bid auction within the independent private values paradigm. Here, the problem is to infer the distribution of bidders’ values for the auctioned object from observed bids. A game-theory model of bidders’ behaviour provides a characterization of the relation between bids and the distribution of private values. Guerre, Perrigne and Vuong (2000) show that this relation nonparametrically identifies the distribution of values if the analyst observes all bids and certain other mild conditions are satisfied. Guerre, Perrigne and Vuong (2000) also show how to
carry out nonparametric estimation of the value distribution.

Dynamic decision models and equilibrium job-search models are other examples of empirical models that are closely connected to economic theory, though they also rely on non-theoretical parametric assumptions. In a dynamic decision model, an agent makes a certain decision repeatedly over time. For example, an individual may decide each year whether to retire or not. The optimal decision depends on uncertain future events (for example, the state of one's future health) whose probabilities may change over time (for example, the probability of poor health increases as one ages) and depend on the decision. In each period, the decision of an agent who maximizes expected utility is the solution to a stochastic, dynamic programming problem. A large body of research, much of which is reviewed by Rust (1994), shows how to specify and estimate econometric models of the utility function (or, depending on the application, cost function), probabilities of relevant future events, and the decision process.

An equilibrium search model determines the distributions of job durations and wages endogenously. In such a model, a stochastic process generates wage offers. An unemployed worker accepts an offer if it exceeds his reservation wage. An employed worker accepts an offer if it exceeds his current wage. Employers choose offers to maximize expected profits. Among other things, an equilibrium search model provides an explanation for why seemingly identical workers receive different wages. The theory of equilibrium search models is described in Albrecht and Axell (1984), Mortensen (1990), and Burdett and Mortensen (1998). There is a large body of literature on the estimation of these models. Bowlus, Kiefer and Neumann (2001) provide a recent example with many references.

14 The bootstrap

The exact, finite-sample distributions of econometric estimators and test statistics can rarely be calculated in applications. This is because, except in special cases and under restrictive assumptions (for example, the normal linear model), finite sample distributions depend on the unknown distribution of the population from which the data were sampled. This problem is usually dealt with by making use of large-sample (asymptotic) approximations. A wide variety of econometric estimators and test statistics have distributions that are approximately normal or chi-square when the sample size is large, regardless of the population distribution of the data. The approximation error decreases to zero as the sample size increases. Thus, asymptotic approximations can be used to obtain confidence intervals for parameters and critical values for tests when the sample size is large.

It has long been known, however, that the asymptotic normal and chi-square approximations can be very inaccurate with the sample sizes encountered in applications. Consequently, there can be large differences between the true and nominal coverage probabilities of confidence intervals and between the true and nominal probabilities with which a test rejects a correct null hypothesis. One approach to dealing with this problem is to use higher-order asymptotic approximations such as Edgeworth or saddlepoint expansions. These received much research attention during 1970s and 1980s, but analytic higher-order expansions are rarely used in applications because of their algebraic complexity.

The bootstrap, which is due to Efron (1979), provides a way to obtain sometimes spectacular improvements in the accuracy of asymptotic approximations while avoiding algebraic complexity. The bootstrap amounts to treating the data as if they were the population. In other words, it creates a pseudo-population whose distribution is the empirical distribution of the data.
population, the exact finite sample distribution of any statistic can be estimated with arbitrary accuracy by carrying out a Monte Carlo simulation in which samples are drawn repeatedly from the empirical distribution of the data. That is, the data are repeatedly sampled randomly with replacement. Since the empirical distribution is close to the population distribution when the sample size is large, the bootstrap consistently estimates the asymptotic distribution of a wide range of important statistics. Thus, the bootstrap provides a way to replace analytic calculations with computation. This is useful when the asymptotic distribution is difficult to work with analytically.

More importantly, the bootstrap provides a low-order Edgeworth approximation to the distribution of a wide variety of asymptotically standard normal and chi-square statistics that are used in applied research. Consequently, the bootstrap provides an approximation to the finite-sample distributions of such statistics that is more accurate than the asymptotic normal or chi-square approximation. The theoretical research leading to this conclusion was carried out by statisticians, but the bootstrap's importance has been recognized in econometrics and there is now an important body of econometric research on the topic. In many settings that are important in applications, the bootstrap essentially eliminates errors in the coverage probabilities of confidence intervals and the rejection probabilities of tests. Thus, the bootstrap is a very important tool for applied econometricians.

There are, however, situations in which the bootstrap does not estimate a statistic's asymptotic distribution consistently. Manski's (1975; 1985) maximum score estimator of the parameters of a binary response model is an example. All known cases of bootstrap inconsistency can be overcome through the use of subsampling methods. In subsampling, the distribution of a statistic is estimated by carrying out a Monte Carlo simulation in which the subsamples of the data are drawn repeatedly. The subsamples are smaller than the original data-set, and they can be drawn randomly with or without replacement. Subsampling provides estimates of asymptotic distributions that are consistent under very weak assumptions, though it is usually less accurate than the bootstrap when the bootstrap is consistent.

15 Programme evaluation and treatment effects

Programme evaluation is concerned with estimating the causal effect of a treatment or policy intervention on some population. The problem arises in many disciplines, including biomedical research (for example, the effects of a new medical treatment) and economics (for example, the effects of job training or education on earnings). The most obvious way to learn the effects of treatment on a group of individuals by observing each individual's outcome in both the treated and the untreated states. This is not possible in practice, however, because one virtually always observes any given individual in either the treated state or the untreated state but not both. This does not matter if the individuals who receive treatment are identical to those who do not, but that rarely happens. For example, individuals who choose to take a certain drug or whose physicians prescribe it for them may be sicker than individuals who do not receive the drug. Similarly, people who choose to obtain high levels of education may be different from others in ways that affect future earnings.

This problem has been recognized since at least the time of R.A. Fisher. In principle, it can be overcome by assigning individuals randomly to treatment and control groups. One can then estimate the average effect of treatment by the difference between the average outcomes of treated and untreated individuals. This random assignment procedure has become something of a gold standard in the treatment effects literature. Clinical trials use random assignment, and there have been important economic and social
experiments based on this procedure. But there are also serious practical problems. First, random assignment may not be possible. For example, one cannot assign high-school students randomly to receive a university education or not. Second, even if random assignment is possible, post-randomization events may disrupt the effects of randomization. For example, individuals may drop out of the experiment or take treatments other than the one to which they are assigned. Both of these things may happen for reasons that are related to the outcome of interest. For example, very ill members of a control group may figure out that they are not receiving treatment and find a way to obtain the drug being tested. In addition, real-world programmes may not operate the way that experimental ones do, so real-world outcomes may not mimic those found in an experiment, even if nothing has disrupted the randomization.

Much research in econometrics, statistics, and biostatistics has been aimed at developing methods for inferring treatment effects when randomization is not possible or is disrupted by post-randomization events. In econometrics, this research dates back at least to Gronau (1974) and Heckman (1974). The fundamental problem is to identify the effects of treatment or, in less formal terms, to separate the effects of treatment from those of other sources of differences between the treated and untreated groups. Manski (1995), among many others, discusses this problem. Large literatures in statistics, biostatistics, and econometrics are concerned with developing identifying assumptions that are reasonable in applied settings. However, identifying assumptions are not testable empirically and can be controversial. One widely accepted way of dealing with this problem is to conduct a sensitivity analysis in which the sensitivity of the estimated treatment effect to alternative identifying assumptions is assessed. Another possibility is to forgo controversial identifying assumptions and to find the entire set of outcomes that are consistent with the joint distribution of the observed variables. This approach, which has been pioneered by Manski and several co-investigators, is discussed in Manski (1995; 2003), among other places. Hotz, Mullin and Sanders (1997) provide an interesting application of bounding methods to measuring the effects of teenage pregnancy on the labour market outcomes of young women.

16 Integration and simulation methods in econometrics

The integration problem is endemic in economic modelling, arising whenever economic agents do not observe random variables and the behaviour paradigm is the maximization of expected utility. The econometrician inherits this problem in the expression of the corresponding econometric model, even before taking up inference and estimation. The issue is most familiar in dynamic optimization contexts, where it can be addressed by a variety of methods. Taylor and Uhlig (1990) present a comprehensive review of these methods; for later innovations see Keane and Wolpin (1994), Rust (1997) and Santos and Vigo-Aguir (1998).

The problem is more pervasive in econometrics than in economic modelling, because it arises, in addition, whenever economic agents observe random variables that the econometrician does not. For example, the economic agent may form expectations conditional on an information set not entirely accessible to the econometrician, such as personal characteristics or confidential information. Another example arises in discrete choice settings, where utilities of alternatives are never observed and the prices of alternatives often are not. In these situations the economic model provides a probability distribution of outcomes conditional on three classes of objects: observed variables, available to the
econometrician; latent variables, unobserved by the econometrician; and parameters or functions describing the preferences and decision-making environment of the economic agent. The econometrician typically seeks to learn about the parameters or functions given the observed variables.

There are several ways of dealing with this task. Two approaches that are closely related and widely used in the econometrics literature generate integration problems. The first is to maintain a distribution of the latent variables conditional on observed variables, the parameters in the model, and additional parameters required for completing this distribution. (This is the approach taken in maximum likelihood and Bayesian inference.) Combined with the model, this leads to the joint distribution of outcomes and latent variables conditional on observed variables and parameters. Since the marginal distribution of outcomes is the one relevant for the econometrician in this conditional distribution, there is an integration problem for the latent variables. The second approach is weaker: it restricts to zero the values of certain population moments involving the latent and observable variables. (This is the approach taken in generalized method of moments, which can be implemented with both parametric and nonparametric methods.) These moments depend upon the parameters (which is why the method works) and the econometrician must therefore be able to evaluate the moments for any given set of parameter values. This again requires integration over the latent variables.

Ideally, this integral would be evaluated analytically. Often – indeed, typically – this is not possible. The alternative is to use numerical methods. Some of these are deterministic, but the rapid growth in the solution of these problems since (roughly) 1990 has been driven more by simulation methods employing pseudo-random numbers generated by computer hardware and software. This section reviews the most important these methods and describes their most significant use in non-Bayesian econometrics, namely, simulated method of moments. In Bayesian econometrics the integration problem is inescapable, the structure of the economic model notwithstanding, because parameters are treated explicitly as unobservable random variables. Consequently simulation methods have been central to Bayesian inference in econometrics.

16.1 Deterministic approximation of integrals

The evaluation of an integral is a problem as old as the calculus itself. In well-catalogued but limited instances analytical solutions are available: Gradshteyn and Ryzhik (1965) is a useful classic reference. For integration in one dimension there are several methods of deterministic approximation, including Newton-Coates (Press et al., 1986, ch. 4; Davis and Rabinowitz, 1984, ch. 2), and Gaussian quadrature (Golub and Welsch, 1969; Judd, 1998, ch. 7.2). Gaussian quadrature approximates a smooth function as the product a polynomial of modest order and a smooth basis function, and then uses iterative refinements to compute the approximation. It is incorporated in most mathematical applications software and is used routinely to approximate integrals in one dimension to many significant figures of accuracy. Integration in several dimensions by means of deterministic approximation is more difficult. Practical generic adaptations of Gaussian quadrature are limited to situations in which the integrand is approximately the product of functions of single variables (Davis and Rabinowitz, 1984, pp. 354–9). Even here the logarithm of computation time is approximately linear in the number of variables, a phenomenon sometimes dubbed ‘the curse of dimensionality.’ Successful extensions of quadrature beyond dimensions of four or five are rare, and these extensions typically require substantial analytical
work before they can be applied successfully. Low discrepancy methods provide an alternative generic approach to deterministic approximation of integrals in higher dimensions. The approximation is the average value of the integrand computed over a well-chosen sequence of points whose configuration amounts to a sophisticated lattice. Different sequences lead to variants on the approach, the best known being the Halton (1960) sequence and the Hammersley (1960) sequence. Niederreiter (1992) reviews these and other variants. A key property of any method of integral approximation, deterministic or non-deterministic, is that it should provide as a by-product some indicator of the accuracy of the approximation. Deterministic methods typically provide upper bounds on the approximation error, based on worst-case situations. In many situations the actual error is orders of magnitude less than the upper bound, and as a consequence attaining desired error tolerances may appear to be impractical, whereas in fact these tolerances can easily be attained. Geweke (1996, s. 2.3) provides an example.

16.2 Simulation approximation of integrals

The structure of integration problems encountered in econometrics makes them often more amenable to attack by simulation methods than by non-deterministic methods. Two characteristics are key. First, integrals in many dimensions are required. In some situations the number is proportional to the size of the sample, and, while the structure of the problem may lead to decomposition in terms of many integrals of smaller dimension, the resulting structure and dimension are still unsuitable for deterministic methods. The second characteristic is that the integration problem usually arises as the need to compute the expected value of a function of a random vector with a given probability distribution $P$:

$$I = \int g(x) \, p(x) \, dx,$$

where $p$ is the density corresponding to $P$, $g$ is the function, $x$ is the random vector, and $I$ is the number to be approximated. The probability distribution $P$ is then the point of departure for the simulation. For many distributions there are reliable algorithms, implemented in widely available mathematical applications software, for simulation of random vectors $x$. This yields a sample

$$\left\{ g(x^{(m)}) \right\}_{m=1, \ldots, M}$$

whose arithmetic mean provides an approximation of $I$, and for which a central limit theorem provides an assessment of the accuracy of the approximation in the usual way. (This requires the existence of the first two moments of $g$, which must be shown analytically.) This approach is most useful when $p$ is simple (so that direct simulation of $x$ is possible) but the structure of $g$ precludes analytical evaluation of $I$. This simple approach does not suffice for the integration problem as it typically arises in econometrics. A leading example is the multinomial probit (MNP) model with $J$ discrete choices. For each individual $i$ the utility of the last choice $u_{iJ}$ is normalized to be zero, and the utilities of the first $I-1$ choices are

given by the vector

\[ \mathbf{u}_i \sim N(\mathbf{X}_i \beta, \Sigma), \]  

(2)

where \( \mathbf{X} \) is a matrix of characteristics of individual \( i \), including the prices and other properties of the choices presented to that individual, and \( \beta \) and \( \Sigma \) are structural parameters of the model. If the \( j \)th element of \( \mathbf{u}_i \) is positive and larger than all the other elements of \( \mathbf{u}_i \) the individual makes choice \( j \), and if all elements of \( \mathbf{u} \) are negative the individual makes choice \( J \). The probability that individual \( i \) makes choice \( j \) is the integral of the \((n-1)\)-variate normal distribution (1) taken over the subspace \( \{ \mathbf{u}_i: u_{ijk} \leq u_{ij} \forall k = 1, \ldots, n \} \). This computation is essential in evaluating the likelihood function, and it has no analytical solution. (For discussion and review, see Sandor and Andras, 2004.)

Several generic simulation methods have been used for the problem (1) in econometrics. One of the oldest is acceptance sampling, a simple variant of which is described in von Neumann (1951) and Hammersley and Handscomb (1964). Suppose it is possible to draw from the distribution \( Q \) with density \( q \), and the ratio \( \frac{p(\mathbf{x})}{q(\mathbf{x})} \) is bounded above by the known constant \( a \). If \( x \) is simulated successively from \( Q \) but accepted and taken into the sample with probability \( \frac{p(\mathbf{x})}{[aq(\mathbf{x})]} \), then the resulting sample is independently distributed with the identical distribution \( P \). Proofs and further discussion are widely available; for example, Press et al. (1992, s. 7.4), Bratley, Fox and Schrage (1987, s. 5.2.5), and Geweke (2005, s. 4.2.1). The unconditional probability of accepting draws from \( Q \) is \( 1/a \). If \( a \) is too large the method is impractical, but when acceptance sampling is practical it provides draws directly from \( P \). This is an important component of many of the algorithms underlying the ‘black box’ generation of random variables in mathematical applications software.

Alternatively, in the same situation all of the draws from \( Q \) are retained and taken into a stratified sample in which the weight \( w(x^{(m)}) = \frac{p(x^{(m)})}{q(x^{(m)})} \) is associated with the \( m \)th draw. The approximation of \( I \) in (1) is then the weighted average of the terms \( g(x^{(m)}) \). This approach dates at least to Hammersley and Handscomb (1964, s. 5.4), and was introduced to econometrics by Kloek and van Dijk (1978). The procedure is more general than acceptance sampling in that a known upper bound of \( w \) is not required, but if in fact \( a \) is large then the weights will display large variation and the approximation will be poor. This is clear in the central limit theorem for the accuracy of approximation provided in Geweke (1989a), which as a practical matter requires that a finite upper bound on \( w \) be established analytically. This is a key limitation of acceptance sampling and importance sampling.

Markov chain Monte Carlo (MCMC) methods provide an entirely different approach to the solution of the integration problem (1). These procedures construct a Markov process of the form

\[ x^{(m)} \sim p(x|x^{(m-1)}) \]  

(3)
in such a way that

\[ M^{-1} \sum_{m=1}^{M} g(x^{(m)}) \]

converges (almost surely) to \( I \). These methods have a history in mathematical physics dating back to the algorithm of Metropolis et al. (1953). Hastings (1970) focused on statistical problems and extended the method to its present form known as the Hastings–Metropolis (HM) algorithm. HM draws a candidate \( x^* \) from a convenient distribution indexed by \( x^{(m-1)} \). It sets \( x^{(m)} = x \) with probability \( \alpha(x^{(m-1)}, x^{(m)}) \) and sets \( x^{(m)} = x^{(m-1)} \) otherwise, the function \( \alpha \) being chosen so that the process (3) defined in this way has the desired convergence property. Chib and Greenberg (1995) provide a detailed introduction to HM and its application in econometrics. Tierney (1994) provides a succinct summary of the relevant continuous state space Markov chain theory bearing on the convergence of MCMC.

A version of the HM algorithm particularly suited to image reconstruction and problems in spatial statistics, known as the Gibbs sampling (GS) algorithm, was introduced by Geman and Geman (1984). This was subsequently shown to have great potential for Bayesian computation by Gelfand and Smith (1990). In GS the vector \( x \) is subdivided into component vectors, \( x' = (x_1', \ldots, x_g') \), in such a way that simulation from the conditional distribution of each \( x_j \) implied by \( p(x) \) in (1) is feasible. This method has proven very advantageous in econometrics generally, and it revolutionized Bayesian approaches in particular beginning about 1990.

By the turn of the century HM and GS algorithms were standard tools for likelihood-based econometrics. Their structure and strategic importance for Bayesian econometrics were conveyed in surveys by Geweke (1999) and Chib (2001), as well as in a number of textbooks, including Koop (2003), Lancaster (2004), Geweke (2005) and Rossi, Allenby and McCulloch (2005). Central limit theorems can be used to assess the quality of approximations as described in Tierney (1994) and Geweke (2005).

### 16.3 Simulation methods in non-Bayesian econometrics

Generalized method of moments estimation has been a staple of non-Bayesian econometrics since its introduction by Hansen (1982). In an econometric model with \( k \times 1 \) parameter vector \( \Theta \) economic theory provides the set of sample moment restrictions

\[ \text{http://www.dictionaryofeconomics.com.proxy.librarycsi...du/article?id=pde2008_E000007&goto=B&result_number=437\[34\]66\[34\]08-12-31 0:16:27} \]
\[ h(\theta) = \int g(x) \ p(x|\theta, y) \ dx = 0, \]

(4)

where \( g(x) \) is a \( p \times 1 \) vector and \( y \) denotes the data including instrumental variables. An example is the MNP model (2). If the observed choices are coded by the variables \( d_{ij} = 1 \) if individual \( i \) makes choice \( j \) and \( d_{ij} = 0 \) otherwise, then the expected value of \( d_{ij} \) is the probability that individual \( i \) makes choice \( j \), leading to restrictions of the form (4).

The generalized method of moments estimator minimizes the criterion function \( h(\theta)'W h(\theta) \) given a suitably chosen weighting matrix \( W \). If the requisite integrals can be evaluated analytically, \( p \geq k \), and other conditions provided in Hansen (1982) are satisfied, then there is a well-developed asymptotic theory of inference for the parameters that by 1990 was a staple of graduate econometrics textbooks. If for one or more elements of \( h \) the integral cannot be evaluated analytically, then for alternative values of it is often possible to approximate the integral appearing in (4) by simulation. This is the situation in the MNP model.

The substitution of a simulation approximation

\[ M^{-1} \sum_{m=1}^{M} g(x^{(m)}) \]

for the integral in (4) defines the method of simulated moments (MSM) introduced by McFadden (1989) and Pakes and Pollard (1989), who were concerned with the MNP model (2) in particular and the estimation of discrete response models using cross-section data in general. Later the method was extended to time series models by Lee and Ingram (1991) and Duffie and Singleton (1993). The asymptotic distribution theory established in this literature requires that the number of simulations \( M \) increase at least as rapidly as the square of the number of observations. The practical import of this apparently severe requirement is that applied econometric work must establish that changes in \( M \) must have little impact on the results; Geweke, Keane and Runkle (1994; 1997) provide examples for MNP. This literature also shows that in general the impact of using direct simulation, as opposed to analytical evaluation of the integral, is to increase the asymptotic variance of the GMM estimator of \( \theta \) by the factor \( M^{-1} \), typically trivial in view of the number of simulations required. Substantial surveys of the details of MSM and leading applications of the method can be found in Gourieroux and Monfort (1993; 1996), Stern (1997) and Liesenfeld and Breitung (1999).

The simulation approximation, unlike the (unavailable) analytical evaluation of the integral in (4), can lead to a criterion function that is discontinuous in \( \theta \). This happens in the MNP model using the obvious simulation scheme in which the choice probabilities are replaced by their proportions in the \( M \)
simulations, as proposed by Lerman and Manski (1981). The asymptotic theory developed by McFadden (1989) and Pakes and Pollard (1989) copes with this possibility, and led McFadden (1989) to use kernel weighting to smooth the probabilities. The most widely used method for smoothing probabilities in the MNP model is the Geweke–Hajivassiliou–Keane (GHK) simulator of Geweke (1989b), Hajivassiliou, McFadden and Ruud (1991) and Keane (1990); a full description is provided in Geweke and Keane (2001), and comparisons of alternative methods are given in Hajivassiliou, McFadden and Ruud (1996) and Sandor and Andras (2004).

Maximum likelihood estimation of $\theta$ can lead to first-order conditions of the form (4), and thus becomes a special case of MSM. This context highlights some of the complications introduced by simulation. While the simulation approximation of (1) is unbiased, the corresponding expression enters the log likelihood function and its derivatives nonlinearly. Thus for any finite number of simulations $M$, the evaluation of the first-order conditions is biased in general. Increasing $M$ at a rate faster than the square of the number of observations eliminates the squared bias relative to the variance of the estimator; Lee (1995) provides further details.

### 16.4 Simulation methods in Bayesian econometrics

Bayesian econometrics places a common probability distribution on random variables that can be observed (data) and unobservable parameters and latent variables. Inference proceeds using the distribution of these unobservable entities conditional on the data – the posterior distribution. Results are typically expressed in terms of the expectations of parameters or functions of parameters, expectations taken with respect to the posterior distribution. Thus, whereas integration problems are application-specific in non-Bayesian econometrics, they are endemic in Bayesian econometrics.

The development of modern simulation methods had a correspondingly greater impact in Bayesian than in non-Bayesian econometrics. Since 1990 simulation-based Bayesian methods have become practical in the context of most econometric models. The availability of this tool has been influential in the modelling approach taken in addressing applied econometric problems.

The MNP model (2) illustrates the interaction in latent variable models. Given a sample of $n$ individuals, the $(J-1) \times 1$ latent utility vectors $u_1, \ldots, u_n$ are regarded explicitly as $n(J-1)$ unknowns to be inferred along with the unknown parameters $\beta$ and $\Sigma$ . Conditional on these parameters and the data, the vectors $u_1, \ldots, u_n$ are independently distributed. The distribution of $u_i$ is (2) truncated to an orthant that depends on the observed choice $j$: if $j < J$ then $u_{ik} < u_j^i$ for all $k \neq j$ and $u_j^i > 0$, whereas for choice $J$: $u_{ik} < 0$ for all $k$. The distribution of each $u_{ik}$, conditional on all of the other elements of $u_i$, is truncated univariate normal, and it is relatively straightforward to simulate from this distribution. (Geweke, 1991, provides details on sampling from a multivariate normal distribution subject to linear restrictions.) Consequently GS provides a practical algorithm for drawing from the distribution of the latent utility vectors conditional on the parameters.

Conditional on the latent utility vectors – that is, regarding them as observed – the MNP model is a seemingly unrelated regressions model, and the approach taken by Percy (1992) applies. Given conjugate priors the posterior distribution of $\beta$ , conditional on $\Sigma$ and utilities, is Gaussian, and the conditional distribution of $\Sigma$ , conditional on $\beta$ and utilities, is inverted Wishart. Since GS provides the
joint distribution of parameters and latent utilities, the posterior mean of any function of these can be approximated as the sample mean. This approach and the suitability of GS for latent variable models were first recognized by Chib (1992). Similar approaches in other latent variable models include McCulloch and Tsay (1994), Chib and Greenberg (1998), McCulloch, Polson and Rossi (2000) and Geweke and Keane (2001).

The Bayesian approach with GS sidesteps the evaluation of the likelihood function and, of any moments in which the approximation is biased given a finite number of simulations, two technical issues that are prominent in MSM. On the other hand, as in all MCMC algorithms, there may be sensitivity to the initial values of parameters and latent variables in the Markov chain, and substantial serial correlation in the chain will reduce the accuracy of the simulation approximation. Geweke (1992; 2005) and Tierney (1994) discuss these issues.

17 Financial econometrics

Attempts at testing of the efficient market hypothesis (EMH) provided the impetus for the application of time series econometric methods in finance. The EMH was built on the pioneering work of Bachelier (1900) and evolved in the 1960s from the random walk theory of asset prices advanced by Samuelson (1965). By the early 1970s a consensus had emerged among financial economists suggesting that stock prices could be well approximated by a random walk model and that changes in stock returns were basically unpredictable. Fama (1970) provides an early, definitive statement of this position. He distinguished between different forms of the EMH: the ‘weak’ form that asserts all price information is fully reflected in asset prices; the ‘semi-strong’ form that requires asset price changes to fully reflect all publicly available information and not only past prices; and the ‘strong’ form that postulates that prices fully reflect information even if some investor or group of investors have monopolistic access to some information. Fama regarded the strong form version of the EMH as a benchmark against which the other forms of market efficiencies are to be judged. With respect to the weak form version he concluded that the test results strongly support the hypothesis, and considered the various departures documented as economically unimportant. He reached a similar conclusion with respect to the semi-strong version of the hypothesis. Evidence on the semi-strong form of the EMH was revisited by Fama (1991). By then it was clear that the distinction between the weak and the semi-strong forms of the EMH was redundant. The random walk model could not be maintained either, in view of more recent studies, in particular that of Lo and MacKinlay (1988).

This observation led to a series of empirical studies of stock return predictability over different horizons. It was shown that stock returns can be predicted to some degree by means of interest rates, dividend yields and a variety of macroeconomic variables exhibiting clear business cycle variations. See, for example, Fama and French (1989), Kandel and Stambaugh (1996), and Pesaran and Timmermann (1995) on predictability of equity returns in the United States; and Clare, Thomas and Wickens (1994), and Pesaran and Timmermann (2000) on equity return predictability in the UK.

Although it is now generally acknowledged that stock returns could be predictable, there are serious difficulties in interpreting the outcomes of market efficiency tests. Predictability could be due to a number of different factors such as incomplete learning, expectations heterogeneity, time variations in
risk premia, transaction costs, or specification searches often carried out in pursuit of predictability. In
general, it is not possible to distinguish between the different factors that might lie behind observed
predictability of asset returns. As noted by Fama (1991) the test of the EMH involves a joint hypothesis,
and can be tested only jointly with an assumed model of market equilibrium. This is not, however, a
problem that is unique to financial econometrics; almost all areas of empirical economics are subject to
the joint hypotheses problem. The concept of market efficiency is still deemed to be useful as it provides
a benchmark and its use in finance has led to significant insights.

Important advances have been made in the development of equilibrium asset pricing models,
econometric modelling of asset return volatility (Engle, 1982; Bollerslev, 1986), analysis of high
frequency intraday data, and market microstructures. Some of these developments are reviewed in
Campbell, Lo and MacKinlay (1997), Cochrane (2005), Shephard (2005), and McAleer and Medeiros
(2007). Future advances in financial econometrics are likely to focus on heterogeneity, learning and
model uncertainty, real time analysis, and further integration with macroeconometrics. Finance is
particularly suited to the application of techniques developed for real time econometrics (Pesaran and
Timmermann, 2005a).

18 Appraisals and future prospects

Econometrics has come a long way over a relatively short period. Important advances have been made in
the compilation of economic data and in the development of concepts, theories and tools for the
construction and evaluation of a wide variety of econometric models. Applications of econometric
methods can be found in almost every field of economics. Econometric models have been used
extensively by government agencies, international organizations and commercial enterprises.
Macroeconomic models of differing complexity and size have been constructed for almost every
country in the world. In both theory and practice, econometrics has already gone well beyond what its
founders envisaged. Time and experience, however, have brought out a number of difficulties that were
not apparent at the start.

Econometrics emerged in the 1930s and 1940s in a climate of optimism, in the belief that economic
time could be relied on to identify most, if not all, of the important factors involved in modelling
economic reality, and that methods of classical statistical inference could be adapted readily for the
purpose of giving empirical content to the received economic theory. This early view of the interaction
of theory and measurement in econometrics, however, proved rather illusory. Economic theory is
variably formulated with ceteris paribus clauses, and involves unobservable latent variables and
general functional forms; it has little to say about adjustment processes, lag lengths and other factors
mediating the relationship between the theoretical specification (even if correct) and observables. Even
in the choice of variables to be included in econometric relations, the role of economic theory is far more
limited than was at first recognized. In a Walrasian general equilibrium model, for example, where
everything depends on everything else, there is very little scope for a priori exclusion of variables from
equations in an econometric model. There are also institutional features and accounting conventions that
have to be allowed for in econometric models but which are either ignored or are only partially dealt
with at the theoretical level. All this means that the specification of econometric models inevitably
involves important auxiliary assumptions about functional forms, dynamic specifications, latent
variables, and so on, with respect to which economic theory is silent or gives only an incomplete guide. The recognition that economic theory on its own cannot be expected to provide a complete model specification has important consequences for testing and evaluation of economic theories, for forecasting and real time decision making. The incompleteness of economic theories makes the task of testing them a formidable undertaking. In general it will not be possible to say whether the results of the statistical tests have a bearing on the economic theory or the auxiliary assumptions. This ambiguity in testing theories, known as the Duhem–Quine thesis, is not confined to econometrics and arises whenever theories are conjunctions of hypotheses (on this, see for example Cross, 1982). The problem is, however, especially serious in econometrics because theory is far less developed in economics than it is in the natural sciences. There are, of course, other difficulties that surround the use of econometric methods for the purpose of testing economic theories. As a rule economic statistics are not the results of designed experiments, but are obtained as by-products of business and government activities often with legal rather than economic considerations in mind. The statistical methods available are generally suitable for large samples while the economic data typically have a rather limited coverage. There are also problems of aggregation over time, commodities and individuals that further complicate the testing of economic theories that are micro-based.

Econometric theory and practice seek to provide information required for informed decision-making in public and private economic policy. This process is limited not only by the adequacy of econometrics but also by the development of economic theory and the adequacy of data and other information. Effective progress, in the future as in the past, will come from simultaneous improvements in econometrics, economic theory and data. Research that specifically addresses the effectiveness of the interface between any two of these three in improving policy – to say nothing of all of them – necessarily transcends traditional sub-disciplinary boundaries within economics. But it is precisely these combinations that hold the greatest promise for the social contribution of academic economics.

Economic anthropology is an empirical science that describes production, exchange and consumption cross-culturally. All societies have economies, but they are variable. Anthropologists evaluate the operations of individual economies and the applicability of Western theories to these cases. Some economic processes work broadly; for example, strategic decision-making, the law of competitive advantage, and calculations of transaction costs help explain many observed patterns. Human economies, however, are often structured as intertwined sectors with distinctive processes. Differences observed in productivity, specialization, institutional structure and social motivations across history and across modern societies are of theoretical significance when constructing the limits of general theory.

Article

Economic anthropology is an empirical science that seeks to describe how production, exchange and consumption operate outside the West (compare Hunt, 1997). The second edition (1952) of Herskovits's (1940) text, titled Economic Anthropology, labelled this sub-discipline in anthropology. The broader mission of anthropology has been to make sense of the diversity in the human experience, which became apparent to Europeans during progressive stages of exploration, colonialization and globalization. Underlying anthropological research is the premise that human societies have developed parallel
institutions of aesthetics, religion, kinship, politics, and of course economics. All societies have
economies, and the economic patterns observed in non-Western economies both comfort and confront
theories developed by Western scholars. Common economic processes, such as rational decision-making, law of competitive advantage, and
institutional economics help explain many patterns across human economies based on variable
conditions of cost, demand and availability. Additionally, however, human economies appear often to be
structured quite differently from Western models, and these differences in institutional structure and
motivation are of theoretical significance. From the beginning, economic anthropology has contained,
and more or less successfully resolved, a tension between the desire to find cross-culturally general
theories and to recognize the uniqueness of each individual case. In economic anthropology this tension
has been represented in the formalist–substantivist debate.

Few anthropologists identify themselves primarily as economic anthropologists, but study economic
matters as part of a broadly integrative approach to human societies. Founded in 1980, the Society of
Economic Anthropology is the primary organization for anthropologists with such interests. Members
include ethnographers, applied development anthropologists, archaeologists and ethnohistorians,
suggesting that economic studies bridge the diversity of the discipline. The society sponsors annual
meetings on themes that range across topics including key institutions of labour, property, markets and
consumption, and special topics from the gift to slow foods. Research Series in Economic Anthropology
and Society for Economic Anthropology Monographs offer edited volumes on the sub-discipline.

History of economic anthropology

From early in the 20th century, anthropologists have questioned whether theories developed to
understand Western market economies apply only to those Western societies for which they were
generated. To answer this question, anthropologists have described traditional economies, which
survived into the 20th century, which existed in the past, and which have been transformed by
engagement with the West. Largely empirical, the work is of substantial theoretical significance for
understanding economies cross-culturally. Gudeman (1998) has compiled many of the most highly
referenced articles.

Economic anthropology's beginning traces to the landmark ethnography Argonauts of the Western
Pacific, in which Malinowski (1922) described the circulation of shell valuables among the islands of
the Kula Ring. Malinowski used the Trobriand Islanders' obsession with certain shell valuables to
challenge simplistic notions of 'economic man', and he argued that a non-Western economy could be
fundamentally different from modern market economies in values and socialized exchange relationships.
Anthropological studies of traditional economies thrived during the first half of the 20th century. As part
of British functionalism, Malinowski and his students developed the approach; in French structuralism,
Mauss (1925) focused on the gift as a social phenomenon; and, within American anthropology,
Herskovits (1940) defined the sub-field. Much of the work was descriptive, emphasizing how traditional
people meet basic needs and how the exchange of primitive valuables fashioned and maintained social
relationships.

By mid-century, however, studies of traditional economy were increasingly adopting the terms and
concepts of Western economic theory. Both Herskovits (1940) and Firth (1939) revised their original
books on traditional economies so as to clarify underlying similarities across world economies. They each took concepts, like scarcity and specialization, and generalized them to show that they apply well to societies in which market penetration is not great. They were making the essential point that traditional economies were not simply driven by the food quest. Although most anthropologists took pains to emphasize the differences between traditional economies and market-integrated systems, some seemed to homogenize the human experience, and a sharp reaction followed.

In the tradition of Max Weber, economic historian Karl Polanyi (1944) wrote his famous treatise *The Great Transformation* to argue that the integrating structure of modern markets, for which prices are set by supply and demand, are a very recent creation of industrialism and capitalism. Theories based on scarcity, rationality, equilibrating price mechanisms operated, he argued, only in the special case of Western capitalism. Modern market conditions should not be taken as inherent in the human experience, but as a recent social artifact malleable in future societies.

Polanyi's impact on economic anthropology was profound and created the debate between substantivists and formalists that raged in the sub-discipline for a generation. *Trade and Markets in the Early Empires* (Polanyi, Arensberg and Pearson, 1957), the seminal edited book, came out of a discussion group which Polanyi led at Columbia University and which included anthropologists who would be influential in the field. Polanyi's chapter 'The Economy as Instituted Process' characterized the substantivist approach. He defined three forms of distribution found in societies with different structured relationships: reciprocity in egalitarian relationships; redistribution in hierarchical relationships; and market exchange in the anonymous relationships of the market. Because economic relations were so deeply embedded in social structure, variation in social organization was thought to explain the differences in the economies. Substantivists recognized that markets were found widely in traditional economies, but argued that those markets were peripheral to most economic activities, which were deeply embedded in social relationships (Bohannan and Dalton, 1962). A compendium collected by Dalton (1967) provided empirical cases that illustrate the embedded nature of traditional economies.

In his critique of those using economic theory in non-Western contexts, Polanyi labelled them as 'formalist', meaning that they focused on 'formal' (mathematical) maximizing models to predict how individuals choose among alternative possibilities to allocate limited time, money and other resources. The substantivists, in contrast, focused on how economies were embedded within cultural institutions to meet the material desires that particular culture might have. The debate raged between the two factions through the 1960s and 1970s. Much of the argument became focused on how extensive markets were in traditional societies. In a classic cross-cultural study, Pryor (1977) showed that markets were very broadly distributed, sometimes moving primitive valuable, tools and food. They certainly did not originate with modern capitalism. In his famously acerbic article, Cook (1969) criticized substantivists for being romantic and naive; after all, even if they had useful points to make, the penetration of market economies, he argued, was so pervasive that formalist theories were now effectively universal.

Articles representing the two sides were collected in a reader by LeClair and Schneider (1968) that has been used to teach the debate ever since. Articulating the substantivist position, Sahlins (1972) then argued that many concepts of Western economic theory were inapplicable to traditional economy. He discussed the affluence of hunter-gatherers, underproduction in household economies, and the social determinants of reciprocal exchanges. Schneider (1974) countered with the fully articulated formalist position, summarizing how Western economics can be applied cautiously to a wide range of non-
Western transactions and decisions, including marriage payments, primitive money, the prestige economy and household production. The debate came to focus on definitions of rationality, scarcity and institutional constraints, but those reading the papers increasingly saw that the participants were talking past each other.

The formalist and substantivist factions represented the inherent tension within anthropology: on the one hand, to seek cross-cultural regularities that reflect shared social process; on the other, to recognize the cultural relativity and uniqueness of each culture. The two sides of the debate fought to exhaustion, as both presented compelling approaches that could be seen as more complementary than alternative. In 1980, Schneider helped organize the Society for Economic Anthropology in order to resolve the debate by bringing the full spectrum of economic anthropologists together. The first meeting, published as *Economic Anthropology: Topics and Theories* (Ortiz, 1983) gathered an eclectic group of scholars to bridge the theoretical divides within the sub-discipline, with broad interests in marketing, institutions, Marxism, ecology, and economic development. An edited text, *Economic Anthropology* (Plattner, 1989), provided a new generation of students with the breadth of economies and economic conditions that anthropologists were trying to make sense of.

Important to the new harmony has been respect for the different objectives of economic anthropologists, including ethnographic work on traditional economies, applied work on developing economies, and archaeological and historical studies of economies. The field has recognized diversity in both the theoretical and historical nature of human economies. To maintain a proper balance between substantivists and formalists (relativists and universalists) in economic anthropology, the role of archaeological and historical studies has been especially important. As ethnographers increasingly study variants of a single modern system, historical and archaeological studies continue to study the true variation in how human economies are organized and operate. Earle (2002), for example, looks at the alternative means by which political economies have emerged to finance the evolution of chiefdoms and states, showing that the development of market systems is quite rare and specific in that process. Although no careful comparative study exists, the extent of exchange in prehistory appears to have been highly variable.

During the 1980s and 1990s, as economic anthropology matured as a sub-discipline, it became marginalized within anthropology. As in many of the social sciences and humanities, postmodernism became popular, and its anti-materialist, anti-scientific critiques were antithetical to much of what the sub-discipline advocated. As the excesses of postmodernism have receded, however, economic anthropology has regained some of its former popularity, and its potential significance for anthropology and economics seems promising. Perhaps the greatest challenge now is that economics and economic anthropology have remained far apart because of the strongly formal (theoretical) basis of the former and empirical basis of the later. The two approaches would, however, seem complementary.

**Economic anthropology and its perspective on world economies**

Economists should consider the empirical value of economic anthropology, and a good place to begin is the compendium *Theory in Economic Anthropology* (Ensminger, 2002a). Economic anthropologists are committed to models of reality. The empirical observations and theoretical inferences of anthropology should help recognize the specific frames of applicability for grand theories. In essence, anthropology
Economic anthropology makes clear that all things are never equal. In this section, I summarize a few conclusions derived from economic anthropology that make a difference to studies of economies. These involve human rationality, consumer behaviour, commodity chains, and the multi-sectored quality of human economies. This list is not meant to be exhaustive, but only to illustrate the importance of cross-cultural evaluations for the models that economists develop. As economics begins to look at such concepts as behavioural economics and personalized networks, the relevance of anthropology's research on these topics becomes particularly significant.

Human decision-making is to a degree rational, and empirical anthropological work significantly improves an understanding of decision-making processes from a cross-cultural and evolutionary perspective. Although rationality underpins much economic theorizing, human cognitive abilities and goals have been under theorized. Recent trends to rectify this within behavioural economics emphasize that individuals do not always actrationally with primary economic objectives and it would appear that economic anthropology could provide valuable cross-cultural validation of these new ideas. Humans prove to be fairly poor decision makers; they appear rather to use simplified proximate measures to estimate such considerations as value and cost (Henrich, 2002). Anthropologists have experimented with various economic games given under controlled conditions in non-Western societies, and their results are often counter-intuitive (Ensminger, 2002b). In a sample of societies representing different levels of economic development, for example, as market integration increases cooperation can be shown in such game-playing experiments to become more highly prized.

To understand the evolutionary roots of human rationality, anthropological research has looked at decision-making in small-scale hunting and gathering societies (see for example, Cashdan, 1989). As seen by the rapid expansion in brain size deep in history, humans must have been under strong selective pressure for expanded cognitive abilities, and this selective pressure took place when humans were low-density hunter-gatherers. Such hunter-gatherers make daily a wide range of decisions about what foods to eat, where to camp, what groups to join, and the like, and the relative scarcity and abundance of food and their different nutritional qualities appear to be considered. Human cognitive skill determines the ability of hunter-gatherers to adjust rapidly to changing conditions of food availability, to occupy diverse habitats from the Arctic to the tropical forests, and to intensify food procurement as required by population growth. In short, cognitive abilities in the food quest, in movement through the landscape, and in deciding which groups to join must have provided a strong selective advantage that resulted in the moulding of human rationality.

As illustrated by economic anthropology, human decisions often have little direct relationship to economic factors of cost and financial gain. Although of more interest recently to economists, with the notable exception of Thorstein Veblen, economic theory has not attempted systematically to explain how potential consumer outcomes are ranked. Rather, within the West, consumer behaviour has been studied with a rather eclectic and under-theorized set of assumptions. Anthropologists, however, have tried to understand consumption cross-culturally as a social process involving issues of identity and association (Rutz and Orlove, 1989). From the anthropological literature, we know how valued objects signify social relationships. The giving and receiving of gifts impart form and meaning to social relationships, and materialize the social distance between actors (Sahlins, 1972).

Economic anthropologists frequently study the movements of objects around the globe. These commodity chains describe how goods are produced, distributed and transformed as they move through
a sequence of markets (Hansen, 2002; Obukhova and Guyer, 2002). Commodity chains illustrate how goods, like used clothing, are transformed in value, form and meaning as they pass through a sequence of social worlds and economic sectors. Social considerations of prestige and personal worth are always of great concern in this highly creative process of economic decision-making.

Economic anthropologists have emphasized that economies are multilayered and that the specific character of an economy has historical routes. Although economists often refer to ‘dual economy’, implying a vestigial survival of traditional practices, they have been reluctant to accept that economies are always multilayered mosaics with spheres of exchange that only partially articulate the different sectors. Economic theory thus radically simplifies reality by focusing on decision-making and outcomes under market conditions, and this simplification makes very different economies appear superficial similar. In the emergence and development of capitalism, since wealth was made in the markets, the primary concern of economists became directed there. As anthropologists seek to understand the different motives and dynamics of economies as articulated in specific social contexts, they have, however, realized that human economies are highly variable, combining subsistence, social, political, and market sectors, each with distinct logics and historical traditions.

The subsistence sector is family-based and involves the daily struggles to meet basic needs. It is universal and represents the economic world of survival in which humans evolved as a species. The primary motivation of humans has probably always been the satisfaction of a family's basic needs. The construction of a general theory of human economies should thus start with how households and communities make a living. Until recently, household requirements were handled largely by family production. Although markets have a long history in human societies, they were typically quite marginal to subsistence needs. Theorized as the domestic mode of production (DMP; Sahlins, 1972), households were oriented to meeting their subsistence needs, and distribution involved sharing between family members with different tasks appropriate to an elementary division of labour by age and gender. In the model, the household is economically self-sufficient, and the economy is not inherently growth-oriented. The amazing conclusion of considerable anthropological research is that the DMP is often at least the model of what the economy should be, and the amounts of goods consumed by households that are produced outside the family have often been but a fraction of the households’ overall consumption budget. Prior to the development of full-scale markets, households probably produced 75 per cent or more of everything that they consumed.

The social sector is community-based and involves the lifetime strategies of individuals to define identity and relationships within a broader social group. The social sector is probably universal, finding its roots among early hunter-gatherers and their need to form networks of support, cooperation and exclusion. In cross-cultural perspective, much of the social sector involves reciprocal exchanges within highly social worlds that can be manipulated to emphasize personal prestige. In traditional societies, such competitive exchanges commonly produce social ranking in what has been called a ‘prestige economy’. The social sector was elaborated following the Neolithic revolution, as the creation of local corporate groups must have placed a premium on group identity and status. With deep and enduring roots in human history, the social sector would seem to provide a cross-cultural understanding of consumer behaviour as part of processes much broader than capitalism.

Economics now questions assumptions about anonymous markets organized independently of other social institutions. Goods and services are seen as flowing through personalized networks that create the institutions for expanding economic transactions. Greif (2006), for example, argues that the social
networks of medieval Europe provided the frameworks for an emergent modern economy. Almost self-evident to anthropologists, such conclusions suggest how economic theory can gain from insights from comparative empirical studies of non-industrial political forms. Political sectors mobilize and allocate goods to finance regional and interregional institutions of domination and stratification (Earle, 2002). Importantly, political economies are not universal. From the fourth millennium BC, the political sector of the economy developed along with chiefdoms and then states. Goods became mobilized as a tax or tribute and then ‘redistributed’ by dominant political organizations as means to finance their activities. Recent archaeology has studied how political sectors were developed and functioned. An inherent contrast is between staple finance and wealth finance. In staple finance, food goods are mobilized and stored centrally as a means to support craftsmen, warriors and labourers working for the state. Many of these systems, especially in chiefdoms but also some states, functioned with few or no markets. Subsistence and social sectors continued largely unchanged, but new patterns of land ownership and domination required the production of a surplus for ruling institutions. Wealth finance worked similarly, but the local surplus was used to support the production of wealth for tribute payments.

And what about the market sector, so fundamental to most economic theorizing? Archaeological evidence documents that exchange and markets were not universal. From case to case, the amount and types of goods exchanged varied greatly according to specific conditions of availability and production costs and to specific objects of value. Based on ethnographic analogies, until quite recently most of the goods traded were probably handled by down-the-line exchanges between social partners. Goods moving any distance were primarily primitive valuables, items of display and tribute. The extent of exchange in Neolithic and later Bronze Age communities, for example, has been discussed for Europe, where the comparative advantage of one region over another would have been based on the availability of special materials (Sherratt, 1997). Subsistence and technological items were rarely exchanged over long distances until the end of the medieval age. Earlier, some market exchange certainly existed, but their extent and elaboration were apparently quite small.

This empirical record from economic anthropology contests economic theories based on asserted long-term trends in the emergence of marketing. A common assumption among economists from Adam Smith onwards has been that the creation of wealth is an outcome of the development of efficiencies associated with specialization and trade. For example, in his analysis of institutional economics, North (1990) argues that states developed to lower transaction costs between locally specialized but political independent regions. To simplify the logic, technological development and specialization should have created increasing productive economies that, with the emergence of integrating political systems to guarantee the peace of the market, would generate the surplus used to support the growth of civilizations. The development of markets, however, was quite late and episodic. Following North, economics might suggest that such failure of markets to develop was an outcome of high transaction costs that made exchange unprofitable. Empirically such a conclusion, however, can be shown to be wrong. As political superstructures were developed and imposed broad regional peace that would have radically lowered transactions costs, markets surprisingly did not emerge. The reason appears to be linked to the nature of finance. When finance was based on staples, markets were only rudimentary and peripheral. The complex Hawaiian chiefdoms, for example, conquered and integrated several islands with local specialties in food, stone and other materials, but trade remained very small-scale and local despite the regional peace. Archaeology has documented only minor trade in basaltic adzes and obsidian in
Hawaiian prehistory, and these exchanges did not increase with the formation of the large-scale chiefdoms. As a dramatic example, the Inka empire conquered a massive territory that extended 3,000 km up the spine of the Andes, imposed an effective regional peace across that territory, and constructed nearly 30,000 km of roads to integrate it. Although these actions would certainly have lowered transaction costs, the regional and distant movements of goods, like metal, ceramics, and foods, remained very limited and completely unchanged from the pre-imperial period (Earle, 2002).

Both markets and currencies seem to have expanded in other circumstances where they were linked with wealth finance of states. In the Aztec empire, tribute to the state was in wealth objects like textiles that could be easily transported long distances, centrally stored, and then used as payment to those working for the state. But the use of wealth objects in payment required that the objects be convertible into the staple goods and other consumables desired by state personnel. The Aztec market system provided the mechanism for conversion and was apparently developed by the state (Brumfiel, 1980). Afterwards, markets appear to have escaped from state sponsorship and control to take on many of the characterizations commonly associated with market systems.

What are the possibilities for a grand theory of economies? The relatively low status of historical and comparative studies within economics is not promising, but economics would do well to test theories claimed for generally applicability by looking closely at the anthropological literature. To the degree that economic models are used to design economic development in non-Western societies, the general relevance of the economic models must demonstrated. Using a uniform method of analysis, the economist Pryor (2005) has compared industrial economies and traditional (hunter-gatherer and agricultural) economies. His primary conclusions are startling, suggesting the advantages of such comparative analyses. All economies appear to consist of a small number of component parts, probably reflecting the processes and constraints involved in the production and movement of material goods. Economies are thus comparable. Furthermore, the factors that affect such variables as gross productivity or volume of exchange appear not to be determined by social structure but by the particular internal characteristics of the economy. Thus, Polanyi would appear to be wrong; economies are rather independent engines of essential processes. As recent work in economics has relaxed simplifying assumptions about information, frictionless trade, and anonymity of markets, the potential links between economics and economic anthropology take on reciprocal value.

In the 1930s, when the classical socialist system emerged, economic decisions were based not on detailed and precise economic methods of calculation but on rough and ready political methods. An important method of economic calculation – particularly in the post-Stalin period – was that of incrementalism. Input norms were a very important method of both inter-industry and consumption planning. Material balances, and later input–output, were also widely used. Project evaluation, linear programming, comparisons with the West, and economic intuition were other methods used. The influence of methods of economic calculation on economic outcomes should not be exaggerated.

Article
Economic calculation and political decisions

An important result of the archival revolution of the 1990s (that is, the access to former Soviet archives made possible by the collapse of the USSR) was the additional knowledge it provided about economic decision-making in the USSR in the Stalin period. This made it clear that in the 1930s, when the socialist economic system emerged, economic decisions were based not on detailed and precise economic methods of calculation but on rough and ready political methods. Interesting light has been thrown on the significance of this for macroeconomic, mesoeconomic and microeconomic decision making.

Macroeconomic policy in the Stalin era aimed to maximize investment subject to the need to provide sufficient consumer goods (mainly food) to maintain labour productivity. The consumer goods were obtained from agriculture by force and allocated by the state in a way which it was hoped would enable investment to be maximized. A schematic representation of short-term macroeconomic calculation under these circumstances is set out in Figure 1.

Figure 1
Maximizing the investible surplus. Source: adapted from Gregory and Harrison (2005, p. 732).
Figure 1 shows an output curve $QQ$ which depends on the effort the workers provide, and an effort curve $E_0,E_{max}$ which depends on the real wage and the level of coercion. If the state chooses too low a level of wages, output will decline and the intended investment level will be impossible to meet. If wages are set at the fair wage level, output will be maximized but investment less than desired. At the wage level $W^*$, investment will be maximized. Hence, macroeconomic calculation involved gathering information about worker attitudes.
the state security organizations), allocating the available food to crucial groups of workers, and using coercive or ideological methods to reduce the food–output ratio. Mesopolicy aimed at developing heavy industry and the defence sector. An important result was what has been termed the ‘structural militarization’ of the Soviet economy. This resulted from the Soviet view of international relations, the stress on mobilization planning, the lessons of 1941, and the use by the general staff of absurdly inflated estimates of the mobilization capacity of the USA and other countries. An example is the USSR’s capacity at the end of the 1980s to produce about four million tons of aluminium annually. This was greatly in excess of the peace-time economy’s need for aluminium. However, in the event of mobilization it would have enabled the country to produce huge numbers of military airplanes. This situation arose as a result of using as a method of economic calculation the attainment of Western levels and of these levels in the military sphere being systematically exaggerated.

On the microeconomic level, Lazarev and Gregory (2003) have studied the allocation of motor vehicles (cars/autos and lorries/trucks) from the central reserve fund in 1932 and 1933. This showed that an economic planning model was unable to explain their allocation (in the regressions the economic variables were insignificant and frequently had the wrong signs). But a political model, in which their allocation was explained as part of a gift-exchange process, explained the data quite well.

**Incrementalism**

A basic method of economic calculation used in the state socialist countries – particularly in the post-Stalin period – was that of incrementalism, or, as it was known in the USSR, ‘planning from the achieved level’. The starting point of all economic plans was the actual or expected outcome of the previous period. The planners adjusted this by reference to anticipated growth rates, current economic policy, shortages and technical progress. For nearly all products, the planned output for next year was the anticipated output for this year plus a few per cent added on. The advantages of incrementalism as a method of economic calculation were its simplicity, realism and compatibility with the functioning of a hierarchical bureaucracy. Its disadvantages were that it provided no method for making technically efficient or consistent decisions, nor did it ensure that the population derived maximum satisfaction from the resources available.

**Planning and counter-planning**

A widely used method of economic calculation was that of planning and counter-planning. If the plan were simply handed down to the enterprises from above, in accordance with the planners’ view of national economic requirements but in ignorance of the real possibilities of each enterprise, then it would be unfeasible (if it was too high) or wasteful (if it was too low) or both at the same time (that is, unfeasible for some products and wasteful for others). Conversely, if plans were simply drawn up by each enterprise, they might have failed to use resources in accordance with national economic requirements. The process of planning and counter-planning involved a mutual submission and discussion of planning suggestions, designed to lead to the adoption of a plan which was feasible for the enterprise and ensured that the resources of each enterprise were used in accordance with national requirements. Unfortunately, the bureaucratic complexity of this procedure militated against both efficiency and consistency.

**Input norms**

The main method of economic calculation used to ensure efficiency was that of input norms. An input norm is simply a number assumed to describe an efficient process of transformation of inputs into outputs. For example, suppose that the norm for the utilization of coal in the production of one ton of steel is $x$ tons. Then the efficient production of $z$ tons of steel is assumed to require $zx$ tons of coal.

The method of norms was widely used in Soviet planning, and considerable effort was devoted to updating them. Very detailed norm fixing took place for expenditures of fuel and energy. Much attention was devoted to the development of norms for the expenditure of metal, cement, and timber in construction. All this work was directed by the department of norms and normatives of Gosplan (the State Planning Commission). Responsibility for elaborating and improving the norms lay with Gosplan's Scientific Research Institute of Planning and Norms.

Nevertheless, the method of norms was incapable of ensuring efficiency. The norms used in planning calculations were simply averages of input requirements, weighted somewhat in favour of efficient producers. Actual technologies showed a wide dispersion in input–output relations. Furthermore, given norms took no account of the possibilities of substitution of inputs for one another in the production process, non-constant returns to scale, and the results of technical progress. Thus in general, the method of norms did not make it possible to calculate efficient input requirements, and plans calculated in this way were always inefficient.

The method of norms was used not only in inter-industry planning but also in consumption planning. In calculating the volume of particular consumer goods and services required, the planners used two main methods. One was forecasts of consumer behaviour, based on extrapolation, expenditure patterns of higher-income groups, income and price elasticities of demand, and consumer behaviour in the more advanced countries. The other method was that of consumption norms. The former method attempted to foresee consumer demand, the
latter to shape it.
An example of the method of norms, and its policy implications, is set out in Table 1.

Sources: Weitzman (1974); Agababyan and Yakovleva (1979, p. 142).

Table 1 makes clear the logic of the Soviet policy in the Brezhnev era (1964–82) of expanding the livestock sector, and also importing fodder and livestock products. Since the consumption of livestock products was below the norm level, the government sought to make possible an increase in their consumption.

The method of consumption norms was an alternative to the price mechanism for the determination of output. It has also been used, however, in Western countries. It is used there in those cases where distribution on the basis of purchasing power has been replaced by distribution on the basis of need. Examples include the provision of housing, hospitals, schools and parks. Calculations of the desirable number of rooms, hospital beds and school places per person are a familiar tool of planning in welfare states.

There are two main problems with the norm method of consumption planning. The first is that of substitution between products. Although consumers may well have a medically necessary need for x grams of protein per day, they can obtain these proteins from a wide variety of foods. Second, consumers may choose to spend their money ‘irrationally’, for example, to buy spirits instead of children’s shoes.

Material balances

A material balance is a balance sheet for a particular commodity showing, on the one hand, the economy’s resources and potential output, and, on the other, the economy’s need for a particular product. Material (and labour) balances were the main methods used in calculating production and distribution plans for goods, supply plans and labour plans. Soviet planners took great pride in the balance method and considered it one of the greatest achievements of planning theory and practice. Material balances were drawn up for different periods (for example, for annual or five year periods), by different organizations (for example, Gosplan, Gossnab – the body responsible for allocating supplies of inputs – and the ministries) and at different levels (for example, national, and republican). The material balances were also drawn up with different degrees of aggregation. Highly aggregated balances were drawn up for the Five Year Plans, and highly disaggregated balances by the chief administrations of Gossnab for annual supply planning. The aim of the material balance method was to ensure the consistency of the plans.

Normally, at the start of the planning work, the anticipated availability of a commodity was not sufficient to meet anticipated requirements. To balance the two, the planners sought possibilities of economizing on scarce products and substituting for scarce materials; they investigated the possibilities of increasing production or importing raw materials or equipment, or in the last resort they determined the priority needs to be fulfilled by the scarce commodity. Even with great efforts, achieving a balance was difficult. The complexity of an economy in which a great variety of goods are produced by different processes, all of which are subject to continuous technological change, was often too great for anything more than a balance that balanced only on paper. Hence it was normal, during the ‘planned’ period, for the plan to be altered, often repeatedly, as imbalances came to light. Particularly important problems with the use of material balances were the highly aggregated nature of the balances and their interrelated nature.

Input–output

A wide variety of input–output tables were regularly constructed in socialist countries. *Ex post* national tables in value terms, planning national tables in value and physical terms, regional tables, and capital stock matrices were widely constructed and used. An interesting and important use concerned variant calculations of the structure of production in medium-term planning.
Because an input–output table can be represented by a simple mathematical model, and because of the assumption of constant coefficients, an input–output table can be utilized for variant calculations.

\[ X = (I - \Delta)^{-1} Y \]

On the assumption that \( A \) is given, \( X \) can be calculated for varying values of \( Y \). Variant calculations of the structure of production were not undertaken with material balances because of their great labour intensity. Variant calculations played a useful role in medium-term planning because they enabled the planners to experiment with a wide range of possibilities. The first major use of variant calculations of the structure of production in Soviet national economic planning was in connection with the 1966–70 Five Year Plan. Gosplan's economic research institute analysed the results of various possible shares of investment in the national income for 1966–70. It became clear that stepping up the share of investment in the national income would increase the rate of growth of the national income, but that this would have very little effect on the rate of growth of consumption (because almost all of the increased output would be producer goods). The results of the calculations are set out in Tables 2 and 3.

The five variants are for the share of investment in the national income, I being the lowest and V the highest. A sharp increase in the share of investment in the national income in the Five Year Plan 1966–70 would have led to a sharp fall in the share of consumption in the national income, and only a small increase in the rate of growth of consumption (within a Five Year Plan period). What is very sensitive to the share of investment in the national income is the output of the producer goods industries, as Tables 2 and 3 show. These results are along the lines of what one would expect on the basis of Fel’dman's model, but the input–output technique improves on Fel’dman's model since it enables the effect of different strategies to be seen at the industry level rather than merely in terms of macroeconomic aggregates.

Another example of the use of input–output for economic calculations concerns the statistical data about the relations between industries contained in the national *ex post* tables in value terms. In his controversial 1968 book *Mezhotsraslevye svyazi sel'skogo khozyaistva*, M. Lemeshev, then deputy head of the sector for forecasting the development of agriculture of the USSR Gosplan's Economic Research Institute, used the Soviet input–output table for 1959 as the basis for a powerful plea for more industrial inputs to be made available to agriculture.

He began by observing that from the 1959 input–output table it was clear that of the current material inputs into agriculture in that year only 23.4 per cent came from industry, while 54.7 per cent came from agriculture itself (feed, seed and so on). He argued that this was most unsatisfactory. In the section on the relationship between agriculture and engineering Lemeshev argued that the supply to agriculture of agricultural machinery was inadequate, in the section on the relationship between agriculture and the chemical industry he argued that the supply of fertilizers was inadequate, and in the section on agriculture and electricity he argued that the supply of electricity to the villages for both productive and unproductive needs was inadequate. In addition, in the section on the relationship between agriculture and the processing industry he argued that the latter was not helping agriculture as it should do; for example, it was sometimes impossible to accept vegetables (although the consumption of these in the towns was below the norms) because of inadequate processing and distribution facilities. Furthermore, he argued that the supply of concentrated feed was inadequate and the processing of milk wasteful. In view of the inadequate development of the food processing industry, he argued for the development of processing enterprises by the farms themselves.
The chapter on the productive relations between agriculture and the building industry was an extensive critique of the practice of productive, and of housing and communal, building in the villages. Lemeshev argued that the state should take on responsibility for building on the collective farms. The chapter on investment argued that investment in agriculture was inadequate, and that in the period 1959–65 there was an unwarranted increase in the proportion of investment in the collective farms which they had to finance themselves. He also argued that a greater proportion of agricultural investment should be financed by bank loans, and that as a criterion of investment efficiency the recoupment period was satisfactory. The concluding chapter was concerned with improving the productive relations between agriculture and the rest of the economy. The author argued for improving central planning by the use of input–output, for replacing procurement plans by free contracts between farms and the procurement organs (if a shortage of a particular product threatened then its price could be raised), and for the elimination of the supply system (that is, the rationing of producer goods) which hindered farms from receiving the goods they wanted and sometimes supplied them with goods that they did not want. Lemeshev also argued for higher pay in agriculture and for the reorganization of the labour process within state and collective farms on the basis of small groups which were paid by results.

This book was a good example of the use of input–output to provide statistical data which could be used, alongside other information, to provide a description of important economic relations and to support a case for important institutional and policy changes.

Project evaluation

In the USSR of the 1930s, it was officially considered that there was no problem of project evaluation to which economists could contribute. The sectoral allocation of investment was a matter for the central political leadership to decide. It was they who decided in which sectors and at which locations production should be expanded. These decisions were based on the experience of the more advanced countries, the traditions of the Russian state (for example, stress on railway building) and of the Bolshevik movement (for example, stress on electrification and on the metal-using industries) and on the needs of defence. As far as decisions within sectors were concerned, here the main idea was to fulfil the plan by using the world’s most advanced technology.

The practical study of methods for choosing between variants within sectors was begun by engineers in the electricity and railway industries. The problem analysed was that of comparing the cost of alternative ways of meeting particular plan targets. A classic example of the type of problem considered was the choice between producing electricity by a hydro station and by a thermal station.

During Stalin’s lifetime, the elaboration by orthodox economists and the adoption by the planners of economic criteria for project evaluation were impossible because they were outside Stalin’s conception of the proper role of economists (apologetics). When economists did make a contribution in this area, as was done by Novozhilov, it was ignored. After Stalin’s death, however, it became possible for Soviet economists to contribute to the elaboration of methods of economic calculation for use in the decision-making process. An early and important example was in the field of project evaluation. An official method for project evaluation was adopted in 1960, and revised versions in 1964, 1966, 1969 and 1981. In a very abbreviated and summary form, the 1981 version was as follows.

In evaluating investment projects, a wide variety of factors have to be taken into account, for example, the effect of the investment on labour productivity, capital productivity, consumption of current material inputs (such as metals and fuel), costs of production, environmental effects, technical progress, the location of economic activity and so on. Two indices which give useful synthetic information about economic efficiency (but are not necessarily decisive in choosing between investment projects) are the coefficient of absolute economic effectiveness and the coefficient of relative economic effectiveness.

At the national level, the coefficient of absolute effectiveness is defined as the incremental output–capital ratio.

\[
E_p = \frac{\Delta Y}{I}
\]

where \( E_p \) is the coefficient of absolute effectiveness for a particular project, \( \Delta Y \) is the increase in national income generated by the project, and \( I \) is the investment cost. The value of \( E_p \) calculated in this way for a particular investment has to be compared with \( E_a \), the normative coefficient of absolute effectiveness, which is fixed for each Five Year Plan and varies between sectors. In the 11th Five Year Plan (1981–85) it was 0.16 in industry, 0.07 in agriculture, 0.05 in transport and communications, 0.22 in construction and 0.25 in trade.

\[\text{If } E_p > E_a\]
then the project is considered efficient. For calculating the criterion of absolute effectiveness at the level of individual industries, net output is used in the numerator instead of national income. At the level of individual enterprises and associations, in particular when a firm's own money or bank loans are the source of finance, profit is used instead of national income. The coefficient of relative effectiveness is used in the comparison of alternative ways of producing particular products. In the two products case

\[ E = \frac{C_1 - C_2}{K_2 - K_1} \]

where \( E \) is the coefficient of relative effectiveness, \( C_i \) is the current cost of the \( i \)th variant, and \( K_i \) is the capital cost of the \( i \)th variant.

If \( E > E_n \), where \( E_n \) is the officially established normative coefficient of relative economic efficiency, then the more capital intensive variant is economically justified. In the 11th Five Year Plan, \( E_n \) was in general 0.12, but exceptions were officially permitted in the range 0.08/0.10–0.20/0.25.

In the more than two variants case, they should be compared according to the formula

\[ C_i + E_n K_i \rightarrow \text{minimum} \]

that is, choose that variant which minimizes the sum of current and capital costs.

At one time a rationalist misinterpretation of socialist planning was widespread. According to this view, a planned economy was one in which rational decisions were made after a dispassionate analysis by omniscient and all-powerful planners of all the alternative possibilities. In such a system, the adoption of rational criteria for project evaluation would have been of enormous importance. Socialist planning, however, was just one part of the social relations between individuals and groups in the course of which decisions were taken, all of which were imperfect and many of which produced results quite at variance with the intentions of the top economic and political leadership.

A good example of the factors actually influencing investment decisions under state socialism was the commencement of the construction of the Baoshan steel plant near Shanghai. The site was apparently chosen because of the political influence of a high-ranking Shanghai party official. The location decision ignored the fact that, because of the swampy nature of the site, necessitating large expenditures on the foundations, this was in fact the most expensive of the sites considered. Very expensive, dogged with cost overruns, involving major pollution problems, the whole project was kept alive for some time by a powerful steel lobby. In due course, as a result of a national policy reversal in Beijing, the second phase was deferred and those involved publicly criticized. To judge from its initial costs of production, it produced gold rather than steel.

In general, the choice of projects owed more to inter-organization bargaining in an environment characterized by investment hunger than it did to the detached choice of a cost-minimizing variant. The development of new and better criteria for project evaluation turned out to be no guarantee that project evaluation would improve since the criteria were often not in fact used to evaluate projects. Their main function was to provide an acceptable common language in which various bureaucratic agencies conducted their struggles. Agencies adopted projects on normal bureaucratic grounds and then tried to get them adopted by higher agencies, or defended them against attack, by presenting efficiency calculations using the official methodology but relying on carefully selected data.

**Linear programming and extensions**

Linear programming was discovered by the Soviet mathematician Kantorovich in the late 1930s. Its relevance for Soviet planning was widely discussed in the USSR in the 1960s and extensive efforts were made actually to use it in Soviet planning in the 1970s. Three examples of its use follow.

**Production scheduling in the steel industry**

Linear programming was discovered by Kantorovich in the course of solving the problem, presented to him by the Laboratory of the all-Union Plywood Trust, of allocating productive tasks between machines in such a way as to maximize output given the assortment plan. From a mathematical point of view, the problem of optimal production scheduling
for tube mills and rolling mills in the steel industry, which was tackled by Kantorovich in the 1960s, is very similar to the Plywood Trust problem, the difference being its huge dimensions.

The problem arose in the following way. As part of the planning of supply, Soyuzglavmetal (the department of Gossnab concerned with the metal industries), after the quotas had been specified, had to work out production schedules and attachment plans in such a way that all the orders were satisfied and none of the producers received an impossible plan. In the 1960s an extensive research programme was initiated by the department of mathematical economics (which was headed by Academician Kantorovich) of the Institute of Mathematics of the Siberian branch of the Academy of Sciences, to apply optimizing methods to this problem. The chief difficulties were the huge dimensions of the problem and the lack of the necessary data. About 1,000,000 orders, involving 60,000 users, more than 500 producers and tens of thousands of products, were issued each year for rolled metal. Formulated as a linear programming problem it had more than a million unknowns and 30,000 constraints. Collecting the necessary data took about six years. Optimal production scheduling was first applied to the tube mills producing tubes for gas pipelines (these were a scarce commodity in the USSR). In 1970 this made possible an output of tubes 108,000 tons greater than it would otherwise have been, and a substantial reduction in transport costs was also achieved.

The introduction of optimal production scheduling into the work of Soyuzglavmetal was only part of the work initiated in the late 1960s on creating a management information and control system in the steel industry. This was intended to be an integrated computer system which would embrace the determination of requirements, production scheduling, stock control, the distribution of output and accounting. Such systems were widely introduced in Western steel firms in the late 1960s. Work on the introduction of management information and control systems in the Soviet economy was widespread in the 1970s, but by the 1980s there was widespread scepticism in the USSR about their usefulness. This largely resulted from the failure to fulfil the earlier exaggerated hopes about the returns to be obtained from their introduction in the economy.

### Industry investment plans

In the state socialist countries investment plans were worked out for the country as a whole, and also for industries, ministries, departments, associations, enterprises, republics, economic regions and cities. An important level of investment planning was the industry. Industry investment planning is concerned with such problems as the choice of products, of plants to be expanded, location of new plants, technology to be used, and sources of raw materials.

The main method used in the 1970s and 1980s in the Council for Mutual Economic Assistance (CMEA, known in the West as Comecon) countries for processing the data relating to possible investment plans into actual investment plans was mathematical programming. After extensive experience in this field, in 1977 a Standard Methodology for doing such calculations was adopted by the Presidium of the USSR Academy of Sciences.

The Soviet Standard Methodology presented models for three standard problems. They were: a static multi-product production problem with discrete variables, a multi-product dynamic production problem with discrete variables, and a multi-product static problem of the production-transport type with discrete variables. The former can be set out as follows:

Let \( I = 1, \ldots, n \) be the finished goods or resources, \( J = 1, \ldots, m \) be the production units, \( r = 1, \ldots, R \) be the production technique in a unit, \( a_{ir}^j \) be the output of good \( I = 1, \ldots, n \) or input of resource \( I = 1, \ldots, n \), using technique \( r \) of production in unit \( j \); \( c_{ij}^r \) are the costs of production using technique \( r \) in unit \( j \); \( D_i \) is the given level of output of good \( i \), \( i = 1, \ldots, n \); \( P_i \) is the total use of resource \( i \), \( i = 1, \ldots, n \) allocated to the industry; \( z_{ij}^r \) is the unknown intensity of use of technique \( r \) at unit \( j \).

The problem is to find values of the variables \( z_{ij}^r \) that minimize the objective function

\[
\sum_{j=1}^{m} \sum_{r=1}^{R_j} c_{ij}^r z_{ij}^r
\]

that is, minimize costs of production subject to

\[
\sum_{j=1}^{m} \sum_{r=1}^{R_j} a_{ir}^j z_{ij}^r = D_i, \quad i = 1, \ldots, n
\]
that is, each output must be produced in at least the required quantities

\[ \sum_{j=1}^{m} \sum_{r=1}^{R_j} \alpha_{j,r} z_{j,r} = p_{i}, \quad i = n' + 1, \ldots, n \]  

(3)

that is, the total use of resources cannot exceed the level allocated to the branch

\[ \sum_{r=1}^{R_j} z_{j,r} \leq 1, \quad j = 1, \ldots, m \]  

(4)

that is, either a single technique of production for unit \( j \) is included in the plan or unit \( j \) is not included in the plan.

In order to illustrate the method, an example will be given which is taken from the Hungarian experience of the 1950s in working out an investment plan for the cotton weaving industry for the 1961–65 Five Year Plan. The method of working out the plan can be presented schematically by looking at the decision problems, the constraints, the objective function and the results.

The decision problems to be resolved were:

1. (a) How should the output of fabrics be increased, by modernizing the existing weaving mills or by building new ones?
2. (b) For part of the existing machinery, there were three possibilities. It could be operated in its existing form, modernized by way of alterations or supplementary investments, or else scrapped. Which should be chosen?
3. (c) For the other part of the existing machinery, it could be either retained or scrapped. What should be done?
4. (d) If new machines are purchased, a choice has to be made between many types. Which types should be chosen, and how many of a particular type should be purchased?

The constraints consisted of the output plan for cloth, the investment fund, the hard currency quota, the building quota and the material balances for various kinds of yarn. The objective function was to meet the given plan at minimum cost.

The results provided answers to all the decision problems. An important feature of the results was the conclusion that it was cheaper to increase production by modernizing and
expanding existing mills than by building new ones.

It would clearly be unsatisfactory to optimize the investment plan of each industry taken in isolation. If the calculations show that it is possible to reduce the inputs into a particular industry below those originally envisaged, then it is desirable to reduce planned outputs in other industries, or increase the planned output of the industry in question, or adopt some combination of these strategies. Accordingly, the experiments in working out optimal industry investment plans, begun in Hungary in the 1950s, led to the construction of multi-level plans linking the optimal plans of the separate industries to each other and to the macroeconomic plan variables. Multi-level planning of this type was first developed in Hungary, but subsequently spread to the other CMEA countries. Extensive work on the multi-level optimization of investment planning was undertaken in the USSR in connection with the 1976–90 long-term plan. (The 1976–90 plan, like all previous Soviet attempts to compile a long-term plan, was soon overtaken by events. The plan itself seems never to have been finished and was replaced by ten-year guidelines for 1981–90.)

**The determination of costs in the resource sector**

In view of the wide dispersion of production costs in the resource sector, the use of average costs (and of prices based on average costs) in allocation decisions is likely to lead to serious waste. An important outcome of the work of Kantorovich and his school for practical policy was (after a long lag) official acceptance of this proposition and of linear programming as a way of calculating the relevant marginal costs. For example, in 1979 in the USSR the State Committee for Science and Technology and the State Committee for Prices jointly approved an official method for the economic evaluation of raw material deposits. This was a prescribed method for the economic evaluation of exploration and development of raw material deposits. What was new in principle about this document was that it permitted the output derived from the deposits to be evaluated either in actual (or forecast) wholesale prices or in marginal costs. For the fuel-energy sector, a lot of work was done to calculate actual (and forecast) marginal costs for each fuel at different locations throughout the country and for different periods. These figures were regularly calculated on optimizing models (they were the dual variables to the output maximizing primal) and were widely used in planning practice for many years.

**Comparison with the West**

An important method of economic calculation in socialist countries was comparison with the West. If a particular product or method of production had already been introduced (or phased out) in the West, this was generally considered a good argument to introduce it (or phase it out) in the socialist countries, subject to national priorities and economic feasibility. Obtaining advanced technology from abroad (by purchase, Lend-Lease, reparations, espionage, direct investment) was an integral part of socialist planning, the importance of the different elements varying over time. Comparisons with the West were particularly important in an economic system which lagged behind the leading countries, lacked institutions which automatically introduced innovations into production (that is, profit-seeking business firms), and found it difficult (because of the ignorance of the planners, stable cost-plus prices and the self-interest of rival bureaucratic agencies) to notice, appraise realistically when noticed, and adopt, innovations.

**Economic calculation and economic results**

It is important not to exaggerate the influence of methods of economic calculation on the performance of an economy. The performance of an economy is largely determined by external factors (such as the world market), economic policy (for example, the decision to import foreign capital or to declare a moratorium), economic institutions (like collective farms) and the behaviour of the actors within the system (for example, underestimation of investment costs by initiators of investment projects). It is entirely possible for an improvement in the methods of economic calculation to coincide with a worsening of economic performance (as happened in the USSR in the Brezhnev period). Realization of these facts led in the 1970s to a shift from the traditional normative approach (which concentrates on the methods of economic calculation and which regards their improvement as the main key to improved economic performance and the main role of the economist) in the study of planned economies, to the systems and behavioural approaches.

**Economic calculation and economic intuition**

In view of bounded rationality, and the huge volume, and distorted nature, of the information available to the central leadership, really existing decision-making relied heavily on rules of thumb and the ‘feel’ for reality of the top decision-makers (sometimes known as ‘planning by feel’). This could quickly lead to an equilibrium, but an inefficient one.

Article
Economic demography is an area of study that examines the determinants and consequences of demographic change, including fertility, mortality, marriage, divorce, location (urbanization, migration, density), age, gender, ethnicity, population size, and population growth. An applied area of research, economic demography draws upon the theoretical and applied fields of economics. For example, the determinants of fertility or migration primarily draw upon microeconomic theory and labour economics, while the consequences of population growth or ageing primarily draw upon macroeconomic theory and development economics.
The field has had a long tradition of controversy, beginning with the publication in 1798 of An Essay on the Principle of Population by the Reverend Thomas Malthus. The basic Malthusian model is founded on two propositions: (a) population, *when unchecked*, increases at a geometric rate (for example, 1, 2, 4, 8…) and (b) food, in contrast, expands at an arithmetic rate (for example, 1, 2, 3, 4…). The result is a population trapped at a meagre standard of living. Short of ‘preventive checks’ (birth control), population is constrained to live at subsistence by ‘positive checks’ (deaths, war, famines and pestilence). In later writings Malthus admitted the possibility of ‘moral restraint’ that could deter births, primarily through the postponement of marriage. However, he held little hope for a notable attenuation of the ‘natural passions’ of the working class.

While much of the controversy relating to Malthusianism has focused on the determinants of population growth, a second premise of his model relates to its economic underpinnings: the determinants of agricultural growth. Here Malthus appealed to the historical law of diminishing returns in agriculture. While this proposition engendered relatively little dispute at the time, history has since documented widespread and sometimes notable improvements in agricultural technology. Indeed, food production has represented an engine of growth in many of the areas that Malthus investigated. In some areas today, governments worry about ‘excess’ food production that depresses prices and farmers’ living standards. Unfortunately, the pessimistic food-production predictions, when confronted by rapid population growth, caused economics to be dubbed the ‘dismal science’.

The enormous popularity of the Malthusian ideas was the result of several factors: the model's simplicity and its explanation of poverty (the poor failed to exercise moral restraint, ending up with large families); the appeal of the message that subsidizing the poor is of questionable efficacy; and the plausibility of the Malthusian argument given the unexpected ‘population explosion’ revealed by the 1801 census. These and other elements of the ‘Malthusian debate’ provide a useful taxonomy for organizing the present article.

Specifically, we highlight the macroeconomic dimensions of the economic consequences of population growth since 1950. As with the early Malthusian debates, an assessment of the macroeconomic impacts of demographic change on economic production has resulted in an outpouring of research, which has spawned further debate. There are periods when vigorous Malthusian-like alarmism has carried the day; there are periods of counter-challenges; and, since the mid-1980s, there has been a productive ‘revisionist’ movement. In short, the simplistic Malthusian notion of diminishing returns in production has given way to more informed modelling of economic–demographic interactions. An assessment of the historical evolution of this literature will constitute the bulk of this review and appropriately delimits the scope of our essay since a wide range of important microeconomic themes are taken up in other articles in this dictionary (see fertility in developing countries, family decision making, marriage and divorce, retirement, and multiple articles dealing with the topics of gender, ageing and mortality).

We begin by examining population impacts in one-sector growth models. This leads nicely into a more detailed assessment of factor accumulation, and in particular, the impacts of demography on saving, investment and technological change. This is in turn followed by an analytical description of the evolution of economic–demographic thinking since 1950. Such a perspective exposes many of the key analytical and empirical linkages of interest. The article concludes with an examination of ‘convergence modelling’, a useful paradigm that exposes the roles of changing demographic structures that take place over the demographic transition.
1 Theory: modelling economic–demographic change

1.1 One-sector growth models

The aggregate production function constitutes the primary organizing device for delineating the impacts of demographic change on economic growth. Within this model, labour productivity depends on the availability of complementary factors of production (land, natural resources, human and physical capital) and technology. If we assume, for convenience, that labour is a constant fraction of population, then population size directly affects aggregate output.

In a production function with constant returns to scale, an increase in population growth will lower the average availability of other factors of production – a ‘resource-shallowing’ effect, and, through diminishing returns, reduce the growth of worker productivity. Such an adverse demographic impact can be magnified (or attenuated) if population growth diminishes (raises) the growth rate of complementary factors.

In a standard growth model with factor inputs of labour and capital, and a saving rate and pace of technological change that are exogenous with respect to population growth, demography affects the long-run level but not the long-run growth rate of output per capita. This is because the capital-shallowing effect of increased population will eventually reduce the capital per worker ratio to a level sufficient to be maintained by a fixed rate of saving. In this case, long-run growth is determined by the pace of technological change. The determinants of the ‘fixed’ saving rate and pace of technology growth, both considered in more detail below, are central to the analysis.

If one relaxes some of the assumptions of this model, the impact of population growth on per capita output growth can be ambiguous. Negative impacts can arise through diminishing returns, diseconomies of scale, and perhaps savings, while positive impacts can arise through induced technological change, economies of scale, and possibly savings. Most economists believe that adverse capital-shallowing impacts will dominate positive feedback effects, although the magnitude of the demographic impacts may not be all that large.

1.2 Saving

Possibly the most investigated linkage of population growth to economic growth has been the impact of demographic change on saving. Two perspectives dominate.

Adult equivalency. Rapid (slow) rates of population growth result in a disproportionate number of children (elderly adults) who consume, but contribute relatively little to, household income. In recognizing that these ‘dependents’ consume less than a working-age adult, the notion of an ‘adult equivalent’ consumer was born. The financing of an additional child’s ‘adult-equivalent’ consumption has been hypothesized to be out of saving. Such a view, however, has been challenged by consideration of several offsetting alternatives. Specifically, children may (a) substitute for other forms of consumption, (b) contribute directly to household market and non-market income, (c) encourage parents to work more (or less), (d) stimulate the amassing (or reduction) of estates, and (e) encourage (or discourage) the accumulation of certain types of assets (for example, education or farm implements).

The net impact of changing dependency rates on saving is therefore theoretically ambiguous. This is particularly the case if one views human capital as an investment financed in part by households and...
governments. At any rate, empirical evidence showing negative impacts of youth dependency on saving are found in several studies.

The life-cycle. A second population-saving linkage is based on a life-cycle formulation incorporated into a lifetime household utility function. Specifically, households attempt to even out their lifetime consumption by setting aside earnings during working years to finance consumption by their children as well as for their own retirement. This formulation can yield positive or negative impacts on aggregate saving depending on the relative sizes of the dissaving youth and elderly cohorts. While empirical evidence from life-cycle modelling is mixed, those studies do tend to show linkages between age structure and saving. However, the direction and magnitude of that impact depends upon time and place. (See, for example, Mason, 1987; Higgins, 1998; and Lee, Mason and Miller, 2001.)

1.3 Population-sensitive government spending

Government spending on population-sensitive activities such as schooling (youth) and health (elderly) has been alleged both to reduce saving and to crowd out spending on relatively growth-oriented investments. These two hypotheses constitute the core of Ansley J. Coale and Edgar M. Hoover's (1958) path-breaking study of India. While these premises are appealing, they require qualification. Governments have many options to accommodate population pressures. Indeed, limited empirical evidence (for example, Schultz, 1987) has shown that education financing can be met all or in part by (a) trade-offs within the public sector, (b) reductions in per pupil expenditures, and (c) efficiency gains. While the second approach can be expected to reduce the quality of education (and therefore future productivity), the importance of population pressures on government spending or educational quality is uncertain.

1.4 Technological change: density, size and endogenous growth

While development economists have for decades harkened the pace of technological change as a (the?) major source of economic growth, most standard growth theory models take the rate of technological change as exogenous. With technological change independent of demographic change, population growth per se will have no impact on the pace of economic growth in long-run equilibrium. By contrast, if technological change is all or in part embodied in new investment, then a vintage specification is appropriate whereby new capital is relatively more productive than old. In this set-up, population growth can be economic-growth enhancing by expanding the rate at which technology is incorporated into production. In yet another specification, population growth can directly affect the rate of technological change and/or its form (factor bias). Kenneth J. Arrow (1962) has hypothesized that learning by doing is quickened in an environment of rapid employment growth.

A fourth linkage between technology and demography is found in ‘endogenous growth’ models that relate the pace of technology directly to population size. In particular, the benefits of R&D are assumed to be available to all firms without cost; that is, an R&D industry generates a non-rival stock of knowledge. As a result, if we hold constant the share of resources used for research, an increase in population size advances technological change without limit. This somewhat controversial prediction has been qualified by models that incorporate various firm- or industry-specific constraints on R&D.
production. Such models typically reduce, but do not eliminate, the positive impacts of population size which, as in the embodiment models above, are manifested largely during the ‘transition’ to long-run equilibrium.

Evidence on the roles of demographic-technology linkages and growth has been fragmentary and sparse. A pioneering study by Hollis Chenery and Moises Syrquin (1975) draws upon the experience of 101 countries across the income spectrum over the period 1950–70. They find that the structure of development reveals strong and pervasive scale effects (measured by population size) that vary by stage of development. Basically, small countries develop a modern productive industrial structure more slowly and later, while large countries have higher levels of accumulation and (presumably) higher rates of technological change. Although these roles for demography may have been important historically, the impacts plausibly have waned somewhat: (a) economies in infrastructure are judged to be substantially exhausted in cities of moderate size; (b) specialization through international trade provides a means of garnering some or many of the benefits of size; and (c) scale effects are most prevalent in industries with relatively high capital–labour ratios and such industries are inappropriate to the factor proportions of developing countries.

It is in agriculture where the positive benefits of population size have been most discussed. Higher population densities can lower per unit costs and increase the efficiency of transport, irrigation, extension services, markets and communications (Glover and Simon, 1975). Possibly the most cited work is that by Ester Boserup (1965; 1981), who observes that increasingly productive agricultural technologies are made economically attractive in response to higher land densities. While this is probably true, the issue becomes one of identifying the quantitative magnitude of such effects over varying population sizes and in differing institutional settings. One must be cautious in attributing causation. For example, while high population densities may have accounted for a portion of expanded agricultural output in recent decades, in several important Asian countries these densities were sufficiently high decades ago to justify the investments associated with the new technologies. Boserup in more recent writing has been less sanguine about the benefits of population size because densities appropriate to modern technologies in Asia are three to four times the average for Africa and Latin America.

In short, a wide-ranging review of the literature does not provide a strong consensus on the quantitative linkages between the size and growth of population, on the one hand, and the pace of technological change and economic growth, on the other hand.

1.5 The bottom line

An evaluation of population growth on economic growth through the filter of formal economic-growth modelling yields limited results: population growth affects the level but not the growth of per capita income in long-run equilibrium. Moreover, the key determinants of long-run growth are saving and technology. Only if these factors depend on demographic change does population matter. This somewhat constraining limitation of growth theory has caused researchers to branch out and explore a host of economic–demographic interactions using less formal paradigms. This blossoming literature has been extensive, lively and sometimes contentious.
2 Evolution of population-impacts thinking: 1950–90

Four major studies, two by the United Nations (1953; 1973) and two by the National Academy of Sciences (1971; 1986), reveal well the evolution of thinking on population matters over the period 1950–90. Three individual scholars, Coale and Hoover and Simon, also played prominent and important roles. (This section draws on Kelley, 2001.)

2.1 United Nations, 1953

The 1953 United Nations report, *Determinants and Consequences of Population Trends*, easily represents the most important contribution to population thinking since the writings of Malthus. Unlike Malthus, however, the UN study was balanced and exhaustive both in detail and in coverage. Some 21 linkages between population and the economy were taken up. For example, the impacts of population on the economy can be: (a) positive due to economies of scale and organization; (b) negative due to diminishing returns; or (c) neutral due to technology and social progress. An evaluation of these and other linkages led to a mildly negative overall assessment that was both cautious and qualified. The most notable feature of this report was its methodology. More than any major study on population to that time, the UN Report embraced a methodology that would ultimately represent elements of modern-day ‘revisionism’. Specifically, the report (a) downgraded the importance of population growth's impact on economic growth by placing it on a par with several other determinants of equal or greater impact; (b) assessed the consequences of population over a long period of time; and (c) emphasized the importance of feedbacks within and between the economic and political systems.

2.2 Coale and Hoover, 1958

The next major contribution to the population-impacts literature was provided by Ansley J. Coale and Edgar M. Hoover in their 1958 book *Population Growth and Economic Development in Low-Income Countries*. Based on simulations of a mathematical model calibrated with Indian data, they concluded that India's development would be enhanced by lower population growth. This was due to the hypothesized adverse impacts of population on household saving. It was also proffered that ‘unproductive’ investments in human capital (such as health and education) would partially displace investments in ‘relatively productive’ forms (such as machines and factories). Economic growth would diminish in response. Empirically, the above hypotheses have not been convincingly established. While several studies have exposed negative dependency-rate impacts on saving, there are others that show little or no impact. Overall, the findings are mixed, with a tilt toward supporting the Coale and Hoover formulation. (See Section 1.2 above for a discussion of the trade-offs that households can make to maintain saving in response to expanding family size.) Similarly, there are alternative ways for governments to organize and finance schooling in response to population pressures. Unfortunately, studies of this are limited, although one by T. Paul Schultz (1987) finds no support for the Coale and Hoover (1958) formulation.
2.3 National Academy of Sciences, 1971

Arguably the most pessimistic assessment of the consequences of population growth was a study compiled by the National Academy of Sciences (NAS). The panel's final submission, *Rapid Population Growth: Consequences and Policy Implications*, issued in 1971, appeared in two volumes: Volume 1, *Summary and Recommendations*, and Volume 2, *Research Papers*. Unfortunately, the *Summary* volume appeared to be more political than academic in goal and orientation, and was not faithful to many of the underlying research reports assembled by the panel. Indeed, the *Summary* volume highlighted some 25 alleged negative consequences of population growth, whereas it downplayed or eliminated impacts that could be considered as ‘neutral’ or ‘favourable’. As a result, the *Summary* represents an upper bound on the negative consequences of population growth. (A detailed documentation exposing the somewhat controversial way in which the *Summary* was compiled is provided by Kelley, 2001.)

What can be learned from the NAS study? First, given its apparent bias and the lack of a systematic vetting of Volume 1 by members of the panel, it is difficult to use that volume, either in full or in part. However, the individual papers are available and they, in total, offer a more balanced treatment. Second, by its own acknowledgment, the study focused on the short run when negative impacts of population change are most likely to prevail. (‘We have limited ourselves to relatively short term issues’; 1971, p. vi.) By contrast, ‘direct’ (short-run) impacts of demographic change are almost always attenuated (and sometimes offset) by ‘indirect feedbacks’ that occur over longer periods of time. Thus the decision by the NAS panel to focus only on the short-run direct impacts resulted in an overly negative assessment of the consequences of population growth.

Third, economists were underrepresented on both the panel and in providing background reports. This is relevant since economists have substantial faith in the capacity of markets, individuals and institutions to adjust in the face of population pressures. Such adjustments, of course, take time and they are not without cost. Finally, this NAS Report provides a striking example of the difficulty of maintaining objectivity when social science research enters the public policy domain.

2.4 United Nations, 1973

In 1973 the United Nations weighed in with an update of its previous seminal work (United Nations, 1953). In contrast to the broadly eclectic stance in the earlier report, the new one ended with a mild to moderate negative overall assessment of rapid population growth. The authors were concerned with the ability of agriculture to feed expanding populations (à la Malthus) and the difficulty of offsetting capital shallowing (à la Coale and Hoover). Still, the 1973 Report, whose conclusions are highly qualified, is not alarmist, nor is it all that pessimistic. The reason for this moderate stance was the exceptionally influential empirical finding of Simon Kuznets (1960, pp. 19–20, 63) that notable negative correlations between population growth and per capita output growth were largely absent in the data. Given the strong priors of some contributors to the UN study, a failure to find a negative association in the aggregate data by a scholar with impeccable credentials had a profound impact. Indeed, this singular finding arguably kept the population debate alive for yet another round of assessments in the 1980s.

2.5 Revisionism, 1980s and beyond
The 1980s represented a decade when many of the underlying assumptions and conclusions of earlier studies of population–development interactions were subjected to critical scrutiny. The result was a revisionist rendering that was both surprising and controversial. Specifically, the revisionists downgraded the prominence of population growth as either a major source of, or a constraint on, economic prosperity in the Third World. The basis of this somewhat startling conclusion was the revisionists’ methodology that (a) assessed the consequences of demographic change over longer periods of time and (b) expanded the analysis to take into account indirect feedbacks within economic and political systems. In general, empirical assessments of population growth will be smaller (less negative or less positive) when using the revisionist’s methodology than when focusing on the short run and ignoring feedbacks. On net, most revisionists conclude that many, if not most, Third World countries would benefit from slower population growth.

2.6 Julian L. Simon, 1981

No one was more important in stimulating the new round of debates in the 1980s than Julian L. Simon, author of *The Ultimate Resource* (1981). This book attracted enormous attention, substantially because of two factors. First, it concluded that population growth would likely provide a positive impact on economic development of many developed, and some less developed, countries. Second, the book was accessible, well written, and organized in a ‘debating’, confrontational style. This included goading and prodding, the setting up and knocking down of straw men, and an examination of albeit popular, but somewhat extreme, anti-natalist positions. Simon's powerful book helped spawn a group of survey articles in the 1980s.

What accounts for Simon's positive assessments? Simon was an early advocate of evaluating the full effects of population over the intermediate to long run. He argued that the negative ‘direct’ impacts in the short run will probably be moderated, or sometimes overturned, when households, businesses, and/or governments react to changing prices which signal problems of resource scarcity. Two important examples of responses to population pressures can be cited: those relating to technological change and those relating to natural resource scarcity, both highlighted by Simon.

*Technological change.* Simon hypothesized and attempted to document that the pace of technological change, and its bias, can be stimulated by population pressures. Technological change, in turn, plays a central role in economic growth theory and has been shown in sources-of-growth studies to be a (the?) key to economic growth. Additionally, with respect to population size impacts in general, Simon observes that major social overhead projects (for example, roads, communications and irrigation) have benefited from expanded populations and scale. (For more detail, see Section 1.4 above.)

*Resource depletion.* Consider next the impacts of population growth on natural resource depletion. Theoretically an exhaustion of non-renewable resources (for example, coal and minerals) would appear to be inevitable in the long run. However, such a period may be in the indeterminably distant future. By contrast, Simon argued that the most relevant measure of resource scarcity is its price. He prepared many graphs of US non-renewable resource prices (deflated by price indexes in order to focus on ‘real’ resource trends).

Surprisingly, virtually every resource has experienced a declining real price over lengthy periods of time. This means, à la Simon, that resources are becoming more abundant over time. It seems that the...
more resources are used, the more abundant they become! How can this happen? Simple. A rising resource price, due in part to population pressures, triggers several reactions that reduce or even eliminate the apparent resource scarcity. Specifically, in the short run, rising prices encourage an economizing of the resource at every level of production and consumption. In the longer run, rising prices stimulate exploration, new methods of extraction and process, and the search for substitutes. Nevertheless, Simon recognized that market failures, institutional failures, and political factors can all result in less-than-complete adjustments when population and economic development press against resource availabilities. This is particularly the case with renewable resources (such as rain forests, fisheries, the environment, and so forth) where market or institutional failures are pervasive. Without mechanisms to assign and maintain property rights, internalize externalities, and address free rider problems of public and quasi-public goods, government regulation may be required to safeguard renewable resources over time.

2.7 National Academy of Sciences, 1986

Some 15 years after the 1971 National Academy Report that highlighted 25 negative consequences of population growth, a new National Academy Report was released. In contrast to the previous study, the new report was balanced, eclectic and non-alarmist. A careful examination of its bottom line is instructive. ‘On balance, we reach the qualitative conclusion that slower population growth would be beneficial to economic development of most developing countries.’ (1986, p. 90; emphasis added)

This qualified assessment reveals key features found in most population assessments in the 1980s. Specifically: (a) there are both positive and negative impacts of demographic change (thus ‘on balance’); (b) the magnitude of the net impacts cannot be determined given current evidence (thus ‘qualitative’); (c) only the direction of the impact from high to low growth rates can be ascertained (thus ‘slower’ rather than ‘slow’); and (d) the net impact varies from country to country. In most cases it will be negative; in some positive; and in others of little impact (thus, ‘most developing countries’).

What accounts for the dramatic turnaround in the two National Academy assessments? Several factors can be advanced. First, the 1986 report extends the short-run time horizon of the 1971 report to examine individual and institutional responses to the initial impacts of population change: conservation in response to scarcity, substitution of abundant for scarce factors of production, innovation and adoption of technologies to exploit profitable opportunities, and the like. These responses are considered to be pervasive and they are judged to be important. According to the report writers: ‘the key [is the] mediating role that human behavior and human institutions play in the relation between population growth and economic processes’ (1986, p. 4).

Second, the 1986 study was assembled almost entirely by economists whose understanding of and faith in markets to induce responses that modify initial direct impacts of population change is far greater than that of other social and biological scientists.

Third, research accumulating over the 15 years between the two reports revealed a need to downgrade: (1) the concern about non-renewable resource exhaustion; (2) the adverse impact of children on the capacity to save, and in turn to undertake productive investments; and (3) the inability to invest in schooling and health facilities.

Finally, the 1986 Report upgrades the concern about population impacts on renewable natural resources.
Overuse can result. It is recognized that the problems of overuse are not solely due to population growth per se, but rather institutional failure. Cutting population growth by one half, or even to zero, would not solve the problem. Rather it would slow the process and postpone the date of resource exhaustion. Government policies are needed to account for negative externalities and market failure. Slowing population growth provides time for institutional response.

3 New paradigms for modelling demography's role in economic growth: 1990 and beyond

As noted previously, Kuznets's empirical finding of an absence of notable negative correlations between population growth and per capita output growth influenced the population debate throughout the 1970s and 1980s. Simple correlations stimulated research during the 1990s as well. This time, however, statistically significant negative correlations during the 1980s drove the discussion. Interestingly, economic-demographic modelling continued in the 'revisionist' vein, incorporating positive and negative as well as short- and long-run influences into an economic growth model. The modelling challenge remains one of accommodating correlations that can be negative, positive or insignificant depending upon time and place.

3.1 Convergence growth models: a framework for assessing demography's impact

Renewed interest in modelling the impacts of demographic change on economic growth coincided with the emergence in the economic growth literature of the ‘technology gap’ or ‘convergence’ model. This model, formulated initially by Barro and Sala-i-Martin (1991), has been used widely to explore many hypothesized influences on economic growth, including openness to trade, form of government, and the rule of law. Since this type of modelling highlights the dynamics of the adjustment process, it is particularly relevant to examining the impacts of major shifts in the population's age distribution associated with birth and death rates that change systematically over the demographic transition. As a result, economic demographers have employed convergence paradigms to explore demographic-economic interactions.

Briefly stated, convergence models focus on the pace at which countries move from their current level of labour productivity to their long-run or steady-state level of labour productivity. The model assumes that all countries converge at the same rate from their current to their long-run levels (which can vary across countries and over time). The greater the productivity gap, the greater are the gaps of physical capital, human capital and technical efficiency from their long-run levels. Large gaps allow for ‘catching up’ through (physical and human) capital accumulation, and technology creation and diffusion across countries and over time. Indeed, many empirical studies indicate that growth rates do slow down as a country approaches its long-run productivity level, especially those studies that provide for country- and period-specific conditions that influence the long-run level of labour productivity.

Since long-run labour productivity is unobservable, empirical implementations of the model substitute a vector of ‘conditioning’ variables thought to influence long-run labour productivity. The actual specification of these conditioning variables varies notably. Consider two of their many representations. The first, by Barro (1997), highlights inflation, government consumption ratios, the rule of law, the form
of the political system, terms of trade, human capital, the total fertility rate, and life expectancy at birth (a proxy for health). The second formulation, by Bloom and Williamson (1998), highlights two categories of growth-rate determinants: economic structure variables (natural resources, schooling, access to ports, location in the tropics, whether landlocked, and extent of coastline); and economic and political policies (openness to trade, quality of institutions, and government savings share of GDP). Clearly there are many defensible perspectives on variable choice, and much is yet to be learned about the appropriate configuration of conditioning variables that influence long-run productivity levels.

3.2 Alternative demographic renderings within a convergence framework

The 1990s witnessed attempts by various researchers to model demography in a manner that accommodates both the insignificant correlations of the 1960s and 1970s as well as the significant negative correlations of the 1980s and 1990s. Three different approaches are described here. All three employ a convergence-type growth model and all employ a broad set of countries spanning the income spectrum.

Modelling through aggregate measures of fertility and mortality. Barro (1997) includes two demographic aggregate measures among his list of conditioning variables, the total fertility rate (TFR) and life expectancy. Barro's formulation thus has demography impacting the long-run equilibrium level of per capita income. The TFR captures, for example, the adverse capital-shallowing impact of more rapid population growth as well as the resource opportunity costs of bringing up children. Furthermore, while Barro treats life expectancy as a human capital proxy for health, demographers consider it to be a demographic variable. Both are statistically significant, with a higher TFR inhibiting, and longer life expectancy enhancing economic growth.

Modelling through population growth components. Kelley and Schmidt (1995) decompose population growth by examining two components (births and deaths) and by modelling their contemporaneous and lagged impacts. This approach allows for disparate impacts of fertility and mortality as well as negative short-run effects (costs of high birth and death rates) and positive long-run effects (favourable impacts of past births on current labour force growth and declining mortality). Consistent with Kuznets's earlier work, they found an absence of a net demographic impact on economic growth in the 1960s and 1970 – the separate impacts of births and deaths are notable but offsetting. Consistent with empirical work of the early 1990s, they found negative impacts throughout the 1980s. These negative correlations were in part the result of (a) rising short-run costs of high birth rates, (b) declining benefits of mortality reduction, and (c) insufficient labour force entry from past births to offset these increased costs.

Modelling through differential age-structure growth. In a series of papers beginning in the late 1990s, several Harvard economists argued for a demographic rendering that incorporates not only population growth but also labour growth (see, for example, Bloom and Williamson, 1998; and Bloom, Canning and Malaney, 2000). They note that, while theorists conceptualize the economic growth process in labour productivity terms, empirical growth models are generally specified in per capita terms. This makes no difference when population and labour grow at the same rate, but does when they grow at different rates.

The authors argue that the post-war period was exactly such a time since during that period demographic transitions took place in different countries at different times and at different paces. At various stages of
the demographic transition, the population and working ages (used within this framework as a proxy for labour) can grow at very different rates. In a predictable pattern, the population initially grows faster, then slower, and then faster than the working-aged population during the transition from a high-fertility, high-mortality to a low-fertility, low-mortality demographic steady-state equilibrium. (For an historical evolution of economic, sociological, and biological factors during the demographic transition, see R.A. Easterlin, 1978.)

Without allowing for differential growth rates of the population and working ages, demographic coefficient estimates (mainly population growth) will be biased. In that case the population–growth coefficient captures net demographic impacts that can be positive, negative, or neutral, depending upon time and place. Bloom and Williamson (1998) demonstrate this point for a broad cross-section of countries over the period 1965–90 in a convergence model that also includes life expectancy as a human capital variable. Consistent with some studies, their simple demographic rendering results in a positive but insignificant coefficient for the population growth rate. When supplemented by the working-age growth rate, however, that coefficient turns negative and the coefficient for the working-age growth rate is positive, both statistically significant.

Effectively, the Harvard economists append an accounting structure to translate labour productivity impacts into per capita terms. The resulting demographic specification is elegant in its simplicity, incorporating only two demographic variables that have unambiguous predicted coefficient values of -1 (for population rate of growth, Ngr) and +1 (for working-age population rate of growth, WAgr) when used to expose demography's impact on income growth per capita relative to income growth per working-age population. In that context, demography exerts its primary impact on the pace at which the long-run equilibrium is reached (Bloom and Williamson, 1998, p. 419) rather than on the long-run equilibrium level of productivity.

This is an intriguing specification. The interpretation is clear: if labour force growth exceeds population growth, then the rate of per capita income growth is boosted by demography. The Harvard economists label this phenomenon the ‘demographic gift’ that may be reaped for several decades after the onset of fertility decline as new labour force entrants from earlier large birth cohorts outpace fertility. The ‘gift’ was large throughout the 1965–90 period for Japan and other Asian Tigers because of the early and rapid pace of their demographic transition. Of course, the converse of the ‘gift’ began to be felt in the 1990s as new labour force entry from smaller birth cohorts was outpaced by labour force exit of the aging population. The model predicts productivity outpacing per capita income growth over several decades into the future in these Asian (and other) countries.

Note that the qualitative predictions are based on theoretically determined coefficients on WAgr and Ngr of +1 and -1, respectively. To the extent that estimated coefficients deviate from +1 and -1, WAgr and Ngr play an additional role in the determination of the long-run productivity level. The Harvard studies provide some guidance in this area. In their earlier study, Bloom and Williamson (1998) estimate coefficients that differ significantly from +1 and -1. However, in a later study that further elucidates the accounting, Bloom, Canning and Malaney (2000) find no significant difference from those values. If that is the case, then the model at once makes an important contribution and is somewhat narrower than many in the literature which admit both short-run and long-run impacts of demographic change as a part of the theoretical structure. Yet modelling demography in growth equations tends to be both imprecise and ad hoc. In contrast, the Bloom and Williamson model is relatively clear in interpretation, and it
targets the shorter-run impacts that are of primary interest to policymakers.

### 3.3 The bottom line

Bloom and Williamson (1998) estimated that as much as one-third of the average per capita income growth rate in East Asian countries over the period 1965–90 is explained by population dynamics. Kelley and Schmidt (2001) evaluated eight distinct demographic renderings within a convergence model using a consistent set of conditioning variables — those described above for Barro’s variant. Among others, these renderings included Barro’s TFR; a ‘naive’ variant predating the 1990s work that simply includes Ngr; a ‘components’ model (contemporaneous and lagged birth rates and the death rate: Kelley and Schmidt, 2001); two variants of the Harvard transitions framework; and demographic extensions to several variants.

Kelley and Schmidt (2001) find that on average, across all eight demographic formulations and over their full 86-country sample (covering the full income spectrum), approximately 21 per cent of the combined impacts on change in the per capita income growth rate is accounted for by changes in the demographic variables in the various models. What is striking about this result is that the 21 per cent is fairly stable across all eight demographic renderings, from one that is quite simplistic (Ngr only) to those that incorporate short-, intermediate- and long-term population effects. On the one hand, this should not be terribly surprising because of the interconnectedness of all of the demographic measures. On the other hand, while population matters, it is still important to determine why.

Although there is an emerging consensus that the magnitude of the impacts of population growth have been sizeable (for example, 21 per cent globally and as much as 33 per cent in East Asia), the reasons why this is the case are still both contestable and not well understood. Are the demographic determinants primarily longer-run impacts, or are they mainly shorter-run transitional dynamics that are diminishing? Will the so-called ‘demographic gift’ of these dynamics in the past reveal themselves as a ‘demographic drag’ in the future, deriving from reduced fertility, slow population growth and ageing? Or will a new mechanism reveal itself? For example, (a) will future modelling better expose the components of labour force change (for example, utilization rates, age- and/or gender-specific participation rates); and (b) will fertility and mortality be endogenously specified to better reveal the dynamics of the demographic transition about which the field of economic demography has much to say? Whatever the outcome, the stage is set for another round of research, pinning down the results of the past with the goal of understanding the future.

### Bibliography

Economic development in low-income economies is initially highly resource-intensive. Resource depletion and pollution damage is often estimated to reduce ‘real’ GDP growth by between one and two per cent per year. Growth and structural change alter the environment–development nexus in nonlinear fashion. Policy reforms, global market integration, and institutional development all alter the propensity for growth to generate environmental damage. The emergence of new trade patterns among developing countries has created new challenges in the measurement and analysis of development–environment interactions. Larger developing economies are now emerging as major sources of emissions that contribute to global climate change.

Article
Economic development depends on sustained per capita income growth and entails dramatic changes in production structure. In low-income economies, growth typically stimulates markets and promotes the evolution of institutions that constrain behaviour according to social norms. The expansion of trade in relation to GDP is another common accompaniment to growth. Each of these has effects on ‘the environment’, which in a developing-country setting refers not only to phenomena such as water and air quality but also, importantly, to natural resource stocks such as forests, fisheries and soils. Conversely, changes in environmental quality, including resource stock drawdowns, may affect
economic development in a dynamic interaction. This feedback is hard to quantify; however, the World Bank's *World Development Indicators* series now includes ‘adjusted’ national accounts data reporting GDP and savings net of the implied value of resource depletion and environmental damage (Bolt, Matete and Clemens, 2002). These indicate that environmental damage can reduce GDP growth by as much as one to two per cent per year. On a broader scale, growth of large low-income economies like China and India is beginning to have ramifications not only for their own environmental conditions, but also for the global environment through transboundary pollution spillovers and greenhouse gas (GHG) emissions.

The welfare of the poor in low-income countries is intimately linked to their access to environmental assets, and especially to the natural resource base. Despite this, the central concerns of environmental and resource economics – the economic costs of pollution and natural resource depletion – have only recently begun to be linked to models of economic development. Publication of the so-called Brundtland Report (WCED, 1987) was a watershed event; since then, ‘no account of economic development would be regarded as adequate if the environmental-resource base were absent from it’ (Dasgupta and Mäler, 1995, p. 2734).

Growth in low-income economies is inevitably associated with higher resource demands and increased pollution intensity per unit of income generated. Other things equal, more economic activity generates more environmental damage monotonically through a scale effect. The relationship may be nonlinear, however. As income grows, environmental damage per unit of additional income may initially rise, then decline. This conjecture, known as the environmental Kuznets curve (EKC), posits that scale effects dominate all other influences on the growth–environment relationship at low income levels, but that, as incomes rise, changes in the composition of production, technological improvements, and income-elastic preferences for conservation and a cleaner environment become more influential (Grossman and Krueger, 1993). Institutional and legal constraints on pollution and resource depletion, initially so weak as to create a form of open access for polluters and resource depleters, may also evolve or be applied with greater vigour as incomes increase, whether due to income effects or to increased recognition of limits to growth imposed by pollution and resource scarcity (Stokey, 1998). Despite the heuristic value of EKC, however, empirical tests in low-income economies are plagued by data and measurement problems. Most notably, there is no robust evidence of an EKC for resource-depleting activities such as deforestation.

Changes in production structure and factor demands are also inherent to development. The most prominent manifestation of structural change in low-income countries is the relative decline of agricultural and resource sectors as contributors to GDP and employment. This has clear environmental implications when the majority of the population is initially dependent on the natural resource base. In capital-scarce economies, forest and land conversion for agriculture and the exploitation of fisheries and other resource stocks are standard strategies for increasing labour productivity and generating surpluses. Accordingly, early stages of development are characterized by rapid resource depletion – most visibly in the form of tropical deforestation. Such processes are abetted by conditions of open access (Barbier, 2005).

Whether the depletion rate eventually slows – a prerequisite for sustainable development – depends largely on the extent to which surpluses are used to build capacity in secondary and tertiary industries making more intensive use of reproducible resources such as labour, technology and human capital. In
this way, the central story of structural change in low-income economies is intimately linked to the evolution of demands on the environmental and natural resource base. Sustained growth leads to a relative reduction in dependence on natural resources, and thus makes it easier for society to agree to promote conservation, biodiversity retention and non-use amenities. Conversely, macroeconomic failures, often in combination with rapid population growth, high transactions costs and market failures, can lead low-income economies into unsustainable cycles of poverty, resource over-exploitation, and institutional failure.

Trade is another influential source of structural change. Early development policies stressing import substitution and de-emphasizing trade have, in most countries, been supplanted by greater outward orientation. Trade-to-GDP ratios have risen and domestic prices have tended to converge on world market prices, thus altering domestic production and investment incentives. With the exception of resource-poor East Asian countries like Korea and Taiwan, the pursuit of comparative advantage in low-income countries initially means expanded exports of tropical agriculture, forestry and fisheries and of resource-based semi-manufactures such as sawnwood. Both the growth of global demand and the pro-trade effects of policy reforms encourage accelerated resource drawdowns; unless property rights and externalities are adequately dealt with, these are likely to occur at socially excessive rates (Coxhead and Jayasuriya, 2003). A related idea known as the pollution haven hypothesis posits that weak environmental laws and unresolved externalities may lead developing countries to specialize in pollution-intensive industrial activities (Copeland and Taylor, 1994).

Whereas early policy advice to developing countries typically stressed the desirability of exploiting resource wealth to create jobs and earn foreign exchange, contemporary concerns about exhaustibility and the integrity of ecological systems have led to more cautious counsel and an emphasis on sustainable development. Such advice, however, is often difficult to implement as policy in the face of pressures to promote growth and alleviate poverty in the current generation.

New issues in the development–environment relationship continue to emerge as economies grow and become more globalized. Traditionally, trade-environment analyses used Ricardian or Heckscher–Ohlin models of North–South interactions in which welfare growth in resource-abundant South is contingent on trade with industrialized North and on domestic externalities or market failures (for example, Chichilnisky 1994). However, South–South trade – or, in the case of China's emergence as a major market for resource exports from Asia, Africa, and Latin America, ‘East–South’ trade – is now growing much faster than trade of the North–South type. South–South trade is a form of internationally fragmented production in which primary products or semi-manufactures are exported from one low-income country to another to be used in production of final goods. The latter low-income economy thus moves to ‘clean’ growth based on labour-intensive manufactures, while growth in the former becomes more resource-intensive. Countries in the South may have comparative advantage in either clean or dirty goods – or both. Conventional models and measures for evaluating environmental costs of growth must be adapted to such new modalities.

Other new trends reflect the growing global influence of large developing economies. In poor countries, about 50 per cent of carbon dioxide emissions (the primary sources of GHGs) comes from land conversion. But total emissions increase rapidly with energy demands driven by growth, urbanization and industrialization. According to the International Energy Agency, China accounted for 13 per cent of global energy-related CO2 emissions in 2006, and is expected to overtake the USA as the largest CO2...
source by 2009; India is now following a similar path (IEA, 2006). Under the 1997 Kyoto Protocol, these economies are not required to limit GHG emissions. But, even if they do take major steps to limit pollution intensity, scale effects of their growth will ensure that global pollution externalities will continue to expand for the foreseeable future. In turn, concerns over the global environmental consequences of growth in low-income countries will find increasingly forceful expression in international negotiations not only on the environment but also on trade and other forms of international integration.

economic epidemiology

Tomas J. Philipson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The economic analysis of epidemiological issues has different implications for disease and its optimal control from those of traditional analysis of such issues. It views undesirable disease occurrence as the result of self-interested behaviour in the presence of constraints. Unlike with methods used in public health, the effects and desirability of disease-reducing public interventions are then evaluated in terms of how they improve the private behaviour essential to controlling disease. Economic epidemiology has been applied to a wide range of topics, including infectious diseases such as AIDS, and also to non-infectious behaviour such as smoking, obesity, and crime.

Keywords

economic epidemiology; health subsidy; morbidity; mortality; programme evaluation; public health; rational epidemics

Article

The fast-growing literature on the economic analysis of epidemiological issues (see Philipson, 2000, for a review) delivers very different implications about disease occurrence and its optimal control from those of traditional analysis of the same issues in the field of public health. At the risk of vastly oversimplifying the positive component of the public health approach, the traditional analysis comprises empirical methods and analysis aimed at identifying and quantifying the effects of ‘risk factors’ on health outcomes. These factors are typically defined as covariates that negatively affect the measured health outcomes – for example, the effects of smoking on lung cancer or the effects of obesity on heart disease. Thereafter, the normative component of the public health approach is concerned with attempts to reduce the measured risk factors, whether through private or public intervention, and to thereby improve health outcomes. This approach drastically differs from that of economic epidemiology, which attempts to explain
undesirable disease occurrence as the result of self-interested behaviour in the presence of constraints. The effects and desirability of disease-reducing public interventions are then evaluated in terms of how they improve the private behaviour essential to controlling disease in the first place. In some sense, the public health approach aims to improve health, whereas the economic approach aims to improve economic efficiency, even if that does not necessarily improve health. Just as closing highways would improve health but impair economic efficiency, the two approaches often clash in desired interventions. The public health approach, therefore, more often favours public intervention, and sometimes simply assumes that the existence of a health problem is sufficient cause for intervention, potentially because it lacks a theory about how private incentives affect the observed level of disease across time and populations.

**Economic epidemiology and infectious disease**

Infectious diseases cause roughly one-third of all deaths worldwide and represent the primary cause of mortality in the world. Historically, the share of worldwide mortality due to infectious diseases has been even greater, although data tend to be less reliable for earlier periods. Morbidity and mortality from infectious diseases such as tuberculosis, malaria and acute respiratory infection have always been at the forefront of public policy in developing countries, where infectious diseases accounted for nearly one-half of mortality in the 1990s.

Worldwide concern about infectious disease has received renewed interest in public policy discussions given the disastrous impacts of HIV/AIDS and the potential threat of bird flu. Like most communicable diseases, especially those that are potentially fatal, HIV has incited an extensive governmental response, consisting of regulatory measures, subsidies for research, education, treatment, testing and counselling. Here we review the main contributions of economic epidemiology in predicting both the short- and the long-run behaviour of infectious disease, as well as the effects and desirability of public health interventions that attempt to reduce such disease.

Philipson and Posner (1993) provide the first systematic analysis of rational infectious disease epidemics in the context of AIDS. Kremer (1996) analyses the effects of a reduction in the number of one’s sexual partners on the growth of disease. The predictions of such models rely crucially on the prevalence elasticity of private demand for prevention against disease, that is, the degree to which prevention increases in response to disease occurrence. Prevalence-elastic behaviour has different implications for the susceptibility to infection than standard epidemiological models of disease occurrence as discussed in Philipson (1995). Evidence of the degree of prevalence-elastic demand is discussed in Ahituv, Hotz and Philipson (1996) and Auld (2003; 2006). Oster (2006) attempts to explain the lack of prevalence-elastic demand in Africa by the competing risks that lower the demand for prevention in that part of the world. Lakdawalla, Sood and Goldman (2006) provide evidence that demand is sensitive to overall risk, both in terms of prevalence and the cost of infection as when reduced by new medical technologies. This type of prevalence-elastic behaviour has two major implications. First, growth of infectious disease is self-limiting because it induces preventive behaviour. Second, since the decline of a disease discourages prevention, initially successful public health efforts actually make it progressively harder to eradicate infectious diseases. Geoffard and Philipson (1996) discuss a very general result concerning the inability of private markets to eradicate disease when demand is prevalence-elastic because a
disappearing disease implies less prevention. Barrett (2003; 2004) also analyses the implications of
economic efficiency for optimal eradication. See also Gersovitz and Hammer (2003; 2004; 2005).
Regarding the value of public health interventions, Mechoulan (2004) analyses the prevalence and
efficiency implications of HIV testing. Geoffard and Philipson (1996) argue that eradication is never
Pareto optimal when only the current generation is considered. However, the missing market is dynamic:
future generations cannot pay vaccine producers for the benefit they derive from the producers’ product.
Brito, Sheshinski and Intriligator (1991) analyse the non-standard efficiency implications of mandatory
vaccinations.
Moreover, the prevalence elasticity of demand lowers the price elasticity of demand, which implies that
Pigouvian-style subsidies to stimulate prevention may have only limited success. This occurs because
demand rises among those who are subsidized and falls among those who are not – in the extreme case,
total demand is inelastic to subsidies. In addition, prevalence competes with public interventions in
inducing protective activity, which makes the timing of the public intervention a crucial factor in
determining its economic efficiency. If the subsidy is not prompt enough, the growth in prevalence will
have already induced protection.
A growing literature examines the optimal control of infectious diseases in the presence of antibiotic
resistance (see, for example, Laxminarayan and Brown, 2001; Laxminarayan and Weitzman, 2002;
Laxminarayan, 2002; and Horowitz and Moehring, 2004). The standard, positive external effect of
treating more individuals with an infectious disease is partly or fully offset by the negative external
effect induced by increased antibiotic resistance. The R&D problem induced by external consumption
effects such as antibiotic resistance is discussed in Philipson, Mechoulan and Jena (2006).
Economic epidemiology has also considered the welfare losses induced by disease, the welfare effects of
R&D in developing new methods of prevention and treatment (Philipson, 1995), and how these contrast
with cost-of-illness studies of disease burden.

Spread of economic epidemiology to other fields

Several other topics have grown out of this more systematic analysis of infectious disease by
economists. One strand is the analysis of public health-related issues such as obesity (Philipson and
Posner, 2003; Lakdawalla, Philipson and Bhattacharya, 2005). The addictive aspect of obesity is
analysed by Cawley (1999). Empirical studies explaining the observed growth in obesity, whether it
includes a rise in caloric intake or fall in caloric expenditure, include Cutler, Glaeser and Shapiro (2003).
the growth of obesity and smoking and fast-food establishments in the United States. The important and
rich set of issues raised by growth in obesity promises a useful role for economic analysis.
Another area in which economic analysis of epidemiological issues has emerged is the economic
analysis of clinical trials (see, for example, Philipson and DeSimone, 1997; Philipson and Hedges, 1998;
Malani, 2006). This literature deals with the non-traditional aspects of programme evaluation that are
unique to clinical trials – for example, the blinding of subjects. Economic analysis of clinical trials
differs from bio-statistical analysis in that subjects are assumed to act in their best interest rather than be
passively observed.
The stark difference between economic explanations of disease occurrence on the one hand and the evaluation of public interventions aimed at limiting disease on the other implies that economics may have a very useful role to play in understanding these issues.

Economic governance consists of the processes that support economic activity and economic transactions by protecting property rights, enforcing contracts, and taking collective action to provide appropriate physical and organizational infrastructure. These processes are carried out within institutions, formal and informal. The field of economic governance studies and compares the performance of different institutions under different conditions, the evolution of these institutions, and the transitions from one set of institutions to another.

Article
Formal and informal institutions arise and evolve to underpin economic activity and exchange by...
protecting property rights, enforcing contracts, and collectively providing physical and organizational infrastructure. The field of economic governance studies and compares these institutions: state politico-legal institutions, private ordering within the law (credible contracting, arbitration), for-profit governance (credit-rating agencies, organized crime), and social networks and norms. Private institutions can outperform the state's legal system in obtaining and interpreting relevant information, and imposing social sanctions on the violators of norms. But private institutions are often limited in size; as economic activity expands, a transition towards more formal institutions is usually observed.

**Concepts and taxonomies**

The term ‘governance’ has exploded from obscurity to ubiquity in economics since the 1970s. A search of the EconLit database shows clear evidence of this explosion. In the relevant categories (title, keywords and abstracts), there are just five occurrences of the word from 1970 to 1979. The number jumps to 112 for the 1980s and 3,825 for the 1990s. Since 2000 to the time of this writing (December 2005), there are already 7,948.

The Oxford English Dictionary gives several definitions of the word ‘governance’: (a) the action or manner of governing; controlling, directing, or regulating influence; control, sway, mastery; the state of being governed; good order; (b) the office, function, or power of governing; authority or permission to govern; that which governs; (c) the manner in which something is governed or regulated; method of management, system of regulations; a rule of practice, a discipline; and (d) the conduct of life or business; mode of living; behaviour, demeanour; discreet or virtuous behaviour; wise self-command. These diverse meanings allow the word to be used (and sometimes misused) for almost any context of economic decision-making or policy.

Two areas of application merit special mention. One is **corporate governance**. This analyses the internal management of a corporation – organizational structure and the design of incentives for managers and workers – and the rules and procedures by which the corporation deals with its shareholders and other stakeholders.

The second is **economic governance**; Williamson (2005) expresses its theme as the ‘study of good order and workable arrangements’. This includes the institutions and organizations that underpin economic transactions by protecting property rights, enforcing contracts, and organizing collective action to provide the infrastructure of rules, regulations, and information that are needed to lend feasibility or workability to the interactions among different economic actors, individual and corporate. Different economies at different times have used different institutions to perform these functions, with different degrees of success. The field of economic governance studies and compares these different institutions. It includes theoretical models and empirical and case studies of the performance of different institutions under different circumstances, of how they relate to each other, of how they evolve over time, and of whether and how transitions from one to another occur as the nature and scope of economic activity and its institutional requirements change.

Corporate governance and economic governance are connected because the boundary of a corporation is itself endogenous, determined by the same considerations of information and commitment costs that raise problems of internal organization as well as those of property and contract (Coase, 1937). Specifically, the nature of transaction costs may make it more efficient to handle some problems of
governance by merging the two parties, for example by vertical integration (Williamson, 1975; 1995). But it is analytically convenient to separate the two. This article concerns economic governance. To avoid constant repetition, I will simply call it ‘governance’ here unless some explicit reference to corporate governance is relevant.

Governance was neglected by economists for a long time, perhaps because they expected the government to provide it efficiently. However, experience with less developed and reforming economies, and observations from economic history, have led economists to study non-governmental institutions of governance.

Governance is not a field per se; it is an organizing or encompassing concept that bears on issues in many fields, including institutions and organizational behaviour, economic development and growth, industrial organization, law and economics, political economy, comparative economic systems, and various subfields of these.

We can organize the subject by classifying institutions along different dimensions. As is usual with such taxonomies, these are conceptual categories to help organize our thinking and analysis. In reality, there are significant differences within each category and overlaps across categories.

The first dimension concerns the purpose of the institution. The categories are: (a) protection of property rights against theft by other individuals and usurpation by the state itself or its agents, (b) enforcement of voluntary contracts among individuals, and (c) provision of the physical and regulatory infrastructure to facilitate economic activity and the functioning of the first two categories of institutions. We might also consider a fourth category, namely, the deep institutions that are essential to avoid serious cleavages or alienation that threaten the cohesion of the society itself. But this has not been studied in this context so far.

The second dimension concerns the nature of the institution. The categories are: (a) the formal state institutions that enact and enforce the laws, including the legislature, police, judiciary and regulatory agencies, (b) institutions of private ordering that function under the umbrella of state law, for example various forums for arbitration, (c) private for-profit institutions that provide information and enforcement, and (d) self-enforcement within social or ethnic groups and network. My discussion is organized in sections along this dimension.

A third dimension distinguishes institutions that arise and evolve organically from those that are designed purposively; self-enforcing groups are often organic while the first three categories in the second dimension usually require some measure of design. This matters for the evolution of institutions of governance (see Greif, 2006, especially ch. 6; Williamson 2005 p. 1).

**Formal institutions of the state**

There is broad agreement that the quality of institutions of governance significantly affects economic outcomes. The importance of protecting property rights, both from other individuals and from predation by the state itself, is generally recognized and documented (for example, De Soto, 2000). But serious disputes about the precise measures of quality of institutions, and about many details of the causal mechanisms by which they affect economic outcomes, remain.

At the broadest level, the distinction is between democracy and authoritarianism, each of which comes in many different varieties. Democracy has many normative virtues, but its worth in governance is less
clear. Barro (1999, p. 61) finds an inverse U-shaped relationship between economic growth and a continuous measure of democracy – ‘more democracy raises growth when political freedoms are weak, but depresses growth when a moderate amount of freedom is already established’ – but the fit is relatively poor. Persson (2005), using cross-sectional as well as panel data, finds that the crude distinction between democratic and non-democratic forms of government is not enough. The precise form of democracy matters for policy design and economic outcomes: ‘parliamentary, proportional, and permanent democracies seem to foster the adoption of more growth-promoting structural policies, whereas … presidential, majoritarian, and temporary democracy do not’ (Persson, 2005, p. 22).

However, Keefer (2004, p. 10), after surveying a wide-ranging literature on electoral rules and legislative organizations, concludes that they affect policies but are not a crucial determinant of success: ‘electoral rules … almost surely do not explain why some countries grow and others do not’, and ‘the mere fact that developing countries are more likely to have presidential forms of government is unlikely to be a key factor to explain slow development.’

Democracy can be important for governance because its reliance on rules and procedures provides citizens with protection against predation by the state or its agents. Indeed, the elite, which might otherwise prefer to rule unconstrained, may find it in its own interest to make a credible commitment not to steal from the population by creating and fostering democracy (Acemoglu, 2003; Acemoglu and Robinson, 2005). Greif, Milgrom and Weingast (1994) discuss how groups of traders (guilds) in late medieval Europe took collective action to counter rulers’ incentives to violate their members’ property rights.

Even in a democracy, agents of the state may pursue their private interests using corruption, complex regulations to extract rent, and favouritism. In fact, an emerging literature argues that economic growth, at least in its early stages, is better promoted under suitably authoritarian regimes. Glaeser et al. (2004) argue that less developed countries that achieve economic success do so by pursuing good policies, often under dictatorships, and only then do they democratize. While these conclusions are controversial, these authors’ criticisms of the measures of institutions used in the research that argues for the primacy of institutions in general, and of democracy in particular, are telling. Giavazzi and Tabellini (2005) find a positive feedback between economic and political reform, but they also find that the sequence of reforms matters, and countries that implement economic liberalization first and then democratize do much better in most dimensions than those that follow the opposite route. In practice, of course, it is difficult to ensure ex ante that an authoritarian ruler will implement good governance.

Many different measures of institutional quality exist. World Bank researchers Kaufman, Kraay and Mastruzzi (2005, which contains citations to their earlier work) have constructed six: (a) Voice and Accountability – measuring political, civil and human rights; (b) Political Instability and Violence – measuring the likelihood of violent threats to, or changes in, government, including terrorism; (c) Government Effectiveness – measuring the competence of the bureaucracy and the quality of public service delivery; (d) Regulatory Burden – measuring the incidence of market-unfriendly policies; (e) Rule of Law – measuring the quality of contract enforcement, the police, and the courts, as well as the likelihood of crime and violence; and (f) Control of Corruption – measuring the exercise of public power for private gain, including both petty and grand corruption and state capture. Of these, (e), (f) and also (b) concern the most basic institutions for protection of property rights and enforcement of contracts, (a) relates to governance because voice and accountability can reduce the severity of the agency problem.
between the citizens and the agencies of the state, and (c) and (d) pertain to what I called provision of the infrastructure of governance. Conceptually they are a mixed bag; the quality of some of them can itself depend on the quality of other more basic ones, and some are closer to being measures of effects than of causes. Their method of construction relies on subjective perceptions, and is subject to error. But when used with caution, they have proved significant as explanatory variables in empirical studies of economic growth, and for observing changes in governance quality over time in specific countries. Corruption and regulatory burdens are major themes of the World Bank’s research on governance in many countries (see World Bank Institute, website).

Empirical estimations of the level or growth of GDP on various measures of institutional quality confront many conceptual and econometric problems. Researchers have tackled the issue of reverse causation by using various instruments, such as the nationality of colonizers (Hall and Jones, 1999), mortality among colonizers (Acemoglu, Johnson and Robinson, 2001), and whether a colony had rich mineral resources or climatic and soil conditions conducive to plantation agriculture and a large or dense native population, or was sparsely populated and poor in the 1500s (Engerman and Sokoloff, 2002; Acemoglu, Johnson and Robinson, 2002). The general idea is that in the former circumstances the European colonizers established institutions of slavery and inequality to facilitate the exploitation of labour on a large scale, whereas in the latter conditions, where the colonizers had to exert their own effort, their institutions provided the correct incentives and became conducive to longer-term economic success. The debate on the factual and econometric validity and the economic interpretation of these findings is fierce and continuing; Hoff (2003) surveys and discusses this literature in detail.

La Porta et al. (1998; 1999) contrast different legal traditions for protecting the rights of small shareholders. If such protection is poor, that will inhibit the flows of capital to its most efficient uses. They find that systems based on common law are better in this regard than those based on civil law. But Rajan and Zingales (2003) and Lamoreaux and Rosenthal (2005) argue that in practice there was little difference between the systems during critical periods of industrialization. These debates are sure to continue, and this section will get out of date very quickly.

At the international level, formal governance works through bodies like the World Trade Organization. Their members are sovereign countries; therefore their procedures must be subject to self-enforcement in repeated interactions, whether through bilateral or multilateral sanctions. These institutions are therefore basically similar to the social networks discussed below. See Maggi (1999) and Bagwell and Staiger (2003) for detailed analyses.

Private institutions

The policing functions for property right protection supplied by the state are often supplemented by private security systems that serve specific clients and purposes – firms employ or hire security personnel, gated communities and neighbourhoods have private (hired or volunteer) patrols. These generally merely supplement the functions of the police for their specific context and work cooperatively with the police, but the two may clash if the private security system goes beyond its permissible functions. Private institutions of contract enforcement similarly coexist with formal law, and become essential when the latter is weak or nonexistent. Explicit or implicit private contractual arrangements are also
important for assignment of property rights as a part of Coasean contracting for efficient outcomes. Therefore, analyses of private institutions often focus on the governance of contracts.

The basic problem of contract enforcement is control of opportunism. If one or both parties have to make transaction-specific investments, the other can attempt to secure a greater part of the benefit by reneging or demanding renegotiation. The prospect of this can jeopardize the potentially mutually beneficial deal in the first place. Williamson (1975; 1995) pioneered the analysis of this issue under the title of transaction cost economics.

Information constitutes a major source of advantage for private ordering over formal law. Enforcement of a contract in a court requires offering proof of misconduct by the other party in the dispute; the relevant information must be verifiable to outsiders. Therefore, formal contracts can stipulate actions by the parties conditional only on verifiable information. Other or more detailed information may be observable to the parties themselves, or can be inferred by specialist insiders to the industry, but cannot be verified to non-specialist judges or juries of the state's legal system, or can be verified only at excessive cost.

The informational advantage of private ordering may be offset by a disadvantage in enforcement. Informal arrangements must be made to overcome each participant's temptation to behave opportunistically at the others' expense. Different methods of this kind underlie the various institutions of informal governance, and achieve different degrees of success. Some are able to exert coercion for immediate punishment of misbehaviour. Others create long-run costs, typically in the form of exclusion from future participation or worse future opportunities, to offset the short-run advantages of opportunism. This is the standard theory of self-enforcing cooperation in repeated Prisoner's Dilemmas.

The following sections discuss some of these alternatives.

### Private ordering with formal law in the background

Perhaps the most remarkable thing about formal legal institutions and mechanisms for the enforcement of commercial contracts is how rarely they are actually used. Business transactions often do have underlying formal contracts, but when disputes arise recourse to the law is often the last resort. Other private alternatives are tried first; these include bilateral negotiation, arbitration by industry experts, and so on. Filing a suit in a formal court of law often signals the end of a business relationship. Most actual practice in business contracting is therefore better characterized as 'private ordering under the shadow of the law' (Macaulay, 1963; Williamson, 1995, pp. 95–100, 121–2).

If one of the parties to an ongoing informal relationship behaves opportunistically, the most common alternative is to fall back on a formal contract based on verifiable contingencies alone. Suppose an outcome based on a tacit understanding of what each party should do in any one exchange (including good-faith negotiation to adapt to changing circumstances) yields both of them higher payoffs than does a formal contract. Consider the implicit arrangement where, if one party deviates from the agreed course of action to its own advantage and to the detriment of the other, their future exchanges will be governed by the formal contract. This yields a subgame-perfect (credible) equilibrium of the repeated game if each party's one-time gain from opportunism does not exceed the capitalized value of the future difference of payoffs between the tacit and the formal contracts. Williamson (2005, p. 2) expresses this well: ‘continuity can be put in jeopardy by defecting from the spirit of cooperation and reverting to the letter.’
When such relationship-based implicit contracting prevails, partial improvement in the formal system can worsen the outcome, due to a problem of the second-best. The partial improvement raises the payoffs the two parties could get from the fallback formal contract. This in turn reduces the future cost of a current deviation from the implicit contract or spirit of cooperation. It tightens the incentive-compatibility constraints, and therefore worsens what can be achieved by relational contracting (Baker, Gibbons and Murphy, 1994; Dixit, 2004, ch. 2).

Arbitration comes in two prominent forms. One is industry-specific, based on expert knowledge of insiders. More information is verifiable in such settings; therefore richer contracts specifying actions for more detailed contingencies become feasible. In many industries there is a large common-knowledge basis of custom and practice, which may even make it unnecessary to write down a contingent contract in great detail. Arbitration can also provide an opportunity for the parties to communicate and renegotiate adaptations to new circumstances. Formal legal systems often recognize these advantages of expert arbitration, and courts stand ready to enforce the decisions of arbitrators if the losing party tries to evade the sanctions. However, industry arbitrators often have severe sanctions at their own disposal; they can essentially drive the miscreant out of business, and even ostracize him or her from the social group of that business community. Examples of arbitration institutions include Bernstein's (1992) classic study of the diamond industry. For further discussion and modelling, see Dixit (2004, ch. 2) and Williamson (2005, p. 14).

The other prominent forums of arbitration deal with international contracts (Dezalay and Garth, 1996; Mattli, 2001). There are several of these, specializing in different legal traditions. They lack direct power to enforce their decisions, but are backed by treaties that ensure enforcement by national courts. These forums do not have industry-specific knowledge, their processes can be slow and costly, and their decisions can be somewhat arbitrary. But parties in transnational transactions may prefer them to either country's courts, suspecting that these will be biased in favour of their own nationals.

For-profit private institutions

If the state is unwilling to protect certain kinds of property or enforce certain kinds of contracts (for example in illegal activities), or is unable to do so (for example in weak and failing states), or is itself predatory, then private institutions can emerge to perform these functions for a profit. Organized crime often fills the niches uncovered by the state. Gambetta (1993), Bandiera (2003) and others argue that the Mafia emerged in just such a situation to fill the vacuum of protection in late 19th-century Sicily. Landowners began to hire guards of former feudal lords, and even the toughest among bandits, to protect their property. Gambetta describes how the Mafia's role expanded to providing contract enforcement in illegal or grey markets. Similarly, the Japanese Yakuza was instrumental in organizing markets at the end of the Second World War in August and September 1945 when the Japanese state had collapsed (Dower, 1999, pp. 140–8), and mafias grew in Russia after the collapse of the Soviet regime (Varese, 2001).

Gambetta (1993, p. 19) argues that this ‘business of protection’ is the core business of the Mafia. It may engage in other activities using in-house protection, but that is just downstream vertical integration – the opposite of upstream integration where an ordinary business firm has its in-house security department. A transaction-cost analysis of the internal organization of mafias, and of their vertical integration
decisions, may provide an interesting link between economic governance and corporate governance. Another dimension in which the protection business can expand is extortion; although private protectors may be welcome when state protection has collapsed, ‘protectors, once enlisted, invariably overstay their welcome’ (Gambetta, 1993, p. 198).

The Mafia can provide contract enforcement because, even though two traders may not have sufficiently frequent dealings with each other to achieve good outcomes in an ongoing bilateral relationship, each trader can be a regular customer of the enforcer. This converts multiple one-shot Prisoner’s Dilemma games among the whole group of traders into several bilateral repeated games of each trader with the enforcer. The intermediary can provide information (keeping track of previous contract violations and informing a customer of the history of a potential trading partner) and/or actual punishment if a customer’s trading partner violates their contract. The information role of the Mafioso is similar to that of credit rating agencies and Better Business Bureaus in the United States. Dixit (2004, ch. 4) constructs a model of such for-profit governance, and establishes the conditions for an equilibrium with for-profit private enforcement. These are lower bounds on the shares of the surplus that the customer and the Mafioso must have, so as to overcome the trader's temptation to cheat and the Mafioso’ temptation to double-cross the customer. Milgrom, North and Weingast (1990) have a related and complementary model of private judges at medieval European trade fairs. They specify the game of each trade, and investigation in the event of cheating, in greater detail, but do not examine the issue of the judges’ honesty.

Group enforcement through social networks and norms

Any institution of contract enforcement must solve three key problems: (a) detection of opportunistic deviations from the contractually stipulated behaviour, (b) preservation and dissemination of information about the histories of the participants’ behaviour, and (c) inflicting appropriate punishments to reduce future payoffs of any deviators. The first is often constrained by the available technology of monitoring, although institutions and regulations such as reporting requirements and auditing can improve the technology. The second and third problems are best resolved in bilateral ongoing relationships: each party has a natural incentive to detect and remember the other's cheating, and can punish the other by breaking off the relationship. However, governance is often needed in groups each of whose members interacts frequently with someone else in the group, but not necessarily bilaterally with the same person every time. Now remembering and transmitting information about your current partner’s behaviour to others, and refusing a potentially beneficial deal because the counter-party has cheated someone else in the past, are privately costly activities and therefore require their own governance mechanisms.

Formal state institutions of governance can solve these problems by fiat; the legal system compels the whole group of traders to commit to good behaviour by subjecting themselves to detection and punishment if they cheat. A third-party supplier of information or enforcement serves similar functions. In the case of a Mafia enforcer, anyone who trades with a customer of the Mafioso subjects himself to the grim punishment if he cheats. In the case of a Better Business Bureau, a firm that joins the organization thereby gives hostage to its own good behaviour: if it misbehaves it will get a poor rating or blacklisting. Transactions vary in their characteristics; therefore we should expect the effectiveness of
such reputation mechanisms to vary also, and should not expect universal success from any one. An institution of social networks and norms can solve the problems of information and punishment in a decentralized manner. Each participant can transmit information about his or her current trading partner's behaviour to others in the group to whom he or she is linked. And each can play his or her assigned part in punishment, typically by refusing to trade, if he or she gets matched with a potential partner who is known to have misbehaved in past dealings with others in the group. Incentives to transmit information or refuse potentially good trades can be established by a norm that regards refusal to do so as itself a punishable offence, as in Abreu's (1986) penal codes for repeated games; see Calvert (1995a; 1995b). Extrinsic incentives may even be unnecessary if people have sufficiently strong natural instincts to punish social cheaters, as found by Fehr and Gächter (2000).

Numerous empirical and case studies of governance based on social relations have been conducted; space constraints allow mention of only a few. Greif's (1993) historical analysis of Maghribi traders' system of communication and collective punishment is well known. So is Ostrom's (1990) synthesis of the evidence on common-pool resource management; she emphasizes the importance of local knowledge and communication, of appropriately designed (generally graduated) punishments, and of incentives for individuals to perform their assigned roles and actions in the system. Fafchamps (2004) studies and compares many different market institutions in Africa; his work highlights the importance of designing systems appropriate to the conditions of each country or group. Ensminger (1992) describes a similarly rich complex of arrangements for trade and employment relationships among the Orma tribe of Kenya, and examines how formal institutions of property right enforcement including title registration can interact dysfunctionally with traditional arrangements based on family and tribal connections. Johnson, McMillan and Woodruff (2002) present and analyse findings from survey research in former socialist economies. Of particular interest are the links between evolving formal and informal governance. Even without a backup of courts, trust in bilateral relationships can build quickly in response to good experiences. New or transient customers are more likely to be offered credit if courts work better, but the effectiveness of courts becomes largely irrelevant for the functioning of established relationships. Casella and Rauch (2002) study the role of ethnic networks in international trade.

Li (2003) points out a key difference between the costs of operating such a system and those of formal governance. A relation-based system of networks and norms has low fixed costs, but high and rising marginal costs. Trading on a small scale naturally starts among the most closely connected people who have sufficiently good communication and common understanding to sustain honesty. No fixed costs need be incurred to establish any formal rules or mechanisms of enforcement. But as trade expands, potential partners added at the margin are almost by definition less well-connected, making it harder to communicate information with them and to ensure their participation in any punishments. By contrast, formal or rule-based governance has high fixed costs of setting up the legal system and the information mechanism, but once these are incurred, marginal costs of dealing with strangers are low. Therefore, relation-based governance is better for small groups and rule-based governance better for large groups. Greif's (1994) comparison between the relation-based system of Maghribi traders and the formal institutions of Genoese traders supports this theory. Dixit (2004, ch. 3) constructs a formal model that compares relation-based and rule-based systems. This characterizes the maximum size of a self-enforcing group, and finds that, when the group exceeds this critical size, the maximum scope of sustainable honesty shrinks absolutely. The intuition is as follows. At the critical size, each trader is
indifferent between honesty and cheating when dealing with the most distant person. When more traders are added, this weakens the communication between the previously marginal person and other almost equally distant ones, tipping the balance toward cheating.

Kranton (1996) models individuals who can either choose bilateral long-lived self-enforcing trading relationships or search for one-time trading partners in an anonymous market with external enforcement. The market thus provides the outside opportunity in the repeated game of bilateral trade. If more people trade in the anonymous market, it becomes thicker and offers better prospects for successful search. Then parties in bilateral relationships have better outside opportunities, which makes it harder to sustain tacit cooperation there, further increasing the relative attraction of the market. Therefore the system can have multiple equilibria – no one uses the market because no one else uses it, or everyone uses the market because everyone else does – and can get locked into a Pareto-inferior equilibrium.

**Evolution and transformation of governance institutions**

A persistent theme in this survey has been that different governance institutions are optimal for different societies, for different kinds of economic activity, and at different times. Changes in underlying technologies of production, exchange and communication change the relative merits of different methods of governance. As the volume and scope of trade expand, formal institutions generally become superior to informal ones, but informal ones serve useful roles under the shadow of formal ones even in the most advanced economies and sectors. All this raises the question of whether we should expect institutions to adapt and evolve optimally.

Williamson's famous ‘discriminating alignment hypothesis’ says that transactions, with their different attributes, align with institutions, with their different costs and competencies; see his recent exposition (2005, p. 6). This gives ground for optimism for synergistic evolution of the need for governance and the institutions that supply it. Others are less sanguine. North (1990) and others argue that institutional change is subject to long delays due to resistance by organized interests favouring the status quo, problems of coordinating collective action to bring about a discrete change in equilibrium, and so on. Dixit (2004, pp. 79–85) discusses some of these problems for transition from relation-based to rule-based contract enforcement. Eggertson (2005) gives a dramatic example of how institutions restricting fishing and requiring costly mutual insurance persisted in Iceland for centuries after they had become obstacles to good economic performance.

I believe that a balanced approach is needed, recognizing the tendency towards synergistic alignment but also the obstacles to its realization. The net outcome will depend on many specifics of each context. Understanding and predicting the process requires a combination of approaches: case-based and analytical, inductive and deductive. Greif (2006) discusses, develops and applies such methodologies using historical studies of trade in medieval Europe.

economic growth in the very long run

Oded Galor
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The evolution of economies during the major portion of human history was marked by Malthusian stagnation. The transition from an epoch of stagnation to a state of sustained economic growth has shaped the contemporary world economy and has led to the great divergence in income per capita across the globe in the past two centuries. This article examines the process of development over the course of human history in light of recent advances in unified growth theory.

Article

The evolution of economies during the major portion of human history was marked by Malthusian stagnation. Technological progress and population growth were minuscule by modern standards, and the average growth rates of income per capita in various regions of the world were even slower due to the offsetting effect of population growth on the expansion of resources per capita.

In the past two centuries the pace of technological progress increased significantly in association with the process of industrialization. Various regions of the world departed from the Malthusian trap and experienced a considerable rise in the growth rates of income per capita and population. Unlike episodes of technological progress in the pre-Industrial Revolution era that failed to generate sustained economic growth, the increasing role of human capital in the production process in the second phase of industrialization ultimately prompted a demographic transition, liberating the gains in productivity from the counterbalancing effects of population growth. The decline in the growth rate of population and the enhancement of human capital formation and technological progress paved the way for the emergence of the modern state of sustained economic growth. Variations in the timing of the transitions from a Malthusian epoch to a state of sustained economic growth across countries lead to a considerable rise in the ratio of GDP per capita between the richest and the poorest regions of the world from 3:1 in 1820 to 18:1 in 2000 (see Figure 1).

Figure 1
The transition from stagnation to growth and the associated phenomenon of the great divergence have been the subject of intensive research in the growth literature in recent years.
economic growth in the very long run : The New Palgrave Dictionary of Economics

in 1820: an average pace of 0.27 per cent per year. Resource expansion over the period 1500–1820 had a more significant impact on the world population, which grew 138 per cent from 438 million in 1500 to 1,041 million resources in the period 1000–1500 permitted the world population to increase by 63 per cent, from 268 million in 1000 to 438 million in 1500; a slow 0.1 per cent average growth rate world from 231 million people in 1 ce to 268 million in 1000 ce: a minuscule average growth rate of 0.02 per cent per year. The more rapid (but still very slow) expansion of Population growth over this era followed the Malthusian pattern as well. The gradual increase in income per capita during the Malthusian epoch was associated with a monotonic per capita fluctuated significantly within regions, deviating from their sluggish long-run trend over decades and sometimes centuries. The Malthusian epoch

During the Malthusian epoch that characterized most of human history, humans were subjected to a persistent struggle for existence. Resources generated by technological progress and land expansion were channelled primarily towards an increase in the size of the population, with a minor long-run effect on income per capita. Improvements in the technological environment or in the availability of land generated temporary gains in income per capita, leading eventually to a larger but not richer population. Technologically superior countries ultimately had denser populations but their standard of living did not reflect the degree of their technological advancement. The Malthusian epoch the average growth rate of output per capita was negligible and the standard of living did not differ greatly across countries. The average level of income per capita in the world during the first millennium fluctuated around $450 per year (in 1990 international dollars) and the average growth rate of output per capita was nearly zero (Maddison, 2001). This state of Malthusian stagnation persisted until the end of the 18th century. In the years 1000–1820, the average level of income per capita in the world economy was below $670 per year, and the average growth rate of the world income per capita was minuscule, creeping at a rate of about 0.05 per cent per year. Nevertheless, income per capita fluctuated significantly within regions, deviating from their sluggish long-run trend over decades and sometimes centuries. Population growth over this era followed the Malthusian pattern as well. The gradual increase in income per capita during the Malthusian epoch was associated with a monotonic increase in the average rate of growth of world population. The slow pace of resource expansion in the first millennium was reflected in a modest increase in the population of the world from 231 million people in 1 ce to 268 million in 1000 ce: a minuscule average growth rate of 0.02 per cent per year. The more rapid (but still very slow) expansion of resources in the period 1000–1500 permitted the world population to increase by 63 per cent, from 268 million in 1000 to 438 million in 1500; a slow 0.1 per cent average growth rate over the period 1500–1820 had a more significant impact on the world population, which grew 138 per cent from 438 million in 1500 to 1,041 million in 1820: an average pace of 0.27 per cent per year.

Unified growth theory explores the fundamental factors that generated the remarkable escape from the Malthusian epoch and their significance in understanding the contemporary growth process of developed and less developed economies. Moreover, it sheds light on the perplexing phenomenon of the great divergence in income per capita across regions of the world in the past two centuries. It suggests that the transition from stagnation to growth is an inevitable outcome of the process of development. The inherent Malthusian interaction between the level of technology and the size and the composition of the population accelerated the pace of technological progress and ultimately raised the importance of human capital in the production process. The rise in the demand for human capital in the second phase of industrialization and its impact on the formation of human capital as well as on the onset of the demographic transition brought about significant technological advances along with a reduction in fertility rates and population growth, enabling economies to convert a larger share of the fruits of factor accumulation and technological progress into growth of income per capita, and paving the way for the emergence of sustained economic growth. Differences in the timing of the take-off from stagnation to growth across countries (for example, England's earlier industrialization in comparison with China) contributed significantly to the great divergence and to the emergence of convergence clubs. These variations reflect initial differences in geographical factors and historical accidents and their manifestation in diversity in institutional, demographic, and cultural factors, trade patterns, colonial status, and public policy. In particular, once a technologically driven demand for human capital emerged in the second phase of industrialization, the prevalence of human capital-promoting institutions determined the extensiveness of human capital formation, the timing of the demographic transition, and the pace of the transition from stagnation to growth. Thus, unified growth theory provides the natural framework of analysis in which variations in the economic performance across countries and regions could be examined based on the effect of variations in educational, institutional, geographical, and cultural factors on the pace of the transition from stagnation to growth.

The process of development

The process of economic development has been characterized by of three fundamental regimes: the Malthusian epoch, the post-Malthusian regime, and the sustained growth regime.

The Malthusian epoch

During the Malthusian epoch that characterized most of human history, humans were subjected to a persistent struggle for existence. Resources generated by technological progress and land expansion were channelled primarily towards an increase in the size of the population, with a minor long-run effect on income per capita. Improvements in the technological environment or in the availability of land generated temporary gains in income per capita, leading eventually to a larger but not richer population. Technologically superior countries ultimately had denser populations but their standard of living did not reflect the degree of their technological advancement.
Variations in population density across countries during the Malthusian epoch reflected primarily cross-country differences in technology and land productivity. Due to the positive adjustment of the population to an increase in income per capita, differences in technology or in land productivity across countries resulted in variations in population density rather than in the standard of living. For instance, China's technological advancement in the period 1500–1820 permitted its share of world population to increase from 23.5 per cent to 36.6 per cent, while its income per capita in the beginning and the end of this time interval remained approximately $600 per year.

The post-Malthusian regime

During the post-Malthusian regime, the pace of technological progress markedly increased in association with the process of industrialization, triggering a take-off from the Malthusian trap. The growth rate of income per capita increased significantly but the positive Malthusian effect of income per capita on population growth was still maintained, generating a sizeable increase in population growth that offset some of the potential gains in income per capita.

The take-off of developed regions from the Malthusian regime occurred at the beginning of the 19th century and was associated with the Industrial Revolution, whereas the take-off of less developed regions occurred towards the beginning of the 20th century and was delayed in some countries well into the 20th century. During the post-Malthusian regime the average growth rate of output per capita increased significantly and the standard of living began to differ considerably across countries. The average growth rate of output per capita in the world soared from 0.05 per cent per year during the period 1500–1820 to 0.53 per cent per year in the years 1820–70, and 1.3 per cent per year during the period 1870–1913. The timing of the take-off and its magnitude differed across regions. The take-off from the Malthusian epoch and the transition to the post-Malthusian regime occurred in western Europe, the Western offshoots (that is, the United States, Canada, Australia and New Zealand), and eastern Europe at the beginning of the 19th century, whereas in Latin America, Asia and Africa it occurred towards the beginning of the 20th century.

The rapid increase in income per capita in the post-Malthusian regime was channelled partly towards an increase in the size of the population. During this period, the Malthusian mechanism linking higher income to higher population growth continued to function. However, the effect of higher population on the dilution of resources per capita was counteracted by accelerated technological progress and capital accumulation, allowing income per capita to rise despite the offsetting effects of population growth.

The western European take-off along with that of the Western offshoots brought about a sharp increase in population growth in these regions and consequently a modest rise in population growth in the world as a whole. The subsequent take-off of less developed regions, and the associated increase in their rates of population growth, brought about a significant rise in population growth in the world. The rate of population growth in the world increased from an average rate of 0.27 per cent per year in the period 1500–1820 to 0.4 per cent per year in the years 1820–70, and to 0.8 per cent per year in the time interval 1870–1913. Despite the decline in population growth in western Europe and the Western offshoots towards the end of the 19th century and the beginning of the 20th century, the delayed take-off of less developed regions, and the significant increase in their income per capita prior to their demographic transitions, generated a further increase in the rate of population growth in the world to 0.93 per cent per year in the period 1913–50, and 1.92 per cent per year in the period 1950–73. Ultimately, the onset of the demographic transition in less developed economies during the second half of the 20th century reduced population growth rates to 1.66 per cent per year in the 1973–98 period (Maddison, 2001).

It appears that the significant rise in income per capita in the post-Malthusian regime increased the desired number of surviving offspring and thus, despite the decline in mortality rates, fertility increased significantly so as to enable households to reach this higher desired level of surviving offspring. Fertility was controlled during this period, despite the absence of modern contraceptive methods, partly via adjustment in marriage rates. Increased fertility was achieved by earlier female age of marriage, and a decline in fertility by a delay in the marriage age.

The take-off in the developed regions was accompanied by a rapid process of industrialization. Per-capita level of industrialization increased significantly in the United Kingdom, rising 50 per cent over the 1750–1800 period, quadrupling in the years 1800–60, and nearly doubling in the time period 1860–1913. Similarly, per capita level of industrialization accelerated in the United States, doubling in the 1750–1800 as well as 1800–60 periods, and increasing sixfold in the years 1860–1913. A similar pattern was experienced in Germany, France, Sweden, Switzerland, Belgium and Canada. The take-off of less developed economies in the 20th century was associated with increased industrialization as well. However, during the 19th century these economies experienced a decline in per capita industrialization, reflecting the adverse effect of the sizeable increase in population on the level of industrial production per capita as well as the forces of globalization and colonialism, which induced less developed economies to specialize in the production of raw materials (Galor and Mountford, 2003; 2006).

The acceleration in technological progress during the post-Malthusian regime and the associated increase in income per capita stimulated the accumulation of human capital in the form of literacy rates, schooling, and health. The increase in the investment in human capital was induced by the rise in income per capita, as well as by qualitative changes in the economic environment that increased the demand for human capital and induced households to invest in the education of their offspring.

In the first phase of the Industrial Revolution, human capital had a limited role in the production process. Education was motivated by a variety of reasons, such as religion, enlightenment, social control, moral conformity, socio-political stability, social and national cohesion, and military efficiency. The extensiveness of public education was therefore not necessarily correlated with industrial development, and it differed across countries due to political, cultural, social, historical and institutional factors. In the second phase of the Industrial Revolution, however, the demand for education increased, reflecting the increasing skill requirements in the process of industrialization. The economic interests of
economic growth in the very long run: The New Palgrave Dictionary of Economics

The sustained growth regime

The acceleration in the rate of technological progress in the second phase of industrialization, and its interaction with human capital formation, triggered a demographic transition, paving the way to a transition to an era of sustained economic growth. In the post demographic-transition period, the rise in aggregate income due to technological progress and factors accumulation was no longer counterbalanced by population growth, permitting sustained growth in income per capita in regions that experienced sustained technological progress and accumulation of physical and human capital.

The transition of the developed regions of western Europe and the Western offshoots to the state of sustained economic growth occurred towards the end of the 19th century, and their income per capita in the 20th century has advanced at a stable rate of about two per cent per year. The transition of some less developed countries in Asia and Latin America occurred towards the end of the 20th century. Africa, in contrast, is still struggling to make this transition.

The transition to a state of sustained economic growth was characterized by a gradual increase in the importance of the accumulation of human capital relative to physical capital as well as with a sharp decline in fertility rates. In the first phase of the Industrial Revolution (1760–1830), capital accumulation as a fraction of GDP significantly increased whereas literacy rates remained largely unchanged. Skills and literacy requirements were minimal, the state devoted virtually no resources to raise the level of literacy of the masses, and workers developed skills primarily through on-the-job training (Green, 1990; Mokyr, 1993). Consequently, literacy rates did not increase during the period 1750–1830 (Sanderson, 1995).

In the second phase of the Industrial Revolution, however, the pace of capital accumulation subsided, skills became necessary for production and the education of the labour force markedly increased. The investment ratio in the UK, which increased from six per cent in 1760 to 11.7 per cent in 1831, remained at around 11 per cent on average in the years 1856–1913 (Crafts, 1985). In contrast, the average years of schooling of males in the labour force that did not change significantly until the 1830s tripled by the beginning of the 20th century. The drastic rise in the level of income per capita in England as of 1865 was associated with an increase in school enrolment of ten-year-old children from 40 per cent in 1870 to 100 per cent in 1900. Moreover, total fertility rate in England sharply declined over this period from about five in 1875, to nearly two in 1925.

The demographic transition swept the world in the course of the 20th century. The unprecedented increase in population growth during the post-Malthusian regime was reversed and the demographic transition brought about a significant reduction in fertility rates and population growth in various regions of the world, enabling economies to convert a larger share of the fruits of factor accumulation and technological progress into growth of income per capita. The demographic transition enhanced the growth process via three channels: (a) reductions in the dilution of the stocks of capital and natural resources, (b) enhancements in human capital formation, and (c) changes in the age distribution of the population, temporarily increasing the size of the labour force relative to the population as a whole.

The timing of the demographic transition differed significantly across regions. The reduction in population growth occurred in Western Europe, the Western offshoots, and eastern Europe towards the end of the 19th century and in the beginning of the 20th century, whereas Latin America and Asia experienced a decline in the rate of population growth only in the last decades of the 20th century. Africa's population growth, in contrast, has been rising steadily.

The process of industrialization was characterized by a gradual increase in the relative importance of human capital in the production process. The acceleration in the rate of technological progress gradually increased the demand for human capital, inducing individuals to invest in education, and stimulating further technological advancement. Moreover, in developed as well as less developed regions, the onset of the process of human capital accumulation preceded the onset of the demographic transition, suggesting that the rise in the demand for human capital in the process of industrialization and the subsequent accumulation of human capital played a significant role in the demographic transition and the shift to a state of sustained economic growth.

Notably, the reversal of the Malthusian relation between income and population growth during the demographic transition corresponded to an increase in the level of resources invested in each child. For example, literacy rate among men in England was stable at around 65 per cent in the first phase of the Industrial Revolution and increased significantly during the second phase, reaching nearly 100 per cent at the end of the 19th century. In addition, the proportion of children aged 5 to 14 in primary schools increased from 11 per cent in 1855 to 74 per cent in 1900. A similar pattern is observed in other European societies (Flora, Kraus and Pfenning, 1983).

The process of industrialization was characterized by a gradual increase in the relative importance of human capital in less developed economies as well. Educational attainment increased significantly across all less developed regions. Moreover, in line with the pattern that emerged among developed economies in the 19th century, the increase in educational attainment preceded or occurred simultaneously with the decline in total fertility rates.

The great divergence
The differential timing of the take-off from stagnation to growth across countries and the corresponding variations in the timing of the demographic transition led to a great divergence in income per capita as well as population growth. Inequality in the world economy was negligible till the 19th century. The ratio of GDP per capita between the richest region and the poorest region in the world was only 1.1:1 in 1000, 2:1 in 1500 and 3:1 in 1820. In the past two centuries, however, the ratio of GDP per capita between the richest group (Western offshoots) and the poorest region (Africa) has widened considerably from a modest 3:1 ratio in 1820, to 5:1 ratio in 1870, 9:1 ratio in 1913, 15:1 ratio in 1950, and 18:1 ratio in 2001.

An equally momentous transformation occurred in the distribution of world population across regions. The earlier take-off of western European countries increased the amount of resources that could be devoted for the increase in family size, permitting a 16 per cent increase in the share of their population in the world from 12.8 per cent in 1820 to 14.8 per cent in 1870. However, the early onset in the western European demographic transition and the long delay in the demographic transition of less developed regions, well into the second half of the 20th century, led to a decline in the share of western European population in the world, from 14.8 per cent in 1870 to 6.6 per cent in 1998. In contrast, the prolongation of the post-Malthusian period among less developed regions, in association with the delay in their demographic transition well into the second half of 20th century, channelled their increased resources towards a significant increase in their population. Africa's share of world population increased from seven per cent in 1913 to 12.9 per cent in 1998, Asia's share of world population increased from 51.7 per cent in 1913 to 57.4 per cent in 1998, and Latin American countries increased their share in world population from two per cent in 1820 to 8.6 per cent in 1998.

**Unified growth theory**

Galor and Weil (2000) advanced a unified growth theory that captures the three regimes that have characterized the process of development as well as the fundamental driving forces that generated the transition from an epoch of Malthusian stagnation to a state of sustained economic growth. The theory replicates the observed time paths of population, income per capita, and human capital, generating: (a) the Malthusian oscillations in population and output per capita during the Malthusian epoch, (b) an endogenous take-off from Malthusian stagnation that is associated with an acceleration in technological progress and is accompanied initially by a rapid increase in population growth, and (c) a rise in the demand for human capital, followed by a demographic transition and sustained economic growth. These qualitative patterns are confirmed in the calibration of the theory by Lagerlof (2006).

The theory proposes that in early stages of development economies were in the proximity of a stable Malthusian equilibrium. Technology advanced rather slowly, and generated proportional increases in output and population. The inherent positive interaction between population and technology in this epoch, however, gradually increased the pace of technological progress, and due to the delayed adjustment of population, output per capita advanced at a minuscule rate. The slow pace of technological progress in the Malthusian epoch provided a limited scope for human capital in the production process and parents, therefore, had no incentive to reallocate resources towards human capital formation of their offspring.

The Malthusian interaction between technology and population accelerated the pace of technological progress and permitted a take-off to the post-Malthusian regime. The expansion of resources was partially counterbalanced by the enlargement of population, and the economy was characterized by rapid growth rates of income per capita and population. The acceleration in technological progress eventually increased the demand for human capital, generating two opposing effects on population growth. On the one hand, it eased households’ budget constraints, allowing the allocation of more resources for raising children. On the other hand, it induced a reallocation of resources towards child quality. In the post-Malthusian regime, due to the modest demand for human capital, the first effect dominated, and the rise in real income permitted households to increase the number as well the quality of their children.

As investment in human capital took place, the Malthusian steady-state equilibrium vanished and the economy started to be attracted by the gravitational forces of the modern growth regime. The interaction between investment in human capital and technological progress generated a virtuous circle: human capital generated faster technological progress, which in turn further raised the demand for human capital, inducing further investment in child quality, and eventually triggering the onset of the demographic transition and the emergence of a state of sustained economic growth.

The theory suggests that the transition from stagnation to growth is an inevitable outcome of the process of development. The inherent Malthusian interaction between the level of technology and the size of the population accelerated the pace of technological progress, and ultimately raised the importance of human capital in the production process. The rise in the demand for human capital in the second phase of the Industrial Revolution and its impact on the formation of human capital as well as on the onset of the demographic transition brought about significant technological advancements along with a reduction in fertility rates and population growth, enabling economies to convert a larger share of the fruits of factor accumulation and technological progress into growth of income per capita, and paving the way for the emergence of sustained economic growth. Quantitative analysis of unified growth theories (Doepke, 2004; Lagerlof, 2006) indeed suggest that the rise in the demand for human capital was a significant force behind the demographic transition and the emergence of a state of sustained economic growth.

Variations in the timing of the transition from stagnation to growth and thus in economic performance across countries reflect initial differences in geographical factors and historical accidents and their manifestation in diversity in institutional, demographic, and cultural factors, trade patterns, colonial status, and public policy. In particular, once a technologically driven demand for human capital emerged in the second phase of industrialization, the prevalence of human capital-promoting institutions determined the extensiveness of human
capital formation, the timing of the demographic transition, and the pace of the transition from stagnation to growth. The theory proposes that the growth process is characterized by stages of development and it evolves nonlinearly. Technological leaders experienced a monotonic increase in the growth rates of their income per capita. Their growth was rather slow in early stages of development, increased rapidly during the take-off from the Malthusian epoch, and continued to rise, often stabilizing at higher levels. In contrast, technological followers that made the transition to sustained economic growth experienced a non-monotonic increase in the growth rates of their income per capita. Their growth rate was rather slow in early stages of development, but increased rapidly in the early stages of the take-off from the Malthusian epoch, boosted by the adoption of technologies from the existing technological frontier. However, once these economies reached the technological frontier, their growth rates dropped to the level of the technological leaders. Hence, consistently with contemporary evidence about the existence of multiple growth regimes (Durlauf and Quah, 1999), the differential timing of the take-off from stagnation to growth across economies generated convergence clubs characterized by a group of poor countries in the vicinity of the Malthusian equilibrium, a group of rich countries in the vicinity of the sustained growth equilibrium, and a third group in the transition from one club to another.

Nonlinearities in growth have important implications for cross-country income inequality. In particular, they imply that countries may spend long periods of time in a low-growth poverty trap. However, finding evidence of such nonlinearities in the data and accounting for their emergence pose unique challenges to researchers.

Nonlinear growth models
Nonlinear growth models are characterized by a country's subsequent performance being critically dependent upon its initial conditions. In particular, these models tend to imply that countries which have unfavourable initial conditions may either experience substantial periods of time in low-growth/low-income poverty traps or be altogether caught in one. In some cases, it has been explicitly suggested that active (exogenous) policy interventions may be necessary in order to kick-start a country into a more favourable equilibrium. Nonlinear growth models can be broadly classified into two classes: structural change (or ‘stages of development’) models, and models that emphasize endogenous technological development and cross-country interactions in terms of technological diffusion. Structural change models focus on the (internal) transformations of an economy as it transits through
critical phases or ‘stages’ (see Lewis, 1956; Rostow, 1960) leading to industrialization. The aim of this work is to clarify the conditions for such transitions to occur. Early work in the economic development literature (see Rosenstein-Rodan, 1943; Nurkse, 1953; Scitovsky, 1954; Fleming, 1955; formalized by Murphy, Shleifer, and Vishy, 1989) emphasized the importance of increasing returns and the size of the market in industrialization. The key idea behind this view is that countries could be locked in a no-industrialization trap because of the small size of the market for each sector of the economy. No single sector can achieve growth on its own. However, the growth of one sector results in the enlargement of markets for other sectors. The enlargement of markets then encourages investment and growth in the corresponding sectors. These spillover effects and strategic complementarities imply that a ‘big push’ that is, coordinated investments (or ‘balanced growth’) across sectors – may be sufficient to push the economy out of the trap and into a ‘take-off’ towards industrialization. Other models are explicitly informed by the analysis of historical data (see Maddison, 2004), and emphasize the importance of explaining simultaneously both historical patterns of other state variables associated with growth and growth itself. An important recent work that models the demographic transition in growth take-offs is Galor and Weil (2000). Because these models require that certain conditions be met before countries are able to achieve take-off, those who do not meet these requirements could find themselves trapped in a phase of economic stagnation for extended periods of time.

The second class of models focuses on the role of technological progress in growth. In particular, the emphasis of these models is on the diffusion of technology from countries which are technological leaders to less developed countries. Lucas (2000) is a seminal work in this area (see also Basu and Weil, 1998; Parente and Prescott, 1994; Howitt and Mayer-Foulkes, 2005). Particular attention has been paid to exploring the channels through which less advanced countries imitate or adopt technologies in leader countries. If there are no barriers to technological diffusion across countries, then these models typically predict that rich and poor countries would gradually converge in per capita income. However, if such barriers exist, then countries may differ in their ability to adopt technologies leading to the creation of ‘clusters’ of countries defined by a set of common barriers to technological adoption. Countries within each of these clusters or ‘convergence clubs’ converge to common levels of mean per capita income. Nevertheless, the per capita incomes across convergence clubs need never converge and the polarization of per capita incomes across countries may be permanent.

Growth empirics

In both classes of models, therefore, the primary concern is that countries may become separated – perhaps permanently – into multiple growth regimes corresponding to different levels of long-run per capita income. The fact that nonlinear growth models imply that global inequality may be persistent has sparked major advances in the area of cross-country growth empirics. Driven by such concerns, the central preoccupation of growth empirics has been to evaluate the conditions under which poor countries catch up with rich ones or fail to do so. Initial work along these lines focused on the concept of ‘conditional convergence’. Conditional convergence is said to occur if permanent per capita income differences between countries can be accounted for solely by structural differences (and not initial conditions). Researchers initially argued that because conditional convergence was predicted by the canonical neoclassical growth model (see Ramsey, 1928; Solow, 1956; Swan, 1956; Cass, 1965;
Economic growth nonlinearities: The New Palgrave Dictionary of Economics

Koopmans, 1965) whereas nonlinear growth models potentially predict dependence on initial conditions, tests for conditional convergence could be used to discriminate between these classes of theories. Following Mankiw, Romer and Weil (1992) and Barro and Sala-i-Martin (1992), the canonical way such tests were conducted was to first construct a linearized version of the neoclassical growth model about the (unique) steady state with average growth rates across a time period as the dependent variable, and measures of physical and human capital, population growth rates, and initial per capita income as covariates. Researchers then applied the linearized neoclassical model to cross-country data with the aim of testing to see whether the data supported a negative coefficient on initial per capita income. A finding of a negative coefficient on initial per capita income was taken to imply that, conditional on countries having similar structural characteristics (as defined by the set of covariates), poorer countries would close the income gap with the rich – that is, conditional convergence.

An important outcome of the, oftentimes heated (see Sala-i-Martin, 1996), convergence debates of the 1990s was precisely to weaken the idea that such tests of convergence could be interpreted as model selection tests. In a highly influential work, Bernard and Durlauf (1996) strongly disputed the interpretation of such ‘conditional convergence’ tests by pointing out that these tests were not able to discriminate against a class of nonlinear growth theories that have dramatically different ergodic implications from the neoclassical model. The class of models they were referring to was developed by Azariadis and Drazen (1990). Azariadis and Drazen extended the spillover models of Lucas (1988) and Romer (1986) and showed that, if (local) nonconvexities in the production function were sufficiently strong, then countries that are similar in all aspects except for initial conditions may nevertheless be organized into multiple growth regimes, each of which corresponds to a different steady state for long-run per capita income.

Bernard and Durlauf showed that the multiple-regimes Azariadis–Drazen model was theoretically consistent with a finding of conditional convergence in the data. Therefore, even in the narrowly restricted sense of countries being structurally similar, the finding of a negative coefficient to initial income in the data was no guarantee that countries would converge to a common steady state. Galor (1997) lent further support to the relevance of the Azariadis–Drazen model by arguing that standard ways of augmenting the traditional Solow model increased the likelihood that the true data-generating process followed a multiple-regimes rather than a single steady-state model. Clearly, evidence of multiple regimes and nonlinearities in growth raises questions about misspecification in empirical studies that assume that all countries follow the same growth process, and casts doubt on inferences and policy recommendations that are drawn from these studies.

The work by Bernard and Durlauf has spurred a large quantity of research searching for the existence of multiple-growth regimes. One direction of this new research has been to argue that the finding of parameter heterogeneity in the neoclassical model may be suggestive of the existence of multiple growth regimes. In a seminal work, Durlauf and Johnson (1995), employing a classification and regression tree methodology, implemented a version of Azariadis and Drazen’s model and showed that there was evidence in the data to suggest that countries grouped according to initial per capita income and literacy rates correspond to four different growth regimes. Their work has inspired a long list of confirmatory works using a wide variety of econometric approaches (for example, Bloom, Canning and Sevilla, 2003; Canova, 2004; Durlauf, Kourtellos and Minkin, 2001; Kourtellos, 2005; Liu and Stengos, 1999; and Tan, 2005).
While there now is a strong consensus in the literature that there exists substantial heterogeneity across countries, it should be emphasized that this finding is only suggestive of multiple-growth regimes and is not conclusive evidence of it. These heterogeneities could arise because of small deviations in the specification of the production function (see Masanjala and Papageorgiou, 2004) which need not correspond to multiple-growth regimes. Further, even within the context of Azariadis–Drazen model, if non-convexities in the production function are not strong enough, the finding of parameter heterogeneity would not imply the existence of multiple regimes (see Durlauf and Johnson, 1995, Figure 2).

An alternative approach to investigating the existence of multiple regimes or convergence clubs has focused on the evolution of the world distribution of per capita income. The aim of this research has been to look for evidence of emerging multimodality (typically, bimodality) in the world income distribution. A secondary aim has been to evaluate the degree of churning within the multimodal distribution. If the world income distribution is characterized by emerging multimodality with little evidence of countries moving freely within the distribution (that is, churning), then this finding would suggest, in a manner analogous with the finding of multiple-growth regimes, that global income inequality is real, intensifying and persistent in nature. In fact, these are the precise findings by Quah (1993). By estimating transition probabilities for the cross-country per capita income distribution, Quah finds emerging ‘twin peaks’ in the world income distribution as well as substantial persistence within the distribution. Quah's seminal work has been confirmed by subsequent work (for example, Bianchi, 1997; Fiaschi and Lavezzi, 2003; and Paap and van Dijk, 1998) even though there had been questions about the robustness of his initial methodology (see Kremer, Onatski and Stock, 2001).

While the findings of the ‘twin peaks’ literature have been suggestive of growth nonlinearities and multiple equilibria, it is not definitive. It is quite possible, for instance, that the aggregate production functions across countries actually exhibit decreasing marginal productivity of capital, so that there is only one steady state. However, other growth factors are sufficiently strong to overcome the convergence effect of diminishing marginal returns to produce divergence and bimodality in cross-country incomes nevertheless. Without an explicit theory to explain the observed income divergence, there is also the question of whether the bimodality in the cross-country income distribution is a transitional or permanent feature of growth (see Galor, 1997; Lucas, 2000).

Conclusion

Nonlinearities in growth have been highly influential in shaping the thinking of both growth theorists and empiricists in recent years. The work on multiple-growth regimes and the world income distribution suggests that there may exist growth factors strong enough to overcome the decreasing marginal productivity of the neoclassical production function, thereby producing increasing inequality across countries. Nevertheless, while an increasingly large body of work finds evidence that is suggestive of growth nonlinearities, many questions remain open and are the subject of current research. What are the factors that are responsible for generating multiple growth regimes or convergence clubs? Are the effects of these factors transient or permanent? If the former, what are the applicable timescales? This area of research continues to be promising and fruitful.

The evolution of economic growth theory throughout the post-war period has been deeply influenced by the effort to explain broad patterns in cross-country behaviour. We discuss some of the salient empirical regularities associated with neoclassical and new growth economics and consider the shift in focus that has occurred. We first describe the stylized facts of Kaldor that played an important role in the assessment of neoclassical growth models. Next, we consider how a switch in focus to a different class of regularities is associated with the new growth economics that began in the 1980s and dominates contemporary research.

Article

The evolution of economic growth theory throughout the post-war period has been deeply influenced by the effort to explain broad patterns in cross-country behaviour. In this entry, we discuss some of the salient empirical regularities associated with neoclassical and new growth economics and consider the shift in focus that has occurred. We first describe the role of empirical regularities in neoclassical growth theory as it emerged in the 1950s. Next, we consider how a switch in focus to a different class of regularities is associated with the new growth economics that developed in the 1980s and continues to dominate contemporary research. Finally, we assess this shift. Durlauf, Johnson and Temple (2005) contains details of the data and methods used to substantiate the claims made here.
Neoclassical growth theory is commonly associated with Kaldor's (1961) well-known ‘stylized facts’ of long-run economic behaviour, which primarily focused on the invariance of long run behaviour for advanced economies. Four of his six facts – (1) the constancy of the growth rate of output per worker over long time horizons, (2) the constancy of the growth rate of capital which is lower than the growth rate of the labour supply, (3) the absence of any systematic trends in the capital–output ratio and (4) the constancy of the rate of profit (and, by implication with the other facts, factor shares in national income) – emphasize common behaviour across countries. Only the fifth and sixth facts – the presence of substantial differences in output per worker across countries, and the positive relationship between the rate of profit and the investment–output ratio – focus on heterogeneity. Kaldor (1957) cites the prediction of constant factor shares as an important test of alternative growth models. An important empirical study at the time was Klein and Kosobud (1961) who investigated constancy by testing for a trend in labour's share, finding none using US data from 1900 to 1953.

While these facts are generally cited as a motivation of neoclassical growth models, their actual relationship to the theory is in fact more complicated. In Solow (1956), for example, the objective is the explanation of long-run economic growth and the constancy of factor shares is only mentioned in passing as an implication of the Cobb–Douglas technology. Indeed Solow (1958) criticizes the literature studying the constancy of factor shares for lacking a precise notion of constancy given that exact constancy cannot reasonably be expected. Bronfenbrenner (1960) argues that, for a wide range of values of the elasticity of substitution between capital and labour, and for reasonable variation in the capital–labour ratio, the theoretical variation in factor shares is consistent with that observed. He concludes that the constancy or otherwise of factor shares is not useful in the assessment of (distribution) theories. Put differently, the first three of Kaldor's stylized facts seem most important to understanding the motivation of the neoclassical program; Solow (2000, p. 4) (in a discussion originally published in 1970) remarks that growth theory is largely devoted to analyzing the properties of steady states and to finding out whether an economy not initially in a steady state will evolve into one …

How do Kaldor's stylized facts appear from the vantage point of modern empirical growth research? Barro and Sala-i-Martin (2004, pp. 12–16) assess the concordance of Kaldor's stylized facts with the data and conclude that, with the exception of the constant rate of profit, each of the first five holds ‘reasonably well’ for developed economies. They cite evidence suggesting some tendency for the real rate of return to decline in some economies. The evidence they present, and that which we discuss below, shows that, at least as far as it concerns the rate of growth of labour productivity, the sixth of Kaldor's facts also fits well with the data. Kaldor's stylized facts are therefore of contemporary use in understanding long-run output behaviour. That said, the facts are no longer central to the research efforts in growth economics as other regularities (or the lack thereof) have become the primary focus of research. We therefore turn to those regularities that have become the focus of contemporary work.

Empirical regularities and the new growth economics
The renaissance in growth theory associated with the rise of endogenous growth models was influenced by interest in the determinants of heterogeneity in growth experiences. While not usually called stylized facts, there is a set of general propositions about heterogeneity that have been very important in influencing research. The most prominent global features evident in the data are the divergence in living standards over the past three centuries and the large disparities in living standards at the end of the 20th century. By modern standards, all countries were poor in 1700 but since then sustained growth, first in the United Kingdom and parts of Western Europe, and more recently in the United States and parts of the Asia–Pacific region, has resulted in large cross-country differences in living standards. In 2000 average GDP per worker in some countries was about one-fiftieth that in the United States while more than 40 per cent of the world's population lived in countries with average levels of GDP per worker of no more than ten per cent of that in the United States.

Divergence in living standards over the 1960–2000 period is also evident in the large group of countries covered by the Penn World Tables (PWT) (Heston, Summers and Aten, 2002). While a substantial group of countries has exhibited prolonged growth over this period, there remains a large mass of countries at the bottom of the distribution. One result was a hollowing out of the middle of the distribution – a phenomenon labelled ‘twin peaks’ by Quah (1996; 1997). Moreover, there is strong persistence within the cross-country income distribution with a Spearman rank correlation of 0.84 between GDP per worker in 1960 and that in 2000. This degree of correlation is not peculiar to the PWT data. Easterly et al. (1993) report a rank correlation of 0.82 between GDP per capita in 1988 and that in 1870 for the 28 countries in Maddison (1989). This sense of a lack of mobility is reinforced by Bianchi (1997), who found that very few of the possible crossings from one end of the distribution to the other actually occurred between 1970 and 1989.

The persistence in levels of GDP per worker contrasts sharply with the wide cross-country variation in the growth rates of GDP per worker especially for those countries with relatively low levels of GDP per worker in 1960. The data show scant support for the proposition that the countries of the world are converging to a common level of income per person or for the belief that poor countries have always grown slowly. Both growth ‘miracles’ – countries exhibited consistently strong growth over the 1960–2000 period – and growth ‘disasters’ – countries that did poorly, often having negative average growth rates – are present in the data. East and South East Asian countries are well represented among the former group while the later is dominated by countries in sub-Saharan Africa. Taiwan, for example, grew at an average annual rate of over six per cent during this 40-year period and increased GDP per worker by a factor of 11 in the process. Hong Kong, Korea and Singapore were not far behind in either respect. By contrast, Mauritania, Senegal, Chad, Mozambique, Madagascar, Zambia, Mali, Niger, Nigeria, the Central African Republic, Angola and the Democratic Republic of the Congo all had negative average growth over this period.

For most countries, the average growth rate from 1980 to 2000 was lower than that from 1960 to 1980. The notable exceptions to this observation are China and India. Moreover, past growth does not seem to be a good predictor of future growth as, for example, the correlation between growth in 1960–80 and that in 1980–2000 is just 0.40. Easterly et al. (1993) suggest that the lack of persistence in growth rates indicates the importance of good luck in economic development. Nevertheless, the cross-decade correlations in growth rates have tended to increase during the 1960–80 period, indicating a sorting of countries into distinct groups of winners and losers.
There seems to be little relationship between the 1960 level of GDP per worker and subsequent average growth rates. The cross-country dispersion of growth rates tends to fall as initial income rises largely due to the rarity of poor performance among the countries with relatively high levels of GDP per worker in 1960. There is, however, a close relationship between geographical group membership and economic growth between 1960 and 2000. As alluded to above, the countries of sub-Saharan Africa performed poorly over this period, with three-quarters of them growing at an average annual rate of less than just 1.3 per cent. The countries in South and Central America did somewhat better with three-quarters of them having grown at an average of less than 1.5 per cent. Among the East and South East Asian countries, three-quarters grew at an average rate of over 3.8 per cent, and a similar fraction of the South Asian countries grew at over 1.9 per cent.

Many of the poor countries of the world were unable to break out of stagnation between 1960 and 2000. A country growing at two per cent per year for 40 years would enjoy a 120 per cent increase in income per person over that period. Yet, between 1960 and 2000, about a quarter of countries never exceeded their 1960 income level by more than 60 per cent, and about ten per cent of countries never exceeded their 1960 level by more than 30 per cent. One reason for this stagnation is the disposition of some economies to large, abrupt output collapses. About half of countries experienced a three-year output collapse of 15 per cent or more between 1960 and 2000. Over the same period, the largest three-year output collapse in the United States was 5.4 per cent, and in the United Kingdom 3.6 per cent, both in 1979–82.

In sum, there are large cross-country disparities in GDP per worker and hence in living standards. These disparities have grown wider since 1960 and the middle of cross-country income distribution has thinned since 1960. There is substantial immobility in a country's position in the distribution. Growth rates are much less persistent and have tended to fall since 1980. In general, the countries of sub-Saharan Africa performed poorly over the 1960–2000 period. The countries in South and Central America did somewhat better while the South Asian countries did better still. The East and South East Asian countries did best of all.

The changing empirical focus of growth economics

The two sets of empirical regularities we have described, while appearing to differ greatly in terms of their implications for understanding the determinants of the growth process, may in fact be reconciled. A key difference between neoclassical and modern growth economics is its domain of explanation: whereas neoclassical theory attempted to understand the long-run behaviour of advanced industrialized economies, the new growth economics attempts to understand worldwide growth patterns. As a result, the differences between the advanced industrialized economies and the rest of the world take on primary importance. Lucas (2002, pp. 2–3) describes his motivation as

to see whether modern growth theory could also be adapted for use as a theory of economic development. Adaptation of some kind was evidently necessary: The balanced path of growth theory, with constant income growth, and the assumed absence of population pressures, obviously did not fit all of economic history or even all the behavior that can be seen in today's world. The theory is, and was designed to be, a model of the recent past of a subset of countries.
Thus, as the domain of inquiry in growth economics has evolved, the stylized facts of interest have shifted to identifying features of international divergence rather than international convergence. Further, the effort to identify patterns that characterize the differences in cross-country growth experiences has led to empirical research that focuses on the identification of particular factors in generating the divergence. Theoretical work in growth economics moved away from the traditional emphasis on factor accumulation and towards the analysis of a wide range of social, historical, geographic, and political factors as sources of cross-country heterogeneity. For example, a major strand of contemporary research focuses on the ways that institutional quality affects growth and development; see Acemoglu, Johnson and Robinson (2005) for a detailed survey. The richness of the modern growth literature has led to the widespread use of regression methods to allow for the simultaneous consideration of multiple growth determinants, with a focus on identifying which determinants in fact matter.

The move towards regression methods as the basis for empirical growth research has altered the nature of the sorts of regularities that link data and theory. It is still the case that theoretical analyses are often motivated by the identification of a bivariate relationship between some factor of interest and growth rates. However, relationships of this type do not represent basic growth regularities in the way that Kaldor's stylized facts did. The reason for this transition is that the different growth factors that have expanded the domain of growth economics are typically mutually consistent (Brock and Durlauf, 2001) and so the empirical significance of one factor can only be assessed when others are considered as well. Put differently, the finding of a bivariate relationship, or lack thereof, can always be rationalized as reflecting a failure to control for other factors.

As a result, the empirical regularities that matter for contemporary research, such as the coefficient relating a measure of institutional quality to growth, are derivative from statistical analyses of the entire growth process. But statistical models of growth are subject to many forms of model uncertainty, ranging from uncertainty about the appropriate theories to employ to uncertainty about the empirical measurement of the qualitative factors identified by a theory to uncertainty about the details of the statistical specification of a model; see Durlauf and Quah (1999) and Durlauf, Johnson and Temple (2005) for a delineation of these issues. Model uncertainty has meant that there is relatively little consensus on the empirically salient determinants of growth and so little consensus on which regularities should be of primary interest. Thus current growth economics has been handicapped as different papers identify different salient empirical regularities, with inadequate attention to the robustness of such claims. The development of sturdy inferences about the growth process thus represents a very active area of current work.

Economic growth is typically measured as the change in per capita gross domestic product (GDP). Sustained long-term economic growth at a positive rate is a fairly recent phenomenon in human history, most of it having occurred in the last 200 years. According to Maddison's (2001) estimates, per capita GDP in the world economy was no higher in the year 1000 than in the year 1, and only 53 per cent higher in 1820 than in 1000, implying an average annual growth rate of only one-nineteenth of one per cent over the latter 820-year period. Some time around 1820, the world growth rate started to rise, averaging just over one-half of one per cent per year from 1820 to 1870, and peaking during what Maddison calls the ‘golden age’, the period from 1950 to 1973, when it averaged 2.93 per cent per year. By 2000, world per capita GDP had risen to more than 8.5 times its 1820 value. Growth has been uneven not only across time but also across countries. Since 1820, living standards in Western Europe and its offshoots in North America and the Antipodes have raced ahead of the rest of the world, with the exception of Japan, in what is often referred to as the ‘Great Divergence’. As shown in Figure 1 below, the proportional gap in per capita GDP between the richest group of countries and the poorest group (as classified by Maddison) grew from three in 1820 to 19 in 1998. Pritchett (1997) tells a similar story, estimating that the proportional gap between the richest and poorest countries grew more than fivefold from 1870 to 1990.

Figure 1

This widening of the cross-country income distribution seems to have slowed during the second half of the 20th century, at least among a large group of nations. Indeed, Figure 1,
which is drawn on a proportional scale, shows that with the acceleration of growth in Asia there has been a narrowing of the spread between the richest and the second poorest group since 1950. Evans (1996) shows a narrowing of the top end of the distribution (that is, among Organisation for Economic Co-operation and Development, OECD, countries) over the period. However, not all countries have taken part in this convergence process, as the gap between the leading countries as a whole and the very poorest countries has continued to widen. In Figure 1 the gap between the Western Offshoots and Africa grew by a factor of 1.75 between 1950 and 1998. Likewise, the proportional income gap between Mayer-Foulkes's (2002) richest and poorest convergence groups grew by a factor of 2.6 between 1960 and 1995.

Jones (1997) argues that continuing divergence of the poorest countries from the rest of the world does not imply rising income inequality among the world’s population, mainly because China and India, which contain about 40 per cent of that population, are rising rapidly from near the bottom of the distribution. Indeed, Sala-i-Martin (2006) shows, using data on within-country income distributions, that the cross-individual distribution of world income narrowed considerably between 1970 and 2000, even as the cross-country distribution continued to widen somewhat. But between-country inequality is still extremely important; in 1992 it explained 60 per cent of overall world inequality (Bourguignon and Morrison, 2002). Another reason that growth economists are typically more concerned with the cross-country than the cross-individual distribution is that many of the determinants of economic growth vary across countries but not across individuals within countries.

The production function approach

The main task of growth theory is to explain this variation of living standards across time and countries. One way to organize one’s thinking about the sources of growth is in terms of an aggregate production function, which indicates how a country’s output per worker $y$ depends on the (per worker) stocks of physical, human, and natural capital, represented by the vector $k$, according to

$$y = f(k, A),$$

where $A$ is a productivity parameter. Economic growth, as measured by the growth rate of $y$, depends therefore on the rate of capital accumulation and the rate of productivity growth. Similarly, countries can differ in their levels of GDP per capita either because of differences in capital or because of differences in productivity. Much recent work on the economics of growth has focused on trying to identify the relative contributions of these two fundamental factors to differences in growth rates or income levels among countries.

Modern growth theory started with the neoclassical model of Solow (1956) and Swan (1956), who showed that in the long run growth cannot be sustained by capital accumulation alone. In their formulation, the diminishing marginal product of capital (augmented by an Inada condition that makes the marginal product asymptote to zero as capital grows) will always terminate any temporary burst of growth in excess of the growth rate of labour-augmenting productivity. But this perspective has been challenged by more recent endogenous growth theory. In the $AK$ theory of Frankel (1962) and Romer (1986), growth in productivity is functionally dependent on growth in capital, through learning by doing and technology spillovers, so that an increase in investment rates in physical capital can also sustain a permanent increase in productivity growth and hence in the rate of economic growth. In the innovation-based theory that followed $AK$ theory, the Solow model has been combined with a Schumpeterian theory of productivity growth, in which capital accumulation is one of the factors that can lead to a permanently higher rate of productivity growth (Howitt and Aghion, 1998).

Capital

Having introduced the production function in a general sense, we now examine the accumulation of different types of capital in more detail, and then turn to an assessment of the relative importance of factor accumulation and productivity in explaining income differences among countries and growth over time.

Physical capital

Physical capital is made up of tools, machines, buildings, and infrastructure such as roads and ports. Its key characteristics are, first, that it is produced (via investment), and second that it is in turn used in producing output. Physical capital differs importantly from technology (which, as is discussed below, is also both produced and productive) in that physical capital is rival in its use: only a limited number of workers can use a single piece of physical capital at a time.

Differences in physical capital between rich and poor countries are very large. In the year 2000, for example, physical capital per worker was 148,091 dollars in the United States,
42,991 dollars in Mexico, and 6,270 dollars in India. These large differences in physical capital are clearly contributors to income differences among countries in a proximate sense. That is, if the United States had India's level of capital it would be a poorer country. The magnitude of this proximate effect can be calculated by using the production function. For example, using a value for capital's share of national income of 1/3 (which is consistent with the findings of Gollin (2002) for a cross-section of countries), the ratio of capital per worker in the United States to that in India would by itself explain a ratio of income per capita in the two countries of 7.9 =((148,091/6,270)1/3).

Differences in physical capital among countries can result from several factors. First, countries may differ in their levels of investment in physical capital relative to output. In an economy closed to external capital flows, the investment rate will equal the national saving rate. Saving rates can differ among countries because of differences in the security of property rights, due to the availability of a financial system to bring together savers and investors, because of government policies like budget deficits or pay-as-you-go old age pensions, differences in cultural attitudes towards present versus future consumption, or simply because deferring consumption to the future is a luxury that very poor people cannot afford.

A second factor that drives differences in investment rates among countries is the relative price of capital. The price of investment goods in relation to consumption goods is two to three times as high in poor countries as in rich countries. If one measures both output and investment at international prices, investment as a fraction of GDP is strongly correlated with GDP per capita (correlation of 0.50), and poor countries have on average between one half and one quarter of the investment rate of rich countries. When investment rates are expressed in domestic prices, the correlation between investment rates and GDP per capita falls to 0.05 (Hsieh and Klenow, 2007).

But levels of capital can also differ among countries for reasons that have nothing to do with the rate of accumulation. Differences in productivity (the A term in equation 1) will produce different levels of capital even in countries with the same rates of physical capital investment. Similarly, differences in the accumulation of other factors of production will produce differences in the level of physical capital per worker.

Human capital

Human capital refers to qualities such as education and health that allow a worker to produce more output and which themselves are the result of past investment. Like physical capital, human capital can earn an economic return for its owner. However, the two types of capital differ in several important respects. Most significantly, human capital is ‘installed’ in a person. This makes it very difficult for one person to own human capital that is used by someone else. Human capital investment is a significant expense. In the United States in the year 2000, spending by governments and families on education amounted to 6.2 per cent of GDP; forgone wages by students were of a similar magnitude.

Information on the productivity of human capital can be derived from comparing wages of workers with different levels of education. So called ‘Mincer regressions’ of log wage on years of education, controlling by various means for bias due to the endogeneity of schooling, yield estimated returns to schooling of about ten per cent per year. In the year 2000, the average schooling of workers in advanced countries was 9.8 years and among workers in developing countries 5.1 years. Applying a rate of return of ten per cent implies that the average worker in the advanced countries supplied 56 per cent more labour input because of this education difference. If labour's share in a Cobb–Douglas production function is two-thirds, this would imply that education differences would explain a factor of 1.35 difference in income between the advanced and developing countries, which is very small relative to the observed gap in income. Allowing for differences in school quality increases somewhat the income differences explained by human capital in the form of schooling.

A second form of human capital is health. The importance of health as an input into production can be estimated by looking at microeconomic data on how health affects individual wages. Health differences between rich and poor countries are large, and in wealthy countries worker health has improved significantly over the last 200 years (Fogel, 1997). Weil (2007), using the adult survival rate as a proxy for worker health, estimates that eliminating gaps in worker health among countries would reduce the log variance of GDP per worker by 9.9 per cent.

Natural capital

Natural capital is the value of a country's agricultural and pasture lands, forests and subsoil resources. Like physical and human capital, natural capital is an input into production of goods and services. Unlike other forms of capital, however, it is not itself produced.

Natural capital per worker and GDP per worker are positively correlated, but the link is much weaker than for the other measures of capital discussed above. The poor performance of many resource-rich countries has led many observers to identify a ‘resource curse’ by which the availability of natural capital undermines other forms of capital accumulation or reduces productivity. Among the suggested channels by which this happens are that resource booms lead countries to raise consumption to unsustainable levels, thus depressing saving and investment (Rodriguez and Sachs, 1999); that exploitation of natural resources suppresses the development of a local manufacturing sector, which holds back growth because manufacturing is inherently more technologically dynamic than other parts of the economy (this is the so called Dutch disease); and that economic inefficiencies are associated with political competition or even civil war to appropriate the rents generated by natural resources.
Population affects the accumulation of all three forms of capital discussed above, and through them the level of output per worker. Rapid population growth dilutes the quantities of physical and human capital per worker, raising the rates of investment and school expenditure required to maintain output per worker. The interaction of natural capital with population growth is at the centre of the model of Malthus (1798). For a fixed stock of natural capital, higher population lowers output per capita. Combined with a positive feedback from the level of income to population growth, this resource constraint produces a stable steady state level of output per capita and, with technology fixed, a stable level of population as well. This Malthusian feedback is the explanation for the long period of nearly constant living standards that preceded the Industrial Revolution (Galor and Weil, 2000). Because of resource-saving technological progress, as well as expansion of international trade, which allows countries to evade resource constraints, the interaction of population and natural capital is much less important today than in the past, with the exception of very poor countries that are reliant on subsistence agriculture.

In addition to its effect on the level of factors of production per worker, population also matters for economic growth because demographic change produces important changes in the age structure of the population. A reduction in fertility, for example, will produce a long period of reduced dependency, in which the ratio of children and the elderly, on the one hand, to working age adults, on the other, is temporarily below its sustainable steady state level. This is the so-called ‘demographic dividend’ (see population ageing).

In addition to these effects of population on the level of income per capital, there is also causality that runs from the economic to the demographic. Over the course of economic development, countries generally move through a demographic transition in which mortality rates fall first, followed by fertility rates. While the decline in mortality is easily explained as a consequence of higher income and technological progress, the decline in fertility is not fully understood. Among the factors thought to contribute to the decline in fertility are falling mortality, a shift along a quality–quantity trade-off due to rising returns to human capital, the rise of women’s relative wages, the reduced importance of children as a means of old age support, and improvements in the availability of contraception.

**Growth accounting and development accounting**

The discussion above makes clear that stocks of different forms of capital are positively correlated with GDP per capita. Similarly, as countries grow, levels of capital per worker grow as well. It is natural to ask whether these variations in capital are sufficiently large to explain the matching variations in growth. The techniques of growth accounting (Solow, 1957) and development accounting (Klenow and Rodriguez-Clare, 1997; Hall and Jones, 1999) attempt to give quantitative answers to this question. Using a parameterized production function and measures of the quantities of human and physical capital, one can back out relative levels of productivity among countries and rates of productivity growth within a country.

Caselli (2005) presents a review of development accounting along with his own thorough estimates. His finding is that if human and physical capital per worker were equalized across countries, the variance of log GDP per worker would fall by only 39 per cent. In other words, the majority of variation in income is due to differences in productivity, not factor accumulation. Differences in productivity growth, rather than differences in the growth of physical and human capital, are also the dominant determinants of differences in income growth rates among countries (Weil, 2005, ch. 7; Klenow and Rodriguez-Clare, 1997); differences in productivity levels among countries are striking. For example, comparing the countries at the 90th and 10th percentiles of the income distribution (which differ in income by a factor of 21), the former would produce seven times as much output as the latter with equal quantities of human and physical capital.

**Productivity, technology and efficiency**

Development accounting shows that productivity differences among countries are the dominant explanation for income differences. Similarly, differences in productivity growth are the most important explanation for differences in income growth rates among countries. And as a theoretical matter, the Solow model shows that as long as there are decreasing returns to capital per worker, productivity growth can be the only source of long-term growth. The question is: what explains these changes over time and differences in the level of productivity? Over the long term it is natural to associate productivity growth with technological change. However, especially as an explanation for differences in productivity at a given point in time, a second possibility is that productivity differences reflect differences not in technology, in the sense of inventions, blueprints, and so on, but rather differences in how economies are organized and use available technology and inputs. We label this second contributor to productivity as ‘efficiency’.

**Technology**

Technology consists of the knowledge of how to transform basic inputs into final utility. This knowledge can be thought of as another form of capital, an intangible intellectual capital. What distinguishes technology from human or physical capital is its non-rival character. For example, the knowledge that a particular kind of corn will be immune to caterpillars, or the knowledge of how to produce a 3.0 GHz CPU for a portable computer, can be used any number of times by any number of people without diminishing anyone's
ability to use it again. By contrast, if you drive a lorry for an hour, or if you employ the skills of a doctor for an hour, then that lorry or those skills are not available to anyone else during that hour.

Different growth theories have different approaches to modelling the accumulation of technology — that is, technical progress. According to neoclassical theory, for example, the relationship between technology and the economy is a one-way street, with all of the causation running from technology to the economy. It portrays technical progress as emanating from a scientific progress that operates outside the realm of economics, and thus takes the rate of technical progress as being given exogenously.

This neoclassical view has never been accepted universally. Specialists in economic history and the economics of technology have generally believed that technical progress comes in the form of new products, new techniques and new markets, which do not spring directly from the scientific laboratory; instead they come from discoveries made by private business enterprises, operating in competitive markets, and motivated by the search for profits. For example, the transistor, which underlies so much recent technological progress, was discovered by scientists working for the AT&T telephone company on the practical problem of how to improve the performance of switch boxes that were using vacuum tubes. Rosenberg (1981) describes many other examples of scientific and technological breakthroughs that originated in profit-oriented economic activity.

What kept this view of endogenous technology from entering the mainstream of economics until recently was the difficulty of incorporating increasing returns to scale into dynamic general equilibrium theory. Increasing returns arise once one considers technology as a kind of capital that can be accumulated, because of its non-rival nature; that is, the cost of developing a technology for producing a particular product is a fixed set-up cost, which does not have to be repeated when more of the product is produced. Once the technology has been developed, then there should be at least constant returns to scale in the factors that use that technology, on the grounds that if you can do something once then you can do it twice. But this means that there are increasing returns in the broad set of factors that includes the technology itself. Increasing returns creates a problem because it generally implies that a competitive equilibrium will not exist, at least not without externalities.

These technical difficulties were overcome by the new 'endogenous growth theory' introduced by Romer (1986) and Lucas (1988), which incorporated techniques that had been developed for dealing with increasing returns in the theories of industrial organization and international trade. The first generation of endogenous growth theory to enter the mainstream was the ‘AAK theory’, according to which technological progress takes place as a result of externalities in learning to produce capital goods more efficiently. The second generation was the innovation-based theory of Romer (1990) and Aghion and Howitt (1992), which emphasizes the distinction between technological knowledge and other forms of capital, and analyses technological innovation as a separate activity from saving and schooling.

Historically, technical progress has engendered much social conflict, because it involves what Schumpeter (1942) called ‘creative destruction’; that is, new technologies render old technologies obsolete. As a result, technical progress is a game with losers as well as winners. From the handloom weavers of early 19th century Britain to the former giants of mainframe computing in the late 20th century, many people’s skills, capital equipment and technological knowledge have been devalued and their livelihoods imperilled by the same innovations that have created fortunes for others.

The destructive side of technical progress shows up most clearly during periods when a new ‘general purpose technology’ (GPT) is being introduced. A GPT is a basic enabling technology that is used in many sectors of the economy, such as the steam engine, the electric dynamo, the laser or the computer. As Lipsey, Carlaw and Bekar (2005) have emphasized, a GPT typically arrives only partially formed, creates technological complementarities and opens a window on new technological possibilities. Thus it is typically associated with a wave of new innovations. Moreover, the period in which the new GPT is diffusing through the economy is typically a period of rapid obsolescence, costly learning and wrenching adjustment. Greenwood and Yorukoglu (1997) argue that the productivity slowdown of the 1970s is attributable to the arrival of the computer, and Howitt (1998) argues that the rapid obsolescence generated by a new GPT can cause per capita income to fall for many years before eventually paying off in a much higher standard of living.

New technologies are often opposed by those who would lose from their introduction. Some of this opposition takes place within the economic sphere, where workers threaten action against firms that adopt labour-saving technologies and firms try to pre-empt innovations by rivals. But much of it also takes place within the political sphere, where governments protect favoured firms from more technically advanced foreign competitors, and where people sometimes vote for politicians promising to preserve traditional ways of life by blocking the adoption of new technologies.

The leading industrial nations of the world spend large amounts on R&D for generating innovations. In the United States, for example, R&D expenditures constituted between 2.2 and 2.9 per cent of GDP every year from 1957 to 2004. But not much cutting-edge R&D takes place outside a small group of countries. In 1996, for example, 73 per cent of the world's R&D expenditure, as measured by UNESCO, was accounted for by just five countries (in decreasing order of R&D expenditure they are the United States, Japan, Germany, France and United Kingdom). In the majority of countries that undertake very little measured R&D, technology advances not so much by making frontier innovations as by implementing technologies that have already been developed elsewhere. But the process of implementation is not costless, because technologies tend to be context-dependent and technological knowledge tends to be tacit. So implementation requires an up-front investment to adapt the technology to a new environment (see, for example, Evenson and Westphal, 1995). This investment plays the same role analytically in the implementing country as R&D does in the original innovating country.

Implementation is important in accounting for the patterns of cross-country convergence and divergence noted above. This is because a country in which firms are induced to spend on implementation have what Gerschenkron (1952) called an 'advantage of backwardness'. That is, the further they fall behind the world's technology frontier the faster they will grow with any given level of implementation expenditures, because the bigger is the improvement in productivity when they implement any given foreign technology. In the long run, as Howitt (2000) has shown, this force can cause all countries that engage in R&D or implementation to grow at the same rate, while countries in which firms are not induced to make
such investments will stagnate. But technology transfer through implementation expenditures is no guarantee of convergence, because the technologies that are being developed in the rich R&D-performing countries are not necessarily appropriate for conditions in poor implementing countries (Basu and Weil, 1998; Acemoglu and Zilibotti, 2001) and because financial constraints may prevent poor countries from spending at a level needed to keep pace with the frontier (Aghion, Howitt and Mayer-Foulkes, 2005).

Efficiency

The efficiency with which a technology is used is not likely to play a major role in accounting for long-run growth rates, because there is a finite limit to how high you can raise living standards simply by using the same technologies more efficiently. But there is good reason to believe that differences in efficiency account for much of the cross-country variation in the level of productivity. Inefficiencies take several different forms. Economic resources are sometimes allocated to unproductive uses, or even unused, as when union featherbedding agreements kick in. Resources can be misallocated as the result of taxes, subsidies and imperfect competition, all of which create discrepancies between marginal rates of substitution. Technologies can be blocked by those who would lose from their implementation and have more market power or political influence than those who would win. The distinction between differences in technology and differences in efficiency is often unclear. Suppose firms in country A are using the same machinery and the same number of workers per machine as in country B, but output per worker is higher in A than B. This may appear to be an obvious case of inefficiency, since the technology embodied in the machines used by workers in the two countries is the same. But maybe it is just that people in country B lack the knowledge of how best to use the machines, in which case it may actually be a case of differences in technology. As an example, General Motors has had little success in their attempts to emulate the manufacturing methods that Toyota has deployed successfully for many years even in their US operations. Moreover, identical technologies will have different effects in different countries, because of differences in language, raw materials, consumer preferences, workers expectations and the like. Euro Disney, for example, was plagued initially with labour disputes when it first opened its park in the outskirts of Paris in 1987. It took the American managers several years to realize that the problem was not recalcitrant workers but rather that French workers consider it an intolerable indignity to be forced to wear items such as mouse ears when serving the public. A minor adjustment in amusement park technology was needed to make it as productive in France as it had been in the United States.

Deeper determinants of growth

Even if we knew how much of the cross-country variation in growth rates or income levels to attribute to different kinds of capital or to technology or efficiency, we would still be faced with the deeper question of why these differences in capital and productivity arise. A large number of candidate explanations have been offered in the literature. These candidates can be classified into four broad categories: geography, institutions, policy and culture. Geographical differences are perhaps the most obvious. As Sachs (2003) has emphasized, countries that are landlocked, that suffer from a hazardous disease environment and that have difficult obstacles in the way of internal transport, will almost certainly produce at a lower level than countries without these problems, even if they use the same technology and the same array of capital. In addition, the lower productivity of these countries will serve to reduce the rate of return to accumulating capital and to generating new technologies. Institutions matter because of the way they affect private contracts and also because of the way they affect the extent to which the returns to different kinds of investments can be appropriated by the government. The origin of a country’s legal system has been shown by La Porta et al. (1998) to have an important effect on private contracts. In particular, these authors show that countries with British legal origins tend of offer greater protection of investor and creditor rights, which in turn is likely to affect both capital accumulation and investment in technology by making outside finance more easily available. Because long-term productivity growth requires technical progress, it depends on political, institutional and regulatory factors that affect the way the conflict between the winners and losers of technical progress will be resolved, and hence affect the incentives to create and adopt new technologies. For example, the way intellectual property is protected will affect the incentive to innovate, because on the one hand no one will want to spend resources creating new technologies that his or her rivals can easily copy, while on the other hand a firm that is protected from competition by patent laws that make it difficult for rivals to innovate in the same product lines will be under less pressure to innovate. Likewise, a populist political regime may erect barriers to labour-saving innovation, resulting in slower technical progress. Economic policies matter not only because of the way they affect the return to investing in capital and technology but also because of the inefficiencies that can be created by taxes and subsidies. But how these policies affect economic growth can vary from one country to another. In particular, Aghion and Howitt (2006) have argued that growth-promoting policies in technologically advanced countries are not necessarily growth-promoting in poorer countries, because innovation and implementation are affected differently by the same variables. For example, tighter competition policy in a relatively backward country might retard technology development by local firms that will be discouraged by the threat of foreign entry, whereas in more advanced countries firms will be spurred on to make even greater R&D investments when threatened by competition. As this example suggests, international trade is one of the policy domains most likely to matter for growth and income differences, because of the huge productivity advantage that is squandered by policies that run counter to comparative advantage, because protected firms tend to become technologically backward firms, and because for many countries
international trade is the only way for firms to gain a market large enough to cover the expense of developing leading-edge technologies. So it is probably no accident that export promotion has been a prominent feature of all the East Asian countries that began escaping from the lower end of the world income distribution towards the end of the 20th century, whereas import substitution was a prominent feature of several Latin American countries that fell from the upper end of the distribution early in the 20th century. Culture is a difficult factor to measure. In principle, however, it is capable of explaining a great deal of cross-country variation in growth, because a society in which people are socialized to trust each other, to work hard, to value technical expertise and to respect law and order is certainly going to be thriftier and more productive than a society in which these traits do not apply. Recent work has begun to quantify the role of culture using measures of social capital, social capability, ethno-linguistic fractionalization, religious belief, the spread of Anglo-Saxon culture and many other variables.

economic history

Alexander J. Field
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Economic history focuses on the historical study of growth and development. Originating in the German historical school and studies of the Industrial Revolution in England, it became professionally differentiated from economics proper with the establishment of associations in Britain (1926) and the United States (1941). As economics continued on its increasingly mathematical and ahistorical path in the 1960s, the ‘new economic history’ advocated applying theory to history. But its emphasis on data analysis retained a bridge to older traditions. As economists have rediscovered an interest in long-term economic growth, often applying traditional institutional approaches, there is continuing evidence of rapprochement.

Article

Economic history is a sub-discipline within economics and, to a lesser degree, within history, whose main focus is the study of economic growth and development over time. It is to be distinguished from the history of economic thought, a branch of intellectual history. Studies in economic growth, whether historical or contemporary, develop and analyse quantitative measures of increases in output and output per capita, emphasizing in particular changes in saving rates and rates of technological innovation and their consequences. Economic development is a larger and more encompassing rubric, also including consideration of the role of cultural changes and changes in
